Regeneration of the Neurones.

The topic includes regeneration of the nervous system in whole or in part during embryonic periods, the regeneration of whole neurones in the adult condition, and the regeneration of portions of a neurone after injury.

In connection with regeneration of the nervous system in the embryo much work has been done. Recent studies have revealed a wholly unexpected capacity for regeneration in young phases of the embryo. The doubling of the whole nervous system, or of one end of it, is by no means uncommon. In later embryonic phases the capacity for regeneration becomes less; but until quite a late period, especially in low forms, very considerable regeneration is possible. Interesting as regards the regeneration of the nervous system are the researches of Harrison, who experimented upon the tails of tadpoles. After cutting off the tail, its peripheral nervous system was regenerated from the spinal cord. There first arose a single pair of nerves from cells lying within the cord. A part of these cells wandered into the nerve root and gave rise to a large spinal ganglion. Subsequently groups of cells wandered farther into the periphery along the newly formed nerves and gave rise to from one to three small ganglia to take the place of those ganglia which had been lost through the operation. The total number of ganglia, however, was never completely replaced.

As to the regeneration of whole neurones in adult vertebrates much doubt has been expressed. The prevailing opinion is that if an adult neurone be once entirely destroyed, it can never be regenerated from neighboring neurones. That karyokinetic figures can occur in nerve cells adjacent to an injury has been shown by Tedeschi and Vitzou. The exact histological details of karyokinesis in neurones have been studied in the cerebral cortex of guinea-pigs after introduction of a hot needle by Levi (*cf. Barbacci's Review, loc. cit.*, p. 785).

Most interesting are the various studies which have been made to explain the well-known fact that regeneration of peripheral nerves after lesion occurs. There has been much dispute as to whether the regeneration of nerve fibres is due to an outgrowth of the axone from

Digitized by Microsoft®

the central stump entirely or to a fusion of the axone of the central stump with a new axone developed in the periphery as a result of the activity of the neurilemma cells. In favor of the former view, the investigations of Waller, Ranvier, Vanlair, Barfurth, von Notthaft, Ströbe, and Kolster may be mentioned, while in favor of the latter view the studies of Beneke, Neumann, von Büngner, Wieting, and Ballance and Stewart may be mentioned.

According to the Waller-Ranvier-Vanlair view there is a continuous regeneration of the nerve fibres in connection with the part of the old axone preserved in the central stump. These authors observed in the distal part of the nerve the proliferation of the cells of Schwann's sheath and the formation of bands of spindle cells therefrom, but they maintain that the new axone is regenerated independently thereof. After the lesion the end of the central part of the axone becomes swollen and subdivides into several fine fibrils. These fibrils grow out from the central axones and ultimately reach the periphery; as they grow out they gradually become surrounded with myelin sheaths. The delicate young fibrils penetrate the intermediate tissue at the site of the lesion and reach the peripheral segment of the nerve, the fibres of which have undergone complete degeneration followed by proliferation of the neurilemma cells. These investigators assert, however, that the altered fibres of this peripheral segment take no active part in the formation of new fibres, but simply act as easy paths along which the new axones from the central stump can grow. If the central and distal stumps of the divided nerve are too far apart, the regenerating axones of the central stump may be unable to bridge the gap, in which event there will be no return of function; hence the importance of the immediate coaptation of the two cut surfaces of a divided nerve. Even when the coaptation has been carefully made by a surgeon, many of the newly forming fibres fail to grow out to the periphery.

According to the opposite view there is a *discontinuous* regeneration of the nerve fibres taking place independently of any connection with the central stump, the new fibres becoming connected with the latter only secondarily. The majority of those who support the view attribute the discontinuous regeneration of the fibres of the distal stump to the development of single segments from elongating cells; these single segments then fuse to form a continuous fibre, which later becomes attached to the end of an old nerve fibre in the central stump. There is thus a series of fusions of single cells to make the new nerve fibre and subsequently a fusion of the new fibre with the end of the old one. The same investigators believe that the cells which are concerned in building the new nerve fibres are derived by karyokinesis from the cells of Schwann's sheath (neurilemma); a few observers in the group, however, deny this, maintaining that the new fibre is derived from the connective-tissue cells of the endoneurium or even from leucocytes.

Neumann's ideas concerning regeneration resemble closely those just described, though they differ somewhat in details. He states that the myelin sheath and axone of the old fibre do not undergo complete degeneration and absorption, but, contemporaneously with the proliferation of the neurilemma nuclei, mix with one another, becoming transformed to a common protoplasmic mass, which possesses the chemical properties of both axone and myelin sheath. This mass, filling up the old nerve tube, gradually gives rise to the new fibre by again becoming differentiated into myelin sheath and axone. This differentiation is not, however, a *continuous* process but takes place in segments, and its origin and progress are, he thought, dependent upon and under the control of the axis cylinder of the nerve of the central stump, for the segmental differentiation begins at the lesion in contact with the old nerve fibre and gradually extends toward the periphery. The segment first differentiated fuses with the extremity of an old fibre of the central stump, and gradually the more peripherally situated segments fuse to form finally a continuous fibre.

Von Büngner undertook the study in 1891 with new methods. He decided that the peripheral portion of the nerve undergoes complete degeneration after section, and that therefore "healing by the first intention," postulated by some surgeons, does not occur. From the third day on, the neurilemma cells proliferate, the nuclei dividing by karyokinesis, and the protoplasm of these cells rapidly increases in amount. These cells fill up the interspaces between the balls of degenerating myelin and probably participate actively in the destruction and absorption of the old myelin sheath and disintegrated axone, since leucocytes are not present. No better illustrations of degenerating nerve fibres are to be found anywhere than those which accompany von Büngner's article. The neurilemma cells next line up in one, two, or more longitudinal rows and soon a slight fibrillation appears near the elongated nuclei until finally the nuclei of the row appear to be connected by bands of fibrils. Herein von Büngner saw the earliest indications of the newly forming axone. Through fusion of the rows of proliferated neurilemma cells and fusion of the segmental bands of fibrils, continuous fibril bands are formed, at the sides of which the nuclei, leaving their former central position, now arrange themselves, so that the fibres go past them in a slight curve. The process is always most advanced near the side of the lesion, the regeneration being slowest at the peripheral extremity of the nerve. Von Büngner believes that the neurilemma cells, and they alone, give rise to the new fibres; he does not hesitate to designate them "neuroblasts," and believes that they are truly "nervous" in nature and origin.

From the beginning of the third week on, new myelin sheaths begin to appear about the newly formed fibres, and a little later the new neurilemma and the new sheath of Henle appear, being derived, von Büngner believes, from the connective-tissue cells of the endoneurium. The nodes of Ranvier can be seen as early as the fourth week.

As to the mode of union of the axone of the central stump with the newly formed fibres in the peripheral nerve, von Büngner asserts that traumatic degeneration occurs in the central end up to the first or second node of Ranvier. Here the end of the old axone undergoes bulbous enlargement and fuses with new segmentally regenerated fibres derived from neurilemma cells of the central stump; the latter fuse with new segments in the space between the two ends of the divided nerve, and they with the newly formed fibre of the peripheral portion of the nerve. He denies anything like an outgrowth of the old axone to the periphery, and even an outgrowth across the space between the two cut ends of the nerve.

Neumann, more recently, states his position as follows: "At present no one doubts that a very important factor in the re-establishment of conduction in an interrupted nerve lies in the outgrowth of young fibres from its central stump; the only dispute possible concerns the extent to which this process takes place. While those who hold the Waller-Ranvier doctrine assume that the young fibres grow out into the peripheral degenerated part as far as its termination, according to the view which I have founded and which has later been supported by von Büngner and Wieting, the outgrowth from the central stump is limited, occurring only in sufficient degree to bridge over the gap in the nerve, whereupon new fibres are formed autochthonously out of the protoplasmic material supplied by the degeneration process."

Wieting agrees with von Büngner in ascribing the regenerative process in the first stages entirely to the nuclei of the neurilemma cells. He believes that the neurilemma cells give rise to a large amount of protoplasm throughout the whole extent of the degenerating nerve, and that it is through further differentiation of this protoplasm that the new structures are formed. As early as the fourth day extremely fine fibrils appear in the protoplasmic contents of the old neurilemma sheath. These fibrils are always continuous with the central axone. About the fifth day, advancing from the central stump toward the periphery, there is a sharper arrangement of

Digitized by Microsoft®

the protoplasmic masses and fibrils with formation of fine fibrillary strips, stained of a pale rose color and otherwise homogeneous. Later, the cell boundaries disappear, the protoplasm is drawn out lengthwise, and is deposited as a finely granular covering upon the strips. The strips represent young axones. The gray covering is the beginning of the new myelin sheath, and is also to be looked upon as an excretory product of the cell, the excretion taking place first from the central stump and advancing toward the periphery. While Wieting emphasizes that the fibril formation takes place in direct connection with the old axones, and that the process advances evenly toward the periphery, he maintains that we do not have to deal with the simple outgrowth of the old fibre for which the neurilemma cells merely point the way, but have in reality to do with a fibrillary transformation of the protoplasm yielded by the nuclei of Schwann's sheath or with a fibril formation in the protoplasm in connection with the fibrils of the old axone.

A somewhat intermediate position is taken by Howell and Huber, though they incline to the view that the young axone grows out of the old one in the central stump; it grows into the young "embryonic fibre" born from the proliferating cells of Schwann's sheath. They think that when the new axone grows into the young "embryonic fibre" the formation of the myelin sheath has already begun in the latter. Their paper is readily accessible to readers of English, and need not, therefore, be further reviewed here. Their work was done independently of von Büngner's, and it is interesting to note the nearness of von Büngner's description of his fibril bands to that of Howell and Huber of their "embryonic fibre."

The whole subject was taken up again by von Notthaft in 1892, his research winning the prize offered by the medical faculty of Würzburg. His studies of degeneration of the nerve, the proliferation of the neurilemma cells, and the formation of fibrils in the protoplasm inside the old sheath confirm very closely the observations of von Büngner; but he differs entirely when he comes to describe farther stages of the process of regeneration. He asserts that the neurilemma cells do not build the young nerve fibres at all. Instead, the young nerve fibres all grow out from the axones of the central stump, and all pass, without exception, into the interior of old sheaths of Schwann. The young fibres pass by nucleus after nucleus of the proliferated neurilemma cells, but any such thing as discontinuous regeneration of nerve fibres from the spindle cells is, he maintains, impossible. The microscopic pictures do not even yield a remote suggestion of such a probability. Von Notthaft cannot conceive how von Büngner came to the idea that the fibrillary construction of the protoplasm of the proliferated neurilemma cells could be the *Anlage* of the new axones. He seems, however, to have neglected a careful study and description of the finer histological relations occurring in the spaces intermediate between the two cut ends of the nerve.

Even more convincing than von Notthaft's confirmation of the Waller-Ranvier theory is that which we owe to the still later researches of Ströbe. Instead of being satisfied with the indirect proof of the view which is embodied in this theory, he determined to make a wholly clear series of observations (so controlled that they should be free from objection) of the phenomena which occur during the earliest period of formation of the new fibres and their connection with the old. He admits that he was influenced by the promulgation of the neurone doctrine, which has emphasized the importance of the nerve fibre as a process of the ganglion cell, but did not permit this to prevent him from studying the actual process in detail. He was helped very much in his investigations by the invention of a special staining method for the axis cylinders. Preparations hardened in Müller's fluid were stained in concentrated aqueous solution of aniline blue (Gruebler), after which they were differentiated in a slightly alkaline alcohol. This gives a deep blue stain to even the finest young axones, while the cell protoplasm in general stains of a very pale blue tint, or by counterstaining in safranin it stains light red in contrast to the deep red stain taken by the nuclei. After studying all stages of the degeneration itself, and confirming again the fact that it is complete for both myelin sheath and axone to the very periphery, he took up the study of the changes of a progressive nature, finding, as had previous investigators, that the degenerative and the regenerative processes in the injured nerve accompany one another in time and place. He separates sharply the progressive phenomena which concern the cellular elements of the old nerve fibre, that is, the cells of Schwann's sheath, and the progressive phenomena of true nervous origin, namely, the new formation of the axone and the myelin sheath. The latter alone have the significance of the true regeneration of the nerves. The phagocytic activities of proliferated neurilemma cells were carefully studied. Ströbe also describes how these cells become transformed into long spindle-shaped elements with longitudinal oval nuclei filling up the old sheath of Schwann. These unite to form spindle-cell rows as the degeneration products disappear; portions of nerve fibres filled up by such rows of spindle cells may alternate with other portions of the same fibre consisting of entirely empty and collapsed Schwann's sheaths. An especial study at the site of lesion showed that the proliferating cells of Schwann's sheath enter into this region from both ends of the divided nerve; but here, instead of forming rows, the cells are prone to be irregularly mixed up and interwoven with proliferating connective-tissue cells of the endo-, peri-, and epineurium. This proved that the neurilemma cells possess no inherent tendency to the formation of longitudinal rows, but do so in the peripheral portion of the divided nerve simply on account of the adaptation of the cells to the special relations of the old nerve tube in which they arise.

True regeneration, according to Ströbe, has nothing to do with this proliferation of the neurilemma cells and the bands of spindle cells resulting therefrom, but depends entirely upon the outgrowth and splitting up of the old fibrillary axis cylinders directed peripheralward from the central nerve stump. These young fibres, by the method of staining employed, appear as sharp microscopic pictures; so sharp, indeed, that there can be no excuse longer for confusing them with the fibril-like structures in the protoplasmic bands described by von Büngner. The impression is never obtained of a new axis cylinder becoming differentiated out of the protoplasm of the rows of neurilemma cells. From the very beginning the young axones are continuous with the old axone, and show on their first appearance a very delicate but distinctly developed continuous myelin sheath. The illustrations which accompany Ströbe's article are very convincing. The new fibres gradually lengthen and grow out farther and farther distalward. The formation is continuous, not discontinuous. Passing from the central nerve stump into the tissue intermediate between the two ends of the divided nerve, the new axones pass between the rows of spindle cells, when such exist, and between the fibroblasts which have not been arranged into rows of spindle cells. Having passed through the site of lesion, the new fibres enter the old peripheral nerve, sometimes entering into the interior of old nerve tubes still open; at other times passing between the bands of spindle cells formed from the degenerated nerve fibres. The course is tortuous and the fibres frequently cross one another. The young fibres frequently possess a knobbed terminal swelling.

The young nerve fibres, delicate at first, gradually increase in thickness, the degeneration products of the old fibres gradually diminish in amount through absorption, and the normal condition is slowly restored. The cells of Schwann's sheath are not nervous elements at all, and the designation of "neuroblast" is wrongly applied to them. They are secondary connective-tissue ensheathing cells, corresponding to their mesoblastic origin in the embryo. Ströbe's work is in complete accord with the neurone doctrine, and furthermore is compatible with what

Digitized by Microsoft®

we know must be the origin of the myelin sheath. Those histologists who assume that the myelin sheath is a product of the metabolic activity of the neurilemma cells seem always to forget that in the central nervous system we have innumerable myelin sheaths with entire absence of the neurilemma covering. That the axone builds the myelin sheath there can scarcely longer be doubt.

Ballance and Stewart have recently made an extensive publication attempting to revive the old doctrine of the discontinuous formation through fusion of rows of single cells. I cannot help but feel that they are falling into the error of a now large group of predecessors.

The bibliography of the subject must be read with great caution. Many of the statements are obvious misinterpretations. Such a finding as that of Korolow, who sees genuine ganglion cells in the central cut end, and that of Garrès, who describes regeneration of branches of the trigeminus after extirpation of the Gasserian ganglion, are based upon mistakes. What Korolow's mistake was, it is difficult to say. Garrès doubtless had to deal with partial instead of complete extirpation of the ganglion.

Regeneration of nerve fibres which have undergone solution of continuity inside the central nervous system is so imperfect that many have questioned whether it takes place at all. The physiological studies of Baer, Dawson, and Marshall, and the pathological researches of Worcester, make it seem probable that at least some regeneration takes place. The evidence in general has been sifted by Ströbe (*loc. cit.*).

Intoxications of the Neurone.

The best review of the literature of nerve-cell intoxication up to 1899 is that given by Barbacci. He has collected with great assiduity almost the entire literature of the subject and arranged the results systematically. He distinguishes sharply between the toxic influences which are the result of the introduction of substances into the normal organism from the outside world—intoxication in the narrower sense—and those intoxications which are the effect of poisons developed in the organism itself through a disturbance of metabolism—auto-intoxications. The former, in turn, can be further subdivided according to the chemical nature of the poisons, whether they be mineral or organic; and in the latter case, whether we are concerned with a so-called organic poison proper or a vegetable alkaloid or a poison of animal origin. Finally the effects of intoxication are considered by themselves, according to the special nature of the intoxication to which the alterations met with in the nerve elements are to be referred.

In his review of the general pathology of the nerve cell Barbacci refers to a series of special modifications which the nerve-cell protoplasm undergoes in various intoxications and infections. Most of these have been dealt with above under the caption, "Degenerations of the Neurone." A few additional ones, however, deserve especial mention.

Golgi's method has been utilized by a number of investigators for the study of pathological alterations in nerve cells, though it has been, of course, of far greater service in revealing the normal anatomical relations inside the central nervous system. One is always more or less in doubt in studying pathological tissues with Golgi's method as to how many of the appearances met with are artefacts. One of the commonest findings in pathological tissues is the so-called *varicose atrophy of the dendrites*. Instead of the normal dendrite, one sees a process studded by rows of round or oval swellings connected by thinner or thicker threads, reminding one of a chain of beads. This change is preceded, as a rule, by a falling of the "gemmules" or lateral thorns from the dendrites. The alteration affects the finest branches of the dendrites first and extends to the thicker trunks, until, finally, all of the protoplasmic process of the cell may be involved. Occasionally, however, the change is limited to a single dendrite or even to a single branch. The changes in the larger protoplasmic trunks of the dendrites, however, are not, as a rule, so typically beadlike. Instead, one sees an irregularity of contour, nodules, indentations, erosions, roughenings, wrinkles, etc., in the Golgi pictures. Any of the appearances described may be met with in normal tissues, but the change may be regarded as pathological when it is extensively distributed. For a list of conditions in which these changes have been noted, Barbacci's article may be consulted (*loc. cit.*, S. 798).

A somewhat similar atrophy affects the axones as seen in Golgi preparations, under certain conditions. What appears to be the same or a similar condition has been described by Golgi as *varicose hypertrophy*.

Of the changes met with in intoxications in tissues studied by Nissl's method, that of *chromatolysis* or *tigrolysis* has already been referred to (*vide supra*). The process has been carefully described by Ewing, Marinesco, and others. It begins, as a rule, with a swelling of the tigroid masses, though this is not always demonstrable. Once begun, the process involves a gradual vanishing of the tigroid from the cell protoplasm. The tigroid masses may disappear in various ways. In the first place, it is not uncommon to see an irregularity of arrangement appear. In the cells of the anterior horn, for example, instead of the typical stichochrome arrangement, one may meet with great irregularity and disorder. Again, instead of sharply isolated tigroid units, these elements may lose their individuality and be connected with others in the cell protoplasm in the form of a network. Instead of sharp, clean-cut pictures of the individual tigroid mass, one frequently sees ragged edges and indefiniteness of outline.

Ewing has described a fine subdivision of the tigroid masses occurring when the tigrolytic process goes on slowly. In other cases, in which the process is more rapid, the tigroid elements are broken up quickly into very fine granules and become evenly distributed throughout the cytoplasm, giving it a very characteristic "dust-like" appearance. This is the change designated by Ewing as "*granular subdivision*" and by the Germans as "staubiger Zerfall." In the final stages all the stainable substance of Nissl has disappeared from the cell (stage of *achromatosis*, described by Marinesco).

The tigrolysis may be total, or it may be limited to smaller or larger portions of the cell, in which case we speak of *partial tigrolysis*. If it involves the region immediately adjacent to the nucleus, the condition is spoken of as *central* or *perinuclear tigrolysis*; when, on the other hand, it is the periphery of the cell which is affected, the central portion remaining almost intact, it is spoken of as *peripheral* or *marginal tigrolysis* (Fig. 3587). By *intermediate* or *concentric tigrolysis* is understood the involvement of the middle zone between the nucleus and the periphery—a very rare condition. Finally the tigrolytic process may involve some particular segment of the

Digitized by Microsoft®

cytoplasm, in which event it is spoken of as *segmental* or *circumscribed tigrolysis*.

The tigrolysis which follows section of the axone has been referred to as *degeneratio axonalis* (Fig. 3588); it is of the central variety as a rule. It was supposed by many that, on the other hand, when a toxic agent acted upon the cell from without, the change nearly always consisted in peripheral or marginal tigrolysis. A review of the extensive bibliography, however, teaches that no hard-and-fast rule can be laid down.

www.libtool.com.cn

The changes demonstrable by

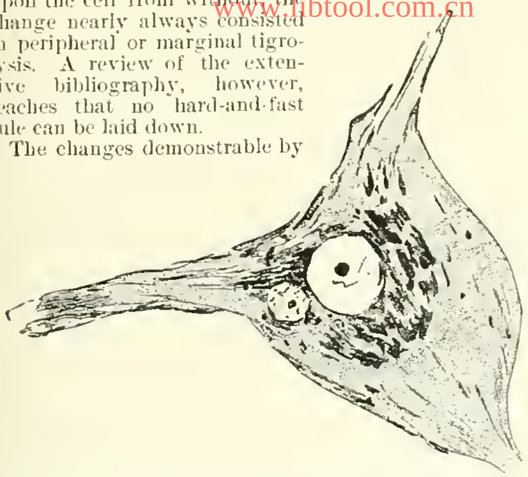

FIG. 3587.—A Nerve Cell from a Part of the Spinal Cord Deprived of Blood for Six Hours Through Ligature of the Abdominal Aorta. (After G. Marinesco, *Presse méd.*, Par., 1897, pl. v., p. 45). The peripheral portion of the cytoplasm contains only a few tigroid masses, although the latter are still numerous near the nucleus. Typical *peripheral tigrolysis*.

Nissl's method in the nucleus in various intoxications include (1) swelling of the nucleus, (2) diminution in the size of the nucleus, (3) alterations in the form of the nucleus, and (4) alterations in the contents of the nucleus.

Swelling of the nucleus may vary in degree. In extreme cases actual dropsy of the nucleus has been met with. Such swelling has been described in a whole series of conditions, including faradic excitation of the cell, commotio, uræmia, cholæmia, tetanus, rabies, and acute delirium.

A diminution in the size of the nucleus may or may not be accompanied by alterations in its nucleolus. As a rule the form of the nucleus is also somewhat altered. The contour is irregular, the nucleus looking as though shrunken. When the contents are altered, they may be homogeneous and stain diffusely and evenly. Sometimes this homogeneity is associated with shrinking—so-called "acute homogenization with atrophy" (Sarbo). Sometimes the contents of the nucleus stain evenly, but take a different tint from other constituents of the cell, especially a shade different from that taken by the nucleolus and the tigroid mass. This "metachromatic" staining has been met with by Barbacci in various pathological conditions, but especially in experimental cholæmia. He points out, however, that metachromatic staining frequently occurs in tissues which have undergone post mortem change, and that therefore great care should be exercised in reporting instances of the alteration.

Vacuolization of the nucleus has been referred to above in connection with vacuolar degenerations in general.

Eccentricity of the nucleus or peripheral disposition of that structure is one of the typical changes in the nerve-cell body following upon lesion to its axone. That it may occur under still other conditions has been manifoldly stated. Thus it has been described after ligature of the aorta, in embolism, and in various intoxications. In some of these instances, however, the eccentricity may depend not upon the direct action of the harmful agent upon the cell body and nucleus, but rather upon a simultaneous injury to the nerve fibre, in which event the change in the nerve cell would correspond to the ordinary axonal degeneration.

Various alterations in the nucleolus, under pathological conditions, have been described. All degrees of pallor of the nucleus have been observed in stained preparations, the pallor occurring most frequently when the volume of the nucleolus is increased. Swelling of the nucleolus is met with under many conditions, but particularly after tetanus or strychnine poisoning. Occasionally the nucleolus is diminished in size (Ewing). Uneven staining of the nucleolus with actual vacuole formation has been emphasized by Lugaro as a common appearance after arsenic poisoning. Similar phenomena have been described by Ewing in hydrophobia.

The shape of the nucleolus is often altered, instead of being round with regular margin, it may become polygonal. In extreme cases it may be fragmented, a condition not to be confounded with the existence of the so-called secondary nucleoli.

When one approaches the subject of special intoxications he is almost overwhelmed with the immense number of researches which have been undertaken in connection with them. The great vulnerability of the Nissl bodies and the observations of marked alterations in them in various intoxications led Nissl and others to hope that we might find in the study of the stainable substance safe criteria for the histological diagnosis of the action of specific poisons. Much disappointment has, however, been met with as the investigations have proceeded. The lesions in the majority of instances are not pathognomonic for the special poisons. If specific alterations are some day to be found, they will probably be in the ground substance of the nerve cell or unstainable substance of Nissl rather than in the tigroid masses. That specific poisons have specific effects is indubitable from the physiological and pathological results of their action. That specific physical and chemical alterations take place in certain groups of nerve cells under such circumstances we cannot doubt, but we are far from having found anything like histological changes corresponding to these specific effects. In all probability we must wait until our technique has become much more refined before we can hope for histological demonstration. It may be that the alterations concern portions of the nerve-cell protoplasm measuring less than the wave length of light, in which event microscopic demonstration would be impossible.

Of the mineral poisons, the effects of which have been studied, may be mentioned arsenic, lead, antimony, mercury, phosphorus, silver, and aluminum. Of the organic poisons proper the effects of alcohol, chloroform, antipyrin, trional, acetone, and malonnitril have been studied. The effects of powerful alkaloids have formed the basis for a large series of histological investigations. Strychnine, morphine, quinine, ergotine atropine, muscarine, nicotine, cocaine, and veratrine are among those which

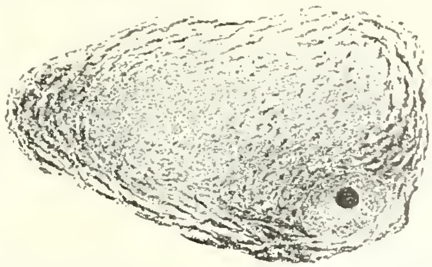

FIG. 3588.—Spinal Ganglion Cell Showing Marked Alterations Following Section of the Sciatic Nerve. Sublimate fixation, thionine staining. (After Lugaro.) Typical *central tigrolysis* with eccentric position of nucleus: *degeneratio axonalis*.

have been used. Of the poisons of animal origin blood serum of animals of the same and of other species, urine, thyreoidine, neurine, and snake poison may be mentioned as those whose effects have been particularly investigated. Special interest has attached to the examination of the changes in the nerve cells which occur in the so called auto-intoxications. Thus in the bibliography

Digitized by Microsoft®

there are multiple references to studies of the nervous system in uræmia, cholæmia, coprostasis, adrenal cachexia, thyreoid cachexia, experimental glycosuria, insomnia, and the auto-intoxications following burns. Finally, the alterations in the neurones, occurring in a whole series of infectious diseases, have been examined and studied; tetanus, diphtheria, hydrophobia, bubonic plague, yellow fever, botulismus, septicæmia due to various micro-organisms, anthrax, infectious peritonitis are among the number. It would be beyond the scope of this article to discuss these in detail, and besides Barbacci has given an excellent epitome of the whole subject in his collective review, to which in this section reference has so frequently been made. Perhaps nothing better can be done, under the circumstances, than to quote Barbacci's summing up of the whole matter. It is his opinion that the alterations perceptible in the nerve cell under various conditions are best understood as follows: "When a harmful influence affects the nerve cell, two series of processes are possible: either the harmful influence is so intense that it quickly kills the cell, in which event the microscopic picture shows only the typical signs of cell necrosis; tigrolysis has neither time nor reason for appearance. The alterations of the protoplasmic masses, and especially those of the nucleus, are those which betray the effect of the morbid causative agent. If, on the other hand, the intensity is less, the cell reacts powerfully at first against the abnormal stimulus and uses up, in the exertion of the reaction, its reserve supply of nutriment more or less quickly. Herein we see the significance of tigrolysis; it is the expression, simply of a phenomenon of reaction. If during this first phase the total activity of the pathological stimulus becomes exhausted, the alterations in the cell progress no farther and the normal condition is quickly regained, the reserve supply of tigroid substance being quickly restored. In this phase of the reaction, the neurones retain their functional capacity unaltered—a fact which explains very well the striking contradictions between the anatomical findings and the clinical symptoms in many affections. During the development of a disease the nervous system may betray no symptoms which would indicate alterations taking place in it, and yet its elements, on microscopic examination, show that extensive tigrolytic processes have already occurred. This is seen especially frequently in infections and intoxications, and particularly in those which follow an acute course. But when the influence of the noxa continues to act upon the neurone after the latter has exhausted all its reactive powers, it becomes affected in its most vital parts and degeneration follows upon the reaction. The cell is irretrievably condemned to death, and the microscopic specimens show most often only the signs of a cell cadaver."

It would seem not unlikely that our knowledge of the general pathology of the neurone will be materially increased through the extension of experimental pharmacology, and of those modern researches which are attempting to explain the phenomena of immunity. A start has already been made in the investigations which bear upon the relations of the chemical constitution of bodies to their distribution in the organism and their pharmacological effects. Since Stahlschmidt, in 1859, proved that strychnine could be robbed of its tetanizing effect through the introduction into it of one methyl group, and so be transformed into a paralyzant, not unlike curare, interest in such problems has rapidly grown. It was soon shown by other investigators that other ammonium bases, derivable from various alkaloids, possess properties not unlike those of curare—a fact of the highest interest, since Böhm has since demonstrated that curarine itself is an ammonium base.

The work which has been done upon artificial antipyretics has furthered the ideas under consideration. The synthetic preparation of antipyrin and phenacetin may be mentioned as an illustration. It has been shown that the antipyretic effect of aniline derivatives and amidophenol derivatives like phenacetin, is proportional, within certain limits, to the amount of para-amido-phenol which is split off in the organism, and it has been demonstrated that the introduction of acid salt-forming residues (like SO_3H and CO_2H) prevents the antipyretic power of such substances. Again the studies upon cocaine and allied bodies support the same principle. It has been shown that it is the benzoyl residue which in cocaine gives it its anæsthetic power. It was a knowledge of this fact which led to the synthetic manufacture of new anæsthetics which contain the anæsthesiophore benzoyl group as their active agents; thus eucaine, orthoform, and nirvanin have been made available. The somniferous effect of the introduction of ethyl groups into molecules has been adduced as further evidence along these lines. Sulfonal, amylene hydrate, alcohol, and dulcin all owe their specific properties largely to the ethyl groups contained in their molecules.

Ehrlich's studies upon the staining of the living nerve tissues by a certain small number of basic aniline dyes (methylene blue, Bismarck brown, chrysoidin, neutral red, etc.) is calculated to throw some light upon the subject. He has shown that these neurotropic dyes entirely lose this power if a sulpho-acid group be introduced into their molecules. The introduction of the acid group alters the distribution in the organism and completely destroys the neurotropic properties. Ehrlich has pointed out as specially significant the fact that the majority of basic dyes which stain the living brain substance have also an affinity for adipose tissue. In other words, neurotropy and lipotropy are intimately connected with one another. It is obvious, therefore, that when substances are ditropic or polytropic their distribution in the organism, and with it their pharmacological effect, will vary more or less with the quantitative relations of the tissues for which they have affinity. Thus the poisons which have at the same time neurotropic and lipotropic effects, if administered in equal amounts per kilogram of body weight, will have a much more marked influence upon the nervous system in an emaciated animal than in one which is very fat; for, according to the *loi de partage*, much more poison will be taken up by the brain.

One of the most important questions which we meet with is that which deals with the reason why certain tissues are selected by certain chemical substances. That the reasons are chemical in nature seems very probable. It is well known, however, that certain indifferent substances possess neither basic nor acid characters; and when introduced into the organism, though they have no marked chemical affinities, they nevertheless often exercise extremely toxic effects. This is true, for example, of ether, alcohol, and various narcotics. In such cases it is thought that direct chemical affinities on the part of the organism are not concerned, but that we have to deal with a sort of contact effect, due to the influence of unaltered and chemically unbound molecules present among the constituents of the tissue. But if this is true, what is it that determines the typical localization of these compounds in certain tissues, such as those of the central nervous system? Ehrlich has compared this kind of localization with the principle of the Stas-Otto extraction procedure. Writing in 1887 he said: "The principle of the mode of extracting poisons introduced by Stas-Otto is based on the fact that in general basic bodies, like the alkaloids, enter into firm chemical combination in acid solutions, and hence can only with difficulty be extracted, while they can easily be shaken out of alkaline solutions. Acid compounds show, of course, the opposite behavior, since they are held firmly in alkaline media, but are easily given up by acid media. If we transfer these principles to the questions in which we are here interested we can easily understand why basic dyes, particularly those which are not retained in the blood by chemical affinities, are preferably taken up by the brain, while the acid dyes and sulpho-acids which are firmly held by the alkalies of the blood in the form of salt, and, as it were, are anchored there, show exactly the opposite behavior." Ehrlich's observations that adipose tissue takes up many substances which are also taken up by the brain is significant when added to the finding of Pohl in 1891, that the

Digitized by Microsoft®

receptivity of the red blood corpuscles for chloroform depends upon the presence in the corpuscles of cholesterin and lecithin, and to his conclusion that the relation of the chloroform to the nerve tissues of the brain is dependent upon the existence of substances of a fatty nature in the brain. These studies afforded the basis for more accurate examinations of the cerebral effects of those substances which are easily soluble in fats and fat-like compounds. That these examinations have been fruitful will be clearly seen from the work of Hans Meyer on alcohol narcosis, and that of H. Overton on the causal relations existing between solubility in fat and narcotic effects.

But this loose contact effect of poison upon the brain and spinal cord will not explain another series of intoxications due to bodies like the antipyretics, various substances of a basic nature (alkaloids and phenols) which are not chemically indifferent, but, on the contrary, may be capable of entering into actual synthetic relations with the tissue cells. Loew suggested some years ago the existence in protoplasm of definite atomic groups endowed with powerful affinities; to these atomic complexes he ascribes an important rôle in the phenomena of intoxication. It was his opinion that atomic groups, on the one hand, perhaps, of the nature of aldehyde groups, on the other hand, the labile amido groups, were active in the protoplasm proper in catching hold of chemical substances circulating near them, and for which they had an affinity. Any compound, he thought, which could combine with either of these atomic groups could act as a protoplasmic poison; and the greater its affinity for these groups the stronger its toxic effect. But Ehrlich's experiments with aniline dyes speak against such a substitutive action of poisons, at least of poisons like the alkaloids; for most of them can be extracted from the tissues by indifferent solvents, and this would scarcely be the case if chemical combination with the protoplasm took place. Ehrlich assumes, on the other hand, that only two modes of explanation are possible, and that in one case one may be true, in another case the other. The one explanation is based upon Knecht's theory of the action of dyes depending upon the formation of insoluble salt-like compounds. Pfeffer, in studying the vital staining of plant cells, has convinced himself that the staining is due to the precipitation of granules of the difficultly soluble tannate of methylene blue. In animal cells the affinity of the tissue for an alkaloid might be due to the formation of a salt with nucleinic acid, or with various products of secretion present in the cell; that is to say, with substances in the protoplasm rather than with the protoplasm proper. The second possibility which Ehrlich sees lies in the probability of the formation under certain circumstances of so-called "solid solutions" (*feste Lösungen* of van't Hoff), a view which Witt has advanced in dye chemistry. Possibly, as he suggests, the distribution of an alkaloid in the organism sometimes depends upon both causes, the selection being due to a combination of "salt formation" and of "solid solution."

There is a class of poisons, however, quite different from all these thus far mentioned, poisons which like food-stuffs may actually enter into the molecules of the protoplasm proper and be *fixed* in the protoplasm and become non-extractable by indifferent solvents; for such poisons a view like that advanced by Loew would be more applicable. Sugar residues, for example, cannot be withdrawn from the cells by simple solvents; they must first be split off by acids in order that they may be obtained in a free condition. For such chemical anchorage, as in all syntheses, two combining groups of maximal chemical affinity must be assumed to exist, one in the cells designated by Ehrlich as a "side chain" or "receptor," the other in the food-stuff molecule and called by him a "haptophore" group. Ehrlich assumes that living protoplasm is supplied with a large series of such "side chains" (*Seitenketten*), which by virtue of their chemical constitution have the power to anchor the various kinds of food-stuffs; in other words, the activities of such side chains underlie the phenomena of cellular metabolism. It is this "side-chain theory" also which forms the basis of Ehrlich's doctrine regarding the action of bacterial toxins and the production of antibodies. He believes that the toxins, like the food-stuffs, possess definite haptophore groups which, uniting with corresponding receptors in the protoplasm-molecules of the cells, permit the toxic effect. As a result of the throwing out of function of these receptors the cells "regenerate" new receptors of the same kind in excess, many of them being thrown off into the blood to form "antitoxins." Only such poisons as possess haptophore groups can give rise to the formation of antibodies; against alkaloids, glucosides, or the antipyretic substances, no true immunity can be produced.

In tetanus, to take a concrete example, the symptoms all point to an intoxication of the central nervous system. According to Ehrlich's side-chain theory, the poison acts on the nerve cells because its haptophore group combines with corresponding receptors in the nerve cells. Tetanus antitoxin consists of such receptors regenerated in excess and thrown off into the circulating blood. When tetanus poison enters the blood of an immunized animal it is bound by these receptors and the side chains in the nerve cells themselves are protected. Wassermann has shown that the normal tissue of the central nervous system of most animals that are susceptible to tetanus is capable of entering *in vitro* into firm combination with tetanus poison, and that a mixture of normal nerve tissue and tetanus poison is harmless when introduced into animals, because the haptophore groups of the poison are saturated with receptors, and so cannot combine with the living nerve tissues of the animal under experiment. Other organs of the body do not combine with the tetanus poison *in vitro*.

Interesting, too, in connection with the pathology of the neurone is another series of facts—those bearing upon specific cytotoxins. It is now known that the injection of the red blood corpuscles of a species *a* into a species *b* leads to the development in the blood serum of species *b* of specific products of reaction which are highly toxic to the corpuscles of species *a*. These toxic substances are the so-called specific hæmolysins. Delzenne and Madame Metchnikoff, by treating animals with the central nerve tissues of other species, have been able to prepare a specific highly neurotoxic serum. Small amounts of this serum injected into the cerebrum of species *a* caused paralysis and epileptiform convulsions. Experiments made with other cells give similar results; thus specific leucotoxins (for the white blood corpuscles) and specific spermotoxins (for spermatozoa) have been produced. The fact that anti-hæmolysins and anti-leucotoxins can be made experimentally is very hopeful for the future of therapy.

Along the pathways just indicated the hope of the experimental pathologist and therapeutist would seem to lie. But an immense amount of work must yet be done before extensive practical application of these ideas in clinical neurology may be expected.

NEUROSES, TROPHIC. — DEFINITION. — Derangements of nutrition determined by variations in the supply of nervous energy, without observable change in the nerve tissues.

Digitized by Microsoft®

The study of the diseases usually included under this head is in large part a matter of the last few years. Several members have been added to the group, and those known for a longer time have been more closely scrutinized and their phenomena described. In spite of this fact considerable doubt exists as to what particular diseases belong in this category. Authorities differ a good deal in regard to the nature of some of the diseases and their ultimate causes. In order to obtain an adequate conception of the general features of trophic disorders it is necessary to consider with them some of the vaso-motor diseases. Nourishment and decay are closely and necessarily linked with the blood supply; this latter is varied, at least in quantity, by a special nervous mechanism constituting the cardio-vaso-motor system, so that the action of the nervous system on nutrition must be divided into its direct action, and the one exerted through the vaso-motors.

www.libtool.com.cn

It is obviously impracticable to include in the group all neuroses associated with trophic change. Nutrition is profoundly affected in many, somewhat affected in most of the neuroses, including such widely varying diseases as chorea, epilepsy, and various neuralgias. Overgrowth or decay should be the predominant and essential feature of the process, and should affect specific structures. The results of ordinary vaso-motor action and mere connective-tissue hyperplasias should not be classed as trophic disorders.

It is first to be noted that a neurosis is properly a nervous disease without observable organic basis in the nerve tissues. It will not be here used in its broader sense of nervous disease, whether organic or functional, as the tropheneuroses would then of necessity include diseases (syringomyelia, poliomyelitis, neuritis, and many others) which, although accompanied by trophic changes in various tissues, are evidently not contemplated in the present classification.

Granted that the changes in these diseases may occur under the immediate influence of the nervous system, whether by so-called trophic nerves or otherwise, there still remains the question whether the nerve changes are determined by the action of poisons or take place as a result of inherited or acquired tendency or from other causes. Nutritional and degenerative abnormalities are usually the result of poisons taken into the body from without, or formed in the body by bacterial or glandular action. The idea that there are purely functional disorders without organic change is being much modified, and is giving place to the conception of function as varied by changes of structure or of environment, and especially by variations of the blood supply and blood content. Especially in the group of diseases known as the trophoneuroses the symptoms from which the patient suffers are almost exclusively those of obvious organic change in the most various tissues. To suppose a functional basis for such changes is a theory to be adopted, if at all, after a careful scrutiny of the facts.

The idea of trophoneuroses is suggested by analogy from the muscular atrophy that supervenes on destruction of the fibres of motor nerves or of motor ganglion cells in the cord. While trophic changes in such diseases as tabes and syringomyelia suggest the possibility of tissue death from deficient innervation alone, facts are rapidly accumulating which tend to show that some trophic diseases formerly classed as neuroses are in reality vaso-motor and trophic disorders determined by lack or superabundance of secretion of some of the ductless glands. The discovery of the importance of the secretion of the thyroid gland in myxœdema, cretinism, and possibly scleroderma, and the close relationship of the latter in its varied forms with the atrophies and hypertrophies, facial hemiatrophy, acromegaly, and other diseases has thrown much light on nutritional variations.

With these facts in view it will be well critically to examine the diseases sometimes classed as trophoneuroses, so as to find out which, if any, of them are entitled to a place in this category.

Acroparæsthesia affects mainly women who are much exposed to cold, and especially those who have their hands much in cold water. The symptoms are numbness and tingling of the extremities, especially of the hands, sometimes increasing to burning or tearing pains. There may be either hyperæsthesia or anæsthesia, and analgesia, usually of moderate degree. The symptoms do not follow the distribution of any nerve or nerves. The sensory symptoms constitute the essential elements of the disease. Vaso-motor phenomena are sometimes added, and consist of either redness or blanching of the hands. Nutritional changes are slight and unessential.

The fact that vaso-motor symptoms are variable and sometimes absent indicates that the disease is an affection of the sensory nerves, possibly a hyperæmia or low grade of inflammation. The efficiency of ergot in controlling the symptoms makes this view probable. The disease usually runs a long but mild course.

Angioneurotic œdema is the name given to œdematous swellings which occur suddenly in various parts of the body, sometimes without apparent cause, sometimes on exposure to cold. The swellings do not pit on pressure; they may be white or pink in color; they disappear completely. The neurotic nature of the disease is sufficiently indicated by the skipping of the œdematous spots from one place to another, sometimes with a rapidity quite remarkable. It is not in any sense trophic, but is purely vaso-motor; sometimes, possibly always, on a toxic basis.

In many people of low vitality one or more fingers become white, cold, and corpse-like on plunging them into cold water in the morning, especially in winter. These are the so-called "dead fingers." The blanching in severe cases may involve the hands and extend to the elbows, or even to the shoulders. Numbness and tingling are present but moderate. The phenomena soon pass off when the hands are warmed by the fire. The disease is not dangerous, nor even threatening except in some cases in which vascular spasm may be so great as to induce faintness. The condition is related on the one side to acroparæsthesia; on the other to Raynaud's disease, the first stage of which it may simulate. Trophic features are absent. A more profound affection of the vaso-motors is seen in Raynaud's disease, one essentially of vascular spasm of extreme degree. The stages of blanching, of local asphyxia with blackish discoloration and of gangrene, are those of tissue death rather than of retrogressive metamorphosis. These phenomena are vaso-motor. There are, to be sure, trophic symptoms in many cases, amounting to marked scleroderma. The fact that scleroderma may exist without perceptible vaso-motor change, that in Raynaud's disease blanching and local asphyxia may go on indefinitely without atrophy, and the lack of proof that there is any necessary connection between the two sets of phenomena, show the non-identity of the two diseases in spite of the existence of mixed forms. Vascular spasm of known origin is usually toxic. An extreme instance of this kind is seen in the gangrene of ergot poisoning. Organic lesion of the vaso-motor centres is also capable of setting up vascular spasm and gangrene. No poisons have been found to account for Raynaud's disease, and organic nerve lesions have not been discovered.

It is hardly necessary to discuss the question whether the foregoing diseases are essentially trophic. The symptoms are those of derangement of the vaso-motor system; variations of nutrition are not prominent and are absent in many cases. The ultimate cause of these diseases is an interesting problem, but is not germane to the present inquiry.

The general diseases connected with abnormalities of the thyroid gland are interesting instances along the boundary between the vaso-motor and the trophic. They have so lately been assigned to their proper place that they still often figure as trophic neuroses, and they are so closely related with the other diseases under discussion that they deserve a brief mention.

Exophthalmic goitre is characterized by vaso-motor phenomena with some secondary nervous manifestations. The rapid heart action, vascular enlargement of the thy-

Digitized by Microsoft ®

roid gland, and bulging of the eyeballs point to an involvement of the sympathetic system, and tremor, nervousness, and vomiting make up the usual picture of the disease. There seems little doubt that the symptoms are caused by increased functional activity of the thyroid gland. The cause of this increase is not known, but there is no ground for thinking it to be a neurosis, and exophthalmic goitre now finds its place among the glandular affections. Changes of nutrition of the body tissues are great but not specific.

www.libtool.com.cn

It is otherwise with myxœdema, a disease now known to be due to lowered function of the thyroid gland. The deposit of mucinous material in the skin, giving the characteristic œdematous appearance, is not a condition of overgrowth, and the changes in the kidneys, blood-vessels, and nerve tissues are degenerative, not trophic. The disease makes good its title to a place among trophic disorders chiefly by arrest of development in patients in whom the disease begins in childhood. To this condition the name of cretinoid idiocy is given. Its dependence on lack of secretion of a ductless gland (the thyroid), its improvement by administration of thyroid extract, and its close relationship with myxœdema are pregnant with suggestions in regard to trophic variations and many so-called trophic diseases. Meanwhile, in spite of the fact that trophic conditions are so largely present in cretinism, and are so closely simulated in myxœdema, neither of them is a neurosis, and neither of them is properly a trophic disease.

So far we have considered diseases that vary by more or less perceptible degrees from sensory into vaso-motor, and from vaso-motor into trophic phenomena. In few of them is trophic change entirely absent; and while sensory symptoms do not increase in proportion with the severity of the remaining symptoms, they are still present throughout the entire series. We now come to a disease in which sensory and vaso-motor symptoms play an entirely minor part, and in which changes mysterious in origin are apparently essentially trophic.

Scleroderma is a disease not, as its name implies, of the skin alone, but in its well-developed form is a wasting of the tissues in general, including skin, bones, muscles, mucous membranes. Clinically the present tendency of authorities is to include in the same category all cases, whether of atrophy limited to a small portion of the skin or of wasting of almost all of the tissues of the body, as in the terrible but happily rare instances of diffuse scleroderma. These cases have the one symptom of skin wasting in common, but it is improbable that they depend upon the same cause. In fact the partial cases, the so-called morphœa, have in some instances been shown to be due to organic changes in the nerve tissues, which is not the case with general scleroderma. The striking features of this disease are the atrophy without sensory disturbance, whether anæsthesia, hyperæsthesia, or pains other than the discomfort due to the shrinking tissues; and the absence of vaso-motor changes as an essential part of the phenomena. The latter is limited to a hyperæmia of moderate degree, shown in the lilac border about the patches of morphœa. Pathologically the tissues show a change into connective tissue and a disappearance of the normal elements.

That so profound and widespread changes as occur in well-marked scleroderma should be brought about by changes in the structure or functions of the nerve tissues without direct involvement of their more familiar functions, those connected with motion and sensation, is sufficiently improbable. We may leave out of account organic change in the nerve tissues. If such were present and could be shown with a fair degree of probability to be in causal relation to the symptoms, the disease would be assigned to the organic nerve diseases. Let us examine in brief the reasons usually urged for considering any disease neurotic in origin.

Symmetry of the lesions or of the symptoms is often supposed to indicate their nervous origin. It is sufficient to observe on this head that although the nervous system is symmetric, so are the other organs of the body. In especial the blood-vessels are in the main symmetrically disposed. Accordingly vascular disturbances, whether conditioned by blood supply or by blood content, are usually symmetric, except when determined by local causes, as heat, cold, violence, pressure. It is to be noted that of the two ways in which these agencies have their effect, one is by mechanical change, and the other is change of tissue through the action of the vaso-motors, so that asymmetry itself is in many cases the result of nerve action. While vascular action is usually symmetric, nerve action is not usually so. Walking is alternate, not symmetric action; the hands are sometimes moved together, usually separately; the finer motor acts, as of speech and writing are functions of one side of the brain; the possession of special sense organs in pairs is an instance of redundance for safety in case of accident rather than a necessary symmetric arrangement.

General sensibility is only symmetric in the sense that the whole of the skin and the other tissues is supplied; the very point and essential feature of the whole mechanism is the distinguishing of one side from the other and of one spot from another. In some special instances, as with contraction of both pupils from the impact of light on one retina, a bilateral result follows from a unilateral cause. Dilatation of the pupils, however, from an injection of atropine is not an instance of the same kind, but is determined by distribution of the poison to the sympathetic on both sides; excitation of the sympathetic in the neck on one side, by galvanism, and the action of atropine on the nerve filaments of one side, by instillation into the eye itself, are followed by dilatation of the pupil of the corresponding eye alone. These and other considerations of a like kind tend to show that symmetry of nerve action is usually the result of causes acting bilaterally.

The proposition that most nervous symptoms are not symmetric, and most symmetric symptoms are not nervous, is susceptible of easy proof, and lends little support to the inference often made that symmetric lesions are of nervous origin if not proved otherwise.

Another usual reason for considering a manifestation of any kind as of nervous origin is its association with so-called neurotic or hysteric symptoms, such as causeless laughing and crying, wandering anæsthesia, clavus, and the like. Leaving aside the inherent improbability that grave organic changes depend on vague and so-called nervous conditions, or that they have no better excuse for being than is implied by the insufficient and unnecessary word hysteria, we may at any rate leave this factor out of account in considering scleroderma, sufferers from which disease are singularly unemotional considering the hideous and destructive changes which they are undergoing.

Acromegaly is characterized by increase of size of the extremities, the hands, feet, and head; and this fact gives the name to the disease. The name, however, is a misnomer, for the enlargements are true hypertrophies affecting almost every organ in the body. The muscles are large, and in the early stages of the disease they are powerful. The bones are thickened and the subcutaneous tissues form great pads in the palms and soles. The lips protrude, there is an undershot lower jaw, the nose is big and bulbous. This is, however, only a superficial view, for the heart, the liver, the kidneys, and the spleen are also enlarged. The brain is increased in size, the skin is thick and coarse, and the voice is heavy from roughening of the vocal cords. When the disease begins in early life the general increase in size produces true gigantism. Marie's saying that "acromegaly is gigantism in the adult, gigantism is acromegaly in the adolescent," while only partly true, is accurate as regards many cases. One feature of the disease, the enlargement of the pituitary gland, early attracted Marie's attention. He considered this the cause of the disease. Further study brings to light the following difficulties in the way of this theory. First, not all cases show enlargement of the pituitary gland. In one case the gland was entirely absent. Second, the changes in the gland are not uniform but of the greatest possible variety. Third, many cases

Digitized by Microsoft®

of disease of the gland are reported in which no symptoms of acromegaly were present. Fourth, pituitary extract administered to patients does not control the disease as does thyroid extract in myxœdema. Last, and possibly most important of all, experimental removal of the hypophysis does not produce the symptoms of the disease in animals.

www.libtool.com.cn

Disregarding for a moment the evidences in regard to the pituitary gland as the cause of the disease, let us consider the theory that acromegaly is primarily the result of disordered nerve action. The only alternative theory worth considering is that it is due to alterations in the blood supply, either quantitative or qualitative. In estimating comparatively the trophic influence on the tissues of nerve and blood supply, the balance is largely in favor of the blood in regard to the importance of its action. That nervous influences do affect nutrition is undoubted, especially in the case of the muscles and of the skin. It is to be observed, however, that even in these instances the muscles increase in size under stimulation, apparently as a result of the increased action of the muscle fibres and their increased vascularity, rather than as a result of any inherent trophic activity of the nerves supplying them. The muscle fibres disappear after the nerves are cut, not directly as a part of the degeneration of the nerve fibres, but as an indirect and remote result of their loss of function. Atrophies of the skin sometimes occur as the apparent result of nerve lesion, but usually there is only a limited amount of change, such as is seen in the glossy skin of neuritis and hemiplegia; ulcerative processes are in such cases probably the result of germ action from lowered resisting power rather than destructive processes the direct result of nerve lesion. But many of the tissues have a much less rich nerve supply than have the muscles and the skin. The widespread hypertrophies of acromegaly would, if of nervous origin, require for their explanation a trophic influence out of all proportion with the comparatively scanty facts at our disposal in regard to the trophic influence of the nervous system on the organs in general.

The blood supply we know, on the other hand, to be everywhere and always of vital importance in nutritional processes. To say that nutrition is always carried on by the blood supply is a platitude, but in this connection it needs statement. The nervous system, when it affects nutrition through the blood-vessels, does so by changing their calibre. In acromegaly congestions play no part in the clinical phenomena. We are driven to the conclusion that, so far as we know, the hypertrophies in acromegaly are due to qualitative changes in the blood; whether these changes consist in an increased or deficient secretion from the ductless glands, the pituitary or the thyroid or both, it remains for the future to determine.

Facial hemiatrophy is characterized by a wasting of all the tissues of one side of the face. The disease occurs at all ages. Various causes have been assigned, especially injury at the time of birth, blows, abscesses, infectious diseases, and cases have been reported in which it has followed division of the fifth nerve. The mechanism of its production is not apparent, as division of the nerve is usually not followed by it. On the other hand, although undoubted changes have been found in the fifth nerve in cases of apparently spontaneous development, the nerve has in these cases seemed to share in the general progress of the disease rather than to be primarily affected.

Severe neuralgic pains may usher in the disease, or it may begin quite painlessly as a small atrophic spot on the skin of the cheek, much like a sclerodermatous patch. The atrophy gradually involves more of the skin and the other tissues, especially the subcutaneous tissue and the bones. One-half of the tongue and the mucous membranes and other structures of the mouth of the affected side share in the process. The cranial bones are thinned and wasted, the forehead is furrowed, and the whole side of the face hollowed and much smaller than the other side. The hair and beard are thinner than normal

The changes in the skin may be accompanied by anæsthesia, especially in cases in which the nerve trunks are much affected. Sensibility to tactile and painful impressions and the temperature sense may be retained, however, even when the skin and the other tissues are markedly atrophic. The muscles often show less change than do any of the other tissues. They may retain voluntary power and electric excitability, or may share in the general atrophy. Tears, saliva, and perspiration may be secreted normally on the affected side. The pupil remains normal and there is no change in the fundus of the eye.

The changes are progressive, but may come to a standstill at any time. The disease is not dangerous to life and the changes do not extend beyond the face, which it disfigures in a way very distressing to the patient. All known methods of treatment are quite ineffective. Electricity, massage, and cod-liver oil have been tried without much apparent effect. The relation of the nervous system to the disease is not definitely known.

Hyperostosis cranii, otherwise known as *leontiasis ossea*, is an enlargement of the bones of the head. The rest of the body tissues are not affected. The fact that the bones alone are enlarged brings the disease into interesting relation with the so-called progressive pulmonary osteo-arthropathy. The latter disease consists in an enlargement of the bones of the extremities, so that patients present a superficial resemblance with those afflicted with acromegaly. These patients, however, show no involvement of the head and no thickening of the soft parts; they lack the pads in the palms and soles, the roughening of the voice, the bulbous nose and thick lips of acromegaly, and simply show enlargement of the bones of the arms and legs, and chronic joint affection with creaking, pains, and resulting disability. While there is not always lung disease, as was at first thought, there is always toxæmia from some cause, tuberculosis, syphilis, gastrectasis among others. The changes in both these diseases are inflammatory, the osteitis in the one disease affecting not only the long bones but the joints as well, in the other the change being curiously limited to the bones of the head. Such peculiarities of distribution do not, in the writer's opinion, show that the poisons work primarily on the nervous system. A similar selective action is exercised by rheumatic poisons on certain joints, on the pericardium, the endocardium, at times the skin and meninges in different patients, and in the same patient at different times. The selective action of poisons is sometimes on the nervous system, at other times through the nervous system; but in these diseases there is nothing to show that the action is not on the affected tissues direct. The organs most richly supplied with nerves are not the ones affected, the nervous system shows no special sign of involvement, and osteitis, even though chronic and proliferating, is not a usual accompaniment of any known nerve change.

Two diseases which may be grouped together are *adiposis dolorosa* and *symmetrical lipomatosis*. Both are characterized by enormous deposits of fat; the essential difference is that in one the fat deposits are the seat of severe pains, in the other the nutritional changes are painless. The symmetry of the lesions, and in adiposis dolorosa the occurrence of pains, have been supposed to indicate a neurotic basis for the overgrowth of tissue. These diseases are certainly essentially trophic. They are both, however, to be traced to either syphilis or overindulgence in alcohol; that is, in either case to poisons which are necessarily symmetrically distributed by the blood stream, apart from any intervention of the nervous system. In the case of adiposis dolorosa it is still somewhat doubtful whether the symptoms are the expression of a separate disease process or are simply an extreme accumulation of fat and a low grade of neuritis, both common results of chronic alcohol poisoning. Symmetrical lipomatosis is a curious symptom of toxic origin.

Localized hypertrophies of varied distribution have been described. Facial hemihypertrophy is the analogue and opposite of facial hemiatrophy. It is much more rare. It is sometimes acquired, but may be congenital.

Digitized by Microsoft®

Hypertrophy of one-half the body has been described, and so also have hypertrophies of single limbs. One finger may be involved alone. These hypertrophies usually involve all the tissues. Nothing is known of their causation. The affected part may be unduly large at birth and may continue to grow or increase in size, or the enlargement may begin in later life. No cause has been traced for these strange variations from the normal, and in the absence of evidence to the contrary they must be regarded as the result of an innate tendency, possibly but not surely of an atavistic character.

www.libtool.com.cn

Returning now to the criteria to be applied in distinguishing toxic from functional nervous diseases, we may observe that functional diseases are properly vicious habits set up in the nervous system by irritants or poisons, and are to be distinguished from symptoms due to their direct and continuing action. The poisons of most of the infectious diseases, as well as alcohol and other volatile poisons taken into the body from without, are apparently capable of leaving their impress on the nervous system, causing symptoms which long outlive their exciting cause. The action of toxins on the affected tissues themselves, and their action by indirection through the nervous system, are not always easy to distinguish. The symmetry of the lesions, as already pointed out, usually means simply bilateral diffusion through the blood stream; in the one case to symmetrically disposed nerve structures, in the other to the affected tissues direct. In especial when inflammatory lesions are the result, the chances are much in favor of direct toxic action and against intervening nerve action.

The above considerations warrant the following conclusions in regard to the diseases under discussion, which permit, however, the elements of a provisional classification only.

Acroparæsthesia is a sensory neurosis. Angioneurotic œdema is a sensori-vaso-motor and Raynaud's disease a vaso-motor neurosis. Exophthalmic goitre and myxœdema, including cretinism, are diseases of the thyroid gland; the first is characterized mainly by vaso-motor symptoms, the second with special trophic features when occurring in adolescence. *Hyperostosis cranii* and progressive osteoarthropathy are inflammatory diseases, the first probably, the second undoubtedly on a toxic basis. Acromegaly and scleroderma are trophic diseases, probably of toxic origin; the same may be said of *adiposis dolorosa* and symmetrical lipomatosis, but the poison in these diseases is usually if not always alcohol or the toxins of syphilis. Facial hemiatrophy and the localized hypertrophies are trophic diseases of unknown origin, possibly neurotic. *Henry S. Upson.*

NEW-BORN, PATHOLOGY OF.—The pathological conditions which may be present in the new-born at the time of birth, or which may develop during the first days of extra-uterine life are very numerous and of the greatest variety. These conditions are of great importance, not only from a scientific standpoint, but also from the fact that they may hinder or render impossible the normal delivery of the child, or cause its death either before, during, or following birth; or finally they may affect its after-development, either by giving rise to pathological states persisting throughout life, or by the establishment of such changes that death, though deferred to a later period, ultimately results.

The conditions known as congenital, further those pathological states acquired from the parents, the causes of still-birth, the disease processes incidental to delivery, the pathological conditions and diseases peculiar to the first days of life, are all to be considered in this connection. For convenience these conditions may be divided into the following groups: *Intrinsic*, inheritable conditions, arising either in the individual sexual cells or through germ variation; *anomalies of development*, due to extrinsic causes affecting the mother, abnormal conditions of the fœtal membranes, etc.; *infections* transmitted from the parents, particularly from the mother, acquired either during intra-uterine life, or during delivery, or after birth; *intoxications*, either acquired through the maternal blood, or auto-intoxications developing in intra- or extra-uterine life; *diseases of individual tissues, organs, or systems*, peculiar to the new born, idiopathic, or produced by infection, intoxication, etc.; *new-growths*, developing in intra-uterine life or immediately after birth.

The Autopsy of the New-born.—The methods employed in the autopsy of the new-born differ in a number of details from the ordinary autopsy technique. These differences are dependent partly upon different anatomical conditions, and partly upon certain procedures which are of great importance in the determination of certain pathological or medico-legal questions. In other respects the autopsy methods are the same as those given under the head of "Autopsy" (Vol. I., page 649). The chief points of difference are as follows:

1. *Section of Spinal Cord.*—The spinal canal is opened by cutting through the laminæ with the curved bone shears.

2. *Section of Cranium.*—After the removal of the scalp the skull cap is opened in the median line, in the posterior angle of the great fontanel. By means of the curved bone scissors the longitudinal sinus is then opened both anteriorly and posteriorly by cutting through the bone in the line of the sagittal suture. The sutures between the frontal and parietal bones and between the parietal and occipital are then cut through from above, downward to the sides of the cranium, far enough to expose the brain sufficiently for its safe removal. The dura being adherent to the inner surface of the skull cap is cut through and turned back with the bones. The two halves of the frontal bone, the parietal and occipital, are pressed back from the brain at the level of greatest circumference. If the head is to be restored the bones are held back by an assistant while the brain is removed, otherwise the bones and dura are cut through at the level of greatest circumference and removed. The anterior falx is then cut and the brain removed, as in the adult.

3. *Section of Thorax, Neck, and Abdomen.*—A small block of wood is placed beneath the lumbar vertebræ. The main incision is then made in the median line, downward from the thyroid cartilage, dividing just above the umbilicus into two diverging cuts, extending on each side of the umbilicus to the pubis. The abdominal cavity is then opened just below the ensiform cartilage, and the opening extended in the line of the skin incision, passing to the left of the umbilicus. The right flap of the abdominal wall is then lifted and turned over to the right, while the umbilical vessels are dissected from their peritoneal covering and slit open toward the liver and toward the umbilicus. The skin incision passing to the right of the umbilicus is now extended downward through the abdominal wall, severing the umbilical vessels. The flap of abdominal wall between the two diverging incisions is now turned back over the symphysis and the two diverging umbilical arteries are exposed, the urachus and bladder lying between them. The arteries are now exposed by careful dissection, cut through at the umbilicus, and slit open.

The thorax is opened by cutting through the ribs instead of the cartilages in order to obtain more room. This may be done with the bone shears or a dull knife. The thymus gland is first examined and then removed. After the opening of the four heart chambers the ductus Botalli is carefully examined. This is done by extending the incision through the conus of the pulmonary artery and through the wall of the artery. The ductus Botalli is then found and probed. When the thoracic organs are removed with the neck organs, the aorta may be opened and the ductus Botalli opened by means of a probe passed from the aorta into the pulmonary artery. The heart is now removed and examined, the foramen ovale receiving careful inspection.

In many cases it is better to take out the neck and thoracic organs together. When the question is raised as to the child's having breathed after birth, the section should be conducted as follows: After the abdominal cavity is opened the height of the diaphragm is taken.

Digitized by Microsoft®

www.libtool.com.cn

The opening of the abdomen must precede that of the neck or thorax. Before the thorax is opened the upper air passages are tightly ligatured. The thoracic cavity is then opened, and pericardium and heart are examined. The larynx and trachea are opened longitudinally above the ligature. The thoracic organs are then removed. The thymus and heart are removed. The buoyancy of the lungs is then tested by placing the organs in a large vessel filled with cold water. The air passages below the ligature are then opened. Incisions are then made into the tissue of both lungs, noting the occurrence of crackling sounds, bubbles, and the amount and character of the blood. Cuts are also made into the lungs beneath the water, in order to see if any bubbles arise from the cut surface. Finally the lungs are cut into small pieces, and the buoyancy of the separate pieces is tested. The presence of air in the gastro-intestinal tract points in general to extra-uterine movements of "swallowing." From this it may be inferred that the child was born alive. The swallowed air collects in the stomach and gradually passes down the intestines. In cases in which the stomach appears to contain air or gas the organ should be ligatured at both ends and removed and opened under water.

The lower epiphysis of the femur is examined with regard to the size of the centre of ossification. The knee-joint is opened by a transverse incision beneath the patella, the leg flexed, and the patella removed. Cuts are then made at right angles into the thin layer of cartilage until the greatest diameter of the centre of ossification is cut through. In the case of premature birth the eye may be examined with regard to the presence or absence of the pupillary membrane. The anterior half of the eyeball is removed and fixed in Müller's fluid for microscopical examination.

Special Points to be Noted in the Examination of the Cadaver of the New-born.—The external examination of the cadaver of the new-born has for its chief aim the determination of those characteristics which give information as to its age and development. The most important of these points are as follows: The average length of a mature new-born child is 50–51 cm., maximum length 58 cm., minimum 48 cm. Boys are somewhat longer than girls. The average weight of a mature fœtus is for boys, 3,310 gm.; girls, 3,230 gm.; maximum weight, 5,500 gm., minimum, 2,500 gm. During the last five months of intra-uterine life the length of the fœtus in centimetres divided by five will give the age of the fœtus in months. The skin of a mature new-born is not wrinkled but smooth, of rather light color, the fine body hair being visible only on the shoulders. The umbilical cord has an average length of about 50 cm., and is inserted about the middle of the body, being thrown off about the fifth or sixth day. The hairs of the scalp measure 2–3 cm. in length. The great fontanel is about 2–2.5 cm. wide. The circumference of the cranium is 34.5 cm. The pupillary membrane vanishes in the eighth month. The cartilages of the nose and ears are firm in healthy mature infants. The finger nails are hard, horny, and extend beyond the finger tips. The shoulder breadth measures 11–12 cm., the distance between the trochanters is 9–10 cm. The testicles should be present in the firm and wrinkled scrotum (the descent of the testicles should begin during the seventh month). In girls the outer labia meet, but occasionally the inner labia are visible. The centre of ossification in the lower epiphysis of the femur usually measures 2–5 mm. in the full-term child, but in very rare cases it may be absent in fully developed children. It is not present before the thirty-seventh week of fœtal life. It appears in the blue-white epiphyseal cartilage as a lenticular mass of reddish or brown color in which minute blood-vessels are distinctly visible. The cranium should be carefully examined for evidence of injury received at birth, "caput succedaneum," hæmatoma, depressions, overlapping, etc. In the judgment of the color, consistence and moisture of the brain substance it should be remembered that the brain of the new-born is normally rosy red, somewhat translucent, and soft. In the examination of the umbilical vessels the thickness of the walls, the contents (blood, pus, thrombi, etc.), infiltrations of the surrounding connective tissue, as well as of the tissue of the umbilicus, should be noted. The lung should be carefully examined for areas of atelectasis or pneumonia. In the case of the heart the foramen ovale and the ductus Botalli (closes on the fourth or fifth day) should receive particular attention. The adrenals should be examined for evidences of hemorrhage; the degree of uric-acid infarction of the kidneys should be noted, and in male infants the spermatic, renal, and adrenal vessels should be examined for thrombi.

1. Intrinsic Pathological Conditions of the New-born.—The intrinsic pathological conditions of the new-born are those which arise in the germ independent of any external influence. They may be inherited, existing in either one or both of the sexual nuclei, or they may occur for the first time, in a given family, as a primary germ variation. The inheritance may be either *direct*, or *collateral*, or *atavistic*. The conditions which are inherited are the same as those arising as primary germ variations. From this the principle may be formulated that only those pathological conditions are inherited which originally occur as primary germ variations. In explanation of such variation we are at present limited to the hypothesis that either one or both of the sexual nuclei which combine to form the new individual are abnormal, or that from the union of two normal nuclei a pathological variety may arise, or finally that the pathological variety may be the result of disturbances in the process of copulation.

The most important of the intrinsic pathological conditions of the new-born are certain malformations, such as *polydactylism, cleft-hand, cleft-foot, webbed fingers, as well as other malformations of hands and feet, harelip, abnormal hairiness, elephantiasis, ichthyosis, albinism*, etc. The majority of the *typical monsters and malformations* may also appear as intrinsic conditions, and are not infrequently inherited. Of these may be mentioned the *malformations of the face and cranium, spina bifida, atresias of the body orifices, transposition of the viscera, malformations of the heart and blood-vessels, and of the sexual organs*, etc. (see also article on *Teratology*). Further, certain tumors, as *fibromata, multiple neurofibromata, angiomata, lymphangiomata, osteomata*, etc., often appear in certain families as inheritable conditions. All of these conditions may be present at birth, though they not infrequently appear in later life.

Abnormal size of the new-born may be explained as due to intrinsic causes. In some cases the weight of the full-term fœtus may reach as high as 12,000 gm., the length of the body exceeding that of the normal. An *abnormal size* of individual parts of the skeleton or of the soft structures may also be referred to intrinsic causes. Similarly, *abnormal smallness* of the new-born, of the body as a whole or of certain parts, may be of intrinsic origin.

Struma congenita is regarded by some writers as of intrinsic origin. *Congenital hæmophilia* may be manifested in the new-born by hemorrhage from the umbilicus, under the scalp, between the meninges, or from the body passages (melæna neonatorum). *Deaf-mutism* and *abnormal conditions of the retina* are also congenital conditions, manifesting themselves in the new-born. It must be borne in mind, however, that many of the above conditions may also be acquired as the result of extrinsic injurious influences exerted upon the fœtus during intra-uterine life.

2. Acquired Anomalies of Development.—In the production of monsters and malformations extrinsic injurious influences probably play the chief rôle. Among the most important of such influences may be mentioned trauma to the mother, jarrings of the uterus, pressure, uterine contractions, tumors of uterus or pelvic organs, dislodgment of the ovum, partial separation of the placenta, hemorrhage into the placenta, placental disease, diseased conditions of the uterus or of the mother, disturbance in the supply of oxygen and nutrition, intoxi-

Digitized by Microsoft®

cations, infections, etc. Abnormal conditions of the amnion are also particularly likely to cause malformations of the fœtus. Abnormal tightness of the amnion, particularly of the cephalic or caudal end, adhesions between amnion and fœtus, etc., cause a great variety of malformations, such as *intra-uterine amputations, aplasias and hypoplasias, anencephalia, acrania, thoracic and abdominal clefts, spina bifida, phocomelia, curvatures of the spine*, etc. Deficiency of the amniotic fluid (oligohydramnios) may also produce various malformations, such as *spinal curvatures, club foot, club-hand*, and a great variety of *malformations of the extremities*. Of especial importance are adhesions between the amnion and the surface of the fœtus; they are found very frequently in association with oligohydramnion. They may occasion a great variety of malformations, particularly those characterized by a *failure of the body clefts to close*. Through the stretching of such adhesions about the fœtal extremities *amputations* of the latter may be produced. Forcible separation of the adhesions from the fœtal surface may cause *wounds of the fœtal skin*. Intra-uterine *fractures* and *dislocations* are also caused by amniotic adhesions. An excess of amniotic fluid (hydramnion) may also cause malformations and disturbances of development in the fœtus. In the case of twins one fœtus may develop at the expense of the other, the latter showing various malformations due chiefly to abnormal pressure. Such abnormalities are especially likely to occur, if in one amniotic sac there is an excess of fluid and in the other a deficiency.

Congenital Fractures.—Not all of the fractures found in the new-born are the results of difficult labor, but a part at least may be referred to trauma affecting the mother. The bones of the fœtal head are more frequently fractured than are the long bones. Abortion or premature delivery usually results from such trauma, but occasionally a fœtus so injured may be carried to full term and be born alive. At birth the fracture may be in the process of healing or entirely healed. Apparent intra-uterine fractures may be caused by deficient ossification or by disease of the fœtal bones (intra-uterine rachitis).

Congenital dislocations are not rare. The hip-joint is most frequently affected; more often in girls than in boys. The causes are partly intrinsic, due to an abnormal smallness and faulty position of the joint, as well as a primary relaxation of the ligaments. Extrinsic causes, pressure, poor nutrition, deficient amniotic fluid, etc., play an important part, however, in the production of the condition.

Pathological Conditions Produced during Labor: Caput Succedaneum.—During the birth of the child an œdematous swelling of the loose connective tissue beneath the scalp often forms, as the result of the passive congestion of the parts presenting. The condition is more marked in cases of protracted labor with unusually severe labor pains. The œdema is often accompanied by minute hemorrhages. It must not, however, be mistaken for the true hæmatoma of the scalp. Caput succedaneum has no pathological significance except in extreme cases; ordinarily it disappears within from twenty-four to forty-eight hours.

Cephalhæmatoma Neonatorum.—Occasionally there occurs during birth an extravasation of blood between the periosteum and the bone, leading to a detachment of the former. The extravasation is usually accompanied by caput succedaneum, and becomes more prominent as the œdematous swelling disappears. The condition occurs most frequently upon the parietal bones, less frequently upon the occipital, near the posterior fontanel. The tumor usually reaches its maximum on the third to fourth day. It may extend over the entire surface of the bone involved, but is limited by the sutures. Bilateral extravasations are rare. The tumor is fluctuating, the scalp covering it bluish, resembling a bruise. If the amount of extravasation is large, or if absorption is delayed, the detached periosteum forms bone around the edge of the hæmatoma. In this way there may arise around the extravasation a wall of newly formed bone, or the latter may become encapsulated by bony plates. In some cases the extravasate becomes purulent. The blood may be absorbed in from four to six weeks, the cavity obliterated, and the bony plates united, so that ultimately there may remain only a localized thickening of the cranium at the site of the extravasation. Rarely there may persist a crater-like depression with a thickened rim.

Hæmatoma of the sterno-cleido-mastoid muscle occurs rarely after prolonged labors, particularly after breech presentations involving traction upon the neck. The swelling of the muscle is probably more the result of a local myositis than of a hemorrhage. Suppuration results very rarely. The condition usually disappears in a few weeks without giving rise to permanent changes.

Fractures, dislocations, and *injuries* of internal organs may result from difficult or instrumental labor. Rupture of the liver or spleen may occur, or in rare cases of the intestines. External soft parts, as the ears, may be damaged by the forceps. Of the greatest importance are the damages caused to the central nervous system in delivery by the forceps or through turning. Schultze and Pfeiffer found multiple hemorrhages in the bulb, medulla, and cord in such cases. Degeneration of the ganglion cells also occurs. From the occurrence of such anatomical lesions it is easy to understand the frequent development of nervous lesions in children born in difficult or instrumental labor.

3. Infections.—According to the views of the majority of writers micro-organisms are not able to pass from the maternal blood through a normal intact syncytium into the fœtal circulation. It must be borne in mind, however, that owing to the natural processes of atrophy and new formation of chorionic villi, which occur constantly in the placenta from the earliest stages of its development onward, and which are especially marked during the later months of pregnancy, there are to be found in every normal placenta atrophic or necrosing villi the syncytial covering of which is either partly or wholly desquamated or is undergoing degenerative changes. Such senile villi form, therefore, points of least resistance to the passage of micro-organisms. The constant presence of such villi in the normal placenta favors the passage into the fœtal blood of micro-organisms which may be present in the maternal circulation; in other words, such a thing as a perfectly intact syncytium throughout the entire chorionic surface does not exist normally, and in every normal placenta there are conditions favoring the passage of micro-organisms. There is, however, good reason for believing that the fœtal tissues are more immune to many infections than are the maternal, and bacteria having passed the chorion may either fail entirely of producing pathological changes, or remain latent until a later period. The probabilities of the transmission of infection from the mother to the fœtus are in direct proportion to the severity of the maternal infection, death of the fœtus usually resulting when the disease of the mother is very severe.

Syphilis.—The most common and most important infection of the new-born is syphilis. This may be acquired from the mother through the ovum, from the father through the sperm, or through a later infection from either parent. The chief pathological changes shown at birth are: skin lesions (in about twenty-four per cent. of cases), either papular, macular, or hemorrhagic, bullous eruptions (pemphigus syphiliticus) affecting chiefly the palms and soles; less frequently macular, papular, or ulcerative lesions of the mucous membranes; fibroid hyperplasia of liver (cirrhosis) and spleen; "white pneumonia"; gummatous processes in the lungs, thyroid, thymus, liver, bones, adrenals, etc.; swelling of the mesenteric lymph glands; osteochondritis; obliterative changes in blood-vessels, particularly in the umbilical vessels. The changes found in the bones are very characteristic, particularly those so frequently present in the zone of ossification of the epiphyseal cartilages. The long bones should be split longitudinally, the change

Digitized by Microsoft®

being found most often in the femur, humerus, and ribs. In normal cases there is seen in the bluish, opaque, resting cartilage a layer of proliferating cartilage recognized by its bluish-gray translucent appearance. This is bounded in turn by a narrow white zone of ossification, which separates the cartilage from the bone by a straight or convex line. In the so-called osteochondritis of congenital syphilis the area of ossification is increased, and the boundary line between it and the cartilage is irregular. The area of proliferating cartilage is also increased and may contain medullary spaces which appear as red stripes. Between the zone of ossification and the bone there is a layer of soft yellowish granulation tissue rich in cells. Three stages may be distinguished; in extreme cases the epiphyses may be completely separated by the softening of the yellow layer. Many authors assert that the so-called syphilitic osteochondritis is pathognomonic of congenital syphilis. According to Mewis it is found only in sixty-two per cent. of cases. By other writers the changes in liver and spleen are regarded as the most characteristic and constant signs of this condition.

Tuberculosis.—Though nearly seventy cases are reported in the literature as instances of congenital tuberculosis, in only six cases (Sabouraud, Lehmann, Henl, Ustenow, Auché and Chambrelente, and Lyle) is the diagnosis placed beyond any doubt by both the histological and bacteriological findings. The other cases must be regarded as doubtful or probable, the diagnosis either not confirmed by the demonstration of the presence of tubercle bacilli, or doubtful because of the age of the child, non-exclusion of syphilis, etc. There is, however, no doubt that in acute miliary tuberculosis, advanced pulmonary or genito-urinary tuberculosis of the mother, tubercle bacilli may pass through the placenta into the fetal circulation, either with or without the production of tuberculous changes in the chorion or decidua, and give rise to characteristic tuberculous lesions in the fœtus. There is also reason to believe that the fœtal tissues possess a greater resistance to the tubercle bacillus, so that tubercle bacilli may be present in the fœtal blood without giving rise to tuberculous lesions. At a later period the disease may become manifest, so that the possibility of a latent infection must be considered.

Variola.—It has long been known that in cases of variola occurring during pregnancy the fœtus may have the eruption during intra-uterine life, or present it at birth or develop it soon after birth. The transmission to the child does not, however, occur in all cases of variola; further, in the case of twins with separate placentas, one fœtus may exhibit the disease, the other escape it. These phenomena have been explained by the hypothesis that the disease does not pass an intact placenta; in the case of twins one placenta may admit the infection, the other not. The stages of the disease in mother and child do not usually coincide, the fœtus as a rule acquiring the infection in the stage of suppuration of the maternal eruption. The occurrence of variola during the earlier months of pregnancy usually causes death of the fœtus and abortion; in the later months the child often survives.

Scarlatina.—Since adults rarely suffer from this disease, there are but few recorded observations (eighteen in all) of its transmission to the fœtus. The child at birth may present the eruption. In other cases of scarlatina of the mother, the child may be born without showing the disease.

Measles.—The recorded observations of the transmission of measles to the fœtus in utero are very few. In maternal measles during pregnancy the fœtus may or may not be affected.

Typhoid Fever.—The child usually dies in cases of maternal typhoid during the early months of pregnancy, but may survive in cases which occur in the later months. The typhoid bacilli can traverse the normal as well as the abnormal placenta. Since the typhoid bacilli pass directly into the fœtal circulation, intra-uterine typhoid is of the nature of a general septicæmia, the classical intestinal lesions are not present. Infection of the fœtus does not, however, always occur in maternal typhoid. Blumer has reported an apparent undoubted case of congenital typhoid, which is of very great importance as indicating a latent infection. The child was born four and a half months after the recovery of the mother from typhoid. On the ninth day it died, after having presented symptoms of hemorrhages from gums and vagina, petechial eruption of skin, slight fever, and convulsions. The autopsy findings were cloudy swelling of organs, presence of phagocytic endothelial cells in the heart, lungs, liver, kidneys, adrenals, pancreas, and uterus. Typhoid bacilli were recovered from the lung, spleen, umbilical cord, bile, and large intestine. Alimentary infection was excluded, the child being breast fed, and the short period between birth and beginning of symptoms made extra-uterine infection very improbable. The case is unique as showing a long period of latency.

Typhus Fever.—Only one case occurs in the literature of a probable case of intra-uterine infection with typhus. The five- to six-months-old fœtus showed black, irregular petechiæ and small vesicles over the body. The spleen was enlarged, the mesenteric glands and Peyer's patches were swollen.

Recurrent Fever.—In a small number of cases the transmission of the disease from mother to fœtus has been observed. Albrecht found the spirillum present in the blood of two cases. He regarded it as most probable that the spores and not the spirillum passed the placenta.

Malaria.—This disease is also sometimes transmitted to the fœtus, which may be prematurely born living or dead, or come to full term. Moncorvo saw four undoubted cases of the transmission of the plasmodium. The new-born child may have fever and enlarged spleen. The autopsy findings are those characteristic of the disease, pigmentation, acute congestion of the spleen, etc.

Cholera.—A small number of observations occurs in the literature, of cases showing the transmission of the cholera bacillus to the fœtus. The occurrence of a hemorrhagic endometritis in this disease favors the passage of micro-organisms through the placenta. Death of the fœtus usually results from the changes in the placenta and decidua. The fœtus may show hyperæmia and hemorrhages of the internal organs, intestinal inflammation, etc.

Influenza.—According to Townsend an intra-uterine infection of this disease occurs.

Pneumonia.—In a few cases the transmission of the pneumococcus from the mother to the fœtus has been observed.

Meningitis.—In two cases the meningococcus has been shown to have passed from the mother to the fœtus.

Erysipelas.—In children born of mothers suffering from erysipelas there may be present a desquamation of the epidermis. The streptococcus is not infrequently transmitted to the fœtus, the infection being manifested in a condition of general sepsis rather than of erysipelas. The so-called erysipelas neonatorum is an affection usually acquired during the early days of extra-uterine life.

Sepsis.—The staphylococcus and the streptococcus are probably frequently transmitted from the mother to the fœtus, though the published observations of such intra-uterine transmission are not numerous. The cases reported as congenital empyema, pleuritis, peritonitis, endocarditis, pericarditis, meningitis, abscesses of internal organs, and certain skin conditions show the frequency of such transmission. The occurrence of puerperal sepsis in the mother, or of intercurrent pyogenic infections gives rise to such transmission; but in certain cases the infection of the fœtus appears to be cryptogenic, a perfectly healthy mother giving birth to a sick child which dies soon after birth, the autopsy findings being a streptococcus pleuritis, peritonitis, etc.

Bacillus Coli Communis.—This organism is also transmitted from the mother to the fœtus, producing in the latter a general sepsis, or a localized infection, such as peritonitis, pleuritis, internal abscess, etc.

Parotitis Epidemica.—According to Müller this disease

Digitized by Microsoft®

may be transmitted to the fœtus. It is possible, however, that the case described by Müller was one of pyogenic infection.

Anthrax.—The fœtus may be infected in utero, or may escape the disease. In the former case the fœtus may be still-born, or be born alive and apparently well, dying from the disease a few days later.

www.libtool.com.cn

Leprosy.—A congenital infection is claimed for this disease, but it has not yet been proved.

4. INTOXICATIONS.—According to Ahlfeld those poisons are capable of being transmitted from the mother to the fœtus which occur in the maternal blood in the form of gases or in solution, providing that such changes have not been produced in the maternal blood as to render diffusion impossible. It is to be noted, however, that even in those cases in which transmission of poisons from mother to fœtus occurs, the effect upon the fœtus is often very different from that upon the mother. In the case of many poisons, particularly the vegetable alkaloids, the effect upon the fœtus is of a much less intense degree. In the case of animal experiments, strychnine and morphine have been found to affect only slightly the fœtus, the undeveloped fœtal nervous system appearing to possess a certain insusceptibility to poisons which have an intense action upon the highly developed nervous system of adults. In the case of certain mineral poisons the fœtus also appears to possess a relative immunity. Inasmuch as the germ cells cannot be regarded as existing in the reproductive organs of the parents wholly independent of the bodily conditions of these individuals, since they must assimilate food from the lymph and discharge their metabolic products, it must follow that diffusible poisons in the body of either parent must be absorbed by the germ cells and so cause pathological changes in their protoplasm. This is well shown in the case of children born of fathers showing lead poisoning or alcoholism. It may be taken as a general principle that intoxications affecting the general metabolism of either parent are very likely to cause deterioration of the germ cells.

Carbon monoxide and *illuminating gas* may cause death of both mother and fœtus. A number of observations have been reported in which the mother recovered, but death of the fœtus resulted.

Chloroform passes directly into the fœtal blood, a few whiffs given to the mother being evident in the blood from the umbilical vessels. The fœtus is, however, very insusceptible to chloroform, even in cases of deep and prolonged anæsthesia of the mother. If in such cases asphyxia of the fœtus occurs, it is probably to be referred to other conditions of the delivery than to the chloroform.

Alcohol.—The sexual cells may be affected by the intoxication of either parent. The new-born of chronic alcoholists very frequently show malformations, and later psychical disturbances. This is particularly the case in maternal alcoholism during pregnancy.

Chloral hydrate in medicinal doses has practically no effect upon the fœtus; in chronic poisoning of the mother the effects are similar to those of alcohol. *Morphine* in ordinary medicinal doses does not affect the fœtus, even when given to the mother for some time. Chronic morphinists may bear healthy children, but these are very likely to show psychical disturbances in later life. Occasionally the offspring may show signs of chronic morphinism. That the drug passes through the placenta is shown by the action upon the fœtal heart. *Digitaline* and *atropine* are said to produce marked and lasting effects upon the fœtus. As mentioned above, the effects produced by *strychnine* are slight. Fatal poisoning of the mother may cause the death of the fœtus or it may be born alive prematurely.

Ptomains and Toxins.—That many poisons produced in the maternal body by micro-organisms pass through the placenta into the fœtal blood and produce pathological effects cannot be denied. Numerous clinical observations support this view, though the actual demonstration of such passage has not yet been made. Likewise, the poisons of certain auto-intoxications of the mother, nephritis, etc., affect the development of the fœtus.

Mineral Poisons.—The passage of mercury into the fœtus has long been known, and advantage has been taken of this knowledge in the hope of curing fœtal syphilis. Chronic mercurial poisoning is well borne by the fœtus.

Lead.—In chronic lead poisoning of the mother death of the fœtus and abortion usually result, although in some cases the child may be born alive. In this case the child is under-developed and very often dies soon after birth. In chronic lead poisoning of the father the spermatozoa are undoubtedly affected, inasmuch as children from such fathers show characteristic changes which without doubt are to be ascribed to the lead poisoning. The bones of the cranium undergo changes in form which may interfere with delivery. A large proportion of the children of fathers affected with plumbism die before term; of the children born alive few pass the age of puberty.

Phosphorus may cause the death of the fœtus with the occurrence of fatty degeneration of the liver and multiple ecchymoses as in the phosphorus poisoning of adults. *Arsenic, copper,* and *silver* also pass the placenta. Copper and mercury are said to accumulate in the placenta; lead on the other hand does not.

5. DISEASES OF COMMON OCCURRENCE IN THE NEW-BORN, IDIOPATHIC OR ACQUIRED, AFFECTING CERTAIN TISSUES, ORGANS, OR SYSTEMS.—*Asphyxia Neonatorum.*—The fœtus at birth may exhibit a condition of apnœa and cyanosis. This may be due to a congenital malformation of the heart or blood-vessels, atelectasis, "white pneumonia," catarrhal or croupous pneumonia, hydrothorax, thoracic tumor, congenital struma, or disturbances of the circulatory and respiratory centres. In normal births the respiratory centres are stimulated by the increase of carbonic acid and decrease of oxygen in the blood, in addition to certain external stimuli. As a result of such stimulation respiration is inaugurated. If placental interchange is rendered difficult or impossible through the compression of the umbilical vessels or prolonged uterine contractions, there may occur intra-uterine respiratory movements of dyspnœic character. As a result the lungs become filled with amniotic fluid and asphyxia follows. Asphyxia may also be produced by the occurrence of rapidly succeeding uterine contractions. Dyspnœic movements are not produced, but from the rapidly increasing venosity of the blood there results a paralysis of the respiratory centre. The cessation of placental circulation through birth of the child is therefore not followed by respiratory activity.

Albuminuria Neonatorum.—According to Virchow, Dohrn, Hofmeier, and many other writers the urine of new-born children almost always contains a varying amount of albumin, hyaline casts, and epithelium. Such findings have been associated with the uric acid infarct. They cannot be regarded as pathological as they are found in wholly healthy children. The albumin usually disappears after from eight to ten days. The cause is not known but is referred to the increased metabolism after birth, imperfect formation of glomeruli, changes in blood pressure and in the character of the blood. The pressure in the renal arteries is increased after birth. This fact may explain the albuminuria and the desquamation of epithelium. *Pathological albuminuria* occurs in rare cases of congenital nephritis. The amount of albumin is always greater than that found physiologically.

Anasarca Neonatorum.—This condition may be found in cases of still-birth in association with hydatid mole. The œdema of the fœtus may depend upon a maternal dropsy, obstruction of the umbilical veins, malformations or disease of the fœtal heart, absence of the thoracic duct, fœtal nephritis, syphilis, œdema of the placenta due to syphilis, leukæmia, etc. Fœtal anasarca is often associated with hydramnion. In some cases the skin of the fœtus shows an elephantiasis-like thickening. In the majority of cases of fœtal anasarca the child is still-born; in those cases in which it survives birth the increased

Digitized by Microsoft®

size of the fœtal body may render delivery more difficult. (See also Œdema neonatorum, in article on *Œdema*.)

Fatty Degeneration of the New-born.—Acute fatty degeneration of the liver, heart, etc., of the new-born is not infrequent. It is explained by decreased oxygenation and increased metabolism of albumin depending upon any of the causes given above, also infections and intoxications. Fatty infiltration of the liver is often associated with fatty degeneration of this organ. The condition occurs most frequently in cachectic and poorly nourished new-born suffering from circulatory or respiratory weakness.

Gangræna Neonatorum.—Symmetrical gangrene may occur in congenital syphilis. Further, symmetrical, diffusely spreading, or localized gangrene (noma) occurs in the new-born as the result of certain infections, diphtheria, measles, etc. A variety of organisms have been found in these cases.

Gonorrhœa Neonatorum.—The new-born is very frequently infected with the gonococcus during birth. An intra-uterine infection may also occur. Usually the conjunctiva, vulva, vagina, and urethra are involved, but there may occur also gonorrhœal peritonitis, pleuritis, pericarditis, endocarditis, meningitis, arthritis, etc. It is very probable that the majority of the cases of peritonitis occurring in the new-born female are of gonorrhœal origin. The presence of a coincident vulvitis or ophthalmia favors strongly the gonorrhœal origin of the peritonitis. (See also *Gonorrhœa*.)

Hemorrhage of the New-born. Umbilical Hemorrhage.—Hemorrhage from the cord may occur at birth, either from laceration, from disease of the vessels, or from imperfect ligation. Fatal hemorrhage may occur from injuries to the cord before or during birth. In other cases of more rare occurrence there may take place a constant oozing from the umbilicus itself or from the properly ligated stump. Such hemorrhage is most likely to occur between the fifth and fifteenth days. The children affected are usually cachectic or under-developed. Congenital hæmophilia, syphilis, abnormal composition of the blood, imperfect coagulability, failure of the normal retrogressive changes in the umbilical vessels so that these remain distended and patulous, vascular ectasis, etc., are causes adduced. In some cases no adequate cause can be discovered. Cachectic conditions of the mother are regarded as predisposing causes.

Hæmatemesis and Melæna Neonatorum.—Hemorrhage from the gastro-intestinal tract occurs occasionally in the new-born without other appreciable symptoms, and has therefore been regarded as an essential pathological condition. Hæmophilia, syphilis, congestion of the gastro-intestinal tract, ulcerations of stomach or intestines, infection, etc., are the chief causes adduced. According to von Preuschen melæna neonatorum is secondary to the occurrence of cerebral hemorrhage resulting from delivery. It is known that under other conditions certain diseases of the brain give rise to secondary hemorrhages in the stomach and intestine.

Hemorrhage of adrenals is of relatively frequent occurrence in the new-born. The cause is not clear, but traumatism during birth, thrombosis of the adrenal vessels, infection, and marasmus are supposed causes.

Hemorrhage into the kidney may result from thrombosis of renal vessels.

Hydrocephalus Neonatorum.—Congenital hydrocephalus is an accumulation of fluid within the ventricles of the brain. The cranial bones, not being united, yield to the internal pressure and are separated, the frontal, parietal, and occipital bones become expanded and thinned. The cerebral convolutions become flattened, the hemispheres finally being spread in thin laminæ on either side, the thickness of the brain substance decreasing from the base to the vertex. The membranes usually become thickened. The head becomes greatly enlarged, soft, and fluctuating. The cause is not clear; the condition by some being regarded as an inflammatory process of the arachnoid, by others as due to stasis, caused by obstruction of the veins of Galen or of the sinuses. (See *Hydrocephalus*.)

Icterus Neonatorum.—A slight degree of yellowish color is of such frequent occurrence in the skin of the new-born that it must be regarded as physiological. In strict usage the term icterus neonatorum should be applied to this condition alone. According to Frerichs the icterus is due to a fall of pressure in the liver capillaries, thus favoring the entrance of bile into the blood. By others the condition is explained as due to the excessive destruction of red blood cells and an increased production of bilirubin which is absorbed. The dilatation of the blood-vessels may cause obstruction of the bile capillaries. According to Birch-Hirschfeld the jaundice is due to compression of the biliary capillaries by the dilated vessels in Glisson's capsule. As a result of the venous congestion the connective tissue of the capsule becomes œdematous, this also aiding in the compression of the vessels. According to Ziegler the icterus is caused by resorption of the bile pigment not only in the liver, but also from the meconium which is absorbed and carried back to the liver. The physiological icterus neonatorum is characterized by a diffuse yellowish pigmentation of the tissues and a deposit of bilirubin in various organs and tissues, especially in the kidneys.

Pathological icterus of the new-born may be caused by sepsis (in the majority of cases), syphilis, malformations of the biliary passages, new formation of connective tissue about the bile ducts, patency of the ductus venosus, acute hepatitis, etc.

Myotonia Neonatorum.—In the early weeks of life the child may be affected by persistent, painless, muscular spasms without increased excitability of the muscles or nerves. In this respect it is distinguished from tetanus, for which it is often mistaken. It is to be regarded as an exaggeration of the physiological hypertonia of the new-born (pseudotetanus). The anatomical basis consists of degenerative changes in the anterior roots and cells of the anterior horns; the exciting causes are gastro-intestinal disturbances, congenital syphilis, etc.

Ophthalmia Neonatorum.—Catarrhal or purulent conjunctivitis is of frequent occurrence in the new-born. The great majority of cases are of gonorrhœal origin, but it must be borne in mind that other organisms (streptococcus, staphylococcus, etc.) may also cause the disease, as well as the use of too strong antiseptic solutions. (See *Conjunctiva, Affections of.*)

Pemphigus Neonatorum.—The condition of the skin characterized by the formation of blebs or bullæ in the epidermis occurs in a great variety of forms, and its pathology has been variously described. The etiology of the affection is not clear. Some of the cases described under this head are of syphilitic origin, others are due to an infection with the streptococcus. The form described as *pemphigus acutus contagiosus neonatorum* is probably a distinct disease of bacterial origin. In certain congenital cases there appeared on the second day a general pemphigus eruption over the palms, soles, and mucous membranes, the fluid of the bullæ being at first clear, later becoming slightly bloody. Bacteriological examinations have been negative; syphilis and all ordinary causes of pemphigus being excluded, the condition is regarded as due to an intra-uterine intoxication. (See *Pemphigus*.)

Pneumonia.—Catarrhal pneumonia occurs very frequently in the first few days of life. In the case of premature births over forty per cent. of the deaths are due to this condition. In eighty per cent. of cases born at term the infant is poorly developed, with congenital weakness of the respiratory tract. The so-called "white pneumonia" is due to congenital syphilis. Pneumococcus pneumonia may be acquired during intra-uterine life as well as in the first weeks of extra-uterine life.

Rachitis.—Congenital rickets is rare. Its etiology is not clear. The condition is associated with hydramnion and hydrocephalus. Premature birth usually takes place. Congenital rickets presents a pathological picture similar to that of extra-uterine rachitis. Two forms of fœtal rickets are described, *rachitis micromelica* and *rachitis annulans*. The true rachitic process is to be distinguished from the disease of the primordial cartilages, the so-called

Digitized by Microsoft®

chondrodystrophia fœtalis, which is associated with cretinism. (See *Rachitis*.)

Sepsis Neonatorum.—Sepsis of the new-born is one of the most frequent and important conditions of this period of life. The streptococcus, staphylococcus, pneumococcus, bacillus coli communis, typhoid bacillus, gonococcus, etc., are the exciting causes. The organism may be transmitted from the mother during intra-uterine life, or acquired through injury received during delivery, through infection of such wounds after birth, or through the stump of the umbilical cord. The latter mode of infection is very common. Cryptogenic infection may occur. The skin of the new-born possesses much less resistance to the entrance of micro-organisms than the skin of adults; the primary seat of infection in infants often being a small localized purulent process in the skin, of relatively slight importance.

www.libtool.com.cn

Struma Congenita.—The condition of congenital enlargement of the thyroid is regarded partly as inherited from mother or father, partly as an idiopathic or endemic disease. The thyroid may present a simple hyperplasia or cyst formation. Delivery may be rendered difficult. The infant may die after birth from the result of compression of the trachea. The condition is of relatively frequent occurrence in the Tyrol.

Uric-acid Infarction.—In the kidneys of the new-born infant there is almost always present an accumulation of urates which appears as glistening, golden, or yellowish-red lines converging toward the papillæ of the pyramids. The urine in the pelvis of the kidneys also contains an abundance of urates. Microscopically the collecting tubules are found to be filled with dark granular masses which on the addition of acetic acid dissolve, uric acid crystallizing out. An albuminous framework is usually left behind. This condition is termed uric-acid infarction. It is most marked after the second or third day, but may be present up to the seventy-sixth day. It usually disappears promptly, but if persistent may lead to irritation of the kidney and nephritis. It was formerly believed that such infarctions occurred only in children breathing after birth, but it has been shown that they are found also in still-born children. The cause is not known. Changes in metabolism following birth, defective oxidation, inability of the urine of the new-born to dissolve the acid, are among the causes adduced in explanation of the phenomenon.

Tetanus Neonatorum.—Tetanus is one of the earliest and most fatal diseases of the new-born, occurring with greater frequency in the first and second weeks of life than at any other age. The infection occurs through wounds received during delivery or through the stump of the cord. The favoring conditions are: uncleanliness, atmospheric and climatic conditions, primary pyogenic infection, etc. In nearly every case evidences of inflammation and suppuration are found in the umbilical vessels.

Thrombosis.—Thrombosis of the adrenal, renal, or spermatic veins may occur in the new-born. Hemorrhage (so-called hemorrhagic infarction) of the adrenal or kidney may result, and in the male infant gangrene of the testicle and scrotum. Such thrombosis may be the result of traumatism during delivery or septic infection. In anæmic and cachectic infants there may occur marantic thrombosis, affecting most frequently the left renal artery. Hemorrhage and necrosis of the kidney result.

Sclerema Neonatorum.—See Œdema neonatorum, under *Œdema*.

6. New Growths.—The most common forms of new growths affecting the new-born are the congenital *fibromata*, *neurofibromata*, *angiomata*, and *lymphangiomata*. Birth-marks, vascular, pigmented and hairy nævi, moles, warts, etc., belong to this class. Special forms of lymphangiomatous tumors occur in the tongue, lips, and neck (*macroglossia*, *macrocheilia*, *hygroma colli congenitum*). *Elephantiasis-like* growths may occur locally or form diffuse thickenings in certain regions. *Lipomata* of the neck, back, and axillary spaces are not rare.

Congenital teratoma, representing either a monogerminal or bigerminal inclusion, are relatively frequent. They may be found in any part of the body, but are especially common on the head, in the mediastinum, kidneys, ovaries, and testicles. Congenital *rhabdomyomata* of the heart, kidney, etc., are to be placed in this class. The most frequent malignant tumor of the new-born is the so-called *embryonal adenosarcoma* of the kidneys (*mixed sarcoma*). Such growths are most probably derived from inclusions of the myotome and are to be classed with the teratomata (*malignant teratomata*). The most common epithelial tumors occurring in the new-born are *papillomatous* growths of the larynx, and cystic tumors of the kidneys, liver, and ovary. Adenomata of the adrenals and kidneys have been described. Carcinoma has also been found in the new-born in a number of cases (carcinoma of the liver, kidneys, stomach, and intestine). Cases have been reported by Jacobi, Wedl, Brown, Friedrich, Ritter, and others. Cystic tumors of the pineal gland, cholesteatomata, dermoid cysts, and teratomata of the brain and meninges have been described.

Aldred Scott Warthin.

NEW MEXICO.—New Mexico has climatically the same features as Colorado, and in a less degree those of Arizona. The State runs from the Raton range, which divides it from Colorado, for 390 miles south, to the boundary line of old Mexico. On the west is the main range of the Rocky Mountains or backbone of the continent, separating it from the State of Arizona. Its eastern boundary ranges with the great State of Texas. New Mexico is for the most part a high plateau rising to 7,000 feet at Santa Fé and dropping to 3,500 feet in the lower Pecos valley. The general tendency of this high plateau is to drop from the northwest corner toward the southeast. As it is on the leeward side of the main range, the winds from the Pacific Ocean are dried for the most part before reaching it, so that there is very little winter rain and only a light snowfall. What rain there is falls, as it does in Colorado, principally during the months of July and August, and New Mexico does not have the well-marked double rainy season of Arizona. The winter precipitation falls usually between January 1st and April 1st, though in the Pecos valley region this period is somewhat extended and the rainfall is heavier than the average for the State. The winter rains or snow-storms are marked by almost parallel curves of from one to seven inches of precipitation. These curves are outside the mountain lines, where, of course, the precipitation is greater. They are caused by the diffuse or diverting influence of topography on the aqueous currents borne to New Mexico from the south Pacific Ocean across Arizona. "The summer rains," writes Captain Glassford, "are otherwise influenced, and the higher precipitations appear upon the levels west of the Canadian River and upon the Cañon course of the Pecos, which includes Las Vegas and Fort Union. At this point the fall reaches seventeen inches. The lowest summer precipitation is found in sections most favorably influenced by the winter rains. The minimum is found in the southwest."

It is very much to be regretted that, in spite of the climate being the chief attraction of New Mexico to the travelling invalid, it is almost impossible to get full and accurate meteorological data concerning the various resorts, and the observations that are reported are usually for only a very short period, and the humidity and wind have very seldom been recorded. Many have written in general terms of the fine climate, but have failed to give the facts about the local topography, aspect, and soil of the towns. Unfortunately for health purposes, on the lower elevations the towns are usually situated upon an adobe soil in the river bottoms. However, the literature being such as it is, we will proceed to discuss the more important places available for health seekers.

In travelling by railway from Colorado into New Mexico, as the descent is made on the southern slope of the Raton range, one notices that the air is warmer and the sunshine more brilliant. However, the elevated towns in the northern portion of New Mexico are very

Digitized by Microsoft®

similar in climate to those of Colorado, although they are somewhat higher in elevation. Las Vegas (6,500 feet) and Santa Fé (7,000 feet) closely resemble Denver in temperature, while Silver City in the southwest, standing at an elevation of 5,800 feet, has a markedly milder climate, which is partly accounted for by its admirable shelter from severe winds.

www.libtool.com.cn

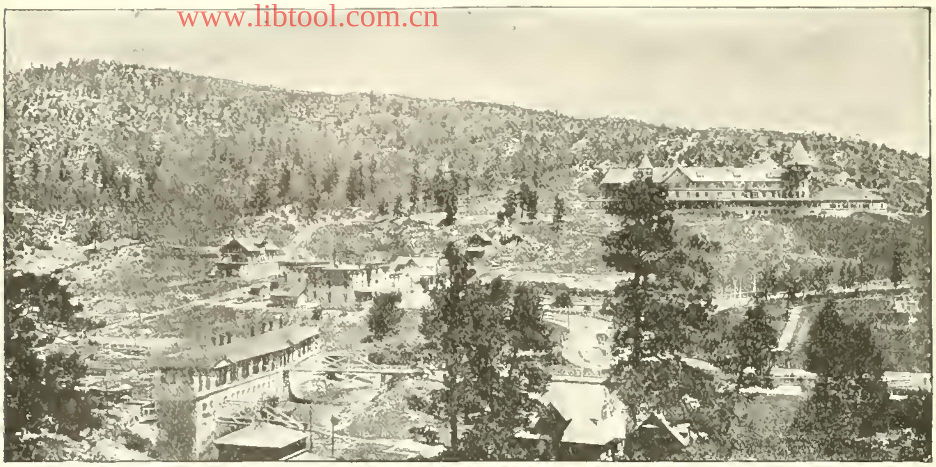

FIG. 3589.—View of the Montezuma and Bath-houses, Las Vegas Hot Springs, New Mexico.

The annual average precipitation for the State is 13 inches, ranging from 5 inches at Deming to 33 inches at Chama, while the average of 13 inches does not include what falls upon the mountain summits, which is probably double this amount.

The annual mean relative humidity approaches 40 per cent. with an annual temperature of 60 per cent.; the absolute humidity is 2.3 grains, a little more than that of Colorado, which the higher temperature accounts for.

In the elevated northern portions of the State the annual wind movement is about the same as that of Colorado, but it is markedly less in the southern and lower portions.

Vegetation is sparse throughout the State, as irrigation has been very little carried out. The soil generally is of the peculiar clay which is known as adobe. This does not readily absorb the moisture, but when baked in the hot sun gives rise to a very fine dust. The treeless character of the most part of the plateaux and valleys combined with the adobe dust, which is light and volatile in character, makes the dust storms in this country peculiarly disagreeable.

Charles F. Lummis, in his delightful book upon New Mexico, which he calls "The Land of Poco Tiempo," summarizes the country in this sentence, "Sun, silence, and adobe." He laments, as all visitors to New Mexico must, the absence of large and well-equipped cities, and the general scarcity of the resources of civilization. All this, however, is rapidly improving each year. Good soft water, gravel soil, and good and well-cooked food are scarce, but the climate is superb. Above the thirty-fifth parallel of latitude the climate resembles that of Colorado, but is somewhat milder in the winter and warmer in the summer. Below this latitude the winters are markedly milder. Those for whom the more bracing climates of the northern latitudes are not desirable, and who also need a somewhat lower elevation, can find in New Mexico almost unrivalled climates for their purpose. The summer heat, however, begins to be felt early in April, and seems to gather force well into October, but for those who can stand a rough camping life the summer climate of the mountains is delightful.

On the southern slopes of the Raton range is a fine farming country with a good all-the-year-round climate. The air is dry, but the soil is adobe, and there is considerable irrigation carried on. There are no towns of any importance, but for those convalescent invalids who can carry on farming and cattle raising it is a good country. Throughout this district the rainfall and humidity are higher, and the temperature lower than they are in the country lying farther south.

Raton is a small town on the main line of the Santa Fé just over the Colorado border. It stands at an altitude of 6,600 feet and has 4,000 inhabitants. It faces south and east with the Raton range behind it. It has an attractive country around it, and there are several small hotels and boarding-houses where the rates are from $25 to $30 per month for board and room.

A few miles farther south and lower down lie Maxwell City and Springer, both of them small villages where cheap accommodations can be found in the town or among the farmers of the neighborhood.

Las Vegas, elevation 6,384 feet, population 8,000, of which perhaps half are Mexicans and Indians. It is somewhat exposed to north winds, and lying in the valley with an adobe soil, is hot and dusty in summer. It is generally warm and pleasant during the winter. The average mean temperature in winter is 40°; spring 55°, summer 80°, autumn 60° F. The rainfall averages twenty inches, of which a large half falls during April and August. The Atchison, Topeka and Santa Fé Railroad has recently built a very handsome and comfortable hotel and eating-house, where the famous Harvey catering can be enjoyed, but accommodations at a more moderate price can be obtained in the town, and there is a good sanitarium in charge of the Sisters of Charity.

Las Vegas Hot Springs, elevation 7,000 feet, is reached by a stub railway running seven miles from the town of Las Vegas up into the western hills. Here is an excellent hotel, The Montezuma, with a few other smaller buildings and some good bath-houses. The Montezuma is situated on the edge of the cañon facing south, and is well sheltered from the winds. Las Vegas Hot Springs has a delightful winter climate, for the most part warm and dry. It is reasonably cool in summer. The springs are both hot and cold. The hot water has a temperature of 144° F. The mineralization of the springs is alkaline and small in amount. They are not very potent waters, but the bathing is good, and there are some excellent mud baths which have been found valuable for rheumatism and allied disorders.

Santa Fé is reached in a similar manner from the main line of the Atchison, Topeka and Santa Fé Railroad. It is one of the oldest and most interesting of the towns of New Mexico. It retains the character of a Mexican town, which is an outgrowth of the old Indian pueblo. It has many quaint features and buildings to interest visitors. The chief hotel is a fairly good wooden structure, but is usually indifferently kept; but there is a sanatorium well managed by the Sisters of Charity. "The town lies on a treeless plateau at the base of one of the spurs of the Rocky Mountains. The general trend

Digitized by Microsoft®

New Mexico.

of the site is west-southwest, the mountains affording protection to the north and east. Within thirty miles are peaks of 12,000 and 13,000 feet elevation. The low hills are covered with a growth of piñon trees. The town has of late improved its water supply, but much is yet to be desired in the matter of drainage, and there are few shade trees. The soil is light and sandy. The climate is not very different from that of Denver. It is somewhat cooler in summer, not quite so cold in winter, and a little less windy throughout the year." *

The climate is very similar to that of Las Vegas Hot Springs, but being less sheltered, is somewhat more bracing, though also more windy.

Continuing the journey southward on the Atchison, Topeka and Santa Fé Railroad, the traveller crosses the lower end of the upper Pecos valley between San Maguel and Glorieta. This is a beautiful upland valley twenty-five miles north of the Glorieta Mountains through which are scattered stock ranches and small farms. It is a well-timbered, park-like district surrounded by mountains. It has a fine climate and good soft water. There are capital hunting and fishing, and much of the country still remains wild, there being a timber reservation covering 702 square miles.

Albuquerque, elevation 5,000 feet, population 10,000, is situated in the valley of the Rio Grande, and it is here that the main line of the Santa Fé Railroad joins its western division along which flows the travel to California. The Atchison, Topeka and Santa Fé Railroad Company have built a handsome and commodious hotel and eating-house similar to that at Las Vegas, where the best food is served. The old town, which lies near the river bed, is not very desirable for residence, but the newer part of the town on the bench above it is well situated. It is a live, modern city with fairly good accommodations. It has a good climate, though it is somewhat too windy in winter and too hot in summer.

Deming, elevation 4,300 feet, population 2,500, stands on a plain, just about fifty miles square, surrounded by mountains. It has a mild climate, it never freezes during the day in winter, the mean seasonal temperature being: winter 44°, spring 63°, summer 87°, autumn 64° F. The wind record has not been kept, but during the spring the winds are said to be quite high. The precipitation is 8.8 inches, the greater part of the rain falling in the summer. Accommodations are good.

Silver City is situated on an elevated plateau in the Chichuachua valley south of the Pinos Altos Hills. The soil is sandy, the rock formation consisting chiefly of slate and limestone. It is at the end of a branch line of the Santa Fé Railroad, forty-eight miles from Deming and about ten and one-half hours by railway from El Paso. Foot-hills several hundred feet in height surround it except toward the south, while a few miles farther back are mountains several thousand feet in height. In this way it enjoys excellent shelter from winds. No wind record is obtainable, but evidence tends to show that the wind movement is moderate. The mean temperature for January is 37°, for July 72°, and for the year 54° F. In ten years there have been only six days in which the temperature fell below 10°, and only twenty-two days when it rose above 90° F. The average annual precipitation is 11.58 inches, of which as much as 8.11 inches must usually be credited to the months of July, August, and Sepember. The average number of cloudy days is 37. The average relative humidity is 46 per cent. The absolute humidity is 1.71 grains; dew point 29. The water is pure, but rather hard.

Silver City lies in the same latitude as Savannah, Ga., but owing to its elevation is, of course, much cooler and dryer. There are four hotels of moderate excellence, and there is a good sanatorium kept by the Sisters of Mercy. The country around, particularly among the pines, lends itself to a delightful camping life.

Nine miles to the north, at an altitude of 6,040 feet, is Fort Bayard. The old army fort has been converted into a general government hospital for the treatment of pulmonary tuberculosis. It is now in the third year of its existence. Major D. M. Appel, M.D., surgeon in command, writes under date of June, 1901, as follows:

"The selection of Fort Bayard as a site for a sanatorium for the treatment of pulmonary tuberculosis has been amply justified by our results. Its location in the arid mountainous region of southern New Mexico, at an altitude of 6,040 feet, affords a climate permitting comfortable outdoor life during the entire year. The mean maximum and minimum temperatures and the precipitation for the past decade are as follows":

Month.	Mean maximum. Degrees Fahr.	Mean minimum. Degrees Fahr.	Precipitation. Inches.
January	52.77° +	23.15°	1891, 19.30
February	54.13	25.83 +	1892, 8.89
March	60.52 +	30.92 +	1893, 15.47
April	68.43	37.10	1894, 9.12
May	77.33	45.45 +	1895, 15.09
June	86.45	52.68	1896, 18.85
July	82.91 +	55.34	1897, 18.00
August	85.32 +	56.98	1898, 15.91
September	81.97	52.09	1899, 10.43
October	71.34 +	41.20	1900, 12.66
November	61.29 +	31.90

www.jibtool.com.cn

Las Cruces, elevation 3,872 feet, population 3,500. This little town is situated on the Old Mexican division of the Santa Fé Railroad, forty-three miles north of El Paso. It lies in the Mesilla valley, which is a portion of the Rio Grande valley. At this point the valley is wide and fruitful under irrigation, there being large fields of alfalfa. The water is pure but somewhat alkaline. There are moderately good accommodations in the town, but more suitable ones for the invalids are found in the ranches around, particularly at the Alameda, which is a mile distant.

www.libtool.com.cn

The Organ Mountains are twelve miles east, rising to a height of 8,949 feet. The winter climate is delightful and continues pleasant until April, when the heat becomes too great for the comfort of Eastern visitors. The mean maximum temperature is, as computed for the three years, 1896 to 1899, autumn, 78°; winter, 58°; spring 76°; summer, 92° F. The mean minimum temperature is: autumn, 41°; winter, 23°; spring, 41°; summer, 60° F. The average annual rainfall for the last twenty years was only eight inches. The number of cloudy days for the year is twenty-five. In the winter the average is four cloudy days a month. The average wind movement is believed to be about five and one-half miles an hour.

The Alameda can accommodate forty guests. The rooms are of good size, and there are plenty of porches. The rates are from $10 to $15 per week. Fifteen miles east of Las Cruces Van Patten's resort stands in a valley of the Organ Mountains at an altitude of 6,000 feet. Here there is a substantial stone house which can accommodate twenty-five persons, and it is surrounded by tents, and is a cool and pleasant place in which to pass the summer.

Pecos Valley.—Separated from the Rio Grande valley by high mountains is the Pecos valley region lying to the east; it comprises a wide belt of land running southward for a distance of one hundred and seventy miles from Roswell to Pecos City. Here irrigation is extensively carried on, and it is a good place for those who have sufficiently recovered their health to carry on farming or stock raising. The accommodations in the hotels and boarding-houses are, however, not very good, and the valley is rather too hot in summer and too windy, particularly in the spring, to make it desirable for most invalids. Roswell, at the northern end of the valley, is rather better sheltered than the town of Carlsbad. The elevation of the valley varies from 4,000 to 3,000 feet. At Carlsbad the mean temperature for autumn is 63°, winter 44°, spring 63°, summer 79° F.

S. Edwin Solly.

NEW ORLEANS, LOUISIANA.—This great Southern city and port is situated upon a double curve of the Mississippi River, one hundred and seven miles from its mouth, although a much less distance from the coast in a straight line. The city lies chiefly upon the left bank of the river, and actually covers about forty square miles, although the city limits embrace an area of something like one hundred and eighty square miles. One of the peculiarities of this city, and one that is doubtless conducive to its healthfulness, is the great area which it covers, thus permitting liberal air spaces and grounds about the buildings in the residential districts. The city is built upon low land, lower than the surface of the river at high-water mark, and huge embankments of earth called "levees" are required to prevent an overflow, and even these are occasionally broken through. The soil is of an alluvial nature, and by digging from three to four feet one usually reaches water; hence the houses have no cellars, and the dead have to be buried in tombs elevated above the ground.

There are a large number of bodies of water—lakes, bayous, swamps, and the like—about the city, and to the north of the city is Lake Pontchartrain, forty miles long and twenty-four miles wide. This lake is connected with the Gulf of Mexico, and forms with the Mississippi River an isthmus upon which the city is built. The population at the census of 1900 was 287,104, composed of Creoles, Americans, and negroes. It is obvious, from the low, level situation of the city, that the problem of drainage is a difficult one; this is partially accomplished by gutters which run into open canals, and these in turn empty with a sluggish current into Lake Pontchartrain. A comprehensive system of sewerage, which will effectually dispose of the house waste and other sewerage and cause it to be discharged into the river below the city, is said to be now under construction. The drinking-water is generally obtained from the rain, stored in tanks or cisterns, each house being provided with such a receptacle, which is a peculiar feature of the architecture. For other purposes the water of the Mississippi River is used, this being taken directly from the river without filtration.

The city itself and its surroundings are very attractive, especially to a Northerner. The vegetation is of a semitropical nature and very luxuriant. The variety of races and the common use of the French language, the streets, markets, cemeteries, parks, and various points of historic interest, and the extensive wharves with the vast amount of inland and foreign shipping, all afford interest and diversion. The French market is the great "sight" of New Orleans, and is best visited in the early morning.

The accommodations are good, the principal hotel being the comparatively new St. Charles, occupying an entire square in the heart of the city. A favorite winter excursion is to New Orleans at the time of the famous "Mardi Gras," which is said to be more brilliant than the carnival at Nice or Rome.

The mortality of the city is about 27.58 per 1,000. The following meteorological table gives the principal characteristics of the climate of New Orleans:

CLIMATE OF NEW ORLEANS, LA. LATITUDE, 29° 58'; LONGITUDE, 90° 4'. PERIOD OF OBSERVATION, THIRTEEN YEARS.

	Jan.	Mar.	June.	Aug.	Nov.	Year.

Average number of fair and clear days	19.8	20.7	24	26.2	19.7	266.9

It will be seen that the climate is tropical or semitropical in nature, warm and moderately moist. The mean temperature of the year is 69.8° F. The highest average summer temperature is 91° F., and the lowest average winter temperature is 27° F. On February 13th, 1899, an extraordinary and unheard-of event occurred, in the formation of ice at the mouth of the Mississippi River, the thermometer indicating a temperature of 10° F. On the 17th of the same month ice flowed past New Orleans into the Gulf of Mexico.*

Snow is a rare phenomenon, but cold waves occasionally occur, accompanied by frost, which nips the sugar cane and cotton plant.

The annual rainfall varies from 31 to 64 inches, the spring and summer being the rainiest seasons. The average mean relative humidity is 71.4 per cent., about the same as that of New York City.

* "The Cold Wave of February, 1899," Guy Hinsdale, Transactions of the American Climatological Association, 1899.

Digitized by Microsoft®

According to Hinsdale ("Climatology, Health Resorts," vol. iv., part ii., of "Physiological Therapeutics") there is about sixty-two per cent. of possible sunshine. Such a climate is more or less enervating, but in itself not unhealthy. A strict quarantine is exercised against the importation of yellow fever, of which several epidemics have in former years occurred. The amount of water about the city would appear to be favorable for the propagation of the mosquito, and hence malaria must be frequent.

www.libtool.com.cn

There are several resorts on the gulf coast at not a great distance from New Orleans, which are frequented both in summer and in winter. Indeed, the entire route from New Orleans to Mobile along the Gulf is very attractive. Pass Christian on this line has a mild winter climate, favorable for persons suffering from bronchial disease, from malaria, or from Bright's disease, for convalescents from some acute disease, and for those of feeble vitality. It possesses a good hotel, cottages, and boarding-houses. The sanitary conditions are good; there is pure artesian well water; the soil is dry and porous; and extensive pine forests lie immediately in the rear of the town. The average mean winter temperature is given by Solly as 70° F. There are opportunities for driving, boating, fishing, and hunting.

Covington, thirty miles to the north of New Orleans, reached by a picturesque journey across Lake Pontchartrain and up the Tchefuncta River, situated in the midst of pine woods, is said to have a very salubrious winter climate, with a "soft air," and is sheltered from all "Northers." It is considered by some local physicians to be favorable for pulmonary diseases.

Bay St. Louis is another resort frequented by the New Orleans Creoles, and said to be rapidly growing in favor with winter visitors. Biloxi, Beauvoir, Ocean Springs, and Long Beach are other resorts on the Gulf coast.

For those seeking rest and diversion the trip down the Mississippi River can be recommended, and from personal experience the writer can testify to its charm and variety. The portion from Baton Rouge to New Orleans along the sugar plantations is of especial delight and interest to the Northern traveller. Below New Orleans, through the "delta country" to the jetties and the Gulf, the voyage is also one of great interest.

New Orleans can be reached from the north by various lines of railroads, and steamers with good accommodations run directly there from New York, occupying about five days on the voyage.

New Orleans is a convenient port of departure for Central America and the West Indies.

Edward O. Otis.

NEWPORT NEWS. See *Old Point Comfort.*

NEWPORT, R. I.—Newport, until very recently one of the capitals of Rhode Island, and in some respects probably the most celebrated of American health resorts, occupies the isthmus and much of the remainder of a peninsula which forms the southwestern termination of the island of Aquidneck or Rhode Island. This island, lying in the middle of the lower portion of Narragansett Bay, is entirely exposed at its southern end to the full sweep of the Atlantic billows, so that Newport, although partly sheltered by the land, partakes in a measure of the climate of the neighboring oceanic islands of Block Island, Martha's Vineyard, and Nantucket. Newport is the seat of the Naval War College, of the United States Torpedo Station, and of the large military post of Fort Adams, at the entrance to the harbor. It has a resident population of 23,000, increased in summer by nine or ten thousand, contains public buildings, many churches, banks, schools, shops of all kinds, an opera house, excellent libraries, the Newport Casino, and an admirably equipped institution, the Newport Hospital; it is also the home of numerous societies, clubs, and associations. It is lighted by gas and electricity and has an electric street railway, running north and south with a branch line to the beach.

The old town, settled in 1639, and built chiefly on the western slopes of a broad and elevated ridge rising directly from the harbor, still retains much of the aspect of colonial days, and in its narrow streets and ancient buildings, of which, in spite of the increasing encroachments of modern civilization, many replete with historic associations are still standing, presents the features of an old New England seaport town and contrasts vividly with the newer suburbs by which it is surrounded. The summer homes are constantly extending until they have already taken up a considerable part of the peninsula. Bellevue Avenue, a modern extension of one of the main city thoroughfares, Touro Street, has been continued due south as far as the ocean, and forms a wide and splendid highway two and a half miles in length, on each side of which are placed the stately houses and beautifully kept grounds of the wealthier summer residents.

The natural features of Newport and vicinity are very attractive. Bishop Berkeley justly described the island to his friends as "pleasantly laid out in hills and vales and rising grounds, and hath plenty of excellent springs, and fine rivulets and many delightful landscapes of rocks, and promontories and adjacent lands." On the one side, the waters of the land-locked harbor and Narragansett Bay studded with islands offer numerous inducements to the lovers of sailing, boating, and fishing. On the other, the ocean is quickly reached at the First or Easton's Beach, at a point where the coast line of the island turns sharply to the east. This beach, seven-eighths of a mile in length, lies in a sheltered bay and in the season is crowded with bathers. Hot salt baths are provided there in summer. Further to the east, beyond Easton's Point, lies the longer, Second or Sachuset Beach, and still farther, facing the east passage of Narragansett Bay, is the Third Beach. Besides these, the principal beaches, the shore near Newport presents a very varied and irregular outline. One of the most striking parts is "The Cliffs" which may be said to extend from the west end of the bathing beach to the end of Bellevue Avenue, for nearly three miles. The public walk along these cliffs through the grounds of some of the finest places constitutes one of Newport's greatest attractions. Of the various drives, the "Ocean drive" from the southern end of Bellevue Avenue, westward along the shore, is justly celebrated. The interior of the island, traversed by two main thoroughfares, the East and West roads, and numerous cross roads, presents a pleasing diversity of hill and dale with charming views of the bay and ocean, and there are many peaceful woodland lanes bordered with dense shrubbery, which remain quite secluded even in summer.

The geological formation underlying Newport and its vicinity is somewhat complex, and consists mainly of various rocks of the carboniferous period. Newport Neck, as the extreme southwestern corner of the island is called, consists of pre-carboniferous rocks, supposed to be partly of igneous origin. In the middle portion of the Neck a conspicuous reddish granite (protogine) is to be observed. On this part of the island the rocks are largely exposed, and are grouped in picturesque masses. The Paradise Rocks back of the second beach offer interesting features to geologists by whom they have been frequently studied. Many of the rocks about Newport have undergone metamorphic processes, and have also been greatly disturbed, and in many cases bent and folded, besides having been eroded by glacial action. There are several large ponds in the vicinity of the city.

The soil under the city proper is a tenacious clay, beneath which frequently occurs a stratum of water-bearing gravel. Most of the wells in the compact quarter of the city receive their supply from this gravel and are for the most part dangerous from liability to contamination from deep cesspools dug through the clay.

The climate of Newport is less trying and more equable than that of most other places on the New England coast. Although snow and ice are far from infrequent, yet the winters are milder and the daily thermometric range is less than in New York, Providence, and Boston. Owing to the influence of the ocean, the spring is rather more

backward, the summer cooler, and the autumn warmer than in the interior. Cultivated flowers have been observed in bloom at Newport late in November. The humidity in summer is often excessive, and in consequence of this there are many days extremely close and relaxing although the temperature is not remarkably high, seldom rising above 85° F. The prevailing winds at Newport are from the southwest. The rainfall is about the average for the New England coast. Fogs are frequent during the warmer part of the year, especially in early summer. Thunder storms are infrequent in Newport itself. The Newport season may be said to last from June 1st to October or even November. The city is, however, much frequented by visitors before and after these dates, and in fact to some extent throughout the year. June, except for those who dislike the occasional heavy fogs, is a very pleasant month, when the foliage is at the height of its beauty. The temperature of the water at Newport in summer is remarkably warm, making bathing very agreeable, and a large proportion of the fishes and marine flora are southern forms. Whether this warmth, as supposed by Lorin Blodget, Storer,* and others, is due to currents from the Gulf Stream, which is more than one hundred miles distant, may be doubted, but there is no question of the fact, and to the temperature of the waters which surround its shores the mild climate of Newport is in large measure undoubtedly due. There are decided climatic as well as other differences between the various parts of Newport. The situations in and about the city, which is two miles from the south end of the island, and some distance from the Atlantic Ocean, are the warmest and most relaxing in summer, though on the other hand generally preferable and more convenient in winter. The cottage sites on the cliffs are cooler and always in great demand both on account of the sea breezes, convenience, and beauty of scenery. The southwest point of the island, Brenton's point, as the prevailing winds are from the southwest, is the most exposed and coolest. Lying along the harbor at the north end of the city is a district known as "The Point," which offers conveniences for boating and is sheltered from easterly winds in winter. Another attractive but limited section is the high ground just south of the harbor.

The accompanying meteorological table is taken from the former edition of this Handbook. The government station at Newport was discontinued in March, 1883, so that no recent records from this source are obtainable. Additional partial observations until 1895 will be found in the Bulletins and Investigations of the New England Meteorological Society and in the Bulletins and Reports of the United States Weather Bureau.

The death rate of Newport is low and the temperate and equable climate seems to be especially favorable to longevity, which is further aided by the abundance of air space and the absence of injurious trades and occupations. Newport is admirably adapted for children, who thrive there greatly, with the exception that in early autumn a tendency is noticed to the prevalence of diarrhœal diseases. For those suffering from tuberculosis and from bronchial, renal, and rheumatic affections, Newport shares too much in the general characters of the New England climate to be recommended, but for convalescents and delicate persons who reside in more inclement places and who for any reason are not able to seek an ideal climate at a distance, it will often be found in winter to be very advantageous. Though well known to the residents, the mildness of the winter climate is as yet hardly appreciated.

The very sedative and soothing effect of the Newport climate renders it useful in many cases of overtaxed brain and nervous system, and neurasthenia—particularly those which require a sedative rather than a tonic treatment. On the other hand, in a limited number of cases, especially in women, the summer climate exercises such a weakening and relaxing influence (felt by every one in a slight degree) that its effect is actually harmful. For gastro-intestinal disorders it is, generally speaking, contraindicated, chiefly during summer. Asthmatics are sometimes benefited, but sometimes the reverse is the case.

The sanitary conditions at Newport, though susceptible of much improvement in the older part of the city, are on the whole good. Newport has a satisfactory sewerage system, the main outlet pipe of which is carried for some distance beneath the waters of the harbor and discharges at the outer side of Goat Island. The city water taken from Easton's Pond and supplementary sources, though not as yet devoid of organic matter which supports a growth of vegetable organisms and infusoria, is of fair quality and has never been recognized as the cause of any epidemic. Everything for comfort and health is attainable to a degree not met with elsewhere outside of the larger cities, though Newport is deficient in hotel accommodations. There are, however, many excellent boarding-houses open at all seasons.

Newport is reached from New York by the large and comfortable night boats on Long Island Sound in ten hours, or by railway to Wickford in five hours, thence by steamboat across Narragansett Bay in another hour. From Boston and Providence there is direct communication by rail. The latter city may also be reached by boat. The neighboring pleasant resorts of Jamestown and Narragansett Pier are readily accessible, and there is also direct communication in summer with Block Island.

William C. Rives.

* "The Mild Winter Climate of Newport, R. I., as the Effect of the Gulf Stream," by H. R. Storer, M.D., Medical Record, December 22d, 1883.

NEWSOM'S ARROYO-GRANDE SPRINGS.—San Luis, Obispo County, Cal.

Post-Office.—Arroyo Grande. Hotel and cottages.

Digitized by Microsoft®

Access.—By rail to Arroyo Grande, thence by stage two miles to springs.

The ocean beach road affords one of the finest drives in that section of the country. The springs are pleasantly situated at an altitude of about four hundred feet. They lie about fourteen miles south of San Luis Obispo. The climate here is one of almost perpetual sunshine, with occasional spring and winter rains. On the place are three principal springs whose waters range in temperature from 40° to 100° F., and flow 49,000 gallons hourly. The following analysis was made by Winslow Anderson:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	4.10
Sodium carbonate	1.75
Sodium sulphate	3.92
Potassium carbonate	.15
Potassium sulphate	2.90
Magnesium carbonate	6.41
Magnesium sulphate	2.47
Calcium carbonate	8.25
Calcium sulphate	.76
Ferrous carbonate	3.98
Alumina	.33
Silica	2.03
Organic matter	.27
Total solids	37.32
Gases.	**Cu. in.**
Free carbonic-acid gas	14.90
Free sulphureted hydrogen	3.56
Temperature of water analyzed, 100.5° F.	

These waters have gained considerable reputation in the treatment of old cases of chronic rheumatism and gout, catarrhal affections of the bladder and bowels, skin diseases, etc. For uterine disorders the hot sulphurous douche has been highly recommended.

James K. Crook.

NEW YORK is situated in 41° north latitude, 74° longitude west from Greenwich. Its temperature range is wide (from −6° F. to 99° F. with a mean of 52.6° F. in 1899), subject to extremes, especially to extreme heat in summer, and often to sudden changes. Owing to its insular and seaboard position, the extreme summer heat is usually a few degrees less in New York than the average of sister cities. Its climate is moist, the relative humidity in 1899 averaging 76 per cent. at 8 A.M. and 73 per cent. at 8 P.M. In the same year the rainfall was 42 inches, but in other years it has often exceeded 52 inches. The average hourly movement of wind varied from 8.6 miles in July to 18.9 miles in March. The prevailing direction of wind is northwest. In 1899 there were 29 thunder-storms, 128 clear days, 127 partly cloudy days, 110 cloudy days. Both in summer and in winter the temperature in New York is milder than that of Chicago, and, compared with that city, its relative humidity is less (in spite of its seaboard situation) and there is less wind, but there are fewer clear days and more foggy days. There is more sunshine in New York than in Boston, Chicago, St. Paul, or Portland, Ore.; but less than in Philadelphia, Baltimore, or Denver. The climate of New York, though stimulating, being moist, changeable, and in winter rather cool, is unfavorable for those subject to bronchial and laryngeal disorders, and for patients ill with, or convalescing from, pulmonary tuberculosis. In spite of this, New York is a healthful city. Its water supply, from Croton and Kensico lakes, is of excellent quality and free from contamination. As to typhoid fever, a large proportion of cases are infected outside of the city or from sources imported into it. The same may be said of malaria in recent years, although this class of affections formerly prevailed in Harlem and the East River districts; and the extensive digging up of the city now in progress (1903) for the construction of the rapid transit tunnel has not altered the morbidity statistics. Contagious diseases, developing at home or in school-houses, are watched by an active health board; and tropical diseases, such as cholera, typhus fever, etc., are almost unknown in New York. The city's annual mortality records for the last three years show an average of 67,503, a death rate of 19.42 per 1,000 per annum. Of these, the average annual mortality from pulmonary and other forms of tuberculosis was 9,491; from pneumonia, 9,032. The average mortality from typhoid fever and from diarrhœal diseases for 1899 and 1900 (1898 being omitted from this calculation because of the unusual increase in those diseases among soldiers returning from the war in that year) was, respectively, 632 and 6,897. Of the deaths from diarrhœal diseases a little more than one-half were among children under five years of age, who supplied one-third of the deaths from all causes. In 1899 there were reported to the city Board of Health 33,486 cases of contagious diseases, of which 1,950 were of typhoid, 99 of smallpox, and 11,001 of diphtheria. Of 41,709 contagious cases reported in 1900, 2,658 were of typhoid, 156 of smallpox, and 12,913 of diphtheria.

In 1901 there were about 4,000 cases of smallpox in New York, but by adopting the most vigorous measures the disease ceased to exist in Manhattan in August, 1902. The total number of deaths from all causes in 1902 in Greater New York was 68,082. The general death rate of New York was reduced in 1902 to 18.74 per 1,000. Up to August 16th it was 17.60 per 1,000 against 21.19 in 1901.

Manhattan's death rate was 17.76; Brooklyn's 16.87; that of the Bronx, 16.45; Queens', 19.97; Richmond's, 24.34. These figures show that irrespective of its population New York is one of the healthiest cities in the country, and ranks in comparative mortality records with thousands of small towns and villages.

Climate of New York, N. Y. Latitude, 40° 43′; Longitude, 74° 0′. Period of Observation, Thirteen Years.

The lessened mortality of 1902 is attributable in part, no doubt, to the remarkable and widespread absence of excessive heat during the summer months. In New York City there was only one day in this year in which the maximum temperature rose to 91° F. During the so-called "dog days" the temperature did not go above 88° F., and the nights were unusually cool. www.libtook.com.cn The State of New York lies in the main track of the cool waves which emerge from the northern Rocky Mountain region and drift thence eastward over the Great Lakes where the conditions have been unusually moderate during the past season, dominated by a series of cool anti-cyclones from the northwest.

The summer rainfall has been excessive, amounting throughout half of the State of New York to more than twelve inches during June and July. This is attributed to an "exceptional strength and persistency in the southerly winds bearing the vapor of the tropical ocean to feed the rain clouds producing the excessive precipitation in our northern States."

The great concentration of population in New York, now embracing over three and a half millions of people, complicates all problems of health and municipal hygiene. There are over forty thousand hotels, apartment and tenement houses in the city. The extremes of society are more widely separated than in any other American city. Philanthropic measures on a very large and generous scale have been carried out for years in New York and have done much to improve the condition of the poor and sick and outcast. It is impossible to enumerate them, but they are rapidly extending their work and are more and more generously supported.

New York is now well provided with small parks in which the poor have an opportunity for recreation and temporarily escape from their crowded quarters. Music is provided on summer evenings, and public-school properties which formerly were tightly closed all summer, are now thrown open as playgrounds for the children. Recreation piers along the river front serve a similar purpose and are specially grateful to tired mothers with sick infants. The floating hospitals of St. John's Guild, the country week associations, kindergartens, and free ice funds contribute largely to diminish misery and promote health. Van Cortlandt, Bronx, and Riverside parks are largely uncultivated, but very popular. Van Cortlandt has fine golf links and skating facilities; in the Bronx there are opportunities for picnicking, rowing, and flower gathering. Prospect Park, Brooklyn, and Central Park, Manhattan, are the largest cultivated parks in the city. Facilities for tennis, baseball, football, croquet, and amusements for small children are provided. Taken in connection with its superb water front, the bay, the rivers, and the sound, New York, aside from its commercial supremacy, is one of the most desirable places of residence in the world. *Guy Hinsdale.*

NICE.—This city is the most popular resort on the Riviera, as it is the largest, containing 93,760 inhabitants. It is one hundred and forty miles northeast from Marseilles, nineteen and one-quarter miles northeast from Cannes, and nine and one-half miles west from Monaco. It is situated on the Baie des Anges, opening toward the south, at the mouth of the little river Paillon. To the east is the hill of Villefranche, affording protection from the east winds, and to the west the promontory Cap d'Antibes, which affords partial protection from the mistral or northwest wind. To the north are the foothills of the Maritime Alps, the highest of which is Mount Chauve, with an elevation of 2,824 feet, and standing seven miles back from the coast. These foothills, as Dr. Sparks has observed, are too far distant and too much intersected by valleys to afford very good protection against winds coming from that direction.

The city of Nice consists of three distinct portions: the old town, on the left bank of the Paillon; the Port, with a seafaring population; and the Strangers' Quarter on the right bank of the river, which is the portion occupied by the winter visitors. This last section is the fashionable part of the city, and contains attractive avenues and gardens, broad streets with fine buildings, and innumerable hotels and pensions.

Along the coast runs the Promenade des Anglais, a beautiful, broad-terraced walk, two miles in length. It is shaded by palms and other trees, with a pier and casino near the beginning, and is bordered with hotels and villas.

In the season from November to May, Nice is visited by one hundred thousand people, and it then resembles a northern capital with all its gayety. During the year about one million people are said to visit it. Between the foothills proper and the shore, a distance of four or five miles, is a sloping area of country consisting of low ridges and shallow valleys. Immediately adjacent to the coast is a level tract of ground.

In seeking a health resort along the Riviera it must not be forgotten that Nice is a large, extensive city, and consequently possesses the disadvantages and perturbing influences of a city, viewed from a health-resort point of view.

The sanitary condition of Nice is said to be the best on the Riviera, and the water supply "excellent in quality and quantity" (Linn).

Nice, by reason of its situation and size, possesses innumerable resources for diversion and pleasure. Here congregate visitors from almost every civilized country, and life in this gay winter city is made most attractive for them. At the height of the season the carnival is celebrated with great display. Nice is considered a healthy city, its death rate comparing favorably with that of most French towns. In 1890 there were 21.63 deaths per 1,000.

The following table from Teysseire's figures give some of the meteorological data for the season, October to April inclusive, extending over a series of years:

	October.	November.	December.	January.	February.	March.	April.
Temperature (degrees Fahr.)							
Mean	61.61°	52.80°	48.2°	46.72°	48.43°	51.22°	57.54°
Absolute maximum	88.16	74.7	65.3	66.6	66	70.5	82
Absolute minimum	36.7	31.1	36.9	36.5	38.3	33.1	37.2
Humidity—							
Mean relative	62.6%	62.4%	63%	65.8%	59.9%	55.7%	60.4%

"The mean annual temperature," according to Burney Yeo, "is 60.3° F. The mean winter temperature 49.1° F., and the mean spring temperature 58.1° F. The minimum temperature at night is 26.6° F. The coldest months are January and February. The relative humidity is small, as is seen by the table. The mean annual rainfall is 32.43 inches, and 19.45 inches for the six winter months November to April. The mean proportion of sunny, cloudy, and rainy days for twenty years is: sunny 219.2, cloudy 77.3, rainy 67.4, and for the winter season, from October 1st to May 31st, sunny 135.8, cloudy 55.3, rainy 52.8." March, April, and May are the windiest months. Of the stormy winds the east wind is the most common, says Burney Yeo, and blows forty-five days in the year.

"Like Cannes," says Huntington Richards, "Nice is one of the windiest of the Riviera resorts. The mistral blows about nine times in the year, chiefly in February and March, and is accompanied by clouds of dust. The average number of days of complete calm during the nine autumn, winter, and spring months, as quoted by Sparks from Teysseire, is 18.6, while the average number of days of gentle wind is 203.8, and that of strong wind days is 69.4, out of which 29.4 occur during the three spring months."

"It must be admitted," says Sir Hermann Weber, "that the changes of temperature are very great, even in sunny places, when passing from a sheltered position to a spot exposed to winds, and likewise on passing from the sun into the shade. A great part of the town is also exposed to the northeast wind, owing to a gap left in the sur-

Digitized by Microsoft®

rounding heights by the Paillon torrent, and the mistral is often very annoying, the protection by some rather low hills to the northwest being inefficient. But the character of the climate is remarkably sunny and invigorating, and the bright days considerably exceed in number the dull and rainy ones". Frost rarely occurs, and then at night. Fogs are unknown. The temperature of the sea water in winter is between 53° and 61° F., and in summer between 64° and 75° F.

www.libtool.com.cn

"Nice enjoys," says Dr. Wendt, in the previous edition of this HANDBOOK, "nothing more nor less than a fair average of Riviera climate. This means that it is not devoid of drawbacks, and that ideal winters are not found there. Nice is more sheltered than some places, but is nevertheless exposed to the mistral, which blows at Nice just as it blows at most other Riviera spots. It should be borne in mind by invalids and tourists that Nice and the Riviera in general really possess two distinct and different climates, viz., seashore or marine climate and an inland or mountain climate. It is quite well known that immediate proximity to the sea may induce sleeplessness and other symptoms, denoting too exciting an action on the nervous system. The dry, sunny inland air is tonic and sedative; the air in immediate proximity to the shores of the sea is bracing and exciting. The air of the city and its suburbs is often a mixture of the two. It is thus apparent that a number of local climates are found at Nice, concerning which the resident physicians will inform invalids."

As a genuine health resort it will be seen from the preceding climatic considerations that Nice possesses grave defects, and is perhaps the least desirable of the Riviera stations, particularly toward the close of winter and the beginning of spring. As has been well said, it is "rather a pleasure resort than a refuge for invalids." It does, however, offer much to a certain class of patients or semi-invalids. Those seeking sunshine, a certain degree of warmth, dry air, and comfortable living, even luxury, will find it here, under most attractive surroundings.

Anæmia, chlorosis, scrofula, gout, rheumatism, dyspepsia, diabetes, Bright's disease, chronic bronchitis, asthma, and catarrhal conditions of the upper air passages are said to be more or less favorably influenced by the climate of Nice. It is not to be recommended for pulmonary tuberculosis, although it was formerly much resorted to by this class of cases. For the feeble, from old age or other cause, it is of value.

The suburb of Cimiez, two miles from the sea, appears to possess especial climatic advantages. It is said to be better sheltered and has a more equable climate, and its influence is more sedative. The late Queen of England visited this quarter of Nice several times.

Three and a half miles to the east of Nice is Beaulieu, said to be one of the best protected spots on the coast. The high mountains rise directly in the rear, cutting off the north winds. The situation of this little place is most attractive, and the groves of olive trees, orchards of orange and lemon, and the luxuriant vegetation enhance the beauty of the scenery.

The excursions in the vicinity of Nice are many and most attractive, affording marvellously beautiful views of this picturesque region. La Turbie, 1,600 feet above the level of the sea, on the Corniche road between Nice and Monaco, is perhaps one of the most strikingly beautiful spots in all this region of magnificent scenery.

For the true invalid the Riviera may possess many disadvantages, but for one weary with the routine of life, to roam along this coast from Genoa to Cannes in the late spring or early summer when the vegetation is at its best, is a source of unending delight, as the writer can testify from personal experience. *Edward O. Otis.*

NIGHTMARE. See *Consciousness, Disorders of.*

NIRVANIN—diethyl-glycocoll-p-amido-ortho-oxybenzoic acid methyl hydrochloride, $HC(C_2H_5)_2NCH_2.CO\,HN.C_6H_4.OH.COOCH_3$—occurs in white neutral prismatic crystals, very soluble in water. Elsberg at Mount Sinai Hospital in New York City, found the toxic dose in rabbits to be 0.22 gm. per kilogram of body weight, while that of cocaine is 0.02 gm. per kilogram. Boiling causes very slow deterioration of anæsthetic power and is practically harmless to the drug for short periods. Solutions purposely infected soon became sterile, and one- to two-per-cent. solutions were still sterile at the end of six months. Joanin found 0.5–0.7 gm. per kilogram toxic for guinea-pigs, while betaeucaine is twice, and cocaine nine times, as toxic. But M. Didrickson affirms that the toxicity is greater than these authors report, very small doses having resulted in excitement, hallucinations, and convulsions.

Clinical evidence seems to favor this new compound as a stable, sterile, very soluble local anæsthetic. In 0.2–0.5-per-cent. solution it is suitable for infiltration anæsthesia, and in five-per-cent. strength for local application. It is somewhat irritating, and if used for the eye should be combined with cocaine. It has but little power of penetration, a five-per-cent. solution applied to a mucous membrane scarcely affecting the submucous tissues. It is said to be of value in pruritus and in dentistry. *W. A. Bastedo.*

NITRIC ACID.—*Aqua fortis.* Under the title *Acidum Nitricum*, Nitric Acid, the United States Pharmacopœia makes official a liquid composed of sixty-eight per cent., by weight, of absolute nitric acid [HNO_3]. Such grade of nitric acid is a heavy liquid of about 1.414 specific gravity, colorless when freshly made and perfectly pure, but, as met with in the shops, apt to be of a distinctly yellowish shade. The acid fumes upon exposure, is powerfully corrosive and stains animal tissues and woollen fabrics a bright yellow. It dissolves silver, mercury, copper, and other metals with evolution of red fumes. It mixes in all proportions with water and alcohol. It is a pretty potent oxidizer, yielding up a portion of its oxygen to oxidizable material, and it has a strong affinity for water, by reason of which affinity, in part, it is powerfully caustic to animal tissues. It should be kept in well-stoppered, dark amber-colored bottles.

The valuable properties of strong nitric acid are the power of the acid to oxidize on the one hand, and to cauterize on the other. By its oxidizing virtues nitric acid is a serviceable disinfectant in situations where its corrosive action will do no injury; and its cauterant powers are convenient for surgical application. The acid burns searchingly and thoroughly, yet not unmanageably. When using nitric acid as a caustic, it is well to bound the area intended for cauterization by a ring of oil or of adhesive plaster, to prevent the action from spreading unduly. The acid is then applied by a glass rod or bit of stick, care being taken to avoid excess. Swallowed in any considerable quantity nitric acid is a powerful corrosive poison, producing effects substantially similar to those caused by sulphuric acid (see *Sulphuric Acid*). The most striking difference between the poisoning by the two agents is, that in sulphuric-acid corrosion the sloughs tend to be brown or blackish, while in that from nitric acid they are yellow. Inhalation of the fumes of nitric acid also may kill.

In proper dilution nitric acid operates physiologically as do all the sour mineral acids (see *Sulphuric Acid*), and shares with hydrochloric acid a sort of selective efficacy in disorders of the digestive apparatus. Vomiting, from many causes, is often relieved effectually by nitric acid, and so is diarrhœa, and so is the functional disorder of digestion commonly ascribed to sluggish action or even congestion of the liver. Even a special curative action over constitutional syphilis has been proclaimed of nitric acid, but is at the present day quite properly discredited. For internal giving, the following preparation of the United States Pharmacopœia is to be used:

Acidum Nitricum Dilutum, Diluted Nitric Acid. This preparation is a simple dilution of the official strong acid with distilled water, in the proportion a little less than six parts of added water to each one of acid. It

Digitized by Microsoft®

represents ten per cent., by weight, of absolute nitric acid; is a colorless and strongly sour liquid, non-corrosive but highly irritant. Its specific gravity is 1.057. The internal dose is from twenty to forty drops, largely diluted with water, and the mouth to be rinsed well after the taking of each dose. *Edward Curtis.*

NITRITES.—Physiological experimentation and clinical testing with a number of different nitrites, both of metallic and ethereal bases, have now developed the fact that such compounds possess certain strongly marked properties in common. These properties evidently belong to the acid radical of these salts, so that the nitrites are to be regarded as forming a natural group of medicines whose peculiar virtues are due to nitrous acid. The effects wrought by nitrites upon the animal system are, broadly, twofold, as follows: On the one hand, a chemical change in the composition of hæmoglobin, and, on the other, an influence upon nervous and muscular structures, showing itself by profound and, in sufficient dosage, even fatal derangement of function. As regards the effects upon the blood, it is observed that in an animal under the influence of a nitrite the arterial and the venous blood both have acquired in common a peculiar chocolate hue, which does not change when the drawn blood is agitated with air. Examined by the spectroscope such blood shows a replacement of the bands of hæmoglobin by those of a new compound (Gamgee) very probably identical with the *methæmoglobin* of Hoppe-Seyler; and, tested chemically, this changed hæmoglobin is found to have its ozonizing power very seriously compromised. Treatment with ammonia restores normal color and normal functional power to this nitrite-poisoned blood. The nervous and muscular derangements produced by nitrites are as follows: In moderate dosage there are felt a fulness and throbbing of the head and neck, with almost simultaneous very rapid and disorderly action of the heart, and excited and panting breathing. The face is deeply flushed and feels uncomfortably hot, but the internal general temperature is found by the thermometer to fall. So, too, though the heart and carotids are felt to throb disagreeably hard, yet arterial tension is proved to suffer a very great decline, obviously due to the general capillary dilatation, of which the flushed face is an evidence. In large doses, as observed in animal experimentation, initial great acceleration of the heart's action, and violent and hurried breathing are followed by slow, irregular, and failing pulse and respiration, fall of temperature, weakened voluntary and reflex motor activity, and finally, death by respiratory arrest. As regards the mechanism of these derangements, the initial circulatory phenomena—acceleration of pulse, capillary dilatation, and sinking of blood tension—are mainly the expressions of paralysis, severally, of cardiac inhibition, of resisting power of the muscular elements of the arterioles, and, to a less degree, of vaso-motor control over the same. The heart failure following large dosage is probably due to direct poisoning of the cardiac musculature; the agitated and panting breathing of the earlier stages of the nitrite effect seems to be secondary to the other derangements, but the final arrest of respiration in fatal poisoning appears to result from direct paralysis of the nerve centres concerned in the function. Similarly, the failure of voluntary and reflex motor power seems to be mainly from paralysis of the motor tract of the cord, although to a certain extent the muscular contractility is itself impaired.

Nitrous acid in combination is thus seen to be an agent that immediately attacks the ozonizing function of the blood and the vital endowments of nerve and muscle tissues. Many have thought that the paralytic phenomena are probably but consequences of the blood lesion, but various physiological considerations make it more likely that they result from immediate and independent poisoning of the substance of the nerve centres.

The principal therapeutic applications of the nitrites are to relieve spasms, or pains referable to spasm, and to arouse the heart in syncope. The most notable instances of the first application are the use of nitrites in the treatment of angina pectoris, spasmodic asthma, and epilepsy. In the first two of these diseases nitrites often prove of astonishing temporary power, but in the last they are, as compared with bromides, second rate in efficacy. Still, in some cases of epilepsy, where bromides have ceased to impress or where the supervention of bromism has forced their discontinuance, nitrites have shown themselves serviceable alternates (Law). For the relief of syncope nitrites are theoretically indicated where the cardiac arrest is presumably referable to excess of inhibition; and, clinically, the nitrite of amyl has been reported to have restored heart action in cases of syncope from emotion, from hemorrhage, and from chloroform poisoning.

The nitrites recognized by the United States Pharmacopœia are the ethereal nitrites of amyl and of ethyl, respectively—the latter in the single preparation, *spirit of nitrous ether* and the salt sodium nitrite. Also, though unofficial, potassium nitrite has been tried in medicine. Properly also, *nitroglycerin* should be included in a summary of the group of nitrite medicines, since, though not itself a nitrite, there is little doubt that its medicinal effects are wrought by a nitrite resulting from decomposition of the nitroglycerin within the body. In this place the nitrites, respectively, of *ethyl, amyl, potassium,* and *sodium* will be discussed, nitroglycerin being treated of under its own title.

Ethyl Nitrite: $C_2H_5NO_2$. Ethyl nitrite, formerly called *nitric ether*, and now *nitrous ether*, is a compound that forms by reaction of nitric acid with alcohol. It is an ethereal fluid of agreeable apple-like flavor and pungent taste—exceedingly volatile, somewhat soluble in water, and more freely in alcohol. Experimented with in the pure condition, this body produces promptly and fully the classical effects of the nitrites as above set forth (Richardson). It is used in medicine, however, only in the form of a weak alcoholic solution—the time-honored and well-known preparation formerly called *sweet spirit of nitre*, but now official in the United States Pharmacopœia under the title *Spiritus Ætheris Nitrosi*, Spirit of Nitrous Ether. This preparation is made by distilling a mixture of solution, in alcohol and water, of sodium nitrite, and of sulphuric acid. After purification of the ethereal product, enough alcohol is added to make a spirit containing in solution four per cent. of ethyl nitrite. Spirit of nitrous ether is a clear, mobile liquid, volatile and inflammable, of a pale straw color, inclining slightly to green, and a fragrant, ethereal odor. Its taste is sharp and burning. Specific gravity, about 0.836 to 0.842 at ordinary temperatures. It slightly reddens litmus paper, but should not effervesce when a crystal of potassium bicarbonate is dropped into it. It should be kept in small glass-stoppered vials, in a dark place, remote from lights or fire. Spirit of nitrous ether as found in the shops is apt to be of deficient strength from the fraudulent addition of water or alcohol.

The effects of this spirit are the conjoint effects of its two constituents, alcohol and ethyl nitrite. In the small doses commonly prescribed for medicinal purposes the peculiar nitrite effects are but faintly seen, and the medicine operates as a grateful stomachic, which is at the same time mildly diaphoretic and antispasmodic. The spirit is accordingly much prescribed as an ingredient of so-called fever draughts or mixtures, its tendency being to ameliorate the discomforts of the febrile state. In large dosage with this preparation the typical nitrite effects are clearly seen—giddiness, headache, and throbbing arteries having been reported as following an overdose, while in another case death occurred from inhaling the fumes from a broken three-gallon jar of the spirit accidentally spilled in a room. Spirit of nitrous ether is prescribed in doses of from 2 to 4 gm. (practically from ♏ xxx. to fl. ʒ i.) several times a day. The dose may be mixed with water for the taking, or prescribed as an ingredient of mixtures containing saline solutions. Such mixtures should not be ordered in quantity beyond present need, since dilution with water tends to set on

Digitized by Microsoft®

foot chemical changes in the ethereal spirit. Spirit of nitrous ether is an ingredient of the official *Compound Mixture of Glycyrrhiza* ("Brown Mixture") of the United States Pharmacopœia.

Amyl Nitrite: $C_5H_{11}NO_2$. Amyl nitrite is used in medicine under its own form. Under the title *Amyl Nitris*, Amyl Nitrite, the United States Pharmacopœia recognizes the ordinary article of pharmacy, which is an ethereal liquid containing about eighty per cent. of amyl nitrite. The remainder of the percentage is made up of various associated but undetermined ethers. The substance is a clear, very mobile ether, of a pale yellow color, having a fruity odor almost exactly resembling that of ripe bananas, and an aromatic taste. When freely exposed to the air it decomposes, leaving a large residue of amyl alcohol. It is insoluble in water, but soluble, in all proportions, in alcohol, ether, chloroform, benzol, and benzin. Its specific gravity is 0.870 to 0.880, and it boils at about 96° C. (205° F.), giving an orange-colored vapor. It burns with a fawn-colored flame. It should be kept in small, dark glass-stoppered vials, in a cool and dark place. Amyl nitrite is excessively volatile, and the utmost care is necessary to preserve a specimen both from loss of bulk and from spontaneous decomposition by exposure.

Amyl nitrite is the nitrite commonly used in medicine for the specific sake of the nitrite effects proper, and it is, perhaps, the most striking of medicines in the matter of rapidity and intensity of action. From its extreme volatility and pleasant odor the ether is efficiently and conveniently given by inhalation. When the quantity of from three to five drops, poured upon a handkerchief, is inhaled, the subject is conscious, within so short a time as from three to ten seconds, of a sensation of heat, fulness, and throbbing of the face and head, immediately followed by an indescribable and most distressing commotion within the chest, the heart beating fast and furiously, and the breathing being panting and hurried. Giddiness and some muscular languor accompany these phenomena, and perspiration may break out; but in a very few minutes the derangements of function begin to recede, and rapidly, and upon their complete disappearance the subject is left without after-effects, save, possibly, a little dull headache and lassitude, lasting from half an hour to an hour. Assuming such dosing with the ether to have been in a case open to the therapeutic powers of the nitrites, the therapeutic effect will have been as swift and pronounced as the physiological derangement. No medical relief, indeed, so nearly merits the designation of "as if by magic," as the sudden and complete abrogation of an anginal or asthmatic seizure that is so often wrought by the swift and profound action of amyl nitrite. The drug, however, must not be expected to be infallible, for many cases of angina pectoris, of asthma, and syncope—notably profound chloroform syncopes—often set the nitrite at defiance.

Amyl nitrite is an important medicine for the conditions enumerated above as being peculiarly amenable to the nitrite influence, and also has proved serviceable in dysmenorrhœa and other affections, painful or spasmodic. The remedy is most conveniently given by inhalation, from three to five drops being poured upon a handkerchief, and the cloth then held to the nose and mouth. Those who are subject to angina or asthma, and who find relief from amyl nitrite, may carry a small vial of the ether about with them, and, upon the occasion of a seizure themselves dash a few drops upon a handkerchief. Or it may be sufficient to sniff strongly at the opened vial itself until the characteristic sense of flushing and arterial throbbing proclaim the absorption of a sufficiency of the vapor. If a vial be so carried and used, it should be but a small one, not over 2 c.c. (♏ xxx.) capacity, since by frequent uncorking of the bottle the contained sample of amyl nitrite gets "flat" and loses its efficacy through chemical change brought about by the exposures to air. More convenient than a vial, both because of better preservation of the medicine and because of combined rapidity ease, and certainty of dispensing of the dose, are what are commonly called *pearls* of amyl nitrite. These pearls are small, flattened, sealed chambers, blown of very thin glass, and charged with fixed quantities of the nitrite, generally from to two to five minims. For use a single "pearl" containing the prescribed dose, is crushed in a handkerchief and the fumes of the liberated ether are inhaled in the usual way. The glass of which the pearl is made is so thin that the broken fragments do no harm. These pearls are not official, but are quite universally to be procured. Amyl nitrite can, if preferred, be given by the mouth, dropped upon sugar, or dissolved in alcohol, in doses of from two to five drops.

Potassium Nitrite: KNO_2. Potassium nitrite is not official in the United States Pharmacopœia. It is a colorless salt, slightly deliquescent, soluble in water, and occurring in crystals or in fused sticks. Tested upon man and the lower animals, potassium nitrite is found to produce all the typical nitrite effects; but, as might be expected, more slowly, while yet more enduringly, than amyl nitrite. In the experiments of Weir Mitchell and Reichert[1] full doses made themselves felt by symptoms during a period of from one and a half to five hours, beginning within one or two minutes after swallowing. The doses ranged from three to ten grains, single or repeated, and one individual experimented upon took, in divided doses, within a period of six hours and thirteen minutes, thirty-five grains of the salt. But from the behavior of sodium nitrite of ascertained purity (see below), the question cannot but protrude itself, Was the sample of the potassic salt used in these experiments tested for purity? In the present condition of knowledge of the subject, the comparatively large quantities cited above should certainly not be prescribed medicinally for an untried subject.

Potassium nitrite gives rise, during the period of its action, to eructations of gas of a very offensive phosphureted odor, so disagreeable as even to lead in some cases to nausea and vomiting (Reichert).

Sodium Nitrite: $NaNO_2$. The salt is official in the United States Pharmacopœia under the title *Sodii Nitris*, Sodium Nitrite. It occurs in crystals or fused sticks, freely soluble in water. Commercial samples are rarely pure, being composed of nitrate and nitrite in varying proportions. The better grades may contain 98.5 per cent. of nitrite, but specimens of a salt sold as sodic nitrite have been found to contain but the merest trace of that body—0.011 per cent. only (McEwen). The condition of small crystals, as against that of large transparent crystalline forms or the fused nitrite, is said to be the best for purity. Sodium nitrite deteriorates on keeping—a fact doubtless accounting for the poor quality of the drug so often found.

Sodium nitrite produces the peculiar nitrite effects in a manner generally similar to potassium nitrite, and, when a good sample is employed, can be fatally poisonous, as has been proved by experimentation upon animals. In full dosage with the human subject, extreme distress, and even an alarming condition, have been reported; the prominent complaint being of excessively violent and turbulent heart action, with great giddiness and general weakness. In such cases lividity of the lips and nails has quite commonly been observed.

Therapeutically sodium nitrite has proved efficient in the usual way of nitrites to control the pain in many cases of angina pectoris, and in cases of frequently recurring paroxysms has, in single dose, established freedom therefrom for half a day in subjects to whom amyl nitrite gave immunity for but an hour or two (Matthew Hay). Such immunity, furthermore, was secured by a dosage small enough not to produce any pronounced throbbing or giddiness or headache. In epilepsy this nitrite has also been used with some abatement of the fits; but it is, in a general way, inferior to bromides for this particular therapeusis. From the experience with the salt so far acquired, sodium nitrite can be said to be available for all the therapeutics of the nitrites, and to have the advantages over the ethereal salts of a more deep-rooted and lasting influence, and of much greater

Digitized by Microsoft®

cheapness. On the other hand, as compared with amyl nitrite, the sodic salt is slower in establishing its effects, so that when urgency of relief is demanded the amylic salt is preferable. Sodium nitrite gives rise to some disagreeable eructations of gas, but in therapeutic dosage the occurrence is slight. The sodium nitrite should, for a pure sample, not exceed 0.13 gm. (gr. ij.), for the larger doses of five, ten, and twenty grains that were at first used by investigators have, with good specimens of the salt, produced very distressing and even alarming effects. The effects of a two-grain dose will persist a number of hours. Care should be taken in prescribing this medicine that the sample is of good quality and not too old. *Edward Curtis.*

NITROBENZENE, POISONING BY.—This substance, also called nitrobenzol, is made by the action of nitric acid on benzene (benzol), which is one of the ingredients of coal tar. The formula of nitrobenzene is $C_6H_5NO_2$; it is a substitution product of benzene. It is a clear, straw-yellow liquid, insoluble in water, and possessing a strong odor, sufficiently like that of bitter almonds to permit of its use in perfumery and confectionery. It has become a rather familiar article of commerce under the name of oil of myrbane. It appears from several recorded cases that small doses of the liquid are poisonous, and even its vapor is active. The symptoms resemble somewhat those of prussic acid, but there are no immediate insensibility and no convulsions. The skin becomes clammy, the lips and fingers purple, the eyes glassy, and the breathing very slow and infrequent. In a case that occurred in the practice of Dr. H. M. Dean, of Muscatine, Iowa (*Medical Bulletin*, vol. i., p. 50), violent effects followed the mere tasting the article. The pulse was not much affected, but the respirations occurred at long intervals. The mind usually remains clear for some time, but unconsciousness ultimately ensues. The diagnosis will generally be determined by the powerful and characteristic odor of the substance, which can easily be distinguished from that of both prussic acid and oil of bitter almonds, which it most nearly resembles.

Nitrobenzene is partly converted in the body into aniline, but its poisonous action does not depend on this conversion.

There is no specific treatment, the symptoms must be combated as they arise. Free washing out of the stomach with lukewarm water has been found to be of great advantage in many cases of poisoning, and would be applicable here. Dr. Dean, in the case above referred to, used fluid extract of digitalis, one drop every hour, and also, every few minutes, a teaspoonful of a mixture of one part of alcohol and two of hot water. He could make the patient swallow by putting the spoon well back on the tongue. *Henry Leffmann.*

NITROGEN MONOXIDE.—Nitrogen monoxide (N_2O) is the body commonly called *nitrous oxide gas*, and formerly popularly known as *laughing gas*. It is a colorless gas, practically without smell, and with a very faintly sweetish taste. It dissolves in a little more than its own measure of cold water, to a less extent in warm water, and to a less extent still in a saturated aqueous solution of sodium chloride. By combined exercise of cold and pressure the gas can be condensed to the liquid condition, yielding a colorless and very mobile fluid. Upon release of pressure this fluid immediately springs again into the state of gas. Nitrogen monoxide actively supports the combustion of inflammable bodies, undergoing decomposition and yielding up its oxygen to the burning substance.

Nitrogen monoxide is, physiologically, absolutely bland, and being also odorless is perfectly respirable even when substituted, pure, for atmospheric air. When so respired, the gas, from its free solubility in watery fluids, is rapidly absorbed into the blood. If inhaled with admixture of enough atmospheric air for the ordinary needs of the system, nitrogen monoxide proves peculiarly exhilarant. A sort of tingling thrill runs through the nerves down to the very finger ends, and, if enough of the gas be taken, the experimenter is irresistibly driven to the commission of some extravagant and silly act, almost always such as betokens an uncontrollably joyous state of mind. Singing, shouting, laughing, dancing, and capering are thus the common expressions of the exhilaration—manifestations whence comes aptly the old name *laughing gas*, applied to a mixture of nitrogen monoxide and air. When inhaled pure, in entire substitution for atmospheric air, there is, first, a very transient exhilaration, and then rapidly follow the same phenomena as when pure nitrogen is respired, namely, such as result from the respiration of an atmosphere devoid of available oxygen. The blood returning from the lungs ceases to acquire the arterial hue, its free oxygen rapidly diminishes in quantity, the animal speedily loses consciousness, and, if the inhalation be continued, dies by asphyxia, in the same time that it dies in an atmosphere of plain nitrogen, and with a similar reduction of the percentage of free oxygen contained in the blood. These various facts sufficiently prove that at the temperature of the animal body nitrogen monoxide resists decomposition, so that the oxygen of its molecule is unavailable for the purposes to which ordinarily respired oxygen is put.

Nitrogen monoxide inhaled pure is, then, practically an agent that will, without other derangement, produce the unconsciousness of coma from asphyxia, while not interfering with the free play of the lungs in the respiratory act. The clinical phenomena of the inhalation are, *subjectively*, a beginning feeling of the peculiar tingling and sense of exhilaration noted above, which, however, is soon overwhelmed in swift-rushing unconsciousness. According to the fulness of the respirations the unconsciousness may supervene in from a few seconds to two or three minutes. In a carefully observed experiment the writer of this, practising the fullest possible forced inspiration and expiration, and beginning the inhaling after a forced expiration, was noted to have passed into complete unconsciousness in the middle of the third inspiration. During the continuance of the unconsciousness anæsthesia is absolute; and upon withdrawal of the gas and substitution of atmospheric air the senses are regained as rapidly as they were lost, and in two or three minutes the experimenter is in perfectly normal physiological status again. *Objectively* the phenomena are a swiftly developed lividity of the skin and mucous membranes, staring, and sometimes convulsively rolling eyeballs, a convulsive twitching of the hands, and, when unconsciousness has supervened, a slow, snoring respiration. The pulse is little affected. During the unconsciousness the muscles, with the exceptions noted above, are quite thoroughly relaxed.

Nitrogen monoxide is used as a medicine proper and as an "anæsthetic." Taken in small quantities, so as not to interfere with normal absorption of oxygen, the substance often seems to abate symptoms of nervous debility or exhaustion, and hence to be of value in the treatment of many so-called functional nervous diseases. For such purposes the gas may be given by inhalation, a few whiffs being drawn from a bag through the usual mouthpiece, while at the same time atmospheric air is breathed through the nostrils, purposely left unclosed. Another method of administration is to give an aqueous solution of the gas by swallowing. A patented solution of such character, made under a pressure of five atmospheres, has been used under the title of *oxygenous aerated water*. Nitrous oxide water has but little odor, and is slightly sweetish to the taste. But by far the commonest use of nitrogen monoxide is the administration of the pure gas by inhalation, in order to produce the anæsthesia of unconsciousness. For this administration a bag of a capacity of from four to thirty-two litres (one to eight gallons), according to the proposed duration of the inhalation, is charged with a pure article of the gas, undiluted. From

Digitized by Microsoft®

the bag the gas is drawn through a connecting tube out of a mouthpiece so constructed that by an arrangement of valves the products of expiration pass into the air and not back into the bag, and also that the operator may, by the turn of a switch, admit air and cut off gas at pleasure. The patient's clothing being so adjusted as to offer no impediment to respiration, the mouthpiece is put in place, the nostrils are gently compressed by the fingers of the administrator, the stopcock that controls the delivery of the gas from the bag is turned, and the patient is enjoined to breathe as fully as possible. As soon as full lividity of the face and stertorous breathing proclaim the development of unconsciousness, the patient is ready for operation, and if such operation be one of brief duration, like the opening of an abscess or the drawing of a tooth, the administrator at once removes the mouthpiece as soon as unconsciousness is attained, anæsthesia persisting for a number of seconds after withdrawal of the gas. If the operation be a prolonged one, then, as soon as coma is complete, the administrator, by turning the switch in the mouthpiece, gives a little air, and then again, by a reverse turn, a little gas, and so, guided by the color of the blood as seen through the skin, by the snore of the respiration, and by the presence or absence of voluntary muscular movements, he skilfully gives, alternately, air to keep his patient alive and gas to keep him in practically continuous unconsciousness. In this way a practised administrator can maintain prolonged anæsthesia with nitrogen monoxide; but by the very necessities of the case the patient is always just on the verge of awakening to consciousness of pain on the one hand, and to the undesirable sudden movement of a limb on the other. Obviously, therefore, despite its advantages of swiftness and pleasantness of action, nitrogen monoxide is more appropriate, given in the above manner, as an anæsthetic for momentary than for prolonged operations. In order to secure an easy continuance of anæsthesia, Dr. Paul Bert, of Paris, has proposed the method of administering a mixture of nitrogen monoxide and oxygen under increased atmospheric pressure. Under such circumstances the oxygen of the mixture prevents asphyxia, yet the characteristic anæsthetic unconsciousness of nitrogen monoxide supervenes with the usual quickness and kindliness, and can be maintained continually without dangerous or even disagreeable effect. Bert mixes the gases in the proportion of 85 parts of nitrogen monoxide to 15 parts of oxygen, and conducts the administration in a special chamber of compressed air representing a total atmospheric pressure of 93 cm. of mercury. Anæsthesia has thus been maintained safely and pleasantly without break for over an hour, but the large volumes of gas required for such prolonged application and the trouble of providing the compressed-air chamber will probably always interfere seriously with the extension of the method into practice. Many surgeons use nitrogen monoxide as a preliminary to ether, in the administration of the latter as an anæsthetic.

Nitrogen monoxide is obtained from the salt *ammonium nitrate* by heating the same in a retort. At an elevated temperature the salt decomposes, and from its constituents water and nitrogen monoxide form ($NH_4NO_3 = 2H_2O + N_2O$). The gas is supplied by manufacturers, condensed to a liquid in strong iron cylinders—a convenient method of storage, since in this way a large volume of gas occupies but a small space. From these cylinders the administration bag is filled as occasion demands. It is not wise to attempt to make the gas, unless provided with apparatus constructed for the purpose, since, unless the distillation be done in a certain precise manner, the resulting gas may contain dangerous impurities. A pure article of fused ammonium nitrate is to be used; the heat is to be gradually applied and never allowed to exceed 400° F. and the gas, after passing through a series of wash-bottles, one of which contains a solution of potassa, is to be collected in a gasometer, over warm water, or over an aqueous solution of common salt.

Edward Curtis.

NITROGLYCERIN.—Nitroglycerin, called also *glonoin*, is, chemically, a trinitrate of the radical glyceryl, represented by the formula, $C_3H_5(NO_3)_3$, equivalent to the replacing of the three hydrogen atoms of the hydroxyl groups in the molecule of glycerin by the nitro-group NO_2. Nitroglycerin is made by the action of nitric acid upon glycerin, and is a transparent, colorless, dense oily fluid, of about the specific gravity 1.6; slightly soluble in water, but freely soluble in ether or alcohol. It is slightly volatile, inodorous, and of a sweet, pungent, aromatic taste. Upon concussion, as is well known, it explodes with extreme violence. Nitroglycerin itself is not official as a medicine, but the United States Pharmacopœia recognizes a one-per-cent. alcoholic solution of the substance under the title *Spiritus Glonoini*, Spirit of Glonoin. This spirit presents only the physical characteristics of alcohol, in appearance, taste, and smell, and is entirely non-explosive. But if some of it be spilled, so that the alcohol has a chance to evaporate, the nitroglycerin will become concentrated, and a dangerous explosion becomes possible. The spirit should, therefore, be handled with great care. It should be kept in tin cans instead of in glass bottles, and these should be well stoppered and stored in a safe and cool place, away from exposure to light or fire.

The effects of a one-per-cent. solution of nitroglycerin upon the animal system are, in kind, exactly those of the nitrites (see *Nitrites*), with the additional symptom of a severe and obstinate headache. In rapidity of action, nitroglycerin occupies a position between amyl nitrite on the one hand, and the nitrites of the alkali metals on the other. The agent is powerful; a single drop of the one-per-cent. solution taken upon the tongue produces within three or four minutes a transient feeling of cerebral fulness and frontal pain, and a dose of four or five drops quickly determines a full nitrite derangement—flushed face, throbbing arteries, violent and disorderly heart action, hurried respiration, and splitting headache. Over-dosage is extremely dangerous, as shown by a reported case in which, after a dose of two and a half drops of a *five*-per-cent. solution, the typical nitrite effects were quickly succeeded by sickness, faintness, and coma with stertorous breathing. The heart's action became alarmingly weak, but the patient finally recovered.

Nitroglycerin produces thus exactly the effects of a nitrite, and accordingly the inference is that in the career of the compound in the animal economy it suffers change into a nitrite, and as such nitrite exerts its activity. This subject of a possible chemical conversion of nitroglycerin within the system was studied by Matthew Hay (*Practitioner*, June, 1883), who found that nitroglycerin is decomposed by alkalies and alkaline carbonates, with the conversion of two-thirds of its nitric acid into nitrous, which nitrous acid then combines with the alkali to form a nitrite of the same. This reaction, furthermore, Hay was able to produce by treating a one-tenth-per-cent. solution of nitroglycerin in water with freshly drawn defibrinated blood, and digesting the mixture for forty minutes in an oven at a temperature ranging between 104° and 113° F. Such mixture assumed the peculiar chocolate color of nitrite-poisoned blood, and by analysis, after an hour's digestion, nearly the whole of the nitroglycerin present was found to have undergone decomposition.

Nitroglycerin thus seems to be, for the pharmacologist and physician, but a nitrite-furnishing compound, whose distinguishing feature is solely the extraordinary intensity of its action, a feature which Hay accounts for by the fact that nitroglycerin is, by the peculiarity of its composition, exempt from the decomposition by the acid of the gastric juice to which nitrites are liable—a decomposition which always renders inert a certain proportion of each dose of a nitrite swallowed as such.

The therapeutic applications of nitroglycerin are those of the nitrites. The remedy has been used with benefit in angina pectoris, asthma, and epilepsy, especially in *petit mal*, and also in the anæmic form of migraine (Hammond), and in nephritis attended with a hard, corded

Digitized by Microsoft®

pulse (Robson). The dose, in an untried subject, should be at first but a single drop of the customary one-per-cent. alcoholic solution, to be repeated every fifteen minutes until four or five drops shall have been taken or relief experienced. In habitual use, as for epileptics, the dose will very [illegible] increase. At the rate of an additional drop per dose each month so large a dosage as twelve drops three times a day of the one-per-cent. solution has been taken without the production of undue derangement. *Edward Curtis.*

NITROHYDROCHLORIC ACID. — (Aqua Regia.) Under the title *Acidum Nitrohydrochloricum*, Nitrohydrochloric Acid, the United States Pharmacopœia recognizes the product of mixing together 180 measures of nitric acid and 820 of hydrochloric. On making such mixture effervescence occurs and a golden-yellow, fuming fluid results, strongly acid and intensely corrosive—more so than the original acids of its composition—and also possessed of the peculiar properties of smelling of chlorine and of dissolving readily gold-leaf. This fluid is wholly volatilizable by heat. As its smell suggests, nitrohydrochloric acid contains free chlorine, and the fresher the sample of the acid the higher the percentage of chlorine, since by keeping, especially if exposed to light, the chlorine constantly tends to undergo conversion into hydrochloric acid, deriving hydrogen by the decomposition of water. Nitrohydrochloric acid should therefore be made and kept only in small quantities, and these, after all effervescence has subsided, should be put up in glass-stoppered bottles, half filled only, and stored in a cool place, protected from the light. The reaction whereby free chlorine is evolved in a mixture of nitric and hydrochloric acids is now commonly regarded by chemists as the following:

$$HNO_3 + 3HCl = 2H_2O + NOCl + Cl_2.$$

As already said, nitrohydrochloric acid is intensely corrosive to animal tissues. The acid is possible, therefore, as a surgical caustic, but the more manageable nitric acid is commonly and properly preferred. The special medicinal value of nitrohydrochloric acid lies in the influence of the preparation over the functions of the liver, and also over certain obscure derangements of metabolic processes, notably over that leading to considerable appearance of calcium oxalate in the urine—the condition, in short, clinically dubbed *oxaluria*. As regards influence over the liver, nitrohydrochloric acid has long enjoyed the reputation of tending to abate congestions of the organ, to oppose the march of cirrhosis, and even to favor the limitation of abscess, and, in so called functional disorders of the liver, to cause recedence of the symptoms. Experimentally, also, Rutherford has shown that the acid possesses considerable cholagogue power. Nitrohydrochloric acid is therefore a standard remedy for the treatment of oxaluria and the various above-named diseases of the liver. The medicine can be introduced into the system either by baths or by swallowing. For a bath the acid should be diluted in the proportion of 8 gm. of the acid to a litre of water (one fluidounce to the gallon), and the bath taken in a *wooden* tub. Such baths should be about blood-warm, and should be administered daily, or twice a week, according to indications. The duration of the bath will range from ten to thirty minutes, or until a tingling or pricking sensation is experienced. After removal from the bath the skin of the bather should be wiped very dry. Instead of a general bath, a foot bath or a sponging with a dilution of the acid of the strength already given may be substituted. These external applications are undoubtedly efficient, and an occasionally developed salivation proves beyond question the absorption of the acid when administered in this way. For internal giving the dose is a very few drops—from three to five—diluted, at the time of taking only, with a wineglassful or so of water, and the draught sucked through a glass tube, with subsequent thorough rinsing of the mouth. For prescription internally there is also in the United States Pharmacopœia an official preparation entitled *Acidum Nitrohydrochloricum Dilutum*, Diluted Nitrohydrochloric Acid, consisting of freshly made nitrohydrochloric acid diluted, after making, with nearly four times its measure of distilled water. The preparation is a colorless or faintly yellow liquid, odorless, or having a slight odor of chlorine, and a very acid taste and reaction. By heat it is wholly volatilized. This dilute acid is, medicinally, objectionable, because the mere fact of dilution tends to favor the conversion of the free chlorine of nitrohydrochloric acid into hydrochloric acid. As actually dispensed and used, this preparation is, therefore, much more likely to be a mere mixture of nitric and hydrochloric acids than the specific chlorine-containing compound represented by a freshly made sample of the strong acid. The dose of the dilute acid may range as high as twenty drops, to be taken in the same manner as a dose of the strong acid. *Edward Curtis.*

NOBSCOT MOUNTAIN SPRING.—Middlesex County, Massachusetts.

POST-OFFICE.—Framingham.

ACCESS viâ Northern Division of Old Colony Railroad or Southern Division of Boston and Maine Railroad to station, one and one-half miles distant from the spring.

The spring is located five miles from Framingham, at the base of Nobscot Mountain, the highest point in Middlesex County, and comes through crevices in what appears otherwise to be a solid ledge of rock. The water has a uniform temperature of 41° F., and an average flow, summer and winter, of fourteen thousand gallons per day. The surrounding watershed is a heavily wooded glacial moraine, free from human habitations of any description. Several sanitary analyses have shown the water to be thoroughly pure and wholesome. The following mineral analysis was made in 1891 by Davenport and Williams, of Boston:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Organic and volatile matter	0.64
Silica	.53
Iron oxide and alumina	.02
Lime carbonate	.75
Magnesium carbonate	.23
Sodium chloride	.36
Sodium carbonate	.38
Potassium sulphate	.30
Total	3.21

There is no hotel on the spring property. The water is shipped in glass packages and supplied to the markets of numerous New England towns and cities. The sales in 1896 amounted to slightly more than six hundred thousand gallons. *James K. Crook.*

NODOSITAS CRINIUM. See *Atrophia Pilorum Propria.*

NODOSITIES, NON-ERYTHEMATOUS, OF ARTHRITIC PATIENTS.—Though known for a long time without any particular attention being paid them, these curious formations have been more specially observed since Barlow and Warner made a careful study of them a few years back. They were followed by several French observers, more particularly Brocq of Paris, who elaborated them into two varieties—a merely clinical distinction, both forms being made up of round and spindle-shaped cells. They are more common in children than in adults. They may be considered as affording positive evidence of rheumatism, though they do not necessarily appear during the fever but may develop on its decline, or even altogether independently of any acute attack. (Osler.) Often their appearance is coincident with the development of symptoms of pericarditis, sometimes of pleurisy, but especially of severe chronic rheumatic endocarditis.

The first variety, which Brocq calls *ephemeral cutaneous nodosities*, is confined entirely to the forehead, occurring there as ill-defined prominences in and movable with the skin, although they are sometimes adherent to the peri-

Digitized by Microsoft®

osteum. They are entirely painless always, and there is no change of color in the overlying integument. They are never very numerous, rarely more than two or three, sometimes only one, being discovered. They vary in size from a small shot to a pea, and their ephemeral nature constitutes their chief characteristic. Appearing toward the end of the day or during the night (Féréol) without any subjective symptoms whatever, they last but a day at most, and disappear, leaving no traces, to spring forth again, without known cause, in a new place on the forehead.

www.libtool.com.cn

The second variety (*rheumatic subcutaneous nodules*), by far the more common and better known, differs from the first form in that the tumors are subcutaneous and are more stationary. The overlying integument, unchanged in color, moves freely over them and they strongly resemble syphilitic exostoses or gummata. To the touch they are firm and elastic, freely movable upon the underlying structures. At times, however, this fact may be demonstrable only with attention, when, for instance, the tumors occur over bone, as in the scalp, where they give the impression at first of being exostoses. They are sometimes tender on pressure, seldom spontaneously painful. In size they vary from a pea to a filbert and are sharply defined. Coming in successive crops without premonition they increase slowly, sometimes quite rapidly, in volume to their maximum, remain stationary for a variable length of time—amounting frequently to weeks or months,—then disappear, leaving no trace of their existence. Their favorite locations are the periarticular regions—elbows, knees, wrists, and joints of the fingers. They occur also superficially along the long bones, over the spines of the vertebræ and scapulæ, over the iliac crests, and frequently over the frontal and occipital bones, these last two being particularly favorite sites. The nodules, which as a rule are separate and distinct from one another, although in rare cases they may be confluent, occur at times in large numbers; more particularly in adults.

They are to be distinguished from the swellings of erythema nodosum by the absence of color and from other cutaneous and subcutaneous tumors by their own peculiar evolution.

Treatment should be directed toward the underlying rheumatic diathesis. *Charles Townshend Dade.*

NOMA. See *Mouth, Diseases of*, in The Appendix.

NORTH HAVEN POOL.—New Haven County, Connecticut. The waters of this pool have had a local reputation for more than one hundred years, and it is said that Dr. Trumbull, the historian of Connecticut, was in the habit of accommodating boarders who came to avail themselves of their medicinal effects. According to an analysis by Prof. S. W. Johnson, the following ingredients are found:

Sodium sulphate.	Ferrous carbonate.
Sodium chloride.	Silicic oxide
Potassium sulphate.	Alumina } Traces.
Calcium sulphate.	Ammonia } Traces.
Calcium carbonate.	Phosphoric acid } Traces.
Magnesium carbonate.	

The iron is present in sufficient quantities to give the waters useful tonic properties. They are said to be of decided value in chronic skin affections. The waters are bottled and sold in one-, two-, and four-gallon jugs.

James K. Crook.

NOSE, INJURIES OF THE.—Injuries of the nose may be caused by firearms or by sharp or blunt instruments. Falls upon the nose and blows with the fist are by far the commonest causes of traumatism. The various lesions which may be produced are: damage to the soft parts, ecchymosis, hemorrhage, emphysema, obstruction to the tear duct, dislocation and fracture, and a variety of deformities resulting therefrom.

The soft parts of the nose, like those of the rest of the face, are abundantly supplied with blood-vessels, and therefore heal readily; hence ragged wounds should be carefully sutured and no tissue cut away even though it is badly lacerated, since its vitality will usually be preserved. Swelling may be limited, if the patient is seen early, by very hot or very cold applications. Later, mild antiseptic lotions, such as a solution of boracic acid, if applied upon a thin layer of gauze so as to facilitate rapid evaporation, will be found most grateful to the patient. At a later stage the wounds may be covered with a dry dressing, such as one of cotton and collodion. Suppuration, on account of the free blood supply, is usually superficial and easily controlled. The skin of the nose is, however, a favorite starting-point for facial erysipelas, for the treatment of which see article on *Erysipelas*. Deeper suppuration should be promptly treated by free incision and drainage on account of the risk of its extending to the cranial cavity.

If the tip of the nose is lost, or the damage to some other portion of it is so great that disfigurement results, a plastic operation will have to be undertaken at a later date to repair the deformity. (See article on *Reparative Surgery*.)

Injuries to the nose, like those to the eye, often give rise to an ecchymosis which is very annoying to the patient. Hot applications and a firm bandage, if applied sufficiently early, may prevent the spread of blood subcutaneously. Later, the discolored skin can be painted so as to be less noticeable. The ecchymosis will begin to fade out in the course of five days or a week.

Hemorrhage from the external parts of the nose is easily controlled. That from the anterior or posterior nares, either with or without accompanying fracture, may be more alarming. It is sometimes kept up by the position of the patient, who, for the sake of convenience, may lean forward over a wash bowl so as to permit the blood to flow out through the anterior nares. Such a position, by producing congestion of the face, tends to keep up the flow of blood. Ice applied to the nose or placed on the back of the neck is sometimes of service in stopping hemorrhage. If the flow of blood is really serious one should not trust to such means, but should attempt to check the blood by pressure directly upon the wounded vessel, or by styptics. Hemorrhage, both that which occurs spontaneously and which has received the name of epistaxis, and that which follows an injury to the nose, usually comes from the septum. If, therefore, the anterior nares be examined by reflected light the bleeding point will usually be discovered. It may be touched with the point of the galvanocautery or with some caustic or astringent preparation, by far the best one being a dilute solution of suprarenal extract which may be applied, after the nostril has been cleansed, either upon a swab of cotton or in the form of a nasal douche or a nasal spray. This remedy is so efficacious that it will rarely be necessary to plug the nostrils with gauze for the purpose of stopping the hemorrhage. When gauze is used, it should be inserted in narrow strips under the guidance of the eye until sufficient pressure is obtained. At the end of from twenty-four to forty-eight hours it should be removed, after thorough moistening, in order to detach it, and the nares should be cleansed by antiseptic irrigation. The old habit of stuffing the nostrils full of sponges or cotton and leaving them undisturbed for several days is absolutely indefensible in view of the modern methods of controlling hemorrhage. (See also article on *Hemorrhage*.)

Emphysema is a complication due to the patient's attempt to cleanse his nostrils by violent blowing. Air is forced through the ruptured mucous membrane and fractured bony framework into the subcutaneous tissue. This complication distorts the visage, but is in no wise a serious one, and the emphysema will speedily disappear of itself as soon as the cause ceases to act. The patient whose nose has been broken should be cautioned against blowing his nose, an act which may also set up hemorrhage and spread infection, as well as cause emphysema.

Obstruction to the tear duct may follow nasal injuries, being usually the result of swelling. It requires no

Digitized by Microsoft®

treatment and will disappear of itself when the swelling subsides.

Fracture and Dislocation.—The solid framework of the nose may be broken or dislocated. It is made up of the vomer and the perpendicular plate of the ethmoid, to which are attached the nasal bones and the quadrilateral cartilage. These structures may be broken in a variety of ways which it is unnecessary to specify, since there are general principles of treatment which should be followed in the case of every fracture or dislocation associated with deformity. Many fractures are compound internally; hence the necessity for perfect cleanliness, to be secured by antiseptic irrigation. Gentle external manipulation will often elicit crepitus and abnormal motion, while examination of the anterior nares will reveal the presence of existing deformity. Such examination is very important, for the future well-being of the patient depends far more upon a free nasal passage than it does upon the correction of external deformity. Internal deformity usually consists of a deviation of the septum so decided as partially to obstruct one or both nostrils. The quadrilateral cartilage may be loosened and rotated upon its articulation with the vomer. A moderate twist of this sort will greatly obstruct both nasal passages. Whatever the deformity, it should be forthwith overcome and the bones kept in a correct position for a few days until they have begun to unite. Instruments for this purpose should be smooth, strong, and not too large. A small periosteal elevator is a suitable instrument with which to raise the depressed bridge of the nose. The septum may be straightened by sequestrum forceps whose blades are protected by short sections of rubber tubing. There are, of course, special instruments for these purposes. It is necessary that the displaced fragments be thoroughly reduced; indeed, over-reduction is generally desirable. When this is accomplished, there is little tendency for a reproduction of the deformity, so that a retaining apparatus is not usually needed. A number of internal and external splints have been devised. Gauze packing carefully applied answers satisfactorily if only one nostril needs to be filled; if the deformity is such that pressure is required in both nostrils, rubber tubes moulded to fit the nostrils are far more comfortable. Various splints have been devised to keep up external pressure upon the nose. The most successful consists of a firm band or plate strapped across the forehead from which by means of a second band or rod pressure can be exerted upon the nose. The direction of the pressure can be regulated by screws or by bending a stiff wire. In some fractures a pin thrust through the nose from side to side will keep the bones in position better than any splints. Such a pin may be withdrawn at the end of four or five days.

Deviation of the septum may also be overcome by two pins passed in the sagittal plane of the body and crossing one another. This is a method of treatment more often used to correct old deformities than fresh ones. (Fig. 3591.)

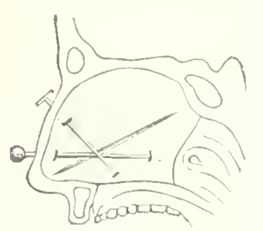

FIG. 3591.—Method of Pinning the Nasal Septum. (Roberts.)

Fracture of the nose is not of itself a serious injury. When the broken bones are replaced they will unite with great rapidity, so that the cure will be complete in from two to four weeks. If the fracture extends upward so as to involve the cribriform plate the patient is exposed to the risk of septic meningitis. Such an injury is really a fracture of the base of the skull, and should be treated as such from the first if the diagnosis can be made. (See article on *Head, Wounds of.*)

Deformity following Injury.—If a fracture or dislocation of the nose is left untreated, or if the surgeon merely pays attention to external appearances and does not correct deviations of the septum, partial obstruction of one or both nares may result. In many cases it is possible to correct such a deformity under a general anæsthetic by forcibly loosening or refracturing the deformed bones with a strong pair of forceps and moulding the nose into the proper shape. Deviations of the septum may require incision or a punching out of certain portions to facilitate complete reduction. (Consult also the article on "*Nasal Cavities, Diseases of: Congenital and Acquired Deformities.*") If the bridge of the nose cannot be lifted, a platinum, or, better, a celluloid support may be inserted underneath the skin and allowed to cicatrize there, thus forming an artificial nasal bridge; which, if it is properly shaped, is not to be told from a natural one. The details of these operations are given in the article on *Reparative Surgery.* *Edward Milton Foote.*

NOSOPHEN — tetra-iodo-phenolphthalein $(C_6H_2I_2OH)_2CO\cdot C_6H_4CO$—is obtained by the action of iodine on phenolphthalein, and is a fine yellowish, odorless, and tasteless powder, insoluble in water and acids, and soluble with difficulty in alcohol, ether, and chloroform. It contains 61.7 per cent. of iodine and may be heated to 220° C. (428° F.) without decomposition. It forms soluble salts with alkalies and insoluble salts with the heavy metals.

Antinosin, the sodium salt of nosophen, is a dark blue amorphous powder, which is freely soluble in water and alcohol.

Eudoxin, the bismuth salt of nosophen, contains 52.9 per cent. of iodine and 14.5 per cent. of bismuth, and is used internally as a gastric and intestinal antiseptic. Dose, 0.2–0.5 gm. (gr. iij.–viij.), or for an infant 0.06 gm. (gr. i.) or less.

Nosophen is a non-irritant iodoform substitute which does not liberate iodine. It is an impalpable powder, of use not only as an antiseptic but also for drying up wound secretions. It forms crusts, however, which must be lifted to allow the escape of the underlying secretions.

Caldwell treats ulcers with nosophen in powder or ten-per-cent. ointment, or with a fifty-per-cent. solution of antinosin. Steele uses three-per-cent. nosophen gauze for the treatment of wounds, abscesses, ulcers, etc., and as intra-uterine packing after curetting. Owing to its freedom from odor, it meets with much favor in nasal cases. E. Klebs uses 0.1-per-cent. solutions of antinosin for mouth and nares, and administers the same solution internally as an antiseptic in dose of 12–24 c.c. (ʒ iij.–vi.). Nosophen has been used in capsule as an intestinal antiseptic, and Millener employed it with success in combination with antinosin in thirty-six cases of chronic suppurative otitis media. The antinosin was instilled into the ear in two- or three-per-cent. solution, and the nosophen dusted into the canal. Antinosin in two-per-cent. solution is also used for bladder irrigations. *W. A. Bastedo.*

NOTIFICATION OF INFECTIOUS DISEASES.—Among the different measures employed by sanitary authorities for the prevention of the spread of infectious diseases, the notification of the occurrence of such diseases now occupies a prominent place. Municipal authorities especially should have the requisite power everywhere to require immediate notice to be given them of every fresh outbreak of diseases dangerous to the public health in order that such authority may take proper measures for the protection of the community.

The chief advantages of a system of notification lie in the possibility which is thus given to a local board of health to determine the extent of prevalence of an epidemic or a localized outbreak, and to inquire into the local causes which have operated to produce it. The board can then act intelligently in applying the proper remedies for preventing its further spread.

Laws enacted with this object in view have been in force in the older States for many years, but not until within the past ten or twenty years have pains been taken to execute such statutes with such degree of efficiency as to make them really protective. The law requiring the householder to report each case of dangerous

Digitized by Microsoft®

disease to the local authority was enacted in Massachusetts in 1792, and that which requires the same duty on the part of the attending physician was enacted in 1827. Little attention, however, had been paid to the enforcement of these laws until toward the end of the 19th century.

www.libtool.com.cn

Various attempts have been made in England to enact a similar statute, but these efforts were unsuccessful until 1889. By the terms of the law then enacted the notification of infectious diseases to the sanitary authority was made compulsory throughout London, while the principle of local option was applied to all other districts.

During the year in which this bill was under consideration by Parliament, intense opposition had been manifested by many of the members of the medical profession throughout England. Objections were offered not only by the people but also by the medical profession, but the bill passed and finally became a law.

The fallacy of the objections has been abundantly proven by the experience of the towns of England where the Notification Act has been adopted. The notification of each case is made by a certificate furnished by the attending physician, for which a fee of two shillings and sixpence is paid, except in a case in which the person giving the certificate is the medical officer of a public institution, when the fee is one shilling.

The diseases to which this act applies are smallpox, cholera, diphtheria, membranous croup, erysipelas, scarlet fever, typhus, typhoid, and puerperal fever, and any other infectious disease which may be added to this list by the sanitary authority of a district.

In 1899 the provisions of the act had been adopted in cities and towns containing more than twenty-eight millions of inhabitants out of a total of about thirty millions, and in that year, by the enactment of a new statute (62 and 63 Victoria, chap. viii.) the law became compulsory throughout the whole kingdom.

There can be no doubt that the law relative to notification has been productive of excellent results in the prevention of disease, especially in the cities and large towns. It has furnished local boards of health with the necessary information relative to the origin of outbreaks of infectious disease, and in many instances has enabled them to take timely steps for preventing its further spread.

In compiling certain data for the Paris Exposition of 1900 the writer collected the statistics of six registration States and nineteen cities outside of those States, including the ten largest cities of the Union, with the following result. The figures are mainly for the years 1891-98:

Diseases.	Reported cases.	Registered deaths.	Fatality, per cent.
Smallpox	9,222	2,385	25.8
Typhoid fever	69,758	13,284	19.0
Diphtheria and croup	195,783	44,411	22.7
Scarlet fever	127,847	9,211	7.2
Measles	217,755	6,424	2.8
Total	619,765	75,715	....

These results agree fairly well with those of the English local government board for the eight years 1890-97, which showed a fatality for typhoid fever of 18.05 per cent., for diphtheria of 23 per cent., and for scarlet fever of 4.9 per cent.

Another advantage of the practice of notification in recent years consists in the exact data which it furnishes relating to improved methods of treating disease, and the consequent saving of human life. In the thirty-third annual report of the State Board of Health of Massachusetts for 1901 it appears that the notified cases of diphtheria in the pre-antitoxin period, 1891-94, in reporting cities and towns were 13,332, and the deaths in the same places and time were 3,768, making a fatality of 28.3 per cent., while in the following seven years, 1895-1901, after the introduction of antitoxin the cases were 56,459 and the deaths 7,416, a fatality of only 13.1 per cent. The fatality of diphtheria in 1901 was only 10.5 per cent. (see also *Disease, Fatality of*). *Samuel W. Abbott.*

NOTOCHORD.—The notochord (*chorda dorsalis, Wirbelsaite*) is a rod of peculiar tissue, constituting the primitive axial skeleton of vertebrates. It begins immediately behind the pituitary body (hypophysis) and extends to

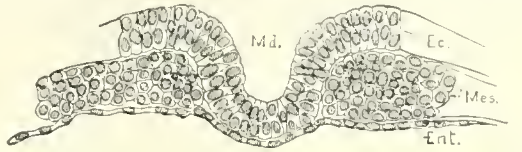

FIG. 3592.—Transverse Section of a Young Mole's Embryo. (After Heape.) *Ec.*, Ectoderm; *Md.*, medullary groove; *Mes.*, mesoderm; *Ent.*, entoderm. Site of the notochord is the central line of the entoderm.

the caudal extremity. It occurs as a permanent structure in the lower types, and as a temporary one in the embryos of amphibia and amniota, including man. Comparative embryology has shown that it is a greatly modified epithelial tube, which arises as a furrow in the median dorsal line of the entoderm, being, in position and mode of development, analogous to the ectodermal medullary canal or primitive tubular nervous system.[5]

DEVELOPMENT IN MAMMALS.—The notochord appears very early in the course of development; its differentiation from the entoderm begins at the time when the medullary groove is not fully marked out posteriorly, and is nowhere closed. The notochordal *Anlage* can be first detected in the entoderm just at the front of the primitive streak, as an axial band of cells, which at first in mammals is not well marked off from the mesoderm; as the medullary groove deepens it pushes down toward the midgut until it comes into actual contact with the notochordal epithelial band (see Fig. 3592), thus dividing the mesoderm into two lateral masses; this also leads to the temporary transverse stretching of the notochordal band, which thereby loses for a while its sharp demarcation. It soon re-acquires it, and becomes considerably thicker (Fig. 3593, *nch*) than the adjoining entoderm, and forms a distinct though shallow groove. Subsequently the band separates off, and the entoderm proper closes across under it so that the notochordal band lies between the entoderm and the floor of the medullary groove (or later canal), as shown in Figs. 3598 and 3604, *nch.* This separation does not take place at the anterior extremity of the chorda until somewhat later, so that for a considerable period its front end remains fused with the walls of the midgut (Fig. 3598). The separation from the entoderm is effected, at least in mammals, by the entoderm proper, showing itself under the notochord toward the

median line, and when the cells from one side meet those of the other, they unite with them and form a continuous sheet of entoderm below the notochordal cells.

The chorda is now a narrow band of cells, starting anteriorly from the wall of the alimentary tract and run-

ning backward to the blastoporic canal or its equivalent, the primitive streak; but, at the period when the canal is open, the chorda terminates in the entodermic epithelium lining the canal (Heape,[9] Pl. xxi., Fig. 50; compare

www.libtool.com.cn

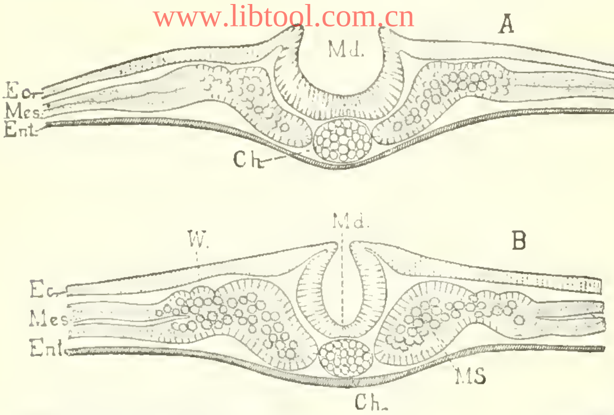

FIG. 3594.—Transverse Sections of an Embryo Chick, with Eleven Pairs of Myotomes. also Vol. II., Fig. 505, *C*). The canal remains open for a time, and is called by some writers on mammalian embryology the chorda canal (*cf. infra*). For a certain period the chorda continues growing tailward by accretions of cells from the walls of the blastoporic passage,

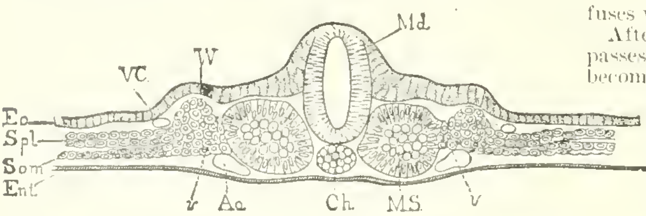

FIG. 3595.—Transverse Section of a Chick Embryo of the Second Day. (After Waldeyer.) *Som.*, The somatic mesoderm, and *Spl.*, the splanchnic mesoderm; *Ec.*, ectoderm; *Ent.*, entoderm; *V.C.*, vein; *W.*, Wolffian duct; *Md.*, medullary canal; *Ao.*, aorta; *Ch.*, notochord; *MS.*, myotome.

and after the canal is permanently obliterated the chorda may still continue its lengthening by acquisitions, at its caudal end, of additional cells from the primitive streak; such cells may, however, properly be regarded as coming from the entodermic lining of the blastopore. We can, then, distinguish three portions of the notochord: the first arising from the entoderm of the midgut; the second from the entoderm of the blastoporic canal; the third presumably from the entoderm of the obliterated blastopore in the primitive streak. Braun and others have sought to attribute essential importance to these differences, but, it seems to me, improperly. It is more reasonable to say that the chorda arises in the amniota, as in the lower forms, directly from the entoderm, but presents certain secondary modifications in its development.

Lieberkühn has directed attention to a special peculiarity in the early development of the notochord in mammals. There appears at first a passage—half canal, half furrow—which extends nearly the whole length of the primitive streak; it may be described as a tube running along the median line, and having an irregular series of openings into the entodermic cavity. The canal is lined by epithelium, which is thickened on the dorsal side to form the *Anlage* of the notochord. In transverse section the chorda appears according to the level of the section to constitute part of a furrow or a canal (compare also Heape,[9] *loc. cit.*, p. 441, Figs. 40 and 41). Lieberkühn calls this canal mesoblastic, and Kölliker follows him; but this opinion seems to me based upon misconceptions. It is more reasonable to suppose that the canal is really the blastoporic canal, which is preserved for an unusually long period. We know that the blastopore first appears well forward, and as the primitive streak grows by concrescence of the ectental line the blastopore moves backward, its anterior portion fusing with the general entodermic cavity. There is no difficulty apparent in assuming that such fusion occurs quite late in mammals; this interpretation is confirmed by the fact that the canal becomes later a furrow throughout its entire length in

front of the blastoporic canal proper, so that its cavity fuses with that of the entoderm proper.

After it is once formed as a band of cells the notochord passes through various changes of form, but ultimately becomes a cylindrical rod with tapering extremities. It attains considerable size in the embryos of most vertebrates, but in those of placental mammals is always small, particularly so in the mole (Heape[10]). It is probable that in mammals the notochord, when first separated from the entoderm, is a broad, flat band, as if compressed be-

This series of changes begins near the anterior end of the chorda, and progresses both forward and backward.

The mesoderm early grows in between the entoderm and the notochord, which, however, for a considerable time remains close to the medullary tube (Fig. 3600). Later the mesoderm penetrates between the notochord and medulla. The layer of mesodermic cells immediately around the notochord, which are of the well-known anastomosing type (Fig. 3601), forms a special sheath, which at first comprises only a single layer of cells, at least in batrachia (Götte,[6] p. 357, Fig. 187). This is the commencement of the so-called outer chorda sheath; it subsequently becomes much thicker. In the lower types it is an important axial structure (Fig. 3602, *s*); in most cases it is replaced by cartilage, and in all the amniota the cartilage is replaced by the osseous vertebræ, the invertebral ligaments, etc. The formation of the vertebral column involves the disappearance of the notochord as described below.

HISTOGENESIS.—After the notochord has been formed as a rod of cells, its cells undergo a process of histological differentiation unique in vertebrates. The cells at first become greatly compressed in the line of length of the chorda; and hence appear quite thin in longitudinal sections (Fig. 3603, A, *nch.*)—hardly greater in diameter than their own nuclei. Thus, in the chick, by the third day some of the central cells become vacuolated, while the peripheral cells are still normal; at first, as in the frog, there seems to be only one large vacuole in each cell (Fig. 3603, B). Around the vacuole is a peripheral layer of granular protoplasm, in which the nucleus lies embedded, while the vacuoles themselves are filled with a perfectly clear and transparent material, which is supposed to be fluid in its natural condition. During the fourth day (chick) all the cells become vacuolated, with the exception of a single layer of flattened cells at the periphery. In the anura, it is said, there is no distinct peripheral layer of protoplasmic cells. The vacuoles go on enlarging until by the sixth day they have so much increased at the expense of the protoplasm that only a very thin layer of the latter is left at the circumference of the cell; at one part of which, where there is generally more protoplasm than elsewhere, the remains of a nucleus may generally be detected. Thus the notochord becomes transformed into a spongy reticulum, the meshes of which correspond to the vacuoles of the cells and the septa to the remains of their cell walls (Foster and Balfour). As Götte has pointed out, the process is accompanied by an expansion of the cells, which is the main factor in the widening and lengthening of the notochord, which goes on *pari passu* with the growth of the surrounding tissue.

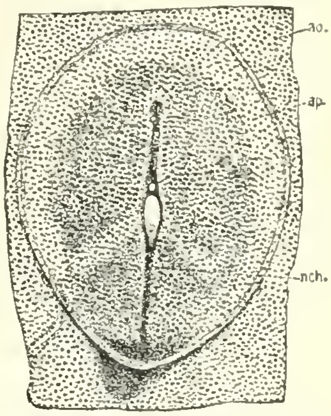

FIG. 3599.—Germinal Area of a Guinea-pig at Thirteen Days and Twenty Hours. (After Lieberkühn.) *ao.*, Area opaca; *ap.*, area pellucida; *nch.*, *Anlage* of the notochord as a canal with several irregular openings on the entodermic side. × 24 diameters.

The histogenetic process is stated to be essentially similar in mammals (W. Müller, 337–338). There is the central layer of vacuolated cells and the peripheral layer of protoplasmic cells. The latter are, however, ultimately converted into vacuolated

www.libtool.com.cn

cells. The cell walls are perforate, having fine pores, that correspond probably to intercellular bridges of protoplasm. The inner chorda sheath appears early and is to be regarded as an anhistic basement membrane secreted by the notochordal cells.

SHAPE AND RELATIONS TO OTHER PARTS.—As soon as the head bend (first cerebral flexure) appears (Fig. 3604) the notochord becomes correspondingly bent, and its anterior extremity lies close to Rathke's pocket (Fig. 3604, *hy.*)—the evagination of the oral epithelium, which is destined to form the pituitary body or *hypophysis cerebri*. The notochord never extends farther forward than this, hence the skull and head may be divided into two parts, the præ-pituitary and the post-pituitary regions. The latter region alone contains the notochord. Romiti finds that in the chick the end of the notochord is united, at the end of the fourth and during the fifth day of incubation, with an irregular solid cord of cells, which grows out from the epithelium of the hypophysis. The cord soon disappears. Its significance is quite unknown. Romiti suggests that it may produce a strain resulting in the pulling out of the hypophyseal evagination. This notion seems to me untenable. The cranial portion of the notochord has not only the bend shown in Fig. 3604, but also follows the other curves of the head; it takes a sinuous course besides within the base of the cranium; finally, in the region corresponding to the middle third of the spheno-occipital cartilage, it makes a great dip ventralward. The sheath of the notochord in the cranial region is converted into the spheno-occipital cartilage; at the dip just mentioned, however, the notochord lies entirely below the cartilage, close against the wall of the pharynx (Froriep, Romiti). Writers before Froriep had represented the chorda as having disappeared at the bottom of the dip.

DISAPPEARANCE.—The disappearance of the notochord in man commences with the second month of fetal life. The first step is an alteration of the characteristic histological structure, accompanied by shrinking of the tissues, so that a clear space appears around it (see Fig. 3605). The inner chorda sheath is lost. The cell walls disappear, the tissue becomes granular, and breaks up into multinucleate, irregularly reticulate masses (Fig. 3606), which are gradually resorbed (Leboucq). In mammals the resorption progresses more rapidly in the cores of the vertebræ than in the intervertebral spaces, and again more rapidly at the ends than in the centre of each vertebra; hence the chorda persists a little longer in the centre of the vertebra, and considerably longer in the intervertebral spaces; in these last the final remnants of the chorda may be detected in man even after birth. The cavity between the vertebral cartilages is a new structure, and is not the space left by the notochord, as has been sometimes asserted. It appears, however, that the resorption of the chorda may leave a small space, which becomes included in the intervertebral cavity. A peculiar feature is the frequent persistence of calcified cartilage immediately around the notochord in ossifying vertebræ.

MORPHOLOGY.—The notochord was for a long time supposed to be exclusively characteristic of vertebrates. It is now known to exist in amphioxus, which is not a true vertebrate, and in the tunicata. Morphologists have long believed that it must have some homologue among the organs of invertebrates. The development of the notochord in the lower vertebrates indicates very plainly what must have been the general character of such an homologous invertebrate organ. In certain fishes and amphibia the notochord has been ascertained to arise as a furrow along the median dorsal line of the entoderm; the furrow deepens and then closes over to form a canal separate from the entodermic canal proper; but the notochordal canal retains for a time its anterior and posterior connections with the entoderm.

Ultimately the lumen is obliterated, the ends become detached, and so arises the solid isolated chorda. In the higher vertebrates the course of development is similar, although several of the primitive features in the formation of the chorda are obscured. Ehlers[3] has pointed out that in various invertebrates there is a similar canal, the "Nebendarm" of German writers, which is derived from the entoderm and connected anteriorly and posteriorly with the entodermal cavity. It is a very plausible suggestion, which homologizes the vertebrate notochord with the invertebrate "Nebendarm." Hubrecht has sought to homologize the notochord with the proboscis of

NOVA SCOTIA.—Nova Scotia is one of the maritime provinces of Canada to the northeast of the State of Maine, lying in latitude 43° to 46° N. and longitude 60° to 66° W. It is a long, rather narrow peninsula, with a great extent of coast line, parallel to the mainland, extending in a direction from northeast to southwest. It is 350 miles in length, including Cape Breton, and varies in breadth from 50 to 100 miles. Its area is 20,550 square miles and it has a population of 450,396. The surface is undulating and is traversed by several ranges of hills. It has a cool, marine climate, and is a favorite summer resort for visitors.

The following table, condensed from the more elaborate ones in the article on Nova Scotia in the previous edition of the HANDBOOK, conveys an idea of the summer and autumn climate of this region, the seasons when one would visit Nova Scotia as a resort. As will be seen, the mean summer temperature is about 61° F., similar to that of the British Isles at this season, the highest temperature being about 80° F. and the lowest between 43° and 46° F.

The relative humidity is high and there is considerable rain. Fogs are also not infrequent. The number of fair days is, moreover, not large for the summer.

Such a climate is manifestly unsuited for an invalid or delicate person, but affords a grateful change to those who have become debilitated by the summer heat of a large city, or for such as need a change of scene and air. One is always sure of finding it cool in Nova Scotia, and it is wise for those intending to visit this region to be provided with warm clothing.

www.libtool.com.cn

"Certain sufferers from hay fever," says Huntington Richards, "enjoy perfect immunity from that disease at Halifax, and probably the same experience may be had at many other points in Nova Scotia." The natural attractions of Nova Scotia are many and varied, and its chief city and port, Halifax, "The Garrison City by the Sea," presents many objects of interest to the American traveller. It possesses a superb harbor in which, in the summer, is the headquarters of the British North Atlantic fleet, and on land a garrison is always quartered here. The public gardens are very attractive, and the drives in Point Pleasant Park afford delightful views of the water. The country round about Halifax offers many attractive excursions; and the roads are fairly good either for driving or for cycling.

In the interior is "Evangeline's Land," a lovely, pastoral region immortalized by Longfellow. The Annapolis basin and valley, the Bay of Fundy, and the numerous shore places likewise offer many attractions, both to the casual traveller and to those interested in the early history of America. Cape Breton, Prince Edward's Island, and Newfoundland are conveniently visited from Halifax.

Good facilities for hunting and fishing are to be had in various portions of this province. One has a choice of various routes to Nova Scotia: by boat from Boston direct to Yarmouth or Halifax; or by boat along the coast to St. John and then across the Bay of Fundy to Digby; by rail to St. John; or all the way by land by the Intercolonial Railway from Montreal or Quebec. The steamers to Yarmouth and Halifax afford excellent accommodations. *Edward O. Otis.*

NUCLEINS are a class of organic bodies of acid reaction, intermediate in composition between proteid and nucleinic acid, and containing from three to ten per cent. of phosphorus. They occur in association with proteids in all animal and vegetable tissues, especially in the nuclei, and in milk. They are separated from the proteids by artificial digestion, the latter being changed to soluble peptones which are removed, while the nucleins undergo little if any alteration (Bunge). The nucleins are then brought into solution by potassium hydroxide. The commercial article is prepared from yeast or yolk of egg, and may be either nuclein or nucleinic acid. According to Chittenden, many of the marketed preparations are worthless.

Nucleins are insoluble in water, alcohol, ether, or dilute mineral acids, but are soluble in alkalies. On boiling with weak acid or alkali, and more slowly with plain water, they yield phosphoric acid in combination with organic bases. Some, at least, of them split in the body into xanthin, hypoxanthin, guanin, and adenin (Piccard). It is not known to what extent nucleins are absorbed, but probably very little is absorbed, as abundant nuclein was found in the fæces of dogs experimented upon (Bókay).

The asserted value of nuclein in medicine depends on its ability to stimulate the antibacterial power of the animal body, and to cause an increase in the number of leucocytes. The solutions have been used in tuberculosis and septicæmia. (Hare.) Vaughan cured guinea-pigs inoculated with tuberculosis, and rendered others quite immune to pneumococcus infection. J. Mount Bleyer used it with good results in diphtheria. Sir R. D. Powell reports recovery in one out of five cases of malignant endocarditis. The dose is 2 to 3 gm. (gr. xxx.–xlv.) daily. (Shoemaker.) *W. A. Bastedo.*

NURSES, TRAINING SCHOOLS FOR.—That "the old order changeth and giveth place to the new" would seem to describe well the condition of nursing affairs during the past decade and to foreshadow the future. It must be confessed that during the first fifteen years of their existence, dating from 1873, training schools for nurses made little if any progress from an educational standpoint; nevertheless, from the very first their influence upon the establishment of hospitals throughout the country has been enormous. Once the value of systematized methods of caring for the sick was realized, hospitals began to multiply rapidly, and in almost every instance a training school for nurses formed part of the organization, until at the present time there are few towns in the United States of any size that cannot boast of one or more hospitals in which the nursing is at least far superior to that of bygone days.

The history of the organization and development of training schools for nurses is of so great interest that I venture to introduce here a part of the excellent sketch which was written in 1889 by Prof. W. Gilman Thompson, of New York, for the first edition of this HANDBOOK.

"Organized nursing schools are of very recent date, and their establishment arose from the experience of army hospitals in European wars, especially the Crimean War. The nurses of religious sisterhoods, midwives, and monthly nurses were originally the women who followed nursing as an occupation. In France the nursing is mainly in the hands of Roman Catholic sisterhoods, and in the hospitals of Paris alone are over six hundred sisters who superintend the hired attendants. In Russia the Sisters of Mercy have done the nursing since the Crimea, and in Italy a similar arrangement obtains. But in January, 1883, the 'St. Paul's Home for Trained English-speaking Nurses' was started in Rome by a few graduates of American and English training schools. This institution has been very successful. Its object is, however, merely to afford a home to nurses who have been trained elsewhere. In Germany, among a great variety of Protestant and Roman Catholic nursing systems, many have become famous. Pastor Theodor Fliedner founded the 'Institute of Deaconesses' at Kaiserswerth in 1836, where, in after years, Miss Nightingale completed the early training which made her such a successful advocate of thorough instruction in nursing. There are upward of three thousand deaconesses at present connected with this institute and with others in Germany modelled after it. There are many Sisters of Charity who serve as nurses, and one of the best secular schools similar to the training schools is at the 'Kaiserin Augusta Hospital' in Berlin.

"The 'International Hospital and Field Service Society of Surgeons and Nurses' became famous on foreign battlefields, and after the experiences of the two last German wars the 'Albert Verein' was organized in Dresden and Leipsic. The nurses of this society are thoroughly trained by practical courses and lectures. Rewards and favors are granted for merit, and, if, after three years of active service, their health should become impaired, they are pensioned. They are sent out from the school to nurse private cases.

"In Vienna the nursing is done by sisters, and also by women who work without special organization. In England female nurses in hospitals are mentioned as early as 1760, and in 1791 they were indorsed by the governors of the London Hospital. In 1801 there were women nurses in the Woolwich Artillery Hospital. For the past thirty years special attention has been directed in England to nursing systems. At Guy's Hospital nurses were trained by Mrs. Elizabeth Fry for many years before a school was formally opened in November, 1879. The Protestant orders of St. John and of All Saints for many years performed satisfactorily the nursing for King's College Hospital, Charing Cross Hospital, and the University College Hospital. The Order of St. John sent nurses with Miss Nightingale to the Crimea. In June, 1860, a training school was founded at St. Thomas' Hospital, London, through the generosity of Miss Nightingale. This school, after being in successful operation for several years, was made the subject of special study by the New York State Charities Aid Association, and taken as a

Digitized by Microsoft®

model for the Bellevue Hospital School, as well as for most of the other American schools. In 1874 a school was opened at Westminster Hospital, London, and ten years later a special building was erected with accommodation for fifty nurses. It is desired to establish district nursing among the poor in connection with this school. In 1861 a training school was founded in Liverpool for district nursing, and a great reform in the quality of nursing was instituted at the Liverpool Workhouse. In 1866 there were two schools in Dublin, and there is now an excellent school at the Glasgow Royal Infirmary. In 1867 a school was founded at the Sydney Infirmary, New South Wales. There are also new schools in Russia, Sweden, and Holland.

"Toward the end of the eighteenth century Dr. Valentine Seaman gave a course of twenty-six lectures to the nurses of the New York Hospital upon important topics in relation to nursing and hygiene. These lectures were published in 1800, and they are the first recorded effort for the improved training of nurses in the United States. In Philadelphia in 1838 the Society of Friends formed a nurse society by which they raised the standard of nursing and relieved the Roman Catholic sisterhoods from doing the work alone. The Philadelphia Lying-in Charity has instructed nurses in special branches for forty-two years. St. Luke's Hospital in New York has been supplied since 1853 (until recently) with nurses of the Protestant Episcopal Order of the Holy Communion. Several Lutheran charitable societies have trained nurses in various parts of the country, and some two thousand of these women served during the War of the Rebellion. During this war women nurses were also sent to the field and hospitals under the auspices of the Sanitary Commission and of the American Society of the Red Cross. The latter society, aided by the enthusiasm of Miss Clara Barton, has done a great deal in recent years to nurse the sufferers from yellow fever and from floods in the South and elsewhere. At Syracuse, N. Y., a Protestant Episcopal sisterhood has nursed for the Hospital of the Good Shepherd for ten years, and the deaconesses are sent out to nurse in private families, in other institutions, and among the poor. Many excellent orders of like nature have long existed throughout the country for the purpose of training and supporting nurses.

"In 1873 three training schools for nurses were almost simultaneously established in New York, New Haven, and Boston, and from this year dates the impetus to the improved nursing system which has led, in fourteen years, to the establishment of over thirty-five schools in various cities of the United States, with an outlay of many thousand dollars. There have been thus far nearly two thousand nurses graduated."

During the period which has elapsed since Professor Thompson wrote this account, many new training schools for nurses have been established, and on the whole these organizations—both those of recent date and the older ones—have accomplished in a fairly satisfactory manner the purpose for which they were created. Nevertheless, while the progress which these schools have made affords much cause for gratitude, there still remain not a few things to deplore. In the first years of the organization of these schools but little thought and care were given to the theoretical part of the nurse's work; her education was almost entirely of a practical nature, and even in this she was allowed to pursue a somewhat haphazard method, so that what she did with her hands was largely mechanical and but little dominated by the mind. The system of nursing as first instituted in the leading hospitals required, as a rule, a two years' course of training, and provided during the first year only theoretical instruction in the form of classes and lectures with examinations, at the end of the time, in medical and surgical nursing; these examinations being conducted by two or three physicians. The didactic course was usually covered in a dozen or fifteen lectures, and as these were given gratuitously by busy practitioners it too frequently happened that the nurses were assembled only to be dispersed again without the lecture, as the doctor was not able to come. Furthermore, since these lectures were almost invariably given at eight o'clock in the evening, a nurse on night duty was necessarily obliged to miss this part of her theoretical training for a whole month. Again, since in those days the pupils were often sent out to care for private cases during the first year, a nurse who averaged attendance at half the lectures given during her period of training was considered as doing well. Added to all this was the fact, which scarcely needs to be emphasized, that a woman who does not reach this portion of her theoretical studies until the end of a long day, after twelve or more busy hours in the wards, is in no mental condition to remember what she hears. An overpowering sense of fatigue usually renders her attitude one of painful but not always successful effort to keep awake. As regards the classes conducted by the superintendent or her assistants the student fared little better, as these were held in the afternoon and her attendance depended entirely upon whether the head nurse could spare her from the ward, or not. Here, again, night duty interfered, as the pupil nurse could not attend the class work without losing a part of her sleeping hours. Thus, when all these drawbacks are considered, it will readily be understood that to attend a consecutive course of class instruction was a rare occurrence with a first-year pupil.

The aids to study, in the way of books especially prepared for teaching the principles of nursing, were meagre in the extreme; the first manuals on nursing being exceedingly elementary in their subject matter. So far as the acquisition of knowledge in anatomy, physiology, and materia medica was concerned the pupil was left practically to her own resources, to obtain it as best she could, from Gray's "Anatomy" and Wood's "Materia Medica"; and as such books were in most cases unknown territory to the women before their entrance into hospitals, the knowledge acquired was seldom very deep or very much to the point. The subject of invalid dietary, if attempted at all, was covered in a few informal lectures delivered by any one who was willing to give them, and the nurse was only required to sit and observe the teacher's methods, being seldom called upon to prepare food with her own hands. Here again, as was true of her other classes, the pupil nurse was so frequently absent that little if any benefit was derived from this course. The only ethical training was that which was unconsciously experienced from the admirable discipline which existed, and from the unquestioning obedience which was always required from the junior nurse toward the medical staff, her superintendent, and the senior nurses. In making this statement I do not wish to be understood as minimizing the importance of these factors, since it was just this discipline which has stood so many nurses in good stead in after years and which has helped them to do their part in winning a favorable recognition of nursing work. In addition to the above, classes and lectures were held at any and all times during the year, and vacations were in order continuously, so that in a school for nurses there was little if any resemblance to the usual order that obtains in almost any kind of institution of learning.

This brief sketch of the educational condition in the early days of training schools for nurses has been given in order that the changes that have come about in recent years and the efforts that nurses have made, and are still making, to improve nursing education may be more readily understood and appreciated, and the obstacles that still hinder the highest order of work may be realized. As training schools increased in number the graduates from the older schools were selected to become the superintendents of the new ones, but unfortunately they were obliged to enter upon their new fields of work without any special preparation for their arduous and responsible duties, and with no experience beyond what they had acquired as pupil nurses. Hence it necessarily followed that much the same methods, or lack of methods, were introduced wherever a school opened, and any improvement over the old régime was due entirely to the superintendent's own originality, powers of imagination, and

Digitized by Microsoft®

aptitude to impart instruction. But among these same superintendents there was gradually developing a feeling of dissatisfaction with the courses of instruction, as outlined in the circulars of information, and they were beginning to appreciate that not enough care was given to these courses, and that justice was not being done the women who entered training schools but who received nothing beyond a thorough course of training in nursing the sick. At the same time came the many changes in methods of medical work, the hospital physicians and surgeons requiring at the hands of their nurses greater thoroughness in the details of the work and a fineness of finish which had not heretofore been expected, and which demanded a higher order of intelligence to execute. I think that hardly any one at the present day would venture to deny that the science of bacteriology and preventive medicine requires both physicians and nurses to be people of intelligence. Of the nurse it is now expected that she shall have some knowledge of the principles of bacteriology in order to appreciate the value of surgical cleanliness in the prevention of disease, and to be able to do effective work. In order to surround her patient with intelligent care she must understand the principles of ventilation and hygiene; for the proper care of the body she requires a knowledge of physiology; to aid it to overcome or resist disease she must be taught more than a mere smattering about foods and the preparation of invalid dietary. Upon the nurse must devolve the execution of all such minutiæ, and to do such work well it is necessary that she should be endowed with good common sense, practical ability, and intelligence, and then receive a proper education in her profession.

As soon as the trained nurse became a factor in everyday life abuses began to creep in, the salaries commanded began to attract the purely commercial woman with no aptitude for nursing, and the fact that a better class of students could be obtained by the offer of a degree, and that cheaper and at the same time better nursing could be secured in this way led the owners of sanatoriums and the trustees of small special hospitals to establish training schools in which the facilities for obtaining a proper professional education did not exist. As a consequence nurses who had devoted some of the best years of their lives to learning their profession were in danger of being classed with those who had obtained a certificate as a price for so many weeks' or months' nursing, but who possessed little real skill or knowledge. Hence arose two evils—the real graduate nurse lost standing and the public was in danger of being imposed upon.

In the face of these many and serious problems it is not to be wondered at that the leaders in the nursing world set to work to find remedies. At first, individual efforts took the form of trying to improve the educational side of nursing by grading the two years' course of instruction, making a junior and a senior year, with a separate course of classes, lectures, and examinations for each year. The junior year now included instruction in the first principles of nursing together with such medical and surgical subjects as were needed to be put into immediate practice. The senior year was devoted to more advanced teaching and the study of more difficult subjects. This theoretical course was confined to the eight scholastic months of each year, beginning in October and ending with examinations in June, while vacations were given only during the summer months. An effort was also made to divide the two years in such a way that each nurse might spend a nearly equal amount of time in the various branches of the medical and surgical services. In many schools the practice of sending the pupil out to private duty during her period of training was done away with, in order that she might follow an uninterrupted course of instruction. Thus by degrees the curriculum in many schools was greatly improved.

But to protect the public and the educated nurse against the badly trained woman, to overcome the commercial spirit, and to establish a uniform standard of education, individual superintendents, however earnest and influential, could at first do little; and until unity among nurses as a body had been effected and the need for reform and improvement had been generally recognized by each individual nurse, nothing in the way of permanent progress could be attained. As this conviction gradually spread among women who regarded their work seriously, it became evident that for nurses, as for other workers, organization was necessary. For many years anything like unity of thought or work, or friendship among superintendents and graduates of training schools in America was practically unknown, and there was even no *esprit de corps* among graduates of the same school. But among the many congresses held in Chicago during the World's Fair there was one made up of trained nurses, working as a subsection of the hospital section of the Congress of the Associated Charities. This was the first time in the history of nursing in America that nurses had come together as members of the same profession. The most important result of this meeting was the organization of the American Society of Superintendents of Training Schools for Nurses, and to the efforts of this society is chiefly due the progress since made in the teaching of nursing. The avowed objects of this organization were to lay a solid foundation upon which a good practical educational standard might be established, and to further the best interests of the nursing profession by promoting fellowship among its members. Recognizing that any advance must come by the creation of an interest and enthusiasm in the work and in the awakening of an *esprit de corps* among graduates of the same school, the first step was the organization of school alumnæ associations. If these were once well established, the leaders foresaw, a national association would naturally follow. With such rapidity were these alumnæ associations formed that at the end of two years thirty-one were reported, and the proper time having now arrived, steps were at once taken to form the national association, which held its first meeting as the Associated Alumnæ of the United States and Canada in April, 1898. Since that time its membership has steadily increased until it now includes fifty-six alumnæ associations.

With the formation of this association, representing the nurses, and that of the Society of Superintendents, representing the teachers and leaders, nurses were prepared to do effective work. Nor was motive wanting, for almost simultaneously with the organization of the Associated Alumnæ, the Spanish-American war began. Although too late in its organization to be of service as a body in the war, the association soon found an opportunity to work for a permanent reform in army nursing. The lessons taught by the lack of an efficient and properly organized nursing force were so severe that at the close of the war the nurses' societies took steps to remedy the evil; and largely to their work and influence was due the establishment of the army nursing service with a properly qualified graduate nurse in charge. The army nurses have passed their probationary stage and have so far overcome the strong prejudice against women in army hospitals that they may now be regarded as a permanency, and another new field of work is opened up to the graduate nurse.

The next important event was the establishment of a nursing journal, controlled and managed by nurses for the benefit of nurses. The need for such a publication had been long felt, and to establish it had been one of the objects of the Associated Alumnæ. In October, 1900, two years after the organization of the association, the *American Journal of Nursing* was started under its auspices, through the exertions of individual members who assumed the financial responsibility. The undertaking is now an assured success.

Both societies have also been active in promoting a system of hourly nursing, by means of which good care of the sick at home is supplied at reasonable rates to people of moderate means and to those who cannot very well go to hospitals. The nurse who lives at home and pays her own carfare visits her patients once a day, or oftener if necessary, at a charge of about fifty cents an hour. By this plan she is enabled to care for several patients dur-

Digitized by Microsoft®

ing the day, undertake the most important duties herself in each case, regulate affairs in the sick-room, and then instruct some member of the family what to do during her absence. The method has been tried in several of the large cities, and physicians who have employed it have pronounced in its favor in many cases. There is much to be said for some such form of private nursing, which, when properly carried out, insures proper care for many whose circumstances do not entitle them to the services of the district nurse, relieves the family of the constant presence and maintenance of the nurse, and lessens the expense of the illness; at the same time it enables the nurse to lead a more systematic life, gives her more rest, and secures for her a greater degree of independence while pursuing her work.

www.libtool.com.cn

New avenues of work and fresh opportunities are constantly opening up to the graduate nurse by which she may be enabled to do her full share in bettering social conditions. Notable among special efforts made by the nurses themselves is that of the Nurses' Settlement in New York, situated in the most densely populated east side portions of the city. It aims, in addition to nursing the sick poor, to be to the neighborhood all that the college settlements stand for. This settlement has steadily increased in size and usefulness, and now has branches in other parts of the city. Those who know whereof they speak are ready to bear witness that it has already done an incalculable amount of splendid work.

Outside of merely caring for the sick, the special training of the graduate nurse is being utilized in many ways. She is now regarded as a useful member on boards of hospital managers, on health commissions, and on inspection boards, and in at least one city a trained nurse is a member of the school board. The project is seriously being considered of having nurses appointed to visit the public schools daily under the supervision of a physician, to report to him suspicious cases, to indicate the homes in which any infectious diseases have developed, to point out unsanitary conditions existing in the schools, and at the same time to care for the numberless minor ailments and troubles to be found among large bodies of children.

As the Society of Superintendents stands first and foremost for the educational advancement of the nurse, much thought and attention has been devoted to the subject by its members, the one chief desire on the part of all being to supply the public with good, intelligent, practical nurses. To this end many changes have been made. The course of training in the majority of schools has been increased to three years, but unfortunately in only a few instances has it as yet been found possible to lessen the daily hours of practical work. Even to-day the pupil nurse spends from nine to ten hours daily at work in the wards. In a few schools, however, in which a serious endeavor is being made to place a true value upon education, a three years' course of training, eight hours of daily practical work, and the non-payment system have been established. According to this arrangement the pupil receives no monetary recompense, her education being considered an ample equivalent for her time and work, but text-books and uniform are allowed her in addition to her board, lodging, and laundry work. Good general and reference libraries are usually provided in the school. Nursing literature has been much improved and good text-books in the subjects taught have been specially prepared in most cases by superintendents themselves who have gained by long experience a far better appreciation of the needs and requirements of the pupils than physicians could possibly attain to. A graded course of instruction is arranged for in most schools, but no uniform curriculum has so far been adopted. Such a course embraces, as a rule, the fundamentals of anatomy, physiology, bacteriology, hygiene, and materia medica, and the principles of nursing in all branches of medicine and surgery. In the third year a course of lectures and demonstrations in massage, obstetrics, and nursing in infectious diseases and in diseases of the eye, ear, and skin are given. More and more attention is being paid to instruction in invalid dietary; and in a few schools a teacher is engaged for this branch alone, and the pupils take a regular four to six weeks' course of study in food constituents and in the preparation and serving of invalid diet. During this time they are not expected to perform any ward duties. In the matter of nursing in cases of infectious disease, in which isolation is necessary, instruction can be obtained in only a limited number of hospitals. This matter belongs to post-graduate work.

Lastly, superintendents are beginning to realize the importance of giving more detailed and systematic teaching in the ethics of nursing, the constant observance of which is just as important to the graduate as that she should be an expert in practical work.

Although the instruction given in all these various branches must of necessity be very elementary in substance, it has been found that the pupil nurse finds it exceedingly difficult to prepare her class work, write up her lecture notes, do any collateral reading, and at the same time pursue her long hours of work in the wards. Lack of time and bodily fatigue make it practically impossible to assimilate the theoretical knowledge imparted in the courses of instruction. Added to this, the women of to-day have not as a rule a thorough systematic practical knowledge of the details of housekeeping, so essential for any one who expects to become a good nurse and a good manager in a ward. For these reasons an attempt has been made in one school in Scotland, one in London, and one in the United States to give the probationers, before entering the wards, a so-called preliminary course in household economics, in the theory of their work, and in the elements of nursing. By this arrangement the probationer is gradually fitted to begin her more arduous tasks in the ward, with an understanding of what is expected of her. Results are much better for the patients, and the head nurse is spared having so much crude material always on hand to teach; while the superintendent of nurses can feel sure that the preliminary ground has been thoroughly covered. The chief drawback to the general adoption of such a plan lies in the extra cost it entails, an outlay which few hospitals can afford. Under the auspices of the Society of Superintendents a course in hospital economics was established in 1899, in connection with the Teachers' College, Columbia University, New York, the object of which is to qualify specially selected graduates for the duties of superintendence in hospitals and training schools.

Among the more pressing matters calling for reform at the present time are the following: (1) The establishment of uniform entrance requirements for probationers and a uniform curriculum, as a result of which a graduate's degree obtained in any part of the country and from any hospital would practically mean the same thing. (2) Some arrangement by which the small general hospital may become a branch of the larger training school, so that every woman after she has been accepted as a pupil in a hospital of good standing—no matter whether it be large or small—shall be assured a thorough practical and theoretical education as a nurse. (3) Some plan in accordance with which only properly qualified graduates shall be employed at reasonable rates to do the nursing in special hospitals, and thus do away with one most objectionable form of training school. (4) The establishment in certain large centres, in different parts of the country, of post-graduate courses in general hospitals, which may be attended by graduate nurses, who will then be able to keep themselves up to date and become acquainted with the latest changes in medical and surgical methods. (5) The establishment of methods by which the public may be protected from inefficient and untrained nurses, while the women who have taken the time and trouble to perfect themselves in their profession may be accorded their proper status.

With the solution of the first four of these problems the Superintendents' Society is more especially occupying itself; the fifth has been left mainly in the hands of the Associated Alumnæ, and on this point it may not be out of place to say a few words. Before a physician is allowed to practise his profession he is obliged to satisfy

Digitized by Microsoft®

the State board that he is properly qualified, after which his name is duly registered. May not some form of State examination and registration equally well find application in the case of graduate nurses? We are not suggesting a panacea—registration will not cure all defects in nurses, but it will at least afford some sort of a guaranty, and to a certain extent put it in the power of the public to learn for itself the legal status of any woman who offers herself as a nurse for their sick; at the same time it will serve as a hall mark, as it were, upon the woman who has spent time and labor to render herself a good nurse, and will distinguish her from the nondescript individual who so often poses as a trained nurse.

In this paper reference has mainly been made to changes which have occurred in the nursing world on this continent during the past decade. But even should we be inclined to flatter ourselves that America has led the van, it must not be supposed that other countries have been far behind in these matters. It should be a matter for sincere congratulation that there has been established an *entente cordiale* between the members of the nursing profession in all countries, whereby we have been brought into closer touch than ever before. One professional link has been forged between America and England in the form of the International Council of Nurses, which has as its object "the furtherance of the social and professional progress of all nurses and the maintenance of a high standard of nursing ethics and *esprit de corps*," and to which we trust nursing associations in all countries may become affiliated in the course of time.

It is a satisfaction to be able to record that in no civilized country has the development of the nursing profession been at a standstill, and everywhere our members have been working out their own problems according to their several needs. A more comprehensive account of the work being done by nurses throughout the world will be found in the Proceedings of the Third International Congress of Nurses held in Buffalo in September, 1902.*

While the greater part of the progress in nursing has been mainly due to the efforts of nurses themselves, they have been fortunate in securing in their undertakings the active sympathy of the medical profession and of hospital authorities who have appreciated the fact that the better the nurse the more are their own efforts strengthened. It still remains for the well-to-do laity to realize how necessary and important to them is every step taken for the betterment of the nurse. After all, the sole object of all the work and progress is to render the greatest good to the greatest number when sick and in sore need of the best that human skill can afford, and were some portion of the financial aid so lavishly poured out upon university and other institutions of learning given to render the profession of nursing still more worthy of its name, such an outlay would assuredly be returned in good measure pressed down and running over.

Isabel Hampton Robb.

NUTGALL.—*Galla*, U. S.; Br., *Galls*; *Galla*; *Galla halapensis*; *G. Turcica*; *G. levantica*; *G. tinctoria*; *G. quercina*. Excrescences on *Quercus lusitanica* Lam. (*Q. infectoria* Olivier, fam. *Cupuliferæ*), caused by the punctures and deposited ova of *Cynips* (*Diplolepis*, Latreille) *Gallæ tinctoriæ*, Olivier (Class *Insecta*, Order *Hymenoptera*).

The species of oak here named is very variable and widely disseminated, growing over the greater part of Southern Europe, in the Levant, and in Western Asia. The variety which produces the galls is usually a mere shrub less than six feet high. The insect named is a small, wasp-like fly. The female punctures certain of the unexpanded buds, leaving a single egg in each, thus causing it to develop into a gall, instead of a leafy branch. A spherical cavity is formed by the growth of the gall, its lining being of a different structure from that of the remainder of the gall. The larva, when fully developed, gnaws its way out, leaving a pinhole perforation. After this occurrence the gall presents quite a different appearance, being larger, lighter in color and weight, and less rich in active constituents, such galls being distinguished in commerce as White galls, and less highly esteemed than those collected at an earlier period.

DESCRIPTION.—Nearly spherical, about 2.5 cm. (1 in.) or less in diameter, with a short stipe, the surface smooth,

FIG. 3607.—The Nutgall Oak, Showing Leaves, Acorns, and One Nutgall. (Baillon.)

except for a number of short, thick tubercles toward the summit; externally deep greenish- or bluish-gray or blackish; heavy and hard, but readily broken with a hammer, exhibiting a more or less dense granular fracture, sometimes with a waxy lustre; internally, yellowish or pale brownish-gray, with a central nucleus or a cavity containing the more or less perfectly developed insect. The granular tissue of the nucleus is mostly filled with small starch granules and surrounded by a layer of thick-walled cells forming a shell, on the outside of which is the cellular tissue containing the tannin. This tissue has often a radiated appearance near the shell, and contains toward the surface small scattered bundles of vascular tissue. Nutgalls are nearly inodorous and have a very astringent taste. Light, spongy, and whitish-colored nutgalls should be rejected.

Nutgalls are distinguished in commerce according to their color, the *blue* or *black galls* of Syria (Aleppo) being preferred. *Smyrna galls* are usually of a grayish olive green, more spongy in texture and intermixed with *white galls*.

Many other varieties of galls, especially the Chinese variety, have a similar composition and uses, though sub-

* This report may be obtained through the American Journal of Nursing, published at 624 Chestnut Street, Philadelphia, Pa.

Digitized by Microsoft®

stitution or adulteration of the medicinal article is hardly to be looked for. Chinese galls are large, occasionally three inches in length, oblong-ovoid and somewhat flattened, coarsely tuberculate, the tubercles very irregular in size and often prolonged into branches. This gall is of a yellowish-gray color, densely and softly tomentose or velvety, light in weight and hollow, the wall being thin and crustaceous.

Nutgalls contain upward of sixty per cent. of gallotannic acid, two or three per cent. of gallic acid, occurring as a natural derivative of the former, and small amounts of resin, sugar, and starch.

Action and Uses.—The properties of nutgall are those of tannic and gallic acids, in a degree corresponding with their percentages as stated above, and the reader is referred to those drugs for an account of its action and uses.

The official preparations of nutgall are the tincture, containing twenty per cent. of nutgall with ten per cent. of glycerin, and the ointment, which consists of twenty per cent. of the drug rubbed up with eighty per cent. of benzoinated lard. *Henry H. Rusby.*

NUTMEG.—(*Myristica*, U. S.; Br. *Semen Myristicæ*; Ger. Muskatnuss; Fr. Muscade.) The dried ripe seed of *Myristica fragrans* Houttuyn (fam. *Myristicaceæ*), deprived of its testa.

Nutmeg is the product of a handsome, small, evergreen, diœcious tree, native of the Molucca Islands, now widely cultivated in tropical regions, such cultivated trees, mostly in the Malay Archipelago, supplying the commercial article. The fruit is fleshy, one-seeded, and when ripe much resembles the peach. The fleshy pericarp is tardily dehiscent and the seed is enclosed, though only partially covered, by a fleshy network, consisting of the aril. This is removed and dried to form *mace* (which see), leaving the seed as an oval body faintly grooved, where the aril has rested upon it. It is dried by a slow and tedious process, requiring about two months. When dry the nutmegs are beaten to break the testa, from which the kernel has now shrunken away, and the latter then constitutes the official nutmeg. It is nearly an inch in length and somewhat more than half as broad, oval to ovoid, very slightly flattened in one direction and not quite equilateral, of a rich brown color, slightly shining, more or less furrowed, with a circular scar at the broader end, from which a slight groove runs to a deeper depression near the smaller end. When cut transversely it exhibits a pale, brownish-yellow surface, of a fatty lustre, and marked by narrow curved brown lines entering from the surface and containing folds of the tegmen or inner coat. The odor is strong and agreeable, the taste similar and somewhat bitter. The ordinary nutmeg of commerce differs from this in being grayish-white from a partial covering of lime, which serves the purpose of protecting it against the attacks of insects, to which it is very liable. Such nutmegs are distinguished as "limed" or "Dutch," the others as "brown" or "Penang."

The important constituent of nutmeg is its volatile oil, stated in most books to amount to from two to eight per cent., but of which there is very much more. The other constituents are the following: about forty per cent. of fixed oil, of which about three-fourths is removable by expression, a small amount of an unstudied bitter principle, starch, protein, gum, and other ordinary constituents. The volatile oil (*Oleum Myristicæ*, U. S., Br., or *Oleum Nucistæ Æthereum*) varies considerably in character, according as a larger or smaller percentage has been distilled from the nutmeg. When freshly distilled it is colorless, but grows yellow or even reddish and thicker with age, at the same time changing its odor to a heavy and somewhat disagreeable character. It has a pleasant flavor, followed by a warming and biting or slightly acrid effect. Its specific gravity ranges from 0.87 to 0.90 at 15° C. (59° F.). It is soluble in an equal volume of alcohol, the solution being neutral, and in the same amount of glacial acetic acid; it is freely soluble in carbon disulphide. It consists chiefly of *myristicol* ($C_{10}H_{16}O$?) and *myristicin* ($C_{12}H_{14}O_3$), together with pinene, myristinic acid, and other unimportant substances. This oil possesses the properties of nutmeg in an intensified degree. The commercial article holds a small amount of the fixed oil in solution. The fixed oil (*Oleum Myristicæ Expressum, Oleum Nucistæ, Adeps* or *Butyrum Myristicæ* or *Nucistæ, Nutmeg Butter*) is expressed by the aid of heat. It usually occurs in the form of cakes, wrapped in palm leaves, is solid and firm at ordinary temperatures, melting at about 45° C. (113° F.), has a mottled, orange-brown and whitish color, a specific gravity of about 0.995, a pleasant buttery taste, but with a slight fragrance and taste of nutmeg, due to the presence of a little of the volatile oil in solution. It dissolves in four parts of boiling alcohol or in two of warm ether. It consists chiefly of *myristin*, $C_3H_5(C_{14}H_{27}O_2)_3$, with three or four per cent. of free myristic acid. This oil is very much subject to adulteration with, or substitution by, the fixed oils derived from other species of *myristica*, especially that from *M. fatua* Houttuyn. This fat has no special medicinal properties but merely those of other vegetable fats.

Whole nutmegs are at the present day scarcely ever sophisticated, though the long, wild, or male nutmegs above mentioned as being used to adulterate nutmeg butter, as well as some other species, are occasionally offered for them. Artificial nutmegs, pressed from a prepared paste and very inferior in odor and taste, have been frequently reported. Ground nutmeg is usually adulterated, often very heavily so, and the freshly grated article should be insisted upon.

Properties and Uses.—Almost the entire use of nutmeg is for flavoring purposes, although it possesses useful properties as an ordinary aromatic stimulant and carminative. Many cases of mild, and several of rather severe poisoning by overdoses (from two to five nutmegs) are reported, the symptoms being those of a narcotic or severe depressant, in some respects similar to those of overdoses of camphor. There is no preparation, properly speaking, of nutmeg, though it enters into the aromatic powder and the compound tincture of lavender. Of the volatile oil there is an official five-per-cent. spirit, the dose of which is 2–4 c.c. (fl. ʒ ss.–i); the dose of the oil as a carminative is ♏ i.—iij., and a small amount of it enters into the aromatic spirit of ammonia.

Henry H. Rusby.

NUTRITION. See *Metabolism.*

NUX VOMICA.—U. S., Br., *Semen strychni*; P. G., *Semen nucis vomicæ*; *Poison Nut*; *Dog Buttons*; *Quaker Buttons.* The dried ripe seed of *Strychnos Nux vomica* L. (fam. *Loganiaceæ*).

Nux vomica seeds are produced in the East Indies by a small tree which bears a fruit similar in appearance to a small orange. There are from one to four seeds, usually with a few undeveloped ones, found embedded in the whitish, jelly-like pulp of the fruit. The smaller the number of seeds the larger they are likely to be, and the richer in active constituents. Although the principal constituent of the pulp of the fruit is the indifferent glucoside *loganin*, yet it also contains strychnine (about 1.5 per cent. in the dried pulp) and brucine (about one per cent.) and is highly poisonous. The leaves also contain a considerable percentage of brucine, and probably some strychnine, and are poisonous to cattle.

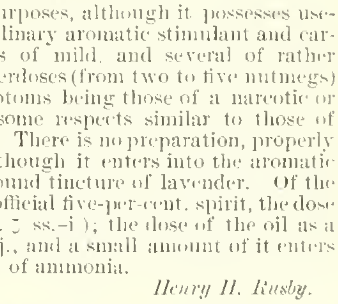

Fig. 3608.—Nux Vomica: outer surface and longitudinal section. (After Baillon.)

Description.—About 1.5–2.5 cm. (⅗–1 in.) broad, lenticular, but irregularly curved, with an elevated central spot upon one or both sides and upon one side a low ridge

Digitized by Microsoft®

(the raphe) running thence to the edge; externally gray, greenish-gray or light yellowish-gray, silky in lustre and to the touch, densely clothed with a coat of closely appressed, shining hairs; internally hard, very tough, somewhat translucent, consisting of two discs of perisperm which www.libtool.com.cn cavity and the embryo which has small heart-shaped, palmately nerved cotyledons; inodorous and intensely and persistently bitter.

Nux vomica seeds are so abundant and cheap that there would appear to be little temptation to adulterate them; yet not only is the powdered drug subject to adulteration, but, what is of more importance, it varies widely in quality. Hence the great importance of insisting upon official standards as to the alkaloidal assay of the preparations.

CONSTITUENTS.—The one important constituent of nux vomica, from a medicinal point of view, is strychnine. The activity of the drug is wholly dependent upon that substance, and the degree of this activity conforms closely to the amount which it contains, although the latter statement is subject to certain modifications, in accordance with the following facts. Associated with the strychnine is a certain quantity of the similar alkaloid brucine,—a quantity which either may be equal to, or may be twice as great as, that of the strychnine present. The action of this alkaloid is almost identical with that of strychnine, although variously estimated at from five to ten times weaker. This variation in the strength of brucine is undoubtedly due to the presence in it of variable amounts of strychnine, which it is almost impossible completely to remove. It is to be remembered that the alkaloids, besides being highly insoluble, exist in nux vomica intimately associated with an extremely tough, horny albuminous substance, so that if the powdered drug be taken, they may be less quickly and completely absorbed than when strychnine alone is administered. Constituents which are not important from a medicinal, though more or less so from a pharmaceutical, standpoint are the tannin-like *igasuric* or *strychnic acid* with which the alkaloids are combined, a considerable amount of fixed oil, a small amount of the glucoside loganin, a little gum, sugar, etc. The combined percentage of strychnine and brucine ranges from two to five per cent. or even more, of which the strychnine represents from one-third to one-half. Strychnine will be fully discussed under that title. *Brucine* ($C_{23}H_{26}N_2O_4 + 4H_2O$) occurs in very fine colorless crystals, forming a whitish powder, soluble in alcohol. It is distinguished from strychnine by being reddened by nitric acid. It forms salts freely, several being upon the market; the sulphate, which is soluble in water, is the one chiefly employed.

ACTION AND USES.—Excepting as to the preparations and dosage, an account of the action and uses of nux vomica would be a duplication of that given under *Strychnine*, to which the reader is referred. Brucine is somewhat used in a similar way, in doses of gr. $\frac{1}{16}$ to gr. $\frac{1}{4}$, the total daily amount not to exceed gr. iij. It is also sometimes applied externally to relieve itching.

The dose of nux vomica, in very fine powder, is 0.06–0.24 gm. (gr. i.–iv.). Of nux vomica the following are the official preparations, subject to assay by processes prescribed by the Pharmacopœia: The extract, to contain 15 per cent. of total alkaloid, dose 0.008–0.06 gm. (gr. $\frac{1}{8}$ to gr. i.); the fluid extract, to contain 1.5 per cent. of total alkaloid, dose ♏ i.–iv.; the tincture, to be made by dissolving 20 gm. of the dried official extract in 1,000 c.c. of a mixture of three volumes of alcohol and one volume of water—this tincture to contain a total of 0.3 per cent. of the alkaloid, and the dose to be 0.3–1.8 c.c. (♏ v.–xxx.). It will thus be seen that the fluid extract is five times as strong as the tincture, and the extract ten times as strong as the fluid extract. *Henry H. Rusby.*

NYE LITHIA SPRINGS.—Wythe County, Virginia. POST-OFFICE.—Wytheville. Hotel and boarding-houses.

ACCESS.—Viâ Norfolk and Western Railroad to Wytheville, thence two miles over macadamized carriage roads to springs.

These springs are located in the southwestern part of Virginia, in a charming, picturesque locality, one-quarter of a mile from the corporate limits of Wytheville. The elevation of 2,360 feet above the sea level gives assurance of a cool and delightful summer temperature. The country about Wytheville has long been celebrated in the South as a summer health resort, and the yearly visitors came from far and near. The average yearly temperature of Wytheville is 53° F. The seasonal temperatures are as follows: Spring, 52° F.; summer, 70.6° F.; autumn, 53° F.; and winter, 32.3° F. The highest summer temperature observed during the past three years has been 88° F. in the shade. The region is quite free from malarial and miasmatic influences. The springs are surrounded by a tract of eighteen acres of the primeval oak forest, which furnishes a delightful shade in the summer. The accommodations for visitors are as yet somewhat limited, but a commodious hotel is in contemplation for the near future. Two good hotels and numerous excellent boarding-houses will be found in Wytheville. The springs are three in number, two lithia and one chalybeate. The summer temperature of the two lithia springs is respectively 53° and 54° F., and the chalybeate 56° F. The following analysis of two of the springs is furnished by Dr. George L. Nye, the resident physician:

NYE LITHIA SPRING, NO. 1.

(Analyzed by W. L. Dudley, Vanderbilt University.)

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Calcium carbonate	10.63
Lithium carbonate	6.41
Iron and alumina oxide	.31
Silicic acid	1.19
Total	18.54

NYE CHALYBEATE SPRING.

(Analyzed by J. L. Jarman, of Emory and Henry College.)

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Potassium carbonate	0.01
Sodium carbonate	.81
Lithium carbonate	1.89
Calcium carbonate	11.60
Magnesium carbonate	2.35
Iron and alumina oxide	1.33
Silicic acid	.66
Total	18.65

Rating the lithium in these analyses as the bicarbonate it would amount respectively to 11.77 and 3.48 grains per gallon.

The waters have long been highly prized in the treatment of a variety of disorders. Dr. Nye presents numerous reports of cases from competent physicians illustrating the beneficial influence of these waters in diabetes and other urinary disorders. Their action in cases of dyspepsia and intestinal affections is also very advantageous. The chalybeate water is in high repute among physicians for the relief of menstrual and uterine disorders consequent upon anæmia. *James K. Crook.*

NYMPHÆACEÆ.—*The Water-lily Family.* This small family of aquatic plants contributes several large, coarse, spongy, dark-colored rhizomes which have been used in medicine. The white water-lilies pertain to the genus *Castalia* Salisb., though long miscalled *Nymphæa*, the latter name still being applied to them as drugs. The species most used are *C. alba* (L.) Lyons (*Nymphæa a.* L.), the European white water-lily, *C. odorata* (Dryander) Woodv. et Wood (*Nymphæa o.* Dryander), the Fragrant or Sweet scented white water-lily, chiefly of Eastern North America, and the *C. tuberosa* (Paine) Greene, the tuberous white water-lily, chiefly of Central North

Digitized by Microsoft®

America. The yellow water-lilies or pond-lilies, Spatter-docks, or Flatter-docks, pertain to the genus *Nymphæa* L., though long miscalled *Nuphar*. The species of this genus which has been most employed, and the nature of which is best known, is *N. lutea* L., the European yellow pond-lily. From this rhizome has been extracted the white amorphous alkaloid *nupharine*, to which its bitter properties are probably due. The constituents of the other species named are but little known, though they contain bitter principles apparently similar to nupharine. All contain resin, tannin, starch, and gum.

The uses of these drugs are not based upon any scientific knowledge other than that they are mild astringents and bitter tonics. In this way they have been used as astringent gargles, intestinal astringents, and for local applications in gonorrhœa, leucorrhœa, etc. The dose of the fluid extract is i.–iv. cc. (fl. ʒ ¼–i.). *Henry H. Rusby.*

NYSTAGMUS is an involuntary rhythmic contraction of the ocular muscles producing oscillation of the eyeballs. It is due to imperfect cortical innervation of the voluntary muscles of the eye, and may result from either central or peripheral causes, or from both. The movements, which usually affect both eyes, may be vertical, rotatory, or lateral, but the most common form is from side to side. It is most commonly observed in eyes that are defective congenitally, as in albinos, or from coloboma of the choroid, microphthalmos, etc. Various inflammatory or degenerative diseases of the eyes, chiefly when they occur in early infancy or childhood, frequently cause nystagmus. This condition must not be confounded with the slight tremor observed upon voluntary movement of the eyes in efforts at fixation in various directions which is so often found in association with weakness of the ocular muscles.

Nystagmus may be acquired, and is often seen in those employed in coal mines, and is due to the work being done in cramped positions under poor illumination, the gaze being directed obliquely upward. Fatigue is thus induced in the superior recti and inferior obliques, and also in the internal and external recti muscles, finally causing their spasmodic action. This type of nystagmus may also be regarded as a fatigue neurosis.

Nystagmus also occurs in various diseases of the nervous system, and is often a conspicuous symptom in multiple sclerosis, cerebellar disease, and Friedreich's hereditary ataxia. It occurs in many diseases of the brain, such as tumor, softening, hemorrhage, meningitis, sinus thrombosis, etc. As a localizing symptom it is of no value, but it is an important diagnostic sign in the early stage of degenerative affections of the central nervous system.

In multiple sclerosis nystagmus is a frequent symptom. Spontaneous movements like those seen in albinism or in congenital ocular defects are rare. The nystagmus is usually manifested when the eyes are moved voluntarily in various directions, especially on lateral movement.

In cerebellar disease nystagmus has been classified as an irritative symptom, being ascribed to pressure on the pons and corpora quadrigemina.

William M. Leszynsky.

OAK ORCHARD ACID SPRINGS.—Geneseo County, New York.

Post-Office.—Medina, Orleans County.

Access.—Viâ New York Central Railroad to Medina, a station forty miles west of Rochester, thence six miles south by stage.

The springs are not used as a resort, but the waters have been sold to some extent. The accompanying analyses show the waters to possess exceptional properties.

These springs are remarkable in the amount of free sulphuric acid which they contain—more, indeed, with one or two exceptions, than is to be found in any other waters known. Waters containing this acid in free state are exceedingly rare. It is said that none of the kind is known in Europe. Among the few known on this side of the Atlantic are the following: One in the town of Byron,

One United States Gallon Contains:

Solids.	Spring No. 1. (Silliman and Norton.) Grains.	Spring No. 2. (E. Emmons.) Grains.	Oak Orchard, acid water, (Prof. Porter.) Grains.
Sodium sulphate	6.34	....	3.16
Calcium sulphate	74.89	12.41	13.72
Potassium sulphate	5.52	....	2.48
Aluminum sulphate	21.69	....	6.41
Magnesium sulphate	35.60	4.98	8.49
Iron sulphate	....	39.23	....
Iron protosulphate	28.62	....	32.22
Sodium chloride	2.44	...	1.43
Silica	4.59	1.84	3.33
Organic matter	....	10.88	6.65
Sulphuric acid	134.73	129.06	133.31
Total	314.42	198.40	211.20

near the Oak Orchard Spring; the Tuscarora Sour Spring in Canada; the Matchless Mineral Well in Alabama; and several acid springs in Texas, California, and Virginia. According to Prof. J. H. Armsby, of Albany, the Oak Orchard water has been used with advantage in "ill-conditioned ulcers, diseases of the skin, passive hemorrhages, diarrhœas depending upon an atonic condition of the mucous membranes, and in depraved and impoverished conditions of the body from specific diseases and from intemperance." The water requires dilution before drinking. *James K. Crook.*

OAK, WHITE.—Quercus Alba. *Oak Bark.* "The bark of *Quercus alba* L. (fam. *Cupuliferæ*)," U. S. P. This species of oak-tree is one of the commonest and most abundant of its genus, as well as the largest, in Eastern and Central North America. It yields one of the most highly prized of American hard-wood timbers. The bark is thus officially described: "In nearly flat pieces, deprived of the corky layer, about a quarter of an inch (6 mm.) thick, pale brown; inner surface with short, sharp, longitudinal ridges; tough; of a coarse, fibrous fracture; a faint, tan-like odor, and a strongly astringent taste. As met with in the shops, it is usually an irregularly coarse, fibrous powder, which does not tinge the saliva yellow." The last character distinguishes it from the largely employed bark of *Quercus tinctoria*. In nearly all temperate countries some locally occurring oak is used as an astringent; the British oak, *Q. Robur* L., in Europe, the holly oak, *Q. Ilex*, in France and elsewhere. In our own country, also, other species besides the white oak are sometimes used and were formerly official (*Q. coccinea vel tinctoria*, Gray, etc.).

White oak bark is simply an astringent. It contains from five to ten per cent. of tannic acid—probably identical with the *quercitannic acid* of *Q. Robur*—and a little coloring matter.

It is used in decoction (5%) for cracked or tender nipples, indolent granulations, leucorrhœa, nasal catarrh, etc., and is occasionally given internally, in doses of i.–iv. gm. (gr. xv.–lx.). Finely powdered white oak is often blown into the nares to check hemorrhage.

Henry H. Rusby.

OBESITY. See *Adipositas*.

OBSTETRIC OPERATIONS.—Induction of Abortion.—This means the interruption of pregnancy before the period at which the child is viable. It is an operation performed solely in the interests of the mother and, as Hirst says, should be undertaken as reluctantly as justifiable homicide. The indications are: pernicious vomiting, pulmonary and cardiac disease, nephritis, chorea, acute mania, melancholia, and pernicious anæmia. Pregnancy may have a very deleterious effect upon each of the above disorders, and in allowing gestation to continue, the physician may sacrifice the lives of both mother and child; the induction of abortion should be regarded only as the last resort and never be undertaken without consultation. Among the local conditions which may call for the termination of the pregnancy must be men-

www.libtool.com.cn

Digitized by Microsoft®

tioned incarceration of the retroflexed uterus, hemorrhage from the normally or abnormally situated placenta, and excessive contraction of the pelvic canal. In this last condition the choice lies between abortion and Cæsarean section; the claims of each operation should be presented to the mother.

www.libtool.com.cn

Methods of Inducing Artificial Abortion.—The uncertain methods of drugs and electricity are to be condemned. The induction of artificial abortion should be made a surgical operation, and, if possible, completed at one sitting. There is but little danger if the procedure has not been delayed until the patient's strength is exhausted and if careful asepsis is observed throughout. The instruments required are: rubber pad, leg-holders, weighted speculum, volsella forceps, steel-branched dilators, a large intra-uterine curette, ovum forceps, intra-uterine irrigating tube, and fountain syringe. The patient, having been anæsthetized, is placed in the dorsal position with knees well drawn up and secured with the leg-holders; the parts about the vulva are shaved and cleansed, the vagina is scrubbed with soap and irrigated with warm sterilized water. By means of the speculum and volsella the cervix is exposed and secured; with the dilators the cervix is gradually stretched up to two or two and a half inches. Owing to the softening the tissues usually yield readily, but this part of the operation must be conducted without haste. The finger is the best instrument for removing the contents of the uterus, and in the first two or three months of pregnancy there is but little trouble in reaching the fundus, especially if counter-pressure be made upon the abdomen with the other hand so as to crowd the womb down upon the internal finger. After the attachments of the ovum have been freed the membranes are drawn out over the hooked finger. In case of difficulty the curette may be used to loosen the tissue and the pieces removed with the forceps, but the finger is the guide for all intra-uterine manipulation, and touch alone will determine when the operation is completed. Finally, an intra-uterine irrigation of hot sterile salt solution will remove clots and act as an efficient stimulant to the uterine muscle. Chemicals should not be injected into the uterus; when strong enough to affect bacteria they become poisonous to the woman. Some operators advise the introduction of a gauze drain, but this should be unnecessary. In some cases the cervix may be rigid or the pregnancy too advanced for the operation to be readily completed at one time. Under these circumstances some authors recommend making use of tents, but the difficulty in rendering them aseptic should forbid their employment. The cervix may be partially dilated with the steel dilators and then the lower uterine segment and cervix firmly packed with gauze supported by a vaginal tampon. Such treatment controls hemorrhage and stimulates the uterus so that at the end of twelve hours the packing can be removed, when the cervix is found softened and contractions are established. If there is no haste the case may be allowed to progress naturally or the operation can be completed, but in all cases the finger must be used before deciding that the uterus is empty. During the performance of artificial abortion there may be profuse hemorrhage which usually ceases as soon as the uterus is emptied and stimulated with the hot saline solution. If oozing continues the hypodermatic administration of ergot and even the introduction of the intra-uterine tampon of gauze are indicated. In bad cases of retroflexed uterus it may be impossible to reach the cervix; in such cases the fundus should not be tapped through the vagina, as some books recommend, but the proper treatment is abdominal section and manual reposition of the uterus.

Induction of Premature Labor.—*Indications.*—Many of the indications for this operation are the same as those mentioned under the heading of Induction of Abortion, the pregnancy having been allowed to proceed in the hope of obtaining a viable child. It is evident that the later the operation can be delayed the better the chances for the child, and that the after-care will make a great difference in the infant mortality. Deformed pelves: Here the operation comes into competition with symphyseotomy and Cæsarean section. Heymann says that in cases of disproportion between child and maternal pelvis the best time for the induction of labor is from the thirty-third to the thirty-fifth week. Among children so born the mortality is 64.3 per cent. In simple flat pelves an internal conjugate of two and three-fourths inches is considered the lowest limit; three to three and three-fourths inches in the generally contracted pelvis. The success of the treatment of deformed pelves by induction of premature labor depends upon careful measurement of the diameters, accurate estimation of the size of the fœtal head, and correct calculation of the duration of pregnancy. Each case must be studied by itself, and for further particulars the reader should refer to the article on *Pelves, Deformed.* Placenta prævia: In the majority of cases the first hemorrhage does not occur until after the period at which the child is viable. Labor should be induced at once, as further delay does not improve the chances for the child and threatens the life of the mother. Eclampsia: most authorities advocate the induction of labor not only when the convulsions appear, but whenever the pre-eclamptic symptoms refuse to yield to treatment. On the other hand, Stroganoff reported fifty-eight successful cases without the induction of labor (*American Gyn. Journal*, May, 1901).

Methods of Inducing Premature Labor.—Puncture of the Membranes: This method is uncertain and contrary to nature. Tamponing the Vagina: This also is uncertain and not advisable unless there is severe hemorrhage. Injection of Glycerin: This is dangerous, although many successful cases have been reported. Insertion of an Elastic Bougie: This is known as Krause's method, and is advocated by many. An aseptic bougie is passed up as far as possible between the membranes and the uterine wall; the bougie is then supported by a tampon placed in the vagina. If no contractions set in at the end of eight hours, a second bougie is introduced. When the labor is induced, the bougies are allowed to be expelled along with the fœtus. This method is frequently unsuccessful, and there is some danger of sepsis, as a bougie is difficult to disinfect without ruining it. The chief advantage lies in the fact that the procedure is an easy one for a person who has very little skill in manipulation. Dilatation of the Cervix: This is the most desirable method and may be carried out in various ways. The patient is anæsthetized, the cervix slightly dilated with the steel dilators, and then the entire cervical canal and vagina are packed with iodoform gauze. If contractions are not evoked at the end of six or eight hours more gauze should be introduced. As soon as the labor is started it may be allowed to proceed unaided. Instead of gauze the rubber bags of McLean or Barnes may be used; these are passed into the cervix and distended with sterile water. Before introduction their strength should be tested and the number of syringefuls of water required should be noted. McLean's bags are divided by a compartment through the centre so that each side can be distended separately. Charpentier de Ribes' bag is made of silk covered with rubber and, when dilated, forms an inverted cone measuring three and one-fourth inches at the base. This bag is folded, introduced into the lower segment of the uterus, and filled with water; the stimulation is increased by making traction upon the tube connected with the apex of the bag. These hydrostatic dilators both open the cervix and cause uterine contractions. De Ribes' bag is very useful in placenta prævia as it makes direct pressure upon the bleeding lower segment. A certain amount of preliminary dilatation is necessary for the passage of any of these bags. When haste is essential, as in placenta prævia, the cervix can be stretched by the fingers, later by the passage of the entire hand; manual dilatation may be independent of, or may supplement, the other methods. The delivery of the fœtus may be accomplished by version or by the application of forceps according to the requirements of the case.

Laceration of the Cervix.—Slight ruptures of the cervix occur in almost every first labor; they may add

Digitized by Microsoft®

somewhat to the danger of septic infection, but are otherwise unimportant. Deep tears are the result of the rapid passage of the fœtal head through a rigid or imperfectly dilated cervix. Precipitate labor, the application of high forceps, and version frequently cause cervical laceration. Malignant disease and the presence of cicatricial tissue are predisposing conditions. The tears usually are longitudinal and situated on the left side, but may also be bilateral or stellate; in rare instances the anterior lip has been torn away by being caught between the inner surface of the pubis and the presenting part. Evidences of Cervical Laceration: The lesion may be suspected whenever the presenting part takes a sudden jump through a partially dilated cervix, but the chief sign of serious rupture is hemorrhage. Whenever hemorrhage continues from an empty and well-contracted uterus the parts should be inspected for lacerations. A speculum is seldom necessary as the parts are so relaxed; the cervix can be caught with a volsella forceps and pulled down into view. *Prophylaxis:* Non-interference with normal labor, care in avoiding premature rupture of the membranes, and the postponement of operative procedures until the cervix is dilated or dilatable are the important points under this head. *Treatment:* Extensive tears, especially those giving rise to hemorrhage, require the introduction of sutures. For this procedure anæsthesia is rarely needed as the parts are not sensitive, particularly just after labor. By means of a speculum and volsella the cervix is exposed and secured; with a curved needle in a holder catgut sutures are introduced from side to side. If the gut be chromicized there is no danger of its too early absorption, although some operators use silkworm gut. No special after-treatment is called for, except the removal of non-absorbable sutures upon the tenth day.

Secondary Trachelorrhaphy.—Neglected lacerations of the cervix may give rise to symptoms and, under some circumstances, they seem to predispose to the development of cervical cancer. The laceration allows the cervical canal to gape open and exposes its interior to friction against the sides of the vagina; hypertrophy and hyperplasia of the epithelial tissue may ensue, giving rise to the so-called "granulations" and being accompanied by profuse leucorrhœa. In other cases there is an extensive deposit of cicatricial tissue making the cervix club-shaped and producing reflex disturbances. A tear in the cervix may cause prolonged congestion of the uterus, thus delaying involution and weakening the supports so that displacements readily occur. *Symptoms:* In chronic cases these may be leucorrhœa, backache, dragging sensations, menorrhagia, and dysmenorrhœa, as well as a wide variety of reflex symptoms. The diagnosis can be readily made by vaginal touch; on inspection we may see a club-shaped cervix or a red, eroded-looking surface covered with exuberant "granulations" and purulent discharge. The varieties of tears are unilateral, bilateral, and stellate.

Trachelorrhaphy. — Lacerations which give rise to symptoms or show signs of irritation should be treated by operation. The instruments needed are: a rubber pad, leg-holders, weighted speculum, a knife or Emmet's scissors for denudation, volsella forceps, tenaculum, hæmostatics, needle-holder, and straight cervix needles with large eyes. The patient is anæsthetized, placed in the lithotomy position, and the vagina cleansed. After the introduction of the speculum and exposure of the cervix the anterior and posterior lips are brought together by means of tenacula so that the extent of the tear and the position of the canal may be judged. Each lip is then denuded, care being taken to remove all the cicatricial deposit from the angle of the tear. In a bilateral laceration a strip of mucous membrane is left in the centre of each lip to form the lining of the canal; stellate lacerations are denuded in such a way as to make the lesion unilateral or bilateral; all diseased tissue containing Nabothian ovules and hypertrophied glands should be removed. The field of operation is kept clean by means of small sponges on holders or by continuous irrigation. Chromicized or formalin catgut answers every purpose as suture material, although many operators use silkworm gut. The sutures are passed from the outside of one lip just below the angle of the tear, the needle coming out at the edge of the undenuded cervical canal, then reintroduced into the other lip and brought out so as to correspond with the point of entrance. The first or angle suture is the most difficult to insert. The sutures are caught in the grasp of a pair of hæmostatic forceps and not tied until all are introduced. After knotting and cutting the ends of the stitches iodoform is dusted upon the cervix and the speculum withdrawn. The patient is kept quiet for a week or ten days at which time non-absorbable sutures are removed.

LACERATIONS OF THE PERINEUM.—Schroeder states that the perineum is torn in thirty-four per cent. of primiparæ and nine per cent. of multiparæ. The general cause of laceration is disproportion between the size of the fœtal head and that of the vulvar opening. Sometimes the child is so rapidly expelled that the tissues have not time to become pliable, or, as is the case with elderly women, the parts may not be sufficiently elastic When the mechanism is faulty the axis of the presenting part may be directed too far backward and plough into the posterior wall; this is the case in occiput permanently posterior. The perineum is often lacerated when the delivery is by means of forceps. Tears are divided into complete and incomplete, according as they rupture through the sphincter ani or not; the incomplete tears may extend as far as the border of the muscle or stop short of it. In rare instances there occurs a "central rupture," the child being born through an opening between the anus and vulva. The laceration extends for a variable distance up the vagina on one or both sides, rarely in the median line. It is important to remember that the function of the levator ani may be impaired by overstretching without there being any evidence of external tear. The prophylaxis of perineal laceration is discussed in the article on *Labor, Normal*. Briefly, this consists in carrying out one or more of the following procedures: 1. Restraining the descent of the head to allow time for the gradual stretching of the tissues. 2. Diminishing the power of the expulsive efforts by the administration of chloroform. 3. Keeping the presenting part well forward under the symphysis. 4. Performing manual extension or flexion, according to the requirements of the mechanism, between the pains by means of a finger in the rectum. After the second stage is over every case should be examined to learn the condition of the pelvic floor.

Treatment.—All lacerations should be repaired immediately if possible; the stitches may often be inserted before the delivery of the placenta while the parts are numb or the woman still under the anæsthetic, the sutures not being tied until after the third stage is completed. When circumstances make postponement unavoidable just as good results in the way of union are obtained at the end of twenty-four hours. Primary Operation—Incomplete Tear: The instruments needed are: curved needles, needle-holder, scissors, thumb forceps, and suture material. The rubber pad is placed beneath the buttocks and the leg-holders are applied; the parts are cleansed and bits of ragged tissue trimmed away with the scissors; a wad of sterile cotton or gauze may be placed in the vagina to prevent blood from obscuring the field of operation. The closure of the incomplete tear is a simple matter and requires the application of none but the ordinary surgical principles. The rent in the vagina should be closed by a running suture of catgut and the remainder of the tear brought together by side-to-side sutures of silkworm gut. If no vaginal stitches are required the silkworm gut may be introduced and the ends secured with a hæmostatic until the placenta is expressed; but if there is much laceration of the vaginal wall, it is best to defer all suturing until after the third stage. Complete Tear: The essential point of this operation is to bring together the ends of the torn sphincter ani. The first suture should be introduced well back, about on a level with the posterior margin of

Digitized by Microsoft®

the anus, then buried in the recto-vaginal septum and brought out at a corresponding point on the other side; usually two sutures suffice for the sphincter. The rest of the operation is the same as that for incomplete tear. If the laceration extends up the rectum, the rent in the bowel should be united by means of catgut stitches introduced from the rectal side of the bowel. There are no special features about the after-treatment; the parts should be irrigated after each urination and kept dusted with iodoform. Even when the tear was a complete one the bowels should be moved on the second and each succeeding day, the fæces being softened by the injection of a little olive oil.

If lacerations involving the pelvic floor are not sewed up at the time of their occurrence there may be unpleasant results. The posterior vaginal wall may begin to roll out, forming a rectocele; as the anterior wall is supported by the posterior a cystocele may be added, and these two conditions interfere with the functions of bladder and rectum. The prolapse of the vaginal walls drags upon the uterus until its supports yield and displacement occurs. The attempt to innervate the weakened or ruptured muscles is a severe strain upon the woman's system, and the general health becomes impaired, while the altered position of the uterus interferes with the functions of the pelvic organs so that menorrhagia and dysmenorrhœa may be present. In cases of complete tear there is incontinence of fæces. The diagnosis of old laceration is made by inspection and digital examination; the tear may be represented by cicatricial tissue; the vulvar opening may gape; on directing the patient to "bear down," the lack of support is manifested by a protrusion of vaginal tissue. The only treatment is by operation, which must not be performed inside of two months after labor in order to give the uterus time for involution.

Secondary Perineorrhaphy.—During the week preceding operation it is well to direct the patient to avoid milk and live upon a diet of animal broths and food which will produce but little residue; such a course of preparation will add greatly to the prospects for success if the operation is to be for a complete tear. For several days in advance the patient should be given daily laxatives and high bowel washes; a large enema should be administered on the morning of the operation. The instruments required are: rubber pad, leg-holders, long scissors curved on the flat, scalpel, rat-toothed forceps, tenacula, hæmostatics, needle-holder, curved and straight needles, suture material of catgut and silkworm gut. After the patient is anæsthetized she is placed in the lithotomy position, the perineum is shaved, and the parts are rendered aseptic. If, by means of tenacula, the two lower carunculæ myrtiformes and a point on the posterior vaginal wall are brought together, a good idea of the area requiring denudation may be obtained. There are two typical operations which meet the demands of the majority of cases, Hegar's and Emmet's.

Hegar's Operation.—The three points to be determined in this operation are the apex of the rectocele and the two lower caruncles. With the scalpel a line is made at the margin of the skin and mucous membrane connecting the lower caruncles of either side, and from these points the line is carried up to the apex of the rectocele on the posterior vaginal wall. This triangular area with a curved base is then denuded with the scissors. Beginning at the point farthest up the vagina catgut sutures are introduced, the needle being directed in a slanting course downward on one side until the centre of the vaginal wall is reached and then upward to a spot corresponding with the starting-point. In this way the upper part of the triangle is closed almost down to the caruncles. A straight needle is now threaded with silkworm gut and a suture is passed from side to side, beginning just above the posterior commissure. The next two sutures are inserted above the first and passed into the vagina and out again on the opposite side, drawing the two caruncles and the centre of the vaginal wall into their correct relations.

Emmet's Operation.—This operation is particularly well adapted to those cases in which the tear involves the lateral aspects of the posterior vaginal wall. The denudation is triangular on either side, leaving a V-shaped piece of mucous membrane in the centre. The lateral areas are closed by catgut sutures; the edges of the lower part of the denuded area are brought together with silkworm gut, the upper suture being known as the "crown suture," as it secures the apex of the V before emerging on the other side. If the tear has extended into the rectum, great care must be taken to freshen the edges of the sphincter ani; the insertion of the sutures and the after-care do not differ from the description given when treating of the primary operation. Non-absorbable sutures are removed on the eighth or tenth day.

Forceps.—Forceps consist of two blades, and are either of the long or the short variety; long forceps may be provided with appliances for axis traction. The curves of a forceps are two, cephalic and pelvic; the former adapts the blade to the side of the fœtal head, and the latter coincides with the axis of the pelvic canal. Short forceps have no pelvic curve. To insure a firm grasp good forceps should have a moderately long handle, and should be as stiff as possible without making the construction too clumsy. The cephalic curve should be of moderate sharpness, viz., about that represented by the arc of a circle whose diameter is nine inches; such a curve will grasp the head securely and yet not be difficult to introduce. The tips of the blades should be about one inch apart when the handles are closed. Long forceps should measure not less than nine and one-half inches from the lock; when the instrument is applied to the head the pelvic curve has its concavity directed upward toward the symphysis. The blades of forceps are locked either by means of a pin and slot, or there are grooves on the shoulders into which the shank of the opposite blade sinks. Shoulders upon the handles or a loop in the shank above the lock for the insertion of the forefinger are desirable features. There are many varieties of excellent forceps in the market, and choice is only a matter of individual taste provided the forceps have the characteristics just enumerated.

Axis-Traction Forceps.—When the blades are applied to the head at or above the brim of the pelvis the traction should be made in the axis of the superior strait, that is, downward and backward. With the ordinary long forceps traction in this direction is very difficult to carry out, and the force exerted acts at a disadvantage. In all axis-traction forceps rods are applied to the blades in such a way that the traction can be made in the axis of the blades, that is, in the axis of that portion of the canal in which they lie. The handles are held in apposition by means of a screw, and there are joints between the rods and bar as well as between the rods and blades, so that the head can move freely either in rotation or flexion and extension. The standard axis-traction forceps is that which was devised by Tarnier, but there are many modifications of the original instrument, one of the best being the Jewett forceps (Fig. 3611). Edward Reynolds has devised rods which hook into the blades of any pair of long forceps, and are fairly satisfactory. Forceps should be made of metal throughout so as to insure perfect cleansing and sterilization; for the same reason all the parts of axis-traction instruments should be detachable.

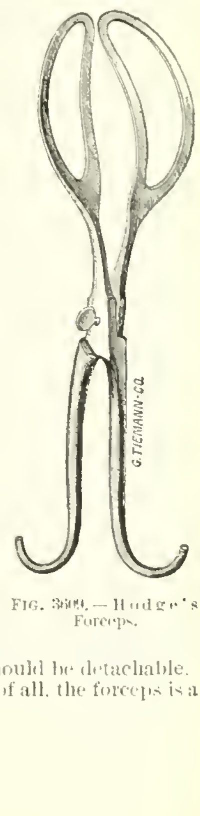

Fig. 3609.—Hodge's Forceps.

Action and Uses of Forceps.—First of all, the forceps is a

Digitized by Microsoft®

tractor; it is also a lever as far as producing flexion and extension of the head is concerned; but leverage carried out by swaying the instrument from side to side is to be avoided as very dangerous to the soft parts of the mother. In rare instances the instrument is used as a rotator, as in turning an occiput forward; but this also is dangerous, and, as a rule, the blades should be allowed to turn with the head as it descends. Finally, the powerful axis-traction forceps are compressors, and great care must be exercised lest this action of the instrument injure the fœtus.

www.fibtool.com.cn

FIG. 3610.—Jenks' Long Forceps.

Indications for Application of Forceps.—Most frequently the application of forceps is required because the maternal forces are unable to expel the fœtus on account of simple uterine or abdominal inertia. Provided there be no contraindications, it is a general rule that when the presenting part has remained stationary for two hours forceps should be applied; of course such a rule is a very rough one, as each case should be managed to suit particular conditions. Forceps may be demanded either in the interest of the child or in that of the mother, and in many instances these interests are combined. Under the head of maternal conditions should be mentioned: pneumonia, valvular disease of the heart, and eclampsia; accidents, such as placenta prævia, accidental hemorrhage and rupture of the uterus; abnormalities of the parturient canal, such as contracted pelvis, tumors, and rigidity of the soft parts. Fœtal indications are undue variation in the strength and rapidity of the heart beat, prolapse of the funis, and sudden death of the mother. There are certain definite contraindications to the use of forceps which are important to bear in mind. The forceps never should be applied when the contraction of the pelvic canal is excessive. As a rule, a conjugate of three and one-half inches is the limit in cases of contracted pelves. Forceps should not be applied to the hydrocephalic head nor to one that has been perforated or is decomposing. Except in a few cases of placenta prævia in which version is contraindicated the instruments should not be applied to a head which is still movable above the brim. Before performing a forceps operation the membranes must be ruptured and the cervix must either be dilated or dilatable. The bladder and rectum should be empty and the position of the head known. It is unjustifiable to make traction upon a head which is descending in such a way as to develop an impossible mechanism, as in persistent mento-posterior and brow cases.

Technique in Applying Forceps. — The operation is known as high forceps when the head is at the brim; as low forceps when on the perineum; and as intermediate forceps when it is between these points. Only the operations of high and low forceps need to be described.

High Forceps.—The operator should have at hand whatever is necessary for the treatment of post-partum hemorrhage and the repair of ruptured perineum; strict asepsis should be observed throughout. The forceps are sterilized by boiling, and the outer surfaces of the blades smeared with sterile vaseline. The patient is anæsthetized and placed across the bed, or better, upon a table, the knees being held by assistants or secured by leg-holders. After the urine is drawn and the parts are cleansed the physician should make a thorough examination in order to determine the exact position of the head. The left blade is introduced first; this is the one lying in the left hand of the operator and occupying the left side of the pelvis. The operator grasps the handle of this blade near the lock, holding it lightly between the thumb and fingers of the left hand in a position almost parallel with the right groin of the mother; two fingers of the right hand are introduced into the vagina, and the tip of the instrument guided gently along their palmar surfaces until the blade comes to lie beside the fœtal head. During introduction the handle of the forceps swings toward the median line of the mother and at the same time downward so as to cause the pelvic curve to adapt itself to the axis of the superior strait. The shank of the instrument presses back the edge of the perineum when the blade is in place. Giving the handle to be steadied by an assistant, the physician passes the other blade in the same way over the one already inserted, reversing the position of his hands to do so. If at any time during the operation contractions of the uterus are evoked the physician must suspend operation until they have passed. The next step is locking the forceps. To do this the handles are gently depressed. If the blades do not readily come together no force must be used, but with a finger within the vagina they should be carefully rotated until they come into proper relation. If it is now impossible to lock them, it is because they are improperly applied, so they should be removed and reinserted. After they have been locked, the handles are brought together or a towel can be placed between them if the operator wishes to avoid the danger of making too much compression upon the head. Before making traction it is well to make an examination to assure one's self that the blades are within the cervix, and that neither the hair nor any of the soft parts are caught in the instrument. At first the tractions are made in a direction downward and as far back as possible; they should imitate the action of the uterus by being intermittent, and the handles should be slightly separated during the interval of rest so as to relieve the head from compression. In difficult cases the traction may be made with the pains, the patient being placed in Walcher's position, viz., at the edge of the table with her heels just touching the floor. This posture increases the antero-posterior diameter of the inlet, but diminishes that of the outlet; so when the head has passed the brim the woman is returned to her original position. As the head descends in the curve of Cärus, the direction of the traction changes more and more to the front until, when the head is on the perineum, the handles of the forceps point almost directly upward. The forceps should now be grasped in the right hand with the palmar surfaces toward the operator; with the left hand he supports the perineum and shells out the head by swinging the handles until they are almost parallel with the woman's abdomen. As flexion or extension of the head is under perfect control when the forceps are applied, ample time may be taken to allow for full dilatation. Sometimes it is wise to remove the forceps just before the largest diameter of the head comes through the vulva. When axis traction is used, the handles are secured by means of the screw and the force is exerted upon the cross-bar. As the axis-traction instruments are very powerful, it is most important to relax the handles between pulls.

Digitized by Microsoft®

Low Forceps.—In applying forceps to the head when low down no regard need be paid to the pelvic curve of the instrument—in fact, there is no such curve upon the short forceps. The application of the blades is easy, and the extraction of the head is performed in the same way as during the last stage of a high forceps delivery.

www.libtool.com.cn

Forceps in Breech Labors.—The forceps are devised to fit the child's head, but they are sometimes applied to the breech when impacted. The blades are applied either over the trochanters or over the sacrum and posterior part of thigh according as rotation has or has not taken place. The first pulls must be gentle as the blades are apt to slip; axis traction is particularly useful in these cases.

Prognosis in Forceps Operations.—Low forceps should cause no danger either to mother or child, but the high operation is not to be undertaken lightly. The dangers to the mother are sepsis and injury to the soft parts; to the child the long and severe compression often proves fatal.

VERSION.—Version or turning is an operation which alters the position of the fœtus in utero so that the presenting part is changed and a different pole of the fœtal ellipse is made to occupy the lower segment. There are three varieties of version: (1) Cephalic, when the head is brought to the internal os; (2) pelvic, in which the breech is made to present itself; (3) podalic, when one or both feet are pulled into the vagina. According to the nature of the manipulations used in its performance, version is divided into external, internal, and combined.

Cephalic Version.—Theoretically this form of version should be performed in all cases of breech and transverse presentation, provided there is no need of immediate delivery and narrowing of the pelvis is absent. The advantage is that there results a normal presentation; but, unfortunately, the field for its employment is limited. It can be carried out only when the liquor amnii is present or immediately after the rupture of the membranes. To perform external cephalic version, the patient is put in the lithotomy position with knees and thighs well flexed. One hand is placed over the head and the other over the breech; then by a succession of gentle impulses the head is pushed toward the pelvis and the breech toward the fundus. During a uterine contraction all efforts at turning should cease, the operator only attempting to hold the fœtus stationary. When the head has once entered the pelvis pads should be placed on either side of the abdomen until engagement has taken place. The *combined method* is known as the bipolar method of Braxton Hicks, and is carried out as follows: The patient is anæsthetized and placed in the lithotomy position; the bladder and rectum must be emptied. After the parts have been rendered aseptic, the disinfected hand is passed into the vagina and one or two fingers into the cervix. The presenting part is pushed away from the internal os in a direction toward the breech, while the outside hand forces the head toward the pelvis. When the fœtus lies obliquely the operator uses externally the hand which corresponds to the position of the head. By the conjoined action of the internal and external hand the head is gradually carried into the pelvis.

Pelvic Version.—This operation is not often performed, as podalic version has largely taken its place. It is indicated in cases in which there is slight pelvic narrowing and no need of immediate delivery, also in transverse presentation when the breech is situated lower than the head. It is carried out by the external and combined methods in the same way as described under Cephalic Version.

Podalic Version.—This is the most common form of version. The indications are: malpresentations and malpositions, minor degrees of pelvic narrowing, especially of the flat type in which this operation may compete with symphyseotomy. A conjugate of three and three-fourth inches is placed as the lowest limit for the elective operation; this limit may be reduced to three inches if the woman be placed in Walcher's position. Podalic version is also indicated in emergencies such as prolapse of the cord and placenta prævia. The contraindications are tetanic contraction of the uterus with marked thinning of the lower segment, rupture of the uterus, impaction of the presenting part, and extreme contraction of the pelvis. The difficulty of the operation increases according to the length of time which has elapsed since the rupture of the membranes. The chief dangers are rupture of the uterus, sepsis, and constriction of the child's neck by an imperfectly dilated cervix. Podalic version is carried out by both the combined and the internal methods. The *Combined* or *Bipolar Method* of Hicks: The first part of the operation is performed in the same way as that described in treating of cephalic version, the breech instead of the head being forced into the pelvis. As soon as a knee or foot is felt opposite the internal os the membranes are ruptured, the extremity is seized and brought into the vagina, and the version is completed by traction upon the leg thus brought down.

Internal Podalic Version.—The bipolar method becomes impossible as soon as the membranes have ruptured and the uterus is closed down upon the fœtus. The hand is introduced into the uterus, one or both feet are seized, and the turning is made by traction, while the external hand makes counter-pressure upon the abdomen. The important points in the technique are as follows: Place the woman in the lithotomy position, empty the bladder and rectum, use an anæsthetic, and carry out strict asepsis. Make sure of the presentation and position, and see that the child is alive and in no immediate danger. Do the version as early as possible after rupture of the membranes. Introduce the hand corresponding to the position of the feet. If the membranes are unruptured, do not rupture them until the feet are reached. Grasp one or both feet, and during the traction keep them in line with the fœtal ovoid. If the hand or arm is delivered, put a tape around it and keep the extremity alongside the trunk.

Extraction after Version.—Usually the child is immediately delivered, after internal podalic version, by pulling successively upon the legs and trunk, the line of traction being directly downward toward the floor until the scapulæ appear. The body of the trunk should be covered with a cloth both for the sake of warmth and to prevent the operator's hands from slipping. The next step is the *freeing of the arms* which have dragged behind and become extended alongside the head. The posterior arm should be freed first in the following manner: The operator holds the child's legs near the malleoli and forcibly swings the trunk upward and outward over the thigh of the mother, keeping the back of the child anterior. If the right fœtal arm is posterior, the trunk is swung over the mother's right thigh and vice versa. The operator passes two fingers over the posterior shoulder into the vagina until he can reach the forearm and sweep it across the child's face by flexion, finally delivering it by extension. The trunk is then swung in the opposite direction, and the other arm delivered in the same way.

Extraction of the Head.—In the delivery of the head firm pressure from above by the hands of an assistant is most important. The child should be made to straddle the left arm of the operator, two fingers being inserted into the mouth to maintain flexion; the fingers of the right hand are laid across the shoulders. Traction is first made downward and then the face carried over the perineum by swinging the child's body up over the abdomen of the mother. If the pelvis is of the flat type, the head should be rotated into the transverse diameter of the inlet. When necessary Walcher's position may be employed. *Prague Method:* The feet are grasped in one hand, and the fingers of the other hand are placed over the child's clavicles; the feet are carried upward while the fingers on the shoulders act as a fulcrum around which the head swings. *Deventer's Method:* No attention is paid to the arms which are left alongside of the head. Tractions are made upon the feet and shoulders directly downward and then the child is swung under the mother's buttocks. This method is said to be very speedy in appropriate cases. Forceps may be applied to the child's head by passing the blades underneath the elevated

Digitized by Microsoft®

trunk. Extraction, as a rule, should not be attempted until the cervix is dilatable, having been rendered so either by nature or by the manual efforts of the operator. Forceps is said to be particularly useful when there is constriction at the cervix. After the extraction of the arms, the head must be delivered in from three to five minutes at the longest if a living child is to be obtained.

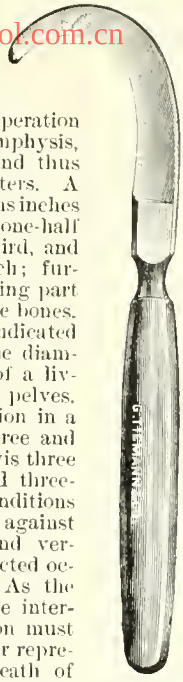

Fig. 3612.—Galbiati's Knife for Symphyseotomy.

Symphyseotomy.—This is an operation for cutting through the pubic symphysis, allowing the bones to separate, and thus increasing all the pelvic diameters. A separation of two and three-fourths inches increases the conjugate about one-half inch, the oblique one and one-third, and the transverse a little over one inch; furthermore, a portion of the presenting part may enter the opening between the bones. *Indications.*—The operation is indicated whenever a slight increase in the diameters will permit of the delivery of a living child, hence in contracted pelves. The lowest limit for the operation in a generally contracted pelvis is three and three-fourths inches; in a flat pelvis three inches (some authors say two and three-fourths). Thus under certain conditions symphyseotomy enters the field against Cæsarean section, craniotomy, and version. Other indications are impacted occiput posterior and chin cases. As the operation is designed solely in the interests of the child, the final decision must usually rest with the woman or her representative. *Contraindications.*—Death of the fœtus, the existence of ankylosis of one or both sacro-iliac joints. The operation should not be performed before the cervix is dilated or dilatable.

Methods of Operating.—The open or direct method should be avoided, as the wound is so situated that septic infection is wellnigh certain. The instruments required are the Galbiati or Morisani sickle-shaped knife, a blunt-pointed bistoury, scalpel, hæmostatic forceps, needles and needle-holder, silkworm gut, metal catheter, iodoform gauze, adhesive plaster, dressings, and a strong binder. Sometimes there is difficulty in cutting through the symphysis (usually because the operator misses the joint), so a chain-saw should be at hand. The patient should be anæsthetized, abdomen and vulva cleansed and shaved, the bladder and rectum emptied. An incision about two inches long is made just above the upper border of the symphysis and the attachments of the recti muscles cut sufficiently to permit the introduction of the left forefinger behind the symphysis. The catheter is inserted into the bladder and the urethra and bladder are depressed downward and to the right. The sickle-shaped knife is passed along the left index finger and hooked under the symphysis; by a sawing motion the joint is cut through in a direction from below upward and from within outward. If a few fibres of the ligament are missed they can be cut with the bistoury. The wound is now packed with gauze to control the hemorrhage and the catheter is removed. The child is delivered by means of the axis-traction forceps while two assistants support the sides of the pelvis to prevent excessive separation of the bones. An excellent method of operating is the *subcutaneous*, as advocated by Dr. E. A. Ayers, of New York. He makes an incision under the elevated clitoris, inserts a probe-pointed bistoury, and cuts through the joint from above downward and from behind forward, the left index finger being in the vagina and pressed against the posterior groove of the joint to serve as a guide.

After-Treatment.—The placenta is expressed and uterine contractions are secured as after normal labor. The catheter is reintroduced to hold the bladder and urethra away while the pubic bones are pressed together, the abdominal wound is sutured with silkworm gut and a broad strip of adhesive plaster passed is about the pelvis. The woman must be confined to bed for at least three weeks and the most scrupulous cleanliness observed. Unless the suspended bed of Dr. Ayers be used, the care of the bowels and bladder is a very troublesome and difficult matter. The patient usually requires catheterization for a certain length of time. The dangers of the operation are sepsis, hemorrhages, development of fistulæ, and lacerations of the soft parts, all avoidable with proper care. In a very few cases undue amount of motility at the symphysis has remained and the sacro-iliac joints have been injured by permitting the separation of the bones beyond three inches.

Prognosis.—The general mortality is given as from eight to twelve per cent., but many of these fatal cases were operated upon after the patient was already exhausted or septic. Ayers has reported thirteen cases without the death of a mother, and eleven children saved. As the chief danger is sepsis, there should be no maternal mortality when the operation is performed under favorable conditions, and, for the average practitioner, it is an easier operation than either craniotomy or Cæsarean section. The fœtal mortality is not the result of the operation, but of the antecedent conditions.

Embryotomy.—This term includes all operations designed to reduce the bulk of the fœtus, namely, craniotomy, decapitation, and evisceration.

Craniotomy.—This operation diminishes the size of the fœtal head. The indications are: Death of the fœtus. If the fœtus is already dead, there is no reason why the suffering of the mother should not be shortened and the case concluded as rapidly as possible, even if the parturient canal is of normal calibre. Contracted pelvis: two and one-half inches in the conjugate is placed as the lowest limit, and even before this limit is reached the operation may be more dangerous for the mother than Cæsarean section. Obstruction of the canal by tumors, monstrosities, large size of the fœtal head, and impacted malpositions of the fœtal head are other indications. The sacrifice of a normal child's life is seldom justifiable when the very favorable results of Cæsarean section and symphyseotomy are considered. How far the physician should go in carrying out the wishes of the patient or her friends is an individual question of ethics. Instruments required for the operation are: volsella forceps, perforator, cranioclast or cephalotribe, metal catheter, and Davidson syringe. The patient is anæsthetized and prepared as for the application of forceps; the fœtal head is steadied by grasping the scalp with the volsella forceps, and the skull is perforated. For this purpose there are several instruments, such as Blot's perforator, Smellie's scissors, and Braun's trephine; this latter instrument is very satisfactory when the head presents, as it removes a button of bone. When the scissors are used, they are thrust through a suture or fontanel and then opened in various directions to enlarge the hole. For the after-coming head the point of selection is the occipito-atloid ligament, but it may be necessary to perforate through the lambdoid suture, near the ear, or even beneath the chin. After the perforation is completed the brain substance is broken up and washed out by means of the catheter. Extraction of the head is performed in one of two ways, either with the cranioclast or with the cephalotribe. When the cranioclast is used

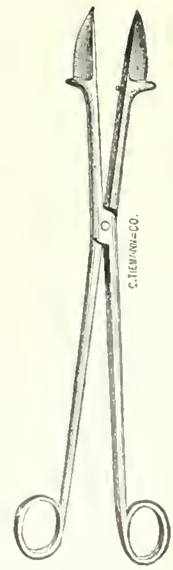

Fig. 3613.—Smellie's Scissors.

Digitized by Microsoft®

one blade is inserted into the opening in the skull, the other blade grasping the head over the face or ear; the handles are brought together by means of a nut and screw and the head is delivered by traction; as the skull is empty the head undergoes compression and is moulded in obedience to the pressure of the parturient canal. The cephalotribe is applied like the ordinary forceps, and when the handles are screwed together the base of the skull is crushed. Tarnier's cephalotribe has a perforator combined with it, but the crushing usually is unnecessary. Before the performance of craniotomy the cervix must either be dilated or dilatable. Apart from the danger of sepsis, the soft parts of the mother may be severely injured in cases of extreme contraction of the pelvic canal.

Decapitation.—The indications for this operation are impacted shoulder presentations with thinned lower uterine segment, interlocked twins, and monstrosities. The usual instrument employed for decapitation is Braun's hook, but scissors, fine wire, or even cord can be employed in an emergency. The patient is anæsthetized and prepared as usual; while an assistant pulls down upon an arm, if prolapsed, the hook, guided by the internal finger, is passed over the neck of the fœtus and the tissues are cut through by a series of twisting motions. The trunk is delivered by traction upon an arm or leg; the head being extracted by hooking one finger into the opening at the base of the skull aided by pressure from above. In difficult cases the head is seized in the forceps or cephalotribe.

Evisceration.—This operation consists in removing the contents of the thoracic and abdominal cavities and is indicated in some neglected cases of transverse presentation and in monstrosities. The puncture is made with the scissors and the viscera are dragged out with the hand or blunt hook; delivery is by podalic version. In difficult cases the child's spinal column is cut and the body doubled up before extracting.

Montgomery A. Crockett.

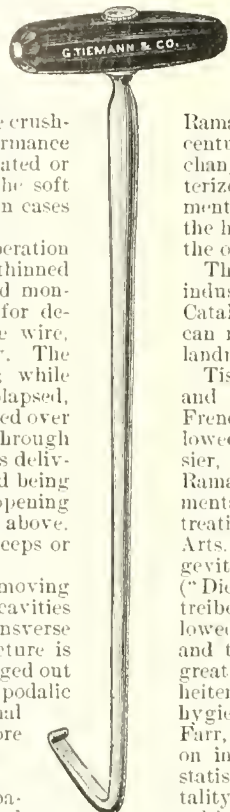

Fig. 3614.—Blunt Hook.

OCCUPATION, HYGIENE OF.—By "occupation" we mean the regular use of our physical functions and mental faculties in business and employment for remuneration, comfort, and luxuries. The functional activity of our organs in a normal way is a physiological condition of health; the disuse, more or less prolonged, of any organ being, as a rule, followed by atrophical changes. While the normal pursuit of occupation is therefore a condition of health, as well as a corollary of economic life, there have always existed, in occupations, certain factors which are productive of pathological changes.

The medicine of antiquity and of the Mediæval Ages ignored the problem of the injurious influence of certain trades on health, partly because these trades were pursued by the lower classes and the slaves, whose health was of no special consideration to the ruling classes, partly because the most injurious effects of occupation on health are but a product of the modern system of industry.

Apart from the few hints in the works of Hippocrates, Celsus, and others, and the mention by Pliny of the "diseases of the slave," we find nothing on the subject of the relations of occupation to health until we come to the seventeenth century, in the latter half of which we first come across a notice of occupational disease in the Transactions of the Royal Society of England, in which we find many pertinent observations on the effects of lead and coal mining, manufacturing of mirrors, etc., on the health of the operatives. To Italy, however, is due the great credit of the first attempt at a detailed description of the evils of certain occupations, the treatise of Bernardo Ramazzini, "De Morbis Artificum Diatriba," published in Modena in 1700, and soon after translated into many languages, being the first work accurately and vividly to describe the special effects of each occupation on health. Ramazzini laid the foundation for all further investigations on the subject, and it is no detraction from his deserved reputation that his book partly suffers from the superstitions and ignorance of his age; indeed we must feel respect and admiration for the many excellent and true observations, and the systematic exposition of the injurious effects of occupations which are found, for the first time in medical literature, in his work.

More than two centuries have passed since Ramazzini's epoch-making work was published—centuries not only full of remarkable revolutionary changes in trades and industries, but also characterized by a no less wonderful, progressive development of the sciences, among which the study of the hygiene of occupation has kept equal pace with the other branches of medical research.

The list of monographs, articles, and books on industrial hygiene fills many pages of the "Index Catalogue of the Surgeon-General's Library," and I can make mention here of only the more important landmarks on the subject in medical literature:—

Tissot's work on "Diseases Incident to Literary and Sedentary Persons," published in 1768 in French, was the next important book; it was followed nearly a half-century later by that of Patissier, who, however, gave but a republication of Ramazzini's work with additional notes and commentaries. After these follow, in succession, the treatises of C. Turner Thacrah ("The Effects of the Arts, Trades, and Professions on Health and Longevity," published in 1831), and of A. C. Halfort ("Die Krankheiten der Kuenstler und Gewerbetreibenden," published in 1845). These were followed by the works of Lévy, Tardieu, and Layet, and then finally, in the year 1871, by that of the great epoch-making work of Hirt—"Die Krankheiten der Arbeiter"—which first placed industrial hygiene on a true scientific basis. In England, Farr, Chadwick, Simon, Ogle, and others worked on in the same line, giving special attention to the statistical part of the subject of occupational mortality and morbidity. Of the later works on the subject, we can mention only the more systematic treatises of Popper, Eulenburg, Merkel, Albrecht, Arlidge, the volume on "Gewerbehygiene" in Weyl's "Handbuch der Hygiene," the work by Thomas Oliver ("Dangerous Trades," published in London, 1902), and the latest work just published in Germany, O. Dammer's "Handbuch der Arbeiter Wohlfahrt."

The immense bibliography and the vast extent of the subject matter of industrial hygiene render any attempt to review or even to summarize our knowledge of this branch of medical science within the limits of a short article, a very ungrateful task, it being utterly impossible to do justice to it under such restrictions.

I have decided to abandon the alphabetical order of treatment by "trades," handed down by Ramazzini, and adopted by the writer on this subject in the former edition of this Handbook, and I shall treat the subject matter under the following heads: Occupational Mortality Statistics; The Diseases of Occupation; The Worker; The Workplace; The Conditions of Work; The Processes of Work; Prophylaxis; and, last, "Offensive Trades."

Occupational Mortality Statistics.

Occupation is a potent factor in the determination of human longevity. If we deduct from man's life the time of infancy and childhood, and the hours devoted to sleep, the greatest part of it is spent within the periods of industrial activity, and is necessarily largely influenced by occupation. The relative number of those who die while in pursuit of their occupations bears an important relation to the healthfulness of the occupations. Moreover, if the figures revealed by the relative mortality statistics corroborate the scientific *a priori* de-

Digitized by Microsoft®

Occupation.

ductions from the study of the processes of occupations and their pathological influences, we then have quite a valuable criterion of the influence of the different trades on the lives of the operatives. Herein lies the importance of mortality statistics, as determined by occupations. In order, however, that these statistics shall have any scientific value, they must cover large periods, embrace great numbers, include various races and countries, and be properly prepared and tested. For it is evident that there are a number of difficulties greatly invalidating the conclusions drawn from occupational mortality statistics. These are as follows:

www.libtool.com.cn

First, occupation, while playing an important rôle in human life, is, nevertheless, only one of the many factors influencing it, there being a great number of others, such as race, country, climate, heredity, geographical, economic, political, and other conditions, each of which undoubtedly affects the lives of operatives; and it is exceedingly difficult to differentiate the causative influences of occupation on longevity from those of all other factors.

Second, there are under the modern system of subdivision of labor several thousands of special branches of trades and industries, only a very few of which, however, and these the most general, being, as a rule, mentioned or tabulated in the mortality statistics. Thus there are about half a hundred occupations in Ogle's tables, not many more in Bertillon's; and in the last (twelfth) census of the United States there are 140 groups, 70 of which are further subdivided, making the whole number in the last census 303. It is obvious that each of the general groups of occupations may embrace a large number of minor trades, each of which will have a different bearing on health and life, thus greatly invalidating the deductions from the general tables.

Third, in our modern industrial production, there are very few trades which are hereditary, as the feudal guilds were, and in which the operatives remained during their whole lives. The greatest number of industries constantly change their *personnel*, most individuals pursuing several trades successively; and the occupation in which they happen to die gives little indication of the one in which they may have spent the greatest part of their lives, and where they perchance had received the injuries to health to which they subsequently succumbed.

Fourth, certain trades can be pursued only by very strong and healthy individuals; while others, being comparatively light, can be carried on by the physically weak and feeble. It is, therefore, manifestly incorrect to base deductions on occupational mortality statistics, seeing that the primary factors (*i.e.*, the workers) are not on an equal basis as to health. All the above considerations make it incumbent upon us to regard occupational mortality and morbility statistics with a certain suspicion, and to apportion them only such value as is warranted by the scientific deductions of the general and special characteristics of each trade, and its effect on health.

Ogle's statistics deserve the great credit attributed to them by hygienists, by reason of their careful elaboration and intelligent preparation. They have been quoted widely and are regarded as standards. I shall give Ogle's table, followed by more recent data from the last United States census, and from J. Tatham's recent morbility figures in Oliver's book.

COMPARATIVE MORTALITY OF MEN, TWENTY-FIVE TO SIXTY-FIVE YEARS OF AGE, IN DIFFERENT OCCUPATIONS, FOR THE YEARS 1881-83, BY W. OGLE, AS REPORTED IN A PAPER READ BEFORE THE SEVENTH INTERNATIONAL CONGRESS FOR HYGIENE, IN 1891.[1]

Occupations.	Comparative mortality.	Occupations.	Comparative mortality.
Clergymen*	100	Grocers	139
Gardeners	108	Fishermen	143
Farmers	114	Carpenters, joiners	148
Agricultural laborers	126	Lawyers	152
Paper-makers	129	Silk manufacturers	152

* The mortality rate of clergymen, being the lowest, is taken at 100.

OGLE'S COMPARATIVE MORTALITY TABLE.—*Continued.*

Occupations.	Comparative mortality.	Occupations.	Comparative mortality.
Drapers	159	Medical men	202
Coal miners	160	Stone & slate quarriers	202
Shoemakers	166	Bookbinders	210
Commercial travellers	171	Butchers	211
Corn millers	172	Glass workers	214
Bakers	172	Lead workers	216
Cabinetmakers	173	Cutlers	229
Masons, bricklayers	174	Brewers	245
Blacksmiths	175	Cab drivers	267
Clerks	179	Liquor dealers	274
Railway laborers	185	Filemakers	300
Gunsmiths	186	Earthenware workers	313
Wool workers	186	Cornish miners	331
Tailors	189	Costermongers, peddlers	338
Hatters	191	Inn, hotel service	397
Cotton workers	196		

OCCUPATIONAL MORTALITY TABLE ACCORDING TO THE (TWELFTH) UNITED STATES CENSUS FOR THE CENSUS YEAR OF 1900 (ONLY IN THE "REGISTRATION AREA"—TEN STATES[2]).

Occupations.	Mortality, per 1,000.	Occupations.	Mortality, per 1,000.
Mercantile and mechanics, average	12.1	Leather makers	12.3
Professional average	15.01	Tin workers	14.5
Laborers and servants	20.2	Marble & stone workers	14.9
Engineers, surveyors	8.2	Engineers, firemen	15.7
School teachers	12.2	Painters	16.2
Lawyers	17.2	Butchers	16.1
Medical men	19.9	Plasterers	17.0
Clergymen	22.5	Carpenters, joiners	17.2
Textile mill workers	8.8	Leather workers	17.5
Plumbers and gasfitters	9.1	Hat, cap makers	17.9
Shoemakers	9.4	Cabinetmakers and Upholsterers	18.0
Machinists	10.5	Blacksmiths	18.3
Iron and steel	10.7	Cigar, tobacco workers	18.7
Glass makers	10.8	Brewers, distillers	19.7
Tailors	11.8	Stone masons	19.9
Printers, pressmen	12.1	Coopers	23.8
Bakers, confectioners	12.3	Millers, flour, grist	26.6

The United States occupation-mortality statistics being only for ten States and only for one year do not have the value of Ogle's tables, which embraced several years and the whole of England and Wales.

COMPARATIVE MORTALITY FROM SPECIFIED CAUSES IN CERTAIN DUSTY OCCUPATIONS. (JOHN TATHAM.[3])

Occupations.	Comparative mortality, all causes.	Phthisis and respiratory diseases.		Mortality figure.	
		Mortality figure.	Ratio.	Phthisis.	Respiratory diseases.
Agriculturists	602	221	100	106	115

"In this table the mortality of the several dust-producing occupations is contrasted with that of agriculturists, who have been shown to suffer the least from the effects of dust. The aggregate death rate from tuberculous phthisis, and diseases of the respiratory system, is shown in this table, as are also the figures relating to each affection separately. Columns 1 and 2 give the combined mortality from these diseases in comparison with that of agriculturists. In the third column the mortality of the latter is taken as one hundred, showing the proportional relation to other workers." [3]

www.libtool.com.cn

Diseases of Occupation.

Disease has been defined as an abnormal condition of the body, a perturbation in the state of the living organism; while life itself is a struggle of the organism with its environment. In the study of the pathogenesis of disease, we come to a complex phenomenon, which on closer study resolves itself into two main branches: First, the intrinsic constitution of the organism; and second, the external world, *i.e.*, the environment. Among the environmental conditions influencing life and health, one, not the least in importance, is that of occupation. In the mortality statistics we have seen that occupation does affect the longevity of man; at least, there is a strong array of figures, corroborating each other, from various races, countries, and localities, which persistently show that some occupations have a very large comparative mortality, and which therefore warrant the deduction that these occupations possess some elements or conditions capable of causing those disturbances in the organism which terminate life more rapidly than is commonly the case when the conditions in question are absent. If death itself, which is but the culmination of all abnormal conditions of life, can be, more or less directly, brought on by occupation, how much more likely is it that occupation will influence the daily life and cause the morbid states called *disease?*

As a matter of fact, since the time of Ramazzini, we do regard many morbid states as due to the influence of occupation, and we call them "industrial diseases," or "diseases of occupation," by which we mean such diseases as are superinduced directly or indirectly by one or more elements existing in occupation. There are, however, two points which we must note in the study of industrial diseases: individual susceptibility, and the relative importance of occupation in the causation of disease. Those who have made a study of the pathogenesis of disease know the remarkable rôle which is played in health and disease by the inherited constitution, personal vital resistance, and power of immunity of each individual. We frequently observe two individuals working in the same trade, side by side, influenced by identical conditions, subject to the same harmful elements, and breathing the same foul, dusty, and poisonous atmosphere; yet while the one, sooner or later, succumbs to these dangers of his trade, and becomes invalidated by the general or special maladies of his calling, the other continues to enjoy life, with apparent immunity from all injurious influences. It is evident that in industrial, as in other diseases, the personal element, the individual susceptibility must be taken into account. So far as the question of the relative importance of occupation in the causation of disease is concerned, there are those who totally deny that there are *any* diseases of occupation. They claim that we may just as well classify diseases by habitation, soil, sewerage; by races, localities, and countries; by monarchies, republics, and constitutional governments, inasmuch as each of these external factors undoubtedly bears some relation to conditions of health, and may, in some more or less remote way, cause disease. This position is, however, untenable; for occupation certainly exerts a greater comparative influence on health than do many of the other external factors; and there are some industrial diseases which may be directly traced to certain specific industries, while this can hardly be said of the other factors.

Among the industrial diseases there are some which can be shown to be directly due to the toxic elements or substances generated in each trade; others there are in which their connection with some particular industry is more remote; and still other diseases in which occupation plays only a predisposing rôle. It is impossible to give here the detailed description of all industrial diseases, nor is it necessary, as all of these diseases are at the same time common to all mankind, and are more fully treated in other parts of this Handbook. The diseases to be briefly alluded to here are only those which bear a direct etiological relation to occupation.

Diseases of the Respiratory System.—The organs of the respiratory system are the greatest sufferers from industrial conditions. The respiratory passages have been very aptly named "the entrance port" of the body where most of the infective agents land on their arrival. All impurities of air, if persistently inhaled for long periods, are liable to produce inflammatory changes in the respiratory passages, and so to weaken them that they readily become a prey to any infective organism. The most pernicious effects on the respiratory organs are produced by the inhalation of dust. In the divers industrial processes, all kinds of materials from animal, vegetable, mineral, and metal substances are undergoing various processes of transformation, with the inevitable result that a great quantity of dust is raised and fills the air of the places of work, and is constantly being inhaled by the operatives. A mere temporary inhalation of dust is followed by increased secretion from the mucous membrane of the respiratory passages, by which these try to get rid of the foreign matter. When, however, the action of the dust is persistent and continuous, the mucous membrane of the passages gets congested, inflamed, and denuded of its protective ciliated epithelia, and, with the weakening of the defensive forces, the entrance of foreign matter or infective materials into the parenchyma of the lungs is no longer prevented. The statistical tables of Hirt, Ogle, Tatham, Bertillon, Kummer, and of the United States census, all agree that the greatest burden of ills due to occupation falls upon the much-abused respiratory organs.

Bronchitis.—Of the diseases of the respiratory system, the most directly traceable to industrial influences is bronchitis. Among the principal causes of bronchitis, Hoffman [4] mentions: (1) catarrhal congestion, (2) inhalation of dust, (3) inhalation of gases. All these factors are preeminently those which are most frequently due to industrial conditions. Excessive muscular exertion, increased body heat due to hard labor, sudden chilling of body surface, exposure to varied and extreme temperatures, etc., are a few of the causes of catarrhal congestion in the bronchi, leading to subsequent chronic inflammatory changes. Inhalation of dust as a cause of bronchitis is easily understood when we remember the irritation which any foreign matter produces in the mucous membranes, and the special irritating qualities of a great many industrial dusts. Poisonous gases and fumes are direct irritants, and cause intense congestion of the bronchial mucous membrane and inflammatory changes which tend to become chronic if the inhalation of such fumes persists. The statistical data, as to the prevalence of bronchitis among workers, are not reliable, for the reason that the disease in its initial forms is hardly one for which the worker discontinues work or seeks medical aid, and certainly not one which would figure in mortality statistics. Hirt [5] gives the percentage of workers suffering from chronic bronchitis as from 11 to 69 per cent. Some dusts are more irritating than others. Thus Hirt found, in an investigation which covered 12,000 workers in a dusty atmosphere, that of those who experienced harmful effects therefrom in a greater or less degree, 11 per cent. were workers in mineral dust, 13.6 per cent. in animal dust, 14.8 per cent. in metallic dust, 18.4 per cent. in dust of a mixed character, and 19 per cent. in vegetable dust.

Emphysema.—Emphysema is a disease of the lungs in which a part of the tissue loses its normal elasticity and

Digitized by Microsoft®

remains in a state of abnormal dilatation. Emphysema is caused by all conditions which interfere with the normal expiratory functions of the lungs. Among the causes of emphysema are: (1) Catarrhal conditions of the passages, leading to accumulation of mucus in the bronchi, to obstruction of the bronchioles and to violent fits of coughing; (2) the lodgment of foreign matter and dust in the bronchioles, and the obstruction of these channels resulting therefrom; (3) constrained attitudes, etc., leading to interference with respiration. Most of these conditions are present in many occupations. We have seen that chronic bronchitis is very prevalent among most workers, and consequently favors the production of emphysema among them. Hirt[5] says that from eight to ten per cent. of all who suffer from bronchitis have emphysema. The filling up of bronchioles with dust is a frequent condition in the lungs of coal miners and others who work in clouds of dust, and such obstruction will cause compensatory hypertrophy and dilatation of other alveoli, also dilatation of the right ventricle of the heart. Work in a constrained attitude, playing on wind instruments, glass blowing, lifting of heavy weights, severe muscular exertion, and alcoholism are among the other predisposing causes of emphysema among workers. According to Kubborn[6] 37 per cent. of miners suffer from emphysema, and according to Seltman[6] 50 per cent. According to Fueller[6] breathing foul air, deficient in oxygen and rich in carbonic acid, predisposes to emphysema; he quotes Seltman's figures to show that, among coal miners, of those who worked in pure air only 7.9 per cent. suffered from this disease, whereas of those who worked constantly in foul air, as many as 62 per cent. were so affected. Hirt[5] gives the following table of the relative frequency of emphysema among workers in dusty occupations: Of 100 cases of sickness there were among metallic workers 3.1 per cent., among those exposed to animal dust 3 per cent., to vegetable dust 4.7 per cent., to mixed dusts 5.1 per cent., and to mineral dusts, 9 per cent.

Pneumonokoniosis.—Zenker applied this term to affections of the lungs due to deposits of dust in their parenchyma. Several forms of pneumonokoniosis are distinguished according to the nature of the dust inhaled and deposited in the lungs. Dust particles are carried to the lung tissue by direct inhalation and also by the action of the lymph channels. These latter play an important rôle in the dissemination of the dust particles, as has been shown by the discovery of some dusts—for instance coal—not only within the lung, but also in the liver, spleen, and kidneys. Fueller[6] quotes the report of a French chemist who found in several samples of lung tissue, weighing respectively 1,800 gm., 2,860 gm., and 220 gm., the following quantities of coal: 85 gm., 140 gm., and 114 gm. According to Merkel[7] the following factors are determining in the etiology of pneumonokoniosis: (1) The state of health and individual susceptibility of the worker; (2) the vulnerability of the respiratory organs; (3) the duration and intensity of the exposure to dust inhalation; and (4) the quality and character of the dust. Quimby (see article on *Lungs, Diseases of: Pneumonokoniosis* in Vol. V. of this Handbook) gives the following more common vocations in which laborers are exposed for prolonged periods to a dusty atmosphere: Mining of various minerals, and the handling of coal in transit to its point of consumption; charcoal grinders and carriers, moulders and those who clean castings, metal and glass polishers, stone masons and plasterers, chimney-sweeps, laborers who tear down old buildings, potters and grinders on various forms of stone, bakers and pastry cooks, gilders and gold and tinfoil beaters, workers in mother-of-pearl and lead, jewellers and glass-cutters, file-cutters, millers, tobacco workers, grain shovellers, etc.

We shall refer to various pneumonokonioses when we come to the subject of dusty occupations and their influence on health.

Tuberculosis.—Pulmonary tuberculosis is a very frequent disease among all kinds of workers, especially among those who work in a dusty atmosphere. The etiological relation of occupation to pulmonary tuberculosis is not difficult to understand, although the connection is not always directly traceable. Occupation is more of a predisposing than an exciting cause of tuberculosis. All conditions of occupations, sex, age, foul air, overcrowding, variety in temperature, exposure, constrained attitude, inhalations of dusts, gases, fumes, and poisons, all tend to predispose the organism to fall a prey to the ravages of the tubercle bacilli. The infection may take place outside of the place of work, but generally happens within its precincts; for there is no better place for the cultivation, distribution, and dissemination of the bacteria than the foul, ill-ventilated, close, damp, overheated, dusty shops, where, if only one tuberculous patient expectorates, enough material may be spread to infect hundreds. The prevalence of pulmonary tuberculosis among various workers has been noted in the already cited table of Tatham on mortality due to this affection. The last United States census gives the number of deaths from pulmonary tuberculosis in the census year as 109,-750. Dusty occupations, as already noted, predispose to phthisis. All statistical data, from Hirt to Tatham, confirm the statement that tuberculosis is the most frequent disease among all occupations, and the frequency is directly proportionate to the amount of dust that is formed in the occupation.

Lobar Pneumonia.—It is difficult directly to connect lobar pneumonia with occupation, although Hirt claims that the largest number of cases of this malady occurs among the laboring class. Congestion and a catarrhal condition of the respiratory passages and exposure to bad weather, etc., are the main predisposing causes. Bronchitis and emphysema, so frequent among workers, predispose to infection with the pneumococcus, by reason of the fact that the normal pulmonary tissue has lost its power to resist infection. Exposure leads to chilling of the surface of the body and congestion of the lungs. The average frequency of pneumonia was found by Hirt[5] to be 7.3 per cent. in some workers, while in millers the percentage was 20.3. According to the figures of the last United States census the laboring class shows the greatest percentage of cases of pneumonia. Merkel[7] denies that dust has any effect on the etiology of pneumonia. In one hundred and forty dead, out of ten hundred and thirty-five cases of pneumonia, he failed to find any trace of dust in the lungs. If dust affects the lungs at all, it may do so by the wounding of the mucous membrane, thus presenting a solution of continuity, favoring bacterial infection. It was claimed that textile workers are prone to this disease, although this is denied by later investigators. According to Hirt's table those who are exposed to vegetable dusts suffer the most from pneumonia.

Diseases of the Nervous System.—The nervous system is the most abused part of the organism of the worker. Modern industry, with its complex mechanical development, enormous rate of speed, intensity of action, and the great demands on the nervous and mental forces of men, tends to overstrain the delicate nervous cells, and sacrifice them to the much-vaunted strenuousness of life. Some of the factors, more or less frequently accompanying all occupations, which lead to nervous disturbances are the following: Excessive cardiac action, intense muscular strain, overuse of an organ or group of muscles, prolonged mental labor, overwhelming responsibility, intense anxiety, mental worry, sudden and continuous shocks and jarrings, extremes of heat, cold, dampness, and variations of air pressure, inhalations of certain gases, and the ingestion of certain poisons.

Among the nervous diseases most frequent among workers are cerebral and spinal hyperæmia, peripheral neuritis, the fatigue neuroses, progressive muscular atrophy, various toxic paralyses, and insanity. According to the last census report, persons engaged in literary and professional occupations suffer relatively more from nervous diseases than do all the other classes. Thus medical men show the largest number of deaths due to nervous

Digitized by Microsoft®

www.libtool.com.cn

diseases. The nervous disturbances due to toxic influences will be treated later.

The Fatigue Neuroses.—These neuroses, also called "functional impotences," are directly due to various occupations. They manifest themselves in loss of motor, sometimes of sensory, power of some organs or groups of muscles; this loss being due to the continuous, prolonged, and excessive use of the same. Causes which predispose to these neuroses are weakness of the nervous system, alcoholism, excessive use of tobacco, mental anxiety, and trouble. According to Oliver[3] the primary seat of the disorder is situated in the cortex of the brain, and he adds that "altered nutrition of the cerebral nerve centres is in all probability responsible for the defective muscular movements; and that the spasm is only the initial fact in the illness." The most common fatigue neuroses are "writer's cramp" or "scrivener's palsy," telegrapher's spasm, as well as the spasms which occur in typesetters, milkers, hammermen, piano players, violin players, etc.

Eye Diseases.—The eyes frequently suffer from effects of occupation. Injury to the eyes may come from a too prolonged close application and straining; from exposure to excessive light or heat; from various dusts; from gases and poisons; from burns and accidents.

Overuse and close application and overstrain produce pain, asthenopia, myopia, presbyopia, and other changes in refraction. Clerks, copyists, engravers, draughtsmen, watchmakers, proof-readers, etc., are those who overstrain their eyes.

Certain occupations which compel very close application with accompanying constrained positions cause *nystagmus.* This disorder of the eyes is chiefly due to the constrained position which some laborers are compelled to assume during their work, and is very frequent in coal miners, five per cent. (according to some authorities, ten per cent.) of whom are afflicted with it; although workers in other trades, such as compositors, metal rollers, etc., are sometimes affected. The comparative frequency of nystagmus among coal miners is due to the unnatural positions assumed by them when undercutting in coal seams, lying on their sides, and straining the eyes in order to follow the pick.

Exposure to excessive light and heat is frequent among certain trades, as those of silver finishers, burnishers, furnace-workers, glass-blowers, electric welders, etc. In some of these occupations, notably in electric welding, the temperature may reach 3,000° F. and over. Conjunctivitis, hyperæmia, hyperæsthesia of the retina are common among this class of workers. Glass-blowers are said to be subject to cataract formations. Those who work in dusty trades very often suffer mechanical injuries to their eyes, owing to accidental and frequently unavoidable entrance of gritty, sharp dust particles into the eyes.

The effects of certain gases, fumes, and poisons on the eyes are well known, and cannot be gone into here. All strong irritants will affect the eyes and produce various diseases in them. Certain toxic substances cause various amblyopias.

Burns and accidental injuries are very common in many industries. Of 18,644 accidents to 25,000 workers, nearly 1,000 were injuries to the eye.[4]

Dermatoses.—Many affections of the skin are directly due to certain conditions in occupations. Thus, the skin is liable to scalds and burns, to the mechanical action of various dusts, to the action of poisons, of irritating gases. Constant pressure and friction will also cause abrasions or callosities. The dermatoses vary in their extent and severity from a simple erythema, to vesicles, pustules, and ulcerations. Occupational eczema is frequent. Scalds and burns are very frequent in some occupations. Dust, mixed with perspiration, will form crusts, which irritate the epidermis, causing itching and erythema, and leading to subsequent infection and more serious lesions. Flax workers very commonly suffer from severe eczema of the hands and fingers. Lead, arsenic, and other poisons produce severe skin affections. Certain workers who are obliged to scrape hides with their fingers suffer from a form of disease of the nails, called "furrier's nails."

The constant friction and pressure on circumscribed places of skin produce thickenings, callosities, and bursæ. These vary in location according to the special character of the work and the parts of body exposed to the pressure and friction. The hand and fingers are the most frequent places of callosities, the knees and olecranon the most frequent places for bursæ.

Cardiac and circulatory diseases owe their origin among workers to excessive strain and muscular effort, the lifting of heavy weights, the strain at too arduous tasks, excessive variations in temperature, etc. Cardiac hypertrophy and dilatation are frequent among athletes, professional pugilists, gymnasts, etc. Disorders of the circulation also depend on alcoholism.

Diseases of the digestive tract, unless caused directly by absorption of certain poisons, like lead, arsenic, etc., are mostly due not to the occupation, but to the poor hygienic conditions under which so many of the workers are compelled to live.

Of the *surgical* diseases, apart from wounds, fractures, and dislocations, occupations may cause hernias, varicose veins, aneurisms, etc.

Infectious Diseases.—There are a number of maladies which are frequently observed in certain occupations,—maladies which are due to infection by pathogenic organisms that happen to cling to the materials of work. All forms of microbes can be at times found in various substances and materials handled by workers. Thus, the microbes of scarlet fever or of typhoid fever may cling to the materials handled by the tailor; gardeners, who are obliged to handle earth, are more liable to contract tetanus; the men who care for horses are almost the only ones who become infected with glanders; the tunnel workmen are specially liable to anchylostomiasis, the wool workers to anthrax, etc. The infection by the last two has been regarded as closely connected with the occupation, although they can hardly be regarded as occupation diseases.

Anthrax.—This is a disease of cattle, induced by the action of the bacillus anthracis. As it forms the subject of an extended article in Vol. I. of this HANDBOOK, it is not necessary that I should enter into any further details in this place.

Anchylostomiasis (maladie des tunnels).—This is an infective disease from which many workers in tunnels of Belgium, Switzerland, Australia, and other places have been found suffering. In one pit in the province of Liège from fifty to sixty-nine per cent. of all workers, and in a Hungarian pit eighty per cent. of all workers, were affected. This malady, of which a pernicious anæmia is the most characteristic sequel, is caused by a minute parasite which fixes itself in the upper part of the small intestine by a number of hooklets and sucks the blood. The disease has been found in others beside tunnel workers. The infective parasite is found in the excreta, from which the infection recurs. Defective sanitary arrangement in the places of work and the lack of care and hygienic supervision are the causes of the spread of this disease, which will disappear whenever better hygienic conditions are established in tunnels.

Of the other industrial diseases, it remains to mention caisson disease and several minor affections, such as "shoddy fever," "glass-blower's mouth," "stamp-licker's tongue," etc.

Caisson Disease.—This term is applied to a group of symptoms the pathology of which is obscure, and which are met with in workers in compressed-air chambers in sinking mines, in excavating for piers for bridges, and in building foundations in boggy soil for large structures. The danger to the workers seems to be greater on going out of the compressed-air chamber into the decompression room than on entering or working in compressed air. The usual symptoms of the disease are vertigo, buzzing in the ears, vomiting, muscular pain, numbness in the legs, unconsciousness, followed, not rarely, by sudden death. The danger is greater the greater the air

Digitized by Microsoft®

pressure and the quicker the entrance of the worker from the compressed air into the decompression chamber; also when the workers are compelled to climb stairs and undergo cardiac and muscular strain soon after coming out of the compressed-air chamber. Oliver[3] thinks that caisson disease is due to increased solution of gases in the blood and sudden liberation of them, and regards the symptoms as due to the increase in carbonic acid. Not all workers exposed to compressed air suffer equally, and there are some who entirely escape harm. In the building of the St. Louis bridge, where the pressure was sometimes as high as from four to six times the normal, there were twelve fatal cases. In the building of the Brooklyn Bridge the fatality was less.

"Shoddy fever" is an influenza-like infection which is met with in workers in rags and shoddy garments. It is due probably to infection with some bacterial organism.

"Glass-blower's mouth" is a swelling of the parotid gland extending from the angle of the mouth to below the ears, and is met with in glass-blowers.

"Stamp-lickers' tongue" is a stomatitis sometimes met with in those who lick labels and stamps, and is due to infection.

The Factors of Occupation.

The relative increase in the mortality and the greater frequency of disease in certain occupations are in a great part due to the complex group of phenomena which we call occupation, and which is composed of a number of factors, each of which has its own special bearing upon life and health. The primary factors of occupation are: the worker, the place of work, the conditions of work, and the processes of work. These primary factors are composed of several minor factors, each of which may play an important rôle in the causation of sickness and may influence the duration of life. A more or less detailed analysis of each factor is necessary to the understanding of the *modus operandi* of industrial influence on health.

The Worker.—The primary state of health, the hereditary "physiological wealth," the physical normal development of all organs of the worker, are fundamental elements in all subsequent influences of occupations on health. Some occupations can be followed only by the very strong and exceptionally robust, while others attract the weakling and the feeble only. The susceptibility of the worker to the injurious elements of his trade and his relative predisposition to succumb to the noxious elements or processes of occupation will greatly depend on his primary condition of health before entering the trade which he has chosen as his life profession. The greater the capital of health the worker takes with himself when starting on his vocation, the greater will be his resistance to the dangerous features of his work; the weaker the worker, the more surely will he be affected by any and all detrimental elements. A perfect eyesight, hearing, and other physical faculties are therefore absolutely paramount conditions of normal occupation. But not less than these are also the habits and the care the worker takes of his life and health while at work. Carelessness in the handling of machinery will result in accidents to limb and life; personal uncleanliness in mine, factory, and shop will be followed by the relatively sooner ingress into the system of deleterious dusts, etc. Similarly, the worker will be affected by too great addiction to alcohol. The excessive heat or cold, the relatively great dryness or too great humidity of the place of work, the foul and dusty atmosphere, the difficult tasks, the arduous labor, the strain and tension of machine work, the worry and fear of the relentless mechanical powers, and the thousand and one demands on the muscular and nervous functions of workers all tend to the creation of a special need and a craving for some stimulating and bracing drug, which is furnished by the ever-present and readily obtainable alcoholic beverages. The use, however, of alcohol leads very often to its abuse, and the excessive drinking of alcoholic liquors is bound, sooner or later, to produce pathological changes, and injuriously to influence the health of the worker. The state of the blood-vessels in alcoholics, and their relatively greater susceptibility to pneumonia and other acute diseases, as well as to chronic digestive and liver troubles, are well known. There are several special trades which are known by their tendency to favor alcoholism in the workers. Brewers, bakers, drivers, innkeepers, bartenders, glass-workers, workers in the iron and steel industry are notoriously addicted to alcohol.

Sex and Age.—In many industries child and female labor is very largely employed; and the effect of work on them is very detrimental to health. The injurious influences of female labor are due to the following factors: (1) The comparative physical weakness of the female organism; (2) the greater predisposition to harmful and poisonous elements in the trades; (3) the periodical semi-pathological state of health of women; (4) the effect of labor on the reproductive organs; and (5) the effects on the offspring. As the muscular organism of woman is less developed than that of man, it is evident that those industrial occupations which require intense, constant, and prolonged muscular efforts must become highly detrimental to their health. This is shown in the general debility, anæmia, chlorosis, and lack of tone in most women who are compelled to work in factories and shops for long periods.

The increased susceptibility of women to industrial poisons and to diseases, has been demonstrated by a great number of observers. The female organism, especially when young, offers very little resistance to the inroads of disease and to the various dangerous elements of certain trades. Hirt[5] says, "it must be conceded that certain trades affect women a great deal more injuriously than men," and he mentions, among others, the effects of lead, mercury, phosphorus, and other poisons. Even where there are no special noxious elements, work may produce, as already mentioned, harmful effects on the health of women; but when to the general effects of industrial occupation are added the dangers of dust, fumes, and gases, we find that the female organism succumbs very readily, as compared with that of the male. Shuler[9] found that the frequency of sickness in females, under eighteen, as compared with that of men of the same age, is as 174 to 100. Miss Mary E. Abrahams[9] found that out of 138 lead-poisoning cases in Newcastle, where the number of men and women workers was about the same, there were 94 cases among the women to 41 among the men. She also found that out of the 23 deaths from plumbism, in the years 1889–1892, 22 were women and only 1 was a man. The women were all between seventeen and thirty years of age. These figures are substantiated by Hirt, Arlidge, C. Paul, Tardieu, and others. The predisposition of women in industrial occupations to disease in general is greater than it is in men, as was proven by Hirt in his statistics of tuberculosis among workers. The effect of work on the physical development of women was found to be very detrimental, especially when they were young. Arlidge[3] says that in those who from their youth work in high temperatures, the bones and joints are imperfectly developed, and that they are liable to female deformities and to narrow pelves. Herkner[9] found in his studies of Belgian female workers that girls who are engaged in mines suffered from deformed joints, from deformities of the spinal column, and from narrow pelves.

It has been estimated that out of every one hundred days women are in a semi-pathological state of health for from fourteen to sixteen days. The natural congestion of the pelvic organs during menstruation is augmented and favored by work on sewing-machines and other industrial occupations necessitating the constant use of the lower part of the body. Work during these periods tends to induce chronic congestion of the uterus and appendages, and dysmenorrhœa and flexion of the uterus are well-known affections of working girls.

The effect of work on the offspring is known to be injurious in female workers. Abortion is very frequent

Digitized by Microsoft®

among female workers, especially when they work in certain dangerous trades. Of one thousand pregnancies among lead workers, reported by Tardieu,[3] six hundred and nine ended in abortions. Arlidge also found the percentage of abortions among female workers in the pottery trade very high.

www.libtool.com.cn

As far as the effect of female work on infant mortality is concerned, it has been shown to be detrimental. The rate of infantile mortality among mirror workers is, according to Hirt, sixty-five per cent. Tardieu and C. Paul found, among lead workers, an infant mortality of forty per cent. According to Greenhow, the "infantile mortality is due to the unwholesome influence to which infants are exposed in the manufacturing town by the industrial employment of married women."[3] Traces of lead, phosphorus, copper, aniline, etc., have been found in the amniotic fluid.

What has been said about the influence of industry on young women can, in some degree, be applied to child labor in general. The effects of industrial occupation on children can be summed up as follows: injury to the weak organism; the stunting or arrest of growth and physical development; the production of deformities in bone, joints, and spinal column; a dulling of mental faculties; the acquirement of a predisposition to moral obliquity; a lessening of the normal powers of vital resistance; a general deterioration of the constitution and a shortening of life by various diseases. Child labor, beyond all doubt, is the greatest curse of modern industry. The influence of child labor on the general health of the community has been demonstrated by the figures of Layet (quoted by Tracy [10]), which show that out of 10,000 conscripts from ten agricultural districts 4,029 were rejected, while in selected manufacturing districts the rejections for rachitism and small stature reached 65 per cent. of the whole number of conscripts.

The Place of Work.—The place where work is done bears an important relation to the health of the workers. Work is performed either indoors or outdoors; the former being pursued in factories, workshops, and homes. It was Dr. Guy who classified all occupations into two primary divisions—"indoor" and "outdoor," and proved that the latter were much healthier.

There are, however, some special occupations which can be classed among dangerous trades. I refer to *mining* and *tunnel work*, which are dangerous to life, limb, and health by reason of the nature of the work, and also on account of the conditions under which they are carried on. The harmful conditions in mining and tunnel work are the following: absence of natural light, foul air, great heat, increased air pressure, too great humidity, dangers of the lifts, of haulage, and of the winding machinery, etc.; the use of explosives, the danger of cave-ins, falls of rocks, etc.; sudden inundations by water; danger of fires from the various gases; the constrained attitudes, the arduous toil, the tension, danger, and worry. All these conditions, apart from the processes of mining and the character of the ground, are potent factors in the great morbidity and high mortality rate among miners and tunnel workers. Surgical diseases are very frequent, owing to the great number of accidents; and among the general diseases favored by work underground are lumbago, rheumatism, diseases of the respiratory, digestive, and circulatory organs.

Factories are places where work is done by the aid of mechanical power; a *workshop* is a place where work is done without any mechanical power. Thus a tailor shop, where the sewing-machines are run by steam or electricity, is a factory; while one in which only foot and hand power are used is a workshop. The sanitary features of the work place, the lighting, ventilation, cleanliness, and the absence or presence of sanitary conveniences all affect the health of the workers. The proper light of workshops and factories is important to the eyesight as well as to the general health of the operatives. A dingy, dark workshop favors not only eye strain, but also general uncleanliness and ill health. The window area of the shop is also of consequence, as is also the nature of the illuminant at night. The air in workshops and factories is usually very foul, owing to the overcrowding of the places and to the lack of proper ventilation. A person at work needs more fresh air than one at rest, because he consumes more oxygen and exhales more carbonic acid and organic impurities. The constant inhalation of foul air acts detrimentally on health, superinduces lack of tone, muscular debility, and anæmia, as well as a predisposition to respiratory diseases and tuberculous infection.

According to Roth [11] the worst workshops are those of shoemakers and tailors. In an investigation made by him it was found that many shoemakers' shops had 7 cubic m., some even less than 3 cubic m. of air space. He also reports that von Rozahegi found in printing shops 4.2 per 1,000 of carbonic acid. In some cotton factories the percentage of carbonic acid was found to be 0.15 per cent. The sanitary care taken of the premises is important, when we remember the large amounts of dust, waste material, and noxious elements which are to be found in workshops. The absence of a proper water supply, of a sufficient number of plumbing fixtures, washrooms and lunch rooms, and of bath and toilet accommodations is also an important factor in rendering the place of work unhealthy for the operatives.

The effects of *home work*, or, as it is termed, "*sweatshop*" work, are due partly to the defective sanitary conditions of the homes where the work is done and partly to other causes. The special dangers of sweatshop work are the following: Increased tendency to child and female labor, the whole family commonly participating in the work; the constant breathing of a confined, foul atmosphere, without the beneficial changes of travel to and from outside places of work; living, cooking, and sleeping in the workroom; the tendency to prolonged and excessive work; the effects of dust, etc., on the children of the home worker; and the danger of infection by the material of work, as well as that of spreading infection from the homes of the workers into places to which the articles manufactured in these homes are sent. The health of sweatshop workers is below the average.

Conditions of Occupations.—To describe here all the possible conditions of various industries and occupations and their effect on health is obviously impossible, and I shall therefore confine myself to a brief consideration of a few of them, and especially of the effects produced upon the workers by such factors as climate, light, air pressure, strain, mental worry, etc.

The healthfulness of *rural* occupations compared to those carried on in *cities* is attested by the lower comparative mortality of agricultural laborers, fishermen, and other outdoor workers, and is due to the abundant clean air, the active life, and the absence of the evils of overcrowded cities. *Active* occupations are healthier than *sedentary*, on account of the greater muscular activity, the more vigorous processes of metabolism, and the unconstrained positions of the workers. Those who are compelled to engage in prolonged sedentary work suffer from digestive disturbances, congestion of the portal circulation, deficient oxygenation, weakness of the muscular system, predisposition to respiratory diseases, and a general low vitality. Among the sedentary workers showing large mortality and morbility are clerks, bookkeepers, literary persons, engravers, tailors, shoemakers, etc.

The evil effects of *exposure* to extremes in climate are attested by the many writers on life and industrial occupation in the tropics. Insolation, extreme muscular and nervous debility, predisposition to infectious diseases, etc., are some of the evils which are encountered in tropical countries. Soldiers, convict laborers, and others who are compelled to do arduous labor in hot climates are especially prone to become affected with these diseases, and their mortality is high. The effects of exposure to extreme cold and inclement weather, as well as those of exposure to extremely high temperatures, are well known. Boatmen, fishermen, drivers, motormen, and others are compelled to work in all kinds of weather,

Digitized by Microsoft®

and are prone to congestions of internal organs, respiratory diseases, rheumatism, and catarrhal affections. Bakers, cooks, blacksmiths, engineers, firemen, stokers, sugar refiners, furnace workers, electric welders, and others suffer from the effects of too high temperatures. Muscular exhaustions, thermic fever, muscular debility, respiratory diseases are some of the effects of a prolonged exposure to great heat. Andrew[8] reports the case of a child who had almost universal paralysis after exposure to great heat in the railroad cars; and several cases of insanity (firemen's frenzy) have also been reported, due to the same causes. Blacksmiths are exposed to direct radiant heat, and are predisposed to respiratory diseases. Oliver[3] says that a great many blacksmiths die from phthisis. He quotes Ogle's tables, showing that "out of 872 deaths of blacksmiths, 194 died of consumption, 183 of other lung diseases, 108 of diseases of heart and circulation, and 85 of diseases of the nervous system." In a number of industries the processes employed expose the men to extremely high temperatures; this is notably the case in the drying rooms of chemical works, in the furnace rooms of the glass and iron trades, in certain deep mines, etc.

Overstrong, radiant, and *glaring light* is met with in the iron and steel industries, in glass furnaces, in engine and forge rooms, and in electric welding, and is very injurious to the eyes and to the general health.

The excessive *relative humidity* of many places of work, while not a direct cause of disease, predisposes to rheumatism, catarrhal conditions, and congestions of the internal organs, and to diseases of the respiratory apparatus. H. Wolpert,[12] after an exhaustive investigation of the effect of various degrees of humidity on the health of workingmen, came to the conclusion that "on the whole, the normal degree of relative humidity in a workroom is when there is no formation of perspiration,"—a degree which is hardly obtainable in most industries. The trades in which the relative humidity is very great are, among others, mines and tunnels, all underground work, textile factories, where steam is introduced in the "sizing" rooms, bath-houses, etc.

Variations in the normal *pressure* of the *air* are indispensable conditions in several occupations. Aëronauts and mountain miners and climbers breathe rarefied air, and suffer on account of the lack of oxygen and diminution of air pressure. Divers, tunnel workers, caisson workers are exposed to an increased air pressure, and are liable to suffer from caisson disease, described above. Those who are subject to violent jarring and concussions in air, such as boiler-makers, blasters, and workers with explosives, are subject to deafness.

The *position* maintained while at work and the *attitude* which the worker is compelled to assume in each trade are not without effect on health. Salesmen and saleswomen in stores and shops and operatives in factories are frequently compelled to be on their feet all the time of work, and as a result the men suffer from varicose veins, and hemorrhoids, and the women from congestion in the pelvic organs. The bending and constrained attitude assumed by shoemakers, copyists, tailors, seamstresses, etc., cause defective development of the chest, deficient oxygenation of the blood, and predisposition to respiratory and other diseases. The constrained attitudes which coal miners are compelled to assume while "kirking" or undercutting the coal seams result in nystagmus, described above.

The *duration* of work is a potent factor in the effects of occupation on health. The normal physiological activity of the body functions is conducive to health and longevity; but the overuse and abuse of one or more organs or the whole body are bound to produce general ill health or special injuries. The standard of normal activity varies with each individual, as well as with the different kinds of labor and conditions under which it is carried on. The most correct standard will be that which is based on the sense of fatigue experienced by the worker; and we may assume that, under normal conditions, work becomes harmful when the worker feels greatly fatigued, and very injurious if the fatigue is pushed to the point of exhaustion. When in a state of great functional activity our organs draw a relatively large supply of blood and produce, as well as eliminate, a greater proportion of waste matter, in the form of carbonic acid, urea, aqueous vapor, organic matter, etc. The result of overfatigue is a retention of waste matter and consequent auto-intoxication. Hence the injurious effects of too prolonged work and of a work day of too great length.

The effects of the duration of work will, in part, depend on the *tension* and effort with which the work is done. When the work requires too great effort and is done under special tension, the worker will sooner reach the state of fatigue than he otherwise would. Carrying heavy loads and lifting great weights require special muscular strain, and may produce hernias, and cardiac dilatation; they also predispose to aneurisms, rupture of tendons and muscles, dislocations, etc. The excessive use of one muscle, organ, or group of muscles leads to their eventual injury. Thus, engravers, watchmakers, writers, tailors, etc., suffer from eye-strain; athletes, gymnasts, hammermen, etc., from hypertrophy of muscles and cardiac affections; speakers, preachers, exhorters, etc., from vocal strain.

The *pauses* in the workday have a great deal to do with the fatigue effect of occupation, for the reason that periodical rest is needed for all organs in a state of activity. It is a fact, that more work is accomplished with several pauses in the working day than when work is continued without pauses. After a prolonged rest, more may be performed in one hour than in several hours at the end of the working day; and the work of the latter part of the day is, as a rule, not so good as that done during the earlier part of the day. In some countries, notably in Russia, the workday lasts for from fourteen to sixteen hours, but there are several pauses and they are quite prolonged (the dinner pause lasting one hour and a half); as a result the workingmen feel less fatigue than when the workday covers a period of nine hours, with only a half-hour's midday pause.

The practice of carrying on the work in mills and factories continuously, by means of a day shift and a night shift of workers, is harmful, first, by reason of the bad air that is to be found in a constantly occupied place, and, secondly, by the bad effects of night work on the general health. Night watchmen, clerks, and all those who are compelled habitually to work through the whole night and sleep during the day, are not, as a rule, in as good health as are the day workers.

A number of occupations are *hazardous* by exposure of the workers to the risks of accidents to life and limb. Roofers, painters engaged on the outside of buildings, bridge builders, etc., are liable to injury and death from falls. Furnace workers, chemical workers, etc., are exposed to the danger of burns. Miners, workers with explosives, etc., are liable to injury by the falling of rocks, by explosions, fires, etc. Factory and mill employees, working near or about machinery, are liable to injury from the engines, belts, running gear, cogs, shafts, etc. Altogether, many trades are pursued under conditions which are extremely dangerous to the worker.

There are a number of occupations which are characterized by the *mental worry* and nervous strain to which those engaged in them are subject. Thus, stock brokers, gamblers, merchants, superintendents, and heads of large industrial and commercial interests, etc., work under prolonged mental and nervous strain, and often break down in the midst of their work.

Compensation.—The wages received by the workers for their labor exercise great influence on their life and health. On the rate of compensation greatly depend the hygienic surroundings of the worker, his personal comfort, his habitation, his proper clothing, and the quality of his food. The physical health of the worker largely depends upon these factors, and they in turn depend on the rate of compensation. As a rule, workingmen who get better wages live better, enjoy better hygienic surroundings, and are in better health. Continen-

Digitized by Microsoft®

tal workers, who receive only a paltry wage, and are unable to afford decent dwelling-houses and sufficient food, are in a bad state of health when compared with American workingmen, who receive higher pay.

The Processes Employed in Different Occupations.—The chief element of danger in most trades lies in the processes which they employ, these often evolving substances or fumes which are more or less dangerous to health. Hirt bases his classification of the different trades upon the three principal harmful elements—viz., dusts, poisons, and gases. This classification, while not without its objections, is still the best for our purposes.

Trades Dangerous to Health on Account of the Dust Produced.—There are a number of industries in which large quantities of dust are produced. This dust being inhaled by the operatives becomes a source of danger to their health, the respiratory organs being the greatest sufferers, although dust may also produce gastro-intestinal disturbances and certain eye affections as well as dermatoses. The various kinds of dusts act alike, in a general way, differing very slightly, according to the form and quality of each. The first effects of dust inhalation are irritation and inflammation in the respiratory passages, the nose, throat, and bronchi, and if the inhalation is allowed to go on for a certain length of time the inflammation is likely to become chronic (chronic bronchitis and emphysema). The deposit of dust in the small bronchioles, and frequently in the parenchyma of the lung, superinduces inflammatory reaction in the lung tissue, followed by connective-tissue formation and sometimes by consolidation in nodules and distinct areas. The later stages of the pneumonokonioses are characterized by degenerative changes in the nodules, and in the other areas where the dust is deposited. Indeed, modern pathologists are of the opinion that "coal-miner's phthisis," "grinder's asthma," "potter's rot," and the other pneumonokonioses are, in their last stages, but tuberculous infections.

Coal Industry.—Coal miners who commonly inhale large quantities of dust are subject to respiratory diseases—to bronchitis, emphysema, and anthracosis. Coal dust has been found in the lungs of miners, and the quantities are sometimes very great. The initial symptoms are those of a catarrhal inflammation of the respiratory passages, accompanied by cough, black sputum, dyspnœa, and in a large percentage of cases by symptoms of emphysema. A time comes, however, though not in all cases, when the symptoms become aggravated, and general constitutional disturbances are seen which are due to degenerative changes and processes in the lung tissue. Merkel, Arlidge, Rindfleisch, Olge, Oliver, and others are of the opinion that the later stages of anthracosis are not necessarily tuberculous, although the analogy seems characteristic. Indeed, it is claimed by them that coal miners are particularly free from tuberculosis. Coal miners are subject, during their work, to many insanitary conditions besides dust inhalations. To mention only a few of the dangers of coal mining would be to repeat all the conditions of work, the dangers of which have already been described in a previous section of this article. Burnt coal or soot seems to possess specially irritative qualities. At least, it is a fact that charcoal burners and chimney-sweeps are great sufferers from pulmonary tuberculosis. Chimney sweeps also suffer from cancer of the scrotum, "chimneymen's cancer," an affection quite frequent in chimney-sweeps in England, although rarer in the same workers in other countries.

Iron and Steel Industry.—The effects of inhaling iron dust are not quite the same as those which result from the inhalation of coal dust. In the first place, iron dust undergoes absorption and oxidation to a greater or less degree in the lung tissues. Thus Zenker and Merkel both found in the lungs of iron workers large deposits of iron oxide; in Merkel's case 7.1 per cent.[7] Then, in the next place, the particles of iron dust often wound, with their sharp corners, the delicate bronchial mucous membrane, and thus open the way for infection with pathogenic bacteria. The branches of the iron and steel industry, especially harmful on account of dust, are those in which polishing and grinding are done. Thus cutlery workers, needle makers, and grinders of steel articles are inhaling large quantities of metallic dust, and are very much subject to respiratory diseases, and particularly pulmonary tuberculosis. Dry grinding is the most injurious process in cutlery work. Lloyd[8] quotes Holland, who says "that the average age of grinders is only twenty-five and three-quarter years; and young men of seventeen to twenty years of age, strong and rough from the plough, who engaged in the work died from its effects, as a rule, before reaching the age of thirty." The general mortality ratio of grinders from respiratory diseases is, according to Tatham, five hundred and fifteen to one hundred and fifteen among agriculturists. The mortality figure from phthisis is very high.

Mineral Industries.—Workers who inhale mineral dust, as stonecutters, masons, plasterers, brickmakers, diamond grinders and polishers, porcelain makers, pottery and china workers, etc., are subject to chalicosis pulmonum, a term applied to the pathological condition which is produced by a deposit of mineral dust in the lung. The deposit of these dusts has been demonstrated by chemical analysis. Meinel and Malpert found that such lungs contained immense amounts of silica, silicic acid, phosphate of lime, and sand.[10] The quantity of dust in the above-named trades is very large. Thus Oliver[5] quotes Lamaister, who analyzed the air in the Limoges potteries, and found "that the dust is composed of earthy particles and fragments of granite, flint, glaze, soot, and charcoal. The atmosphere which the brushers-off, the finishers, and the porcelain makers generally work in contained 640,000,000 of dust particles to the cubic metre, while in some of the rooms the number reached 680,000,000 per cubic metre." That the breathing of air laden with such quantities of dust is injurious is self-evident, and the mortality rate of these workers from respiratory diseases is very great. Hirt found the average life of stone grinders to be forty-two and a half years. The mortality rate of potters is the highest; but this is due to the fact that potters are also subject to plumbism. The number of trades in which mineral dust abounds is very large.

Textile Industries.—Workers in textile industries are subject to inhalation of organic dust, animal and vegetable. Among the textile trades which are unhealthy on account of dust are those which deal in flax, linen, cotton, jute, silk, wool, and hair-working. The dust in each of these branches of the textile industry differs from that of any other industry in some of its features, but retains its irritating qualities in common with all dusts. Besides the effect on the respiratory system, these dusts seem to be very irritating to the skin, producing various dermatoses. Those who clean and work at the crude materials are compelled to inhale more dust than the spinners and those who work at the later stages of manufacture. Greenhow found that out of one hundred and seven flax spinners seventy were affected with respiratory diseases.

Cotton workers are said to suffer from "pneumonic cotoneuse," a form of pulmonary tuberculosis due to the irritating dust habitually breathed by the operatives. As in other textile industries, those who work at the crude material suffer the most from dust. Cotton dust is also said to be very irritating to the skin, producing dermatoses.

Silk workers are prone to tuberculous affections, and to all respiratory diseases. Thus, in one silk spinnery in Sagrado the percentage of respiratory disease was twenty. Netolitzky[1] quotes Combassedes, who on examination found 760,000,000 of particles of dust per cubic metre in the work-rooms of the silk mills. He says that silk workers suffer from respiratory and digestive diseases, and from anæmia, and that they present a very high death rate.

Wool workers are exposed to animal dust, and also to the danger of infection by any pathogenic organisms which may cling to the animal substances, such as hair, wool, hides, etc. Anthrax is the principal infectious dis-

Digitized by Microsoft®

ease afflicting woolworkers. The effect of dust inhalation is seen in the large number of cases of sickness from bronchitis and other respiratory diseases. Furriers very frequently suffer from what is called "furriers' asthma," the symptoms of which, however, are due not so much to the effects of dust inhalation as to the various poisonous dyes used in coloring fur.

www.libtool.com.cn

The inhalation of *wood dust* is claimed to be without any effect, although Merkel states that workers in pencil factories, who inhale large quantities of dust formed in the processes of sawing the wood for the pencils, suffer very much from phthisis. Carpenters, sawmill workers, etc., are exposed to wood dust.

Tobacco dust, in tobacco, cigar, cigarette, and snuff manufactories, acts on the worker mechanically, also chemically, by reason of the nicotine contained in it. There is a tendency among writers on the subject to deny the evil effects of tobacco dust on the operatives. This is hardly true. There is abundant evidence that cigar, cigarette, and snuff workers suffer greatly from respiratory diseases, as well as from anæmia and digestive disturbances.

Flour dust has always been regarded as peculiarly injurious to those who are compelled to inhale it. Millers, bakers, and confectioners, but the first especially, have been stated as having the highest death rate among workers in non-poisonous dusts. Of 108 cases of sickness among millers, Shuler[3] found 34 cases of respiratory disease, 12 cases of tuberculosis, 19 diseases of the skin, 17 of the digestive organs, 4 eye diseases, and 3 of circulatory system. In the modern forms of flour milling the greatest part of dust production is done away with, and the effect of flour milling is not very harmful to the workers. Those who are exposed to the inhalation of *mixed dust*—for instance, street cleaners, carpet sweepers, carpet beaters, etc.—are liable to bronchial affections. In Hirt's tables mixed dusts show a larger percentage of all respiratory diseases than do most of the other dusts.

Trades Dangerous to Health on Account of Poisonous Substances.—There are a large number of trades, the chief element of danger in which consists in the poisonous nature of the materials and substances made in the processes of manufacture, etc. As the toxicology of most of these substances is dealt with in other parts of this HANDBOOK, only a very brief description of their effects upon the health of the workmen will be given here.

Arsenic.—Arsenic in its various forms is used in medicine and the arts for many purposes. It is employed for preparing dyes for textile fabrics and for coloring artificial flowers; it is an ingredient in many forms of wall paper, and is used in carpet manufacturing; it is sold as an animal and parasitic poison, and is used in many other ways and in combination with various substances. All persons manufacturing articles in which arsenic is employed are subject to arsenical poisoning. Arsenic affects the skin, gastro-intestinal tract, respiration, and especially the nervous system. On the skin the effects of arsenic are seen in the eczematous eruptions and various vesicular and pustular sores. On the respiratory passages arsenic acts as an irritant, and causes a catarrhal condition of the nose, throat, and bronchi. In the gastro-intestinal tract arsenic causes severe irritation, anorexia, diarrhœa, colic, gastritis; and among the nervous disorders which it produces may be mentioned a general diffuse multiple neuritis, progressive muscular atrophy, loss of tendon reflexes, local anæsthesia, trophic sores, and ataxia. Not all who are exposed to arsenic suffer equally from its effects. A large number of workers in arsenic seem to enjoy a peculiar immunity from its toxic effects. As an example of such immunity I can cite a patient of mine who for the last eight years has worked in a paint manufacturing establishment, packing Paris green in boxes, for from ten to sixteen hours a day, and seemingly he has good health all the time; while new men, who were engaged to assist him in his work, usually showed signs of toxic effects of arsenic within a very short period after exposure to the atmosphere full of arsenical dust.

Lead.—Lead is the most widely and largely used metal. The number of its uses can hardly be stated; indeed, the trades and arts in which lead is not employed, in one or another form, are not very many. Hence a very large contingent of workers are exposed to plumbism. The mode of introduction of lead into the system is through the lungs, digestive tract, and skin. Lead dust is prevalent in most places where it is used. Lead is ingested in the form of dust or through the medium of the particles which cling to the hands, fingers, and person of the worker. Its absorption through the skin is slight. Among the trades in which the workers are exposed to the danger of plumbism are the following: Lead miners, white-lead workers, lead-paint manufacturers, painters, potters, calico printers, compositors, pressmen, stereotypers, linotypers, printers, plumbers, filemakers, platers of iron and makers of hollow ware, solderers, makers of lead toys, vessels, etc., glazers of cards, paper, etc., and a very large number of other trades into which lead goes in some of its forms. The effect of exposure to lead is not the same on all workers. Women and children are especially prone to plumbism. The effects of lead poisoning are seen in the anæmia, cachexia, metallic taste in the mouth, vomiting, constipation, lead colic, bluish line along the margin of the gums, retraction and ulceration of the gums; but the most marked effects are those on the nervous system. There are a loss of motor power in the hands and feet, wrist drop, progressive muscular paralysis, multiple neuritis, temporary and sometimes permanent blindness, convulsions, insanity. The mortality of lead workers is very great. Tatham[3] says it is ninety per cent. above that of other workers, and three times greater than that of agriculturists. Of the total deaths which occurred among lead-workers, one-fourth were due to pulmonary tuberculosis, one-eighth to lead poisoning. Plumbism is especially frequent among those engaged in manufacturing white lead, printers, filemakers, and painters.

Stubler, of Berlin, taking his statistics from the reports of the sick-benefit societies, states that of 3,000 printers in Berlin, 313 were annually sick with lead colic."[3] The analysis of the dust in some printing shops gave nearly 15 per cent. of lead.[3] File-makers also suffer very largely from plumbism. Ogle gives the following statistics of the comparative mortality from lead poisoning, based on the death register for 1879–82, in males over fifteen years of age: File-makers, 466 per million living; painters, plumbers, glaziers, 224; earthenware-makers, 152; gasfitters, 62; printers, 27, and all other males, 4. According to Tatham, the comparative mortality from lead poisoning in the several trades is the following: Males occupied in one manner or another, 1, wool manufacturers 3, cutters 3, printers 3, leadmakers 5, gasfitters, locksmiths 6, coachmakers 7, copper workers 8, glassmakers 12, potters 17, painters and glaziers 18, plumbers 24, filemakers 75, and lead workers, 211.[3]

Mercury.—The effects of mercury upon workingmen who labored in cinnabar mines had been noted as far back as in 1665, when reference to the tremor caused by it was made by Dr. Walter Pope in the Philosophical Transactions.[3] Detailed accounts of the mercurial poisoning of operatives is also found in Ramazzini's work. The industries in which mercury is used, and in which the workers are exposed to the danger of mercurialism, are the following: Cinnabar mining, gold and silver mining, where mercury is employed to form amalgams; the manufacture of scientific instruments, such as thermometers, barometers, etc.; the manufacture of electric meters and lamps, where mercurial pumps are used to create a vacuum; the gilding and silvering of mirrors, etc.; the manufacture of certain paints; the making of pharmaceutical preparations; also the making of felt where the felts are brushed with a solution of the nitrate of mercury. The mode of introduction of mercury into the system is by inhalation of the fumes, or by ingestion of the salts of mercury through deposits on the hands, fingers, clothing, etc. Stomatitis, salivation, gastric disturbances, emaciation, cachexia, are symptoms of chronic mercurialism. The effects on the nervous system are

Digitized by Microsoft®

marked tremors, paralysis, and psychical changes. The tremors and paralyses are noticeable especially in the muscles of the face, hands, and arms. Melancholy, depression, loss of memory, and hallucinations are some of the psychic forms. Kussmaul has shown that mercurialism acts very badly upon women, predisposing to abortions and to diseased conditions of the infants.

Phosphorus.—The danger of phosphorus poisoning is almost entirely restricted to the manufacture of matches from yellow phosphorus. The making of matches from red phosphorus (safety matches) is not accompanied by any dangers. The principal effect of phosphorus is its action on periosteum and bones, the maxillary bones being the most easily affected. A prolonged exposure to the action of phosphorus is necessary before the specific effects of it are noticeable. Some writers claim that phosphorus has no effect on healthy periosteum and bone and that only those who suffer from caries of the teeth and other affections exposing the periosteum of bones to the phosphorus fumes are affected. The disease manifests itself in necrosis and sequestration of the affected bone or of that portion of it which is diseased. The number of cases of phophorus poisoning in the United States is not large. Sweden is the country where most of the match factories are located, and where phosphorus poisoning is most frequently met.

Copper and Brass.—Copper is a metal which is found in a pure state, and which is also procured from various ores. Brass is an alloy of copper and zinc. The mining of copper and the manufacture of copper vessels, etc., are not considered as dangerous as the manufacture of brass and brass articles. It has been said that workers in copper have often found that their hair, urine, and skin turn green. The salts of copper are more poisonous than the metal. Arlidge thought that inhalation of copper dust produces the "copper colic," which is a form of digestive disturbance characterized by pain, purging, vomiting, and prostration. This is denied, however, by later investigators, who assert that the symptoms are due to a mixture of the carbonate of copper and lead.

Workers in brass-smelting and the manufacture of brass articles are subject to inhalation of brass dust and fumes. A general catarrhal condition of the respiratory passages and gastro-intestinal tract results from exposure to brass dust. What is known as "brassmen's ague," which is characterized by chills, fever, cephalalgia, nausea, depression, prostration, and collapse, is thought to be due more to the zinc in the brass than to the copper.

Noxious Gases and Fumes.—The occupations in which perceptible quantities of dust or definite poisonous substances are produced are few in comparison with the numerous industries in the processes of which noxious gases and fumes are evolved. The industrial processes in which chemical agents and gases are produced which, when absorbed or inhaled, may become dangerous to health, are so manifold and diverse that it is absolutely impossible to give even a brief description of them. Nor is it always possible to trace the harm done to health in these chemical industries to any one of the elements or gases prevalent in the process, for in most of these industries various and complicated processes are being simultaneously carried on, and the workers may be exposed to a number of agents and gases at the same time or successively. If we take, as an example the coal-tar color industry, there are several dozens of various agents produced, either together or as by-products, and each of them may be more or less injurious to health; and it is exceedingly difficult sometimes to determine which of them has produced the most harm in the case of any particular individual. So widely do chemical manufactures permeate the whole range of human industries that there is hardly an article or substance made in which chemical processes of some kind do not take place.

Some of the principal agents and gases evolved in chemical trades are the following: Sulphur and its compounds; carbon and its compounds; sodium, sodium chloride, chlorine gas; potassium and its salts, ammonia, ultramarine, carbon bisulphide, dynamite, nitroglycerin and other explosives; chromium, alum, iron and its oxides; lead and its salts; arsenic, copper, zinc, illuminating gas, coal tar and its products, nitrobenzol, the various drugs, india-rubber, turpentine, cyanogen compounds, and many others too numerous to mention.

Most of these agents are used, in one or another form, singly or in combination, in most of the human industries and arts; and many of them are also toxic to a large degree, and injuriously affect the health of those engaged in their production and in handling them.

The effects of the work with noxious agents and gases are either acute or chronic, and the dangers are from (1) the toxicity of the substances; (2) the danger of explosions, burns, and corrosions; and (3) the excessive temperatures which are necessary in most of the chemical processes. The mode of introduction of these noxious agents into the system is somewhat different from that of the dusts produced in other trades; and the effects are also somewhat different. While the inhalation of dust acts chiefly upon the respiratory system, the gases and other noxious agents of the chemical industries have each their own effect, each having specific action, but mostly of a toxic character. Moreover, while dusts affect the human system only after long exposure and continuous and prolonged inhalation, the effects of gases and chemical agents are produced after comparatively short exposures. Again, while the effects of dust inhalations may always be seen on the respiratory system, and at times pathologically demonstrated by the presence of the dust in the lung tissue, the effects of toxic agents and gases cannot, in most cases, be demonstrated, and, if at all, only in the blood, by chemical and spectroscopic examinations.

Roth cites Austrian statistics of mortality and morbility among chemical workers. He found the mortality to be 7 per 1,000. The diseases with which they were affected were distributed as follows: 25.7 per cent. for burns, contusions, and the like accidents; 17.9 per cent. for affections of the respiratory system; 14.7 per cent. for disorders of the digestive tract; 10.8 per cent. for diseases of the skin, and 10.5 per cent. for general constitutional diseases.

Prophylaxis.

Having briefly examined the various dangers of different trades, we now come to the most important phase of our subject, that of prophylaxis; the most important, for, after all, the aim and purpose of hygiene in general, and industrial hygiene in particular, is the prevention of disease and preservation of life. On a closer study of industrial conditions we find that many, if not most, of the dangerous elements in trades are preventable, and that there is no need for the terrible waste of health and vast destruction of life prevailing in modern industries, as shown in the mortality and morbility statistics.

In the endeavor to improve industrial conditions, and prevent unnecessary suffering in the dangerous trades, medicine and legislation are allied: the one to study and expound the rules of health, the other to enforce the laws based on scientific hygiene. Unfortunately, the ignorance of the workingmen and the cupidity and negligence of employers are the two stumbling-blocks to the general acceptance of the better laws of health.

In discussing the hygiene of occupations we propose to consider the subject under two heads—General Prophylaxis and Special Prophylaxis.

General Prophylaxis.—The first personal requirement for preventing the evil influence of occupation on health is the proper selection of a trade; this is commonly done by natural selection, or more frequently by accident; yet it is very important that certain trades be followed only by the best physically endowed constitutions. Were there a medical supervision and control of the selection of trade by individuals, persons of a scrofulous diathesis, with a tuberculous family history, would not be permitted to embrace indoor, inactive, sedentary occupations, and

Digitized by Microsoft®
www.libtool.com.cn

certainly not any in which large quantities of dust must be inhaled; nor would nervous, delicate, choleric persons be allowed to enter industries which subject the workmen to great nervous strain, mental worry, and responsibility, nor those in which they may be exposed to toxic agents which act specifically on the nervous system. Perhaps the proper medical supervision of the selection of a trade is as yet a dream of hygienists, but it is bound to be realized.

www.libtool.com.cn

Already there are legislative enactments in all civilized countries restricting, limiting, and partly prohibiting *child labor*, and the highest aim of hygiene is that no child under eighteen should be allowed, under any circumstances, to engage in any occupation except that of developing its physical and mental faculties.

Female labor is also largely restricted, and even prohibited in some trades; and in many States legal provision is made to limit the industrial activity of women during pregnancy, after childbirth, and in specially dangerous trades.

The *personal cleanliness* of the workers is an important condition in the general prophylaxis of the effects of occupations. It is a fact that in specially dangerous trades, such as printing houses, lead works, etc., and in all industries where poisonous substances are manufactured and manipulated by the employees, those workers who have the least regard for personal cleanliness, who are careless in washing themselves, and who eat their food with hands and clothing full of the toxic materials, are the readiest victims of industrial poisoning; while the more careful often escape all harm. Workers in dusty and poisonous trades should have their hair on face and head cropped short and they should be compelled to observe rigid rules of personal cleanliness, the compulsion being necessary on account of the ignorance of the workingmen and their contempt for the dangers lurking in their trade,—a contempt bred by familiarity.

The wearing of *proper clothing* is an important prophylactic measure in all trades. It must suit the kind of trade in which the individual is engaged. Those who are exposed to low temperatures should wear woollen sweaters or flannel underwear, while workers in high temperatures should wear light absorbing cloth. All who work in damp, moist, and wet places should have their footwear impermeable to dampness, and their clothing should be made of a material which will absorb moisture without letting it penetrate the undercloth. The wearing of rubber-impregnated cloths is inadvisable as it interferes with evaporation of perspiration; mackintosh capes, protecting from moisture and at the same time allowing evaporation, are recommended by some authorities. Persons working in dusty occupations should wear fabrics with smooth surfaces only, and, whenever possible, without any seams, folds, or pockets where dust may accumulate. But the most important prophylactic measure in this respect is that no clothes worn while at work should be taken out of the workplace, but must be exchanged for other clothes which are to be worn only outside the workshop. In some trades the employers are compelled to furnish the workers with two suits of overalls to be worn while at work. In those trades in which corrosive poisons and gases are likely to burn or injure clothing, the worker should wear leather cloth or other not easily destructible material; and wherever the hands come in contact with the same substances leather gloves should be worn. In dusty trades it is advisable to cover the head with closely fitting caps. There are some industries in which the cloth worn is the result of established custom and is usually consistent with hygienic principles. Thus the chimney-sweep's suit, so often seen on the Continent, is very appropriate to his calling, and protects him from contact with the irritating soot.

Duration of Work should be adjusted to the nature of the work and the standard of health of the operatives. Economists agree that there has been no loss of productive capacity since the work day was reduced from sixteen to eighteen hours to the ten-hour-day standard; and owners who frantically struggled against every attempt to reduce the working day, and prophesied the decadence of industry if it was done, have at last come to see that a shorter workday means actually a greater productive capacity and a better state of health in the workers. No universal workday can be established or is applicable to all trades and persons; the length of work should be carefully adjusted to the age, sex, and health of the worker, to the place of work, to the conditions under which it is carried on, and to the character and nature of the processes of each industry. The more unfavorable the conditions under which the work must be carried on, the shorter should be the workday. This is the rule followed in specially dangerous trades; thus, caisson workers are allowed to work for only from two to four hours at a time; furnace workers, or those who are exposed to fumes and gases in lead and other trades, work, as a rule, only in three- to four-hour shifts. The same rule should be applicable to all other trades.

The number and length of the *work pauses* bear an important relation to the health of the employees in each trade, for every physical or mental activity requires periodical relaxation. It has been proven that more work can be done in two hours at the beginning of the workday than in twice that time at the end of the day. In England forenoon and afternoon pauses are required for child workers, besides the usual midday lunch hour. This rule should be adopted for adults also, especially in the dangerous trades. The length of the midday lunch pause should not be less than one hour in any trade, as a shorter pause leads to carelessness and haste in cleaning up, to high speed of food consumption, and to failure of the worker to go outside of the shop for a short breath of fresh air.

Night work is more unfavorable to health than work during the day, and, whenever this is practicable, such work should be restricted; at any rate, the working hours should be comparatively shorter and the pauses longer and more frequent than in day work, and there should also be periodical changes between the day and night shifts, so that those who for one period are engaged during nights should at other times be working by day.

Overwork leads to ill health and to fatigue neuroses, and should be restricted if not entirely abolished. The prophylaxis of the fatigue neuroses can be accomplished only by due regard to the working capacity of the muscles and organs employed. The burden of work, whenever this can be avoided, should not be put on one group of muscles or on one organ. Thus writers, copyists, clerks, and others who have much handwriting to do should train themselves to employ both hands, and besides they should use them in such easy positions as not to overfatigue the muscles. The same principles may be applied to overstrain of other organs.

The proper *education* of the worker in general hygiene, and especially in the dangers of his specific trade, is an important factor in the prophylaxis of many of the occupational diseases.

The problem presented by the unhealthy condition of *sweatshop* work is a difficult one for legislators, but very simple to hygienists, who are unanimously of the opinion that all home work should be entirely prohibited; and that there should be a complete separation of the factory from the home. It is therefore merely a question of time when the economic obstacles to the abolition of the sweatshop method will be surmounted.

The *construction* of workshops, factories, mills, etc., cannot be gone into here, but there is one requirement which should not be overlooked in this respect, and that requirement is that industrial establishments should be constructed for the specific processes to be carried on therein, and that the plan of adapting any ramshackle, out-of-date building, unfit for any other purpose, to the uses of factory or workshop, as is frequently the case, must be absolutely prohibited. The size of the workplace should, of course, correspond to the number of employees, and to the needs of each establishment. The minimum of four hundred cubic feet of space for each worker, which is established by legislation in many places, is entirely in-

Digitized by Microsoft®

adequate; there should be at least one thousand cubic feet of space for each individual, as a general rule, and this allowance should be increased in special dusty and otherwise dangerous trades. The walls, ceilings, floors, and all surfaces of each establishment should be constructed with due regard to the process of industry carried on within them. Thus, in all places where dust abounds, the walls, and especially the floors, should be made without any cracks, nooks, etc., where dust may accumulate, and should be constructed of smooth material, glass, tiles, or the like, which may easily be washed and scrubbed. In all workplaces where the humidity is relatively very great, the walls and other surfaces should be made of impervious materials. Whenever practicable, the floor should be made of asphalt, concrete, or cement, so as to be impermeable to moisture; it should also be properly graded and drained so as to be easily washed off. This precaution is especially to be recommended in mercury and lead work establishments where the poisonous substances are likely to collect on floor surfaces. Of the cleanliness of industrial establishments it is sufficient to say that it is an indispensable condition of the healthy workshop.

Lighting.—On the proper lighting of workshops depends not only the condition of the eyesight but also the general good health of the workers. The ideal of workshop lighting is the avoidance of anything but daylight as a source of light during work; and, if artificial illumination is absolutely required, the use of electricity only, whenever possible, as other illuminants produce many impurities and unduly raise the temperature of the workshop.

Bussing[14] gives the following requirements for the artificial lighting of factories: (1) The quantity of light should correspond to the normal requirements of the room space and the occupants, (2) the light should approximate the quality of daylight as much as possible, and be white, and in this respect the hygienic value of different lights stands in the following order: electricity, argand burners, open gas flames, and petroleum oil; (3) stability of flame, all flickering and jumping lights being injurious to the eyes; (4) low proportion of impurities given off; (5) low heating capacity. To these requisites may also be added proper distance from the persons at work, proper location of lights, uniform distribution, and shading of eyes when light is too glaring.

Ventilation is the corner-stone of industrial hygiene; for the greatest part of the dangers which threaten the workers are due to the impurities in the air of the places of work, impurities which can be done away with only by efficient methods of ventilation. The impurities in industrial establishments are the following:

I. Impurities caused by the workers: (*a*) decrease in oxygen; (*b*) increase in carbonic acid; (*c*) increase in amount of aqueous vapor; (*d*) increase in temperature; (*e*) increase in amount of organic matter.

II. Impurities due to the place of work: (*a*) detritus from walls, ceilings, floors, and other surfaces; (*b*) increased humidity, due to dampness absorbed and retained in the walls and materials of building; (*c*) moulds, fungi, and other low organisms.

III. Impurities due to artificial lighting and heating: (*a*) increase in amount of carbonic acid and other gases; and (*b*) increased temperature.

IV. Impurities due to presence of machinery, etc.: (*a*) increase in temperature from motion and friction of machinery, etc.; and (*b*) detritus and waste from tools, etc.

V. Impurities due to industrial processes: (*a*) waste and detritus from crude materials being crushed, torn, milled, ground, polished, etc.; (*b*) dust from organic and inorganic substances of manufacture; (*c*) poisons, gases, and fumes; (*d*) infective agents and bacteria. Without going into the detailed study of each of these impurities we shall only consider here how they are to be removed by ventilation. Ventilation is either natural or artificial, according to the natural or mechanical means employed to further it. The natural modes of ventilation are the following:

1. The porosity of the walls and other parts of the building.
2. The various openings made in rooms, such as windows, transoms, doors.
3. Special openings made in windows, walls, ceilings, etc.
4. Chimney flues and other ducts connecting rooms with external air.
5. Cowls and warming devices, made in chimney flues and other ducts.

The last three methods are regarded by some writers as belonging to artificial ventilation, although it is best to limit the meaning of this term to modes of ventilation which are accomplished by mechanical means only. The methods of artificial ventilation are two: extraction and propulsion. By "extraction" methods we mean the ventilation by which: (1) impure air of a room is extracted by means of exhaustors, fans, etc., without special means being provided for the substitution of fresh air; and (2) the extraction of the impure air by the same methods and the provision, at the same time, of special openings or ducts and inlets for the ingress of pure air from the outside. The propulsion method of ventilation consists in: (1) blowing in, propelling, and forcing in air from the outside into the room to be ventilated without making any other provision for the escape of the impure air from the room; and (2) the same methods, plus the addition of special means of escape for the impure air. A combination of the two methods is the best. The motor power for the ventilating devices may be compressed air, water, steam, or electricity. In the propulsion method of ventilation special means may be also provided: (*a*) for filtering the incoming air from its impurities; (*b*) for warming it to a desired temperature; and (*c*) for regulating its relative humidity. In the extraction method of ventilation provision may be made for: (*a*) collecting the impurities of the extracted air in proper receptacles; (*b*) cleaning it by precipitation, filtration, compression; and (*c*) for absorption of gases, etc., by chemical means.

For further details see special books on ventilation, also the works referred to at the conclusion of this article.

Provision should be made in all industrial establishments for artificial ventilation, for by natural ventilation alone it is hardly possible to remove all the impurities to be found in them. In small workshops, with a limited number of employees, with a minimum of waste matter and dust, with no machinery in use, no gases or fumes liberated, natural ventilation may be adequate. But in all other places, especially in large factories, mills, mines, and tunnels, no reliance whatever can be placed on natural methods of ventilation, mechanical means being absolutely indispensable. There is hardly an industry in which some of the above-mentioned motor powers are not used, and wherever there is motive power artificial ventilation need not cost more than the initial expense of the installation of the ventilating apparatus, and should be insisted upon and properly supervised by competent authorities.

In mines the air is full of impurities, and contains various deleterious gases, known as "black damp," "white damp," "fire damp," and "after damp,"—gases which are dangerous on account of either their toxic or their explosive nature. Here artificial ventilation must be provided for on a large scale, though even then much of the danger is difficult to avoid.

SPECIAL PROPHYLAXIS. *Dust.*—The following are the prophylactic measures to be observed in those occupations which are characterized by the production of large quantities of dust.

1. Separation, from all other processes, of those in which dust abounds.
2. Substitution of machinery for handwork, whenever this is possible.
3. Substitution of wet for dry processes of production.
4. Instant and continuous removal of formed dust by special ventilators.
5. Isolation of the worker from the dusty process.
6. Frequent change of air and frequent pauses.

Digitized by Microsoft®

7. Special devices for preventing dust from entering the respiratory organs.

1. The processes in which dust is largely formed should be confined to special rooms, which should be kept isolated as much as possible from the other rooms of the establishment.

www.libtool.com.cn

2. The production of dust may largely be avoided by substituting for hand work carefully enclosed machines. Machine production requires comparatively few operatives, thus lessening the number of persons exposed to dust inhalation. Industries in which the dust has an economic value have already partly accomplished this. In flour and cement mills, and in sawmills provision is made for the collection of the valuable dust and its further utilization. Flour milling was once considered an unhealthy trade; but since the introduction of self-regulating machinery, enclosed in chambers, the formation of dust, from the crushing of the coarse grain to the packing of the finest flour, has been reduced to a minimum. What has been accomplished in a few industries may be repeated in others.

3. Dust is produced only when the industrial processes are performed by dry methods. Wherever possible, wet processes should be substituted by either wetting the material, or the implements, or the place of work, the wetting materially reducing the dust. Wools are sometimes oiled for this purpose. The wet methods are especially imperative in work with poisonous substances, and in the metal grinding industries. Needle, cutlery, stone, and other grinding and polishing can very well be done by wet methods, thus preventing dust formation.

4. The instant and continuous removal of dust can be done only by artificial ventilation and specially constructed devices for each trade. Dust is removed by precipitation, filtration, and absorption. Precipitation of dust is accomplished by the action of the specific gravity of the dust, by the action of water, a stream or shower of which is allowed to fall on the dust thus precipitating it, and also by centrifugal action. Filtration is accomplished by letting the dust filter through cotton, wool, or other material which may be kept dry or wet. The proper ventilating devices for removal of dust consist of the following several parts: (*a*) An expansion or hood, properly fitting or enclosing the tool, machine, or stand of each dust-producing process and worker. This hood must be so adjusted as to cover all surfaces or projections where dust is formed. (*b*) The tubes or ducts with which hoods or expansions are connected; the dust is drawn into the hoods, and conducted from these into the tubes. These latter must be tight, and should be provided with cleaning caps to facilitate periodical cleaning in case of obstruction, etc. (*c*) The *wetting* appliances are in the form of jets, rosettes, streams, showers of water which are applied to the dust in the hood, tubes, or receptacles. (*d*) The *fans*, exhaustors, and other means for aspirating the dust from the hoods and tubes by the creation of a vacuum within the same. The aspirating force must be nicely adjusted to the needs of each trade and process, otherwise the draughts may be too strong. (*e*) *Receptacles* which are connected with the tubes, etc., and in which the dust collects and settles by its specific gravity, by the action of water, or by centrifugal motion.

5. In those industries in which the dust, for one or another reason, cannot be removed, and in which there is great danger that it will impinge upon the face and get into the eyes of the operatives, special appliances have been devised for isolating the worker from his work by an intercepting window, put between him and the dust; or he is separated from it by a complete glass partition, in which openings are made for his arms to go through for the necessary manipulations; or, finally, the work may be done by means of long poles and other tools, manipulated by the workers from the outside of the closed chambers.

6. Wherever dust is produced in large quantities the workers should be given frequent opportunities for inspiring pure outside air, by making the pauses as frequent as possible, and by compelling the operatives to go outside of the shop during these pauses.

7. Workers in dusty trades very often stuff their nostrils and their mouths with flannel or cloth to keep out the dust. The appliances called "respirators" are an extension of the same principle. They consist of a framework made of vulcanite, wire, or metal, which is so constructed as closely to fit the lower part of the face, covering the mouth alone, or the mouth and nose together. Within this framework some filtering material is placed for intercepting and collecting the incoming dust, thus preventing its inhalation. There are a great number of more or less ingenious respirators on the market. One of these, devised by B. W. Richardson[15] consists of a mask in which a breathing tube is fitted, on the inside, with rolled feathers which are so arranged that during inspiration they will rise up and filter, while in expiration they will lie down, like a valve, against the wall of the tube. This is an example of the ingenuity spent on the construction of respirators. The respirators have, however, never been popular with workers; indeed, they are seldom, if ever, worn, unless by compulsion. The objections made by operatives against the wearing of respirators while at work are the following: they are clumsy, uncomfortable, and unsightly; they interfere with respiration; if the filtering material is thick and closely woven, respiration is very difficult—if not, the dust gets through; they interfere with talking, spitting, chewing, and smoking; they get wet by the moisture of the breath, and in general they are a great inconvenience to the wearers, who would rather inhale the dust than wear one of them. In trades where the worker is exposed to violent poisons or specially irritating gases, special masks, entirely air-tight, are provided, and are fitted with tubes to bring in air from the outside, and with complicated valves, etc., to let out the expired air. The objections against respirators already alluded to apply in greater force to those instruments which are used only in very exceptional cases.

The *prophylaxis* in industries where *poisons, gases, and fumes* are evolved and liberated does not differ in its essential features from the prophylactic principles laid down for dusty occupations, except that they must be more strictly and carefully enforced if they are to be effective in protecting the health of the workers. In specially dangerous trades the periodical medical examination of the employees goes very far toward remedying the evils of the trade. Wet methods of production should be insisted upon wherever toxic substances may produce dust. Certain poisons should be entirely prohibited from being used and for them should be substituted other materials less poisonous. Thus the use of any but red phosphorus should be prohibited in the match industry; no arsenic should be used in textile fabrics, on wall papers, etc.; the manufacture of lead toys and utensils should be prohibited, and so also should the employment of lead in pottery glaze and other manufactures. Mirrors may be backed by silver instead of by mercury; and in the place of the latter poison glycerin may be substituted in the manufacture of air pumps. The ideal will be reached when all toxic substances are replaced by non-toxic, and with time and vigorous agitation this ideal may be realized.

Wherever gases and fumes are in such abundance that toxic effects are feared, the wearing of proper protective clothing, respirators, and masks should be insisted upon in spite of the objections of the workers.

Other prophylactic measures, applicable to each industry, differ according to the nature of the toxic substance in each. No alcoholic beverages or acidulated drinks are allowed to arsenic and lead workers, but may be permitted in moderate doses to mercury workers. Workers in lead manufacturies are given from ten to fifteen minutes for washing their hands. Sapolio and ammonium tartrate are recommended for the hands, potassium permanganate for a mouth wash. As food, milk and pork enjoy special favor with lead workers, and are furnished by some employers. A number of so-called "sanitary"

Digitized by Microsoft®

drinks have been proposed for lead as well as other workers. The value of potassium iodide as a prophylactic for plumbism, though high in the estimation of some, is doubted by Blum,[16] who made a special study of plumbism

Chromium workers should have their faces and noses protected with masks to prevent ulceration.

www.libtool.com.cn

Those who work in soda manufactories and come in contact with chlorine gas are advised to drink a two-per-cent. solution of dilute sulphuric acid

Phosphorus workers are to be examined periodically by dentists for caries of the teeth. Chalk, milk, saponified water are recommended for those who work in or are exposed to sulphur and its compounds

The use of common salt is interdicted to mercury workers on account of the danger of the formation of sublimate.

Each industry in which special toxic agents are being manufactured should be provided with special rules for the guidance of the employees, and should also be under the constant care and supervision of proper medical authorities.

The *prophylaxis of infection* from crude materials, or from manufactured articles, is important in the hair, wool, hide, and fur trades especially, on account of the danger of anthrax infection, but it is also important in all trades in which goods are imported from Oriental countries, where certain contagious diseases are endemic. The only effective prophylactic measure, under these circumstances, is proper and thorough disinfection of all suspected materials.

The *special prophylactic* measures against *accidents* to the *eyes* have already been spoken of to some extent in the section relating to the methods of removing dust and toxic materials Where the danger from flying particles, dust, etc., is very great, it is recommended to wear protective spectacles. A large number of special spectacles have been manufactured for persons whose eyes are thus exposed, but, as in the case of respirators, they are strongly objected to by the workers. The wearing of spectacles is made obligatory in some trades. Koenigshoefer[17] sums up the objections against spectacles as follows: they limit the field of vision, they may impair vision, they sometimes cause headache and pain in the eyes, they are apt to get dimmed by condensed moisture, the metal frame is apt to get hot, and finally, they are uncomfortable. All of these objections may be removed by a proper construction of the glasses.

Prophylaxis against Accidents by Machinery.—This is a science by itself, the study of which requires special technical training. In most countries laws are enacted to safeguard machinery and prevent accidents. Motor engines, flywheels, etc., must be fenced in and provided with proper guards and rails. Wheels, shafts, drums, belts, and all gearing must be provided with special protective appliances. Circular saws, planes, power looms, and other machinery and tools are all to be properly guarded with approved devices. Many machines and parts of them are at present provided with proper safeguards by their makers. Workers should be thoroughly drilled in the art of self-protection and educated to the dangers of machinery as well as to all other dangers of their calling. This remark applies with special force to workers in large electrical establishments, where a man may lose his life, by coming in contact with a wire carrying a powerful current of electricity.

Offensive Trades.

Thus far the effects of occupations have been considered only with reference to the health of those engaged in them—the workers themselves. There are a number of occupations, however, which affect not only their workers, but the community at large, or, at least, that part of it which lives in their immediate vicinity. These occupations have been named "offensive trades," also "public nuisances." Except in trades which allow poisonous substances or noxious gases to escape outside their precincts, and thus directly injure the health of the surrounding neighborhood, the dangers to health of the so-called "offensive trades" are not direct; at least, it is difficult to show the existence of any diseases or pathological lesions which owe their origin to those trades. Most of the harmful effects of these trades are due to the smoke, noise, and smell produced, which may give rise, in those predisposed to such ailments, to certain disorders such as anorexia, nausea, neurasthenia, anæmia, and kindred ills. The number of offensive trades is very large, and a classification of them has been attempted by the French Government, which divided them into three classes, according to the degree of their offensiveness. Tracy,[18] in his article on "Public Nuisances" in Buck's "Hygiene and Public Health," and S. A. Goldsmith in his article in the former edition of this Handbook, gave full lists of those trades, based on the French classification, as well as detailed technical descriptions of the various processes of the offensive businesses. The space here being limited, only the prophylactic part will be noted, and all technical details will be omitted. The following are the annoying factors in most offensive trades: *Noise*, *Smoke*, *Dust*, *Smell*, and *Noxious Gases and Fumes*.

Noise.—The number of businesses which are characterized by excessive noise is quite large, especially in populous towns. Surface and elevated railroads, driving of heavy wagons over rough pavements, machine shops, forge rooms, blacksmith shops, saw and planing mills, street venders, street music, etc., are a few of them. Excessive noises affect especially nervous, neurasthenic, and sick persons, causing irritability, sleeplessness, anorexia, and general disturbances. A New York physician gave to these symptoms the name of "Newyorkitis," but the malady, if there is such, could better be termed "urbantis," as it is characteristic of all large cities. The prevention of excessive noise is possible in a large degree by municipal action. Thus in New York it is not allowed to create unnecessary noises, especially at night, and near residential streets; street-band music is prohibited in the boroughs of Manhattan and the Bronx, railroad companies are compelled to remove "flat-wheel cars," street peddling is not allowed at night, etc.; with a wider introduction of asphalt pavement a fruitful cause of noises will also be largely abolished.

Smoke.—Among the many nuisances incident to city life is the black smoke belched forth from the chimneys of manufacturing establishments. The composition of the smoke as it leaves the chimney depends on the character of fuel burned, as well as on the methods of combustion and the care with which it is carried on. Black smoke consists of carbon mechanically suspended, and also of other gases, such as carbonic acid, carbonic oxide, and hydrogen sulphide. Wood and bituminous coal give off very abundant and black smoke, while hard coal gives off very little on account of its cohesiveness and complete combustion. When furnaces are of adequate capacity, with grates having a large area, with the coal spread in a thin continuous sheet, and with the requisite amount of air, the production of smoke is greatly diminished.[19] The other remedies, outside of using anthracite coal, are the providing of tall chimneys, so that the smoke shall be emitted above the windows of living houses; and the voluntary or compulsory introduction of smoke-consuming devices. There are a very large number of patented smoke consumers, most of them based on the principle of making a more thorough and complete combustion of all particles of carbon in the fuel.

Dust.—There are only a few businesses in which large quantities of dust may escape outside of the establishments and become a public nuisance. These are carpet-cleaning and beating works, sandblasting of glass, and street sweeping. Carpet-cleaning is now done in large establishments without producing dust. Proper methods have been devised for collecting the dust and preventing its coming outside. Sandblasting of glass is to be relegated outside of residential streets, the dust usually not falling farther than about three hundred feet from the establish-

Digitized by Microsoft®

ments. Street sweeping may be done with comparatively little dust if the streets are previously well sprinkled with water and the cleaners are careful.

Smell.—The trades and businesses which are or may become offensive on account of their smells are very numerous indeed. They include the greatest bulk of generally offensive trades, as they are composed of all the numerous industries in which animal or vegetable matter is manufactured or stored, and which may at certain periods of the procedure give rise to offensive odors. We shall here allude only to the following: (1) The keeping of live animals and of animal matter. (2) Killing of animals. (3) Manufacture and utilization of animal substances. (4) Manufacture of vegetable substances, etc.

Keeping of Live Animals.—As in all offensive trades, the keeping of live animals becomes a nuisance only in populous towns. The nuisance created by the keeping of live animals, such as horses, cows, calves, swine, sheep, goats, birds, poultry, and rare and wild animals consists in: (1) the specific odors peculiar to each kind of animal; (2) the smell from the urine, excreta, and other organic matter from the animals; (3) the noises which are made by them and which disturb the rest of the neighborhood; (4) the flies and parasites which they attract to themselves; and (5) possible infective materials and germs likely to be transmitted to men.

Most municipalities have laws which are intended to abate the nuisances created by the keeping of animals. The remedies for the nuisance are the following: (1) total prohibition of the keeping of certain animals within the city limits, or at least in overcrowded neighborhoods; (2) restricting the building of new places for animals; (3) proper veterinary supervision and disinfection, to prevent disease of animals and infection; (4) proper construction and maintenance of the places where they are kept; (5) removal of all animal matter likely to give offensive odors, or to become putrefied. The rules and regulations of municipalities embrace all of the above-enumerated prophylactic measures. Thus in New York no cows, horses, calves, swine, sheep, or goats are allowed to be kept in tenement houses; no stables are allowed on the same lot with a tenement house; and the keeping of all kinds of animals, even pigeons and chickens, requires a permit from the Health Department. In Boston [19] stables are prohibited within two hundred feet of a church; in Chicago, in order to build a stable, it is necessary to get the permission of the owners living within six hundred feet of the proposed stable.

Most of the offence given by the keeping of live animals is given by horse stables, as comparatively few other animals are kept in cities. Stables should be specially constructed for the purpose. They should contain at least twelve hundred cubic feet of space and one hundred and twenty cubic feet of floor space for each horse; stalls should be at least six feet wide and nine feet long, and the stable should be well ventilated. The floors of stables should be of some impervious material, such as concrete, cement, bricks set in cement; no woodwork that cannot be easily taken off should be laid on flooring. There should be provision for an unlimited supply of water, and the floor should be properly graded and drained, and the stalls provided with longitudinal "valley drains," provided with adjustable covers easily taken up, and the drains should all be tightly connected with the sewer by a properly trapped, extra heavy drain. [19] No accumulations of manure are to be allowed; as soon as it is collected, it should be put into barrels or pressed into bales and daily removed. The removal of manure should be done within the stable, and the carts should be well covered before they start out from the stable. The removal hour should be at night or early in the morning. Thus in Boston manure can be removed only after 12 (midnight); in Jersey City between 6 P.M. and 7 A.M. The stables should be kept scrupulously clean and frequently disinfected with a solution of one pint of formalin to three gallons of water or a similar solution of carbolic acid; corrosive sublimate solution and creolin can also be used. There is no reason why, with such precautions, the keeping of horses should be attended with offence. The keeping of other animals may be made inoffensive by means of similar methods.

The Keeping of Animal Matter.—The storage or keeping of animal matter, manure, offal, bones, hides, horns, skins, fish, garbage, etc., may be attended with offence, on account of the tendency to speedy putrefaction and decomposition, when the decomposing matters may emit very offensive and sickening odors, unbearable by many, and causing headache, loss of appetite, and nausea in others. The prevention of their becoming nuisances can be summed up in the following measures: Immediate destruction, by burning all needless matter likely to decompose; immediate removal from habitations; scrupulous cleanliness; disinfection; keeping of matter in tightly closed vessels.

The Killing of Animals.—The killing of animals is one of the oldest industries of mankind, and has been always in need of state supervision and control from the time of Moses in ancient Egypt until the present. The nuisance created by slaughtering animals consists mostly in the odors peculiar to the slaughter-houses, although other things, such as the noise created by the animals, the flies and parasites attracted by the animal matter, as also the possibility of infection by animal diseases, all play their part in the creation of this nuisance. The offensive smell is due to the animals themselves, the fresh animal guts, blood and other products, and the decomposing animal matter within the buildings. The remedies for the nuisance are: prohibition of slaughtering in any but specified localities; the construction of special municipal abattoirs; the proper building and maintenance of the slaughter-houses, their supervision and inspection; the immediate removal of all by- and waste products; the refrigeration of meat; the absolutely clean condition of the places; the provision of special means for destroying foul- and ill-smelling matter, and the disinfection of the premises.

Municipal provisions about slaughter-houses were inaugurated in the United States as early as 1692 in Boston, [20] and are now found in nearly every community. In New York City slaughter-houses are located only in specified localities, of which there are only four or five. In Boston the slaughtering of animals is concentrated in the Brighton abattoir; and in New Orleans in the municipal abattoir. Cleanliness in the slaughter-houses is provided for in the various sanitary codes, the following being from a section of the New York law: "All those who are responsible for the places should cause such places and their yards and appurtenances to be thoroughly cleansed and purified, and all offal, blood, fat, garbage, refuse, and unwholesome or offensive matter to be removed, at least once in every twenty-four hours after the use thereof; and they shall also at all times keep all woodwork, save floors and counters, thoroughly painted or whitewashed." An unlimited supply of water is even more needed in abattoirs than in stables. Goldsmith quotes Tardieu as saying that in Paris (where the buildings are of iron and glass) ninety thousand litres are used daily in each of the five abattoirs, and adds that in New York a slaughter-house in Forty-fifth Street uses nearly five million gallons a day. [22] The slaughtering of poultry and smaller animals should also be controlled by the municipalities, and most of the prophylactic measures used in slaughter-houses of larger animals are applicable to them also.

Utilization and Manufacture of Animal Substances.—Modern industry does not allow anything to go to waste, and in animal trades there is hardly a substance which is not utilized in some way. Among the many branches of these utilization industries to be discussed here are the following: The rendering of fat and lard; bone and blood-boiling; gut-cleaning; manufacture of glycerin, soap, and glue, and the preparing and tanning of skins and hides.

Fat Rendering, Lard Refining.—Most of the rendering of fat is done by the action of heat, although there are several chemical methods in vogue. Since the trade be-

Digitized by Microsoft®

www.libtool.com.cn

came concentrated in large establishments, the old method of rendering fat in open kettles has become happily obsolete. The chief nuisance of fat rendering consists in the odors "which are all caused, partly by the storage of decomposing fat on the premises, but mainly by the distillation of portions of the fat, which produces certain ill-smelling substances, such as acrolein and allylic alcohol, with sometimes capric, caprylic, and caproic acids."[18]

The prevention of fat-rendering from becoming a nuisance is accomplished by the following measures: (1) The use of undecomposed animal matter; (2) the employment of a low temperature in rendering; (3) the boiling of fat in tightly closed vessels; (4) the use of condensers for the removal and destruction of the gases and odors. The New York Sanitary Code has the following section: "That no fat, tallow, or lard shall be melted or rendered except when fresh from the slaughtered animal; and taken directly from the place of slaughter, and in a condition free from sourness and taint, and all other causes of offence at the time of rendering; and that all melting and rendering are to be in steam-tight vessels; the gases and odors therefrom to be destroyed by combustion or other means equally effective." Hines[21] says: "The great secret in preventing nuisance is the avoidance of burning the materials, or even raising them to high temperature. The lower the temperature at which the work can be successfully carried on, the less is the risk of producing offensive smells. The temperature need not exceed 120° F." When steam methods of rendering are used, the need of condensers is imperative. "Condensers may be of several styles and shapes. The water may be introduced at the top, and broken by means of a plate, a short distance below, the shower may also be made by means of a rosette. The condenser itself may be made of iron, copper, or even wood. It should be made as high as possible, in proportion to the diameter. The gases should be introduced at the bottom, and passing up through the water shower, connect with the furnace fires by a pipe near the top." (Goldsmith.[22]) Of the chemical methods of fat-rendering D'Arcet's method is by separation of the fat from its membranes by the action of sulphuric acid. Lard refining differs little from the general rendering of other fats, and, being done mostly by the low temperature method, it is not offensive.

Bone and Blood Boiling.—In the processes of boiling these animal substances odors may arise which may be quite offensive. The following preventive measures are recommended by the Philadelphia Board of Health:[20] "The floors of all bone-boiling establishments and depositories of dead animals shall be paved with asphalt, or with brick or stone, well laid in cement, and shall be well drained. The boiling of bones, etc., shall be conducted in steam-tight kettles, boilers, or cauldrons, from which the foul vapors shall first be conducted through scrubbers or condensers, and then into the back part of the ashpit of the furnace fire to be consumed. When bones are being dried after boiling, they shall be placed in closed chambers, through which shall be passed, by means of pipes, large volumes of fresh air, the outlet pipe terminating in the fire-pit."

Gut Cleaning.—The utilization of the small intestines of animals for sausage skins and the manufacture of catgut is necessarily accompanied by a great deal of stench from the foul-smelling contents of the guts and the decomposition of animal matter. "The processes should be carried on away from habitations; the guts, etc., should not be allowed to come in a foul state, but must be utilized immediately, and proper precautions taken to let no foul matter cling to the floor or surfaces of the establishment. This may be accomplished by the use of plenty of water. The water in the tank where the intestines are macerated may be disinfected by a weak solution of chloralum or chlorinated soda."[18] Parent Duchatelet (Tardieu) denies that gut cleaning is harmful to health.

The Manufacture of Soap.—Soap is manufactured from fat and alkalies. It may become a nuisance: (1) On account of the large quantity of fat, tallow, and fat animal residue, which are collected from all animal waste matter, and which are, by the time they reach the soap factory, in a decomposing state. (2) By the processes inherent in fat rendering. (3) By the odors arising from the huge vats and tanks where the fat is being boiled with the alkaline lye. The prevention of the first nuisance is accomplished by insisting that only fat in a fresh state shall be allowed in the soap factories. The means of preventing fat-melting and rendering from becoming a nuisance have already been described. The nuisances caused by the odors arising from the boiling tanks can be prevented by fitting these with covers, and conducting the vapors either outside through a tall chimney, or, as in fat-rendering, through proper condensers.

Glycerin.—When the fatty acids of the fats in soap manufacture combine with the alkalies, the base left is a residue in the form of glycerin, which, before being fitted for the market, must be refined several times. During this process sweetish unpleasant odors are given off, which can be prevented by the same means as those which are used in treating odors from fat rendering.

Glue-Making.—All kinds of animal waste matter, hoofs, horns, skin scraps, leather scraps, etc., are used for the extraction of glue. As in the other processes employed for the utilization of all animal waste matter, the nuisance comes from the decomposing material, from the odors given out during boiling, etc., and from the offensive residue or "scrutch." The remedies are the same as in other kindred processes.

Treating and Tanning of Skins and Hides.—Animal skins, before they are converted into lasting leather, must go through a number of complicated processes. In the scraping, salting, hairing, brining, liming, puering, tanning, curing, and other processes very offensive and disgusting odors often arise; and in liming some sulphureted hydrogen may also be evolved. The process named "puering" consists in soaking the hides in a liquid composed of dog's dung. Tanning establishments should not be allowed in residential localities. The various manipulations may be done with little offence if the places are properly constructed and well kept.

Manufacture of Other Substances.—Among the other substances, the manufacture of which may become offensive, are the following: Illuminating gas, petroleum refining, distilling, brewing, vinegar-making, sugar-refining, boiling of oil, manufacture of varnish, cooking, etc.

Illuminating Gas.—The nuisance caused by the presence of gas works in populous localities is due to various gases and odors given off, during the many stages required, in the process of distilling gas from bituminous coal. The process especially objectionable is the "liming," or passing the gas through a closed chamber filled with quicklime, which is afterward deoxidized and gives off ammonium sulphide and sulphureted hydrogen. Oxide of iron has been substituted for quicklime, with a material lessening of offensiveness. Notwithstanding all the care employed and despite the modern inventions of condensers, scrubbers, and other means for destroying and absorbing offensive gases during the manufacture of illuminating gas, this business is still quite a nuisance to a neighborhood, and the best remedy is to remove it as far as possible from habitations.

In the processes of refining petroleum, offensive odors are given off. These are due to the escape of fumes during its distillation, as well as during the agitation of the refuse or "sludge" acid with alkaline solutions. Goldsmith recommends that the wash water from the agitators should be passed through a series of troughs furnished with cross slots, to retain all oily or tarry matter; and the treatment of the sludge should be carried on at a distance from crowded neighborhoods.

The nuisances caused in the processes of brewing, distilling, sugar refining, and other industries mentioned, consist in the odors given off at certain stages of manufacture and may be prevented by the same methods as those described in the section on Fat Rendering.

Tracy lays down the principles of controlling the nuisance caused by the odors and vapors which are given off

Digitized by Microsoft®

during the manufacture of various substances as follows: (1) Conveying and storing in tight vessels. (2) Substitution of less offensive processes for the more offensive. (3) Proper construction of the places where nuisances arise. (4) The use of plenty of water, proper cleanliness, and drainage. (5) The destruction of all offensive odors by passing them through condensers, etc., and from there into the fire pits where they will be consumed.

Gases and Vapors.—The number of the trades which may become a nuisance to the community on account of the vapors, acid fumes, and gases which are evolved in their processes, and are allowed to escape into the surrounding air, is very large. Among the more important of these are all the chemical trades; the manufacture of alkalies, ammonia, bleaching powder, soda, and glass; assaying, smelting, and the manufacture of jewelry, lead paint, certain drugs, etc.

The nuisance created by all of these trades can be summed up in the following: (1) Odors offensive to the neighborhood. (2) Deleterious gases. (3) Destruction of vegetation in the neighborhood.

The remedies advised for the prevention, or at least mitigation, of the nuisances are: (1) Removal, whenever possible, from crowded localities. (2) Dilution of the gases and vapors by air. (3) Condensation of gases by cooling them with water, by passing them once, or several times, either through condensers filled with water or through scrubbers filled with wet coke. (4) Absorption through discharging all gases into fire-pits, where they are destroyed by the action of fire, or by passing them through neutralizing substances, which are of course different for each of the different gases.

OCEAN SPRINGS.—Jackson County, Mississippi. POST-OFFICE.—Ocean Springs. Hotels.

This is a station on the railroad between New Orleans and Mobile, eighty-three miles east of the former, and fifty-seven miles west of the latter. It may also be reached by coast steamers from either city. The name of the springs is derived from their proximity to the gulf, the beach being but half a mile distant. According to Walton the springs are most resorted to by citizens of New Orleans and Mobile. The following analysis was made by Prof. J. Lawrence Smith:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	47.77
Potassium chloride	Trace.
Calcium chloride	3.88
Magnesium chloride	4.97
Ferrous oxide	4.71
Organic matter	Trace.
Ammonia	Trace.
Iodine	Trace.
Total	61.33
Gases.	**Cu. in.**
Sulphureted hydrogen	1.28
Carbonic acid	9.79

The water is a potent chalybeate, the iron being no doubt held in solution in the form of a carbonate. The unusual combination of carbonate of iron, chloride of sodium, and sulphureted hydrogen especially adapts this water to the treatment of diseases of the skin in persons of a scrofulous diathesis. *James K. Crook.*

OCHEE SPRINGS.—Providence County, Rhode Island. POST-OFFICE.—Johnston.

The Ochee Springs are not properly a health resort, although there are many visitors in pleasant weather. There are a number of springs in the neighborhood, but only one is improved at the present time. The following analysis was made by Prof. John H. Appleton, of Brown University:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Magnesium carbonate	1.13
Calcium carbonate	3.20
Calcium sulphate	.44
Potassium sulphate	.88
Sodium sulphate	.41
Sodium chloride	.57
Iron oxide and alumina	.75
Insoluble mineral matter	.58
Organic and volatile matter	.87
Undetermined	.15
Total	8.98

This water is pure and wholesome, and is said to act as a mild cathartic and diuretic when used continuously. It has been accorded a considerable reputation as an auxiliary in the treatment of kidney, liver, and stomach troubles. The water is used commercially. *James K. Crook.*

OCHRONOSIS. See *Pigment, etc.*

OCONEE CHALYBEATE SPRING.—Putnam County, Georgia. POST-OFFICE.—Eatonton.

Lake Eaton branch of Central Railroad to Eatonton, and from thence by private conveyance to spring. This spring has had considerable local reputation for a number of years. The waters contain the following ingredients:

Iron carbonate.	Calcium sulphate.
Calcium carbonate.	Sodium chloride.
Potassium sulphate.	Silica.

The iron is insufficient in quantity to warrant us in placing the water in the chalybeate class. The flow is small but constant, the water issuing from a fissure in a granite rock. *James K. Crook.*

OCONEE WHITE SULPHUR SPRINGS.—Hall County, Georgia. POST-OFFICE.—Bowdre. Hotel and cottages.

Location, six miles from Gainesville and two miles from Sulphur Springs Station, on the Southern (Richmond and Danville) Railroad. Hacks meet all trains.

This is one of the most attractive watering-places of the South. Long before the war Southerners of wealth and fashion gathered there annually. A few years ago the property was purchased by Mr. Ferdinand Phinizy, of Athens, and many improvements were made. The old buildings were torn down and a large, well-appointed hotel and handsome cottages were erected. The excellent and liberal management has kept the place popular, and

www.libtool.com.cn
Digitized by Microsoft®

it now numbers among its guests visitors from far and near. No analysis is furnished, but the waters are said to be valuable in rheumatism, dyspepsia, and diseases of the blood. There are also bathing conveniences, including shower and plunge baths and a large swimming pool.

www.libtool.com.cn
James K. Crook.

ODONTOMA.—This term has been applied in a general sense to a great variety of tumors arising in connection with the teeth—from the tooth follicle, the dentine, the cement, the enamel, the tissue about the tooth, or from the tooth structure as a whole. Different names have been applied to these growths by various authors, and at present the classification of these tumors is in a confused state. The majority of the observations are rather old, very little study having been made recently of this subject. By most writers the term *odontoma* is limited to those growths which arise at an early period of development of the tooth before the formation of the dentine. Those developing during later life from the dentine, cement, or enamel of the mature tooth are classed as *odontinoids*. These are further divided into *dentinoids*, arising from the dentine; *emailloids*, arising from the enamel; *dentalosteoma*, arising from the cement. The *true odontomata* are rare, and for the greater part form soft growths corresponding to the stage of development of the tooth, and presenting such varied appearances as to justify the diagnosis of myxoma, cystoma, sarcoma, or fibroma. Dentine may develop later in the tumor, the growth becoming hard, and after complete dentification stationary in development. Occasionally they may reach such a size as to cause erosion of the jaw bone. They may be single or multiple. They are usually irregular or nodular; after dentification they resemble dentine in structure. The *odontinoids* are usually very small and unimportant excrescences of the teeth, which are more of the nature of inflammatory hyperplasias than of true tumors, and are found in pathological conditions of the teeth, particularly in association with diseased roots. In caries of the teeth there may arise from the exposed pulp masses of granulation tissue of a polypoid character, the so-called *pulp-polyps* or *pulp-granulomata*.

The *cystic tumors* found in the jaw are sometimes included with the odontomata, but by other writers are placed in a class by themselves. Three forms of these cysts occur: *follicular* and *periosteal cysts* and the *multilocular cystoma*. The *follicular cysts* are found only during the period of dentition. They are usually monolocular, rarely multilocular cysts, having a wall lined by cylindrical epithelium. With the exception of those arising from the wisdom teeth they develop at an early age and grow slowly, taking several years to reach an important size. They arise from the cystic degeneration of a normal tooth follicle, or from supernumerary follicles or Anlage. In the cyst cavities there are occasionally found imperfectly developed teeth. The *periosteal cysts* arise chiefly as a result of chronic inflammatory processes affecting the roots; they are termed accordingly *peridental, periodontal, subperiosteal,* or *root cysts*. A portion of these formations arise from collections of pus beneath the periosteum; others take their origin from granulation tissue growing about the roots. The inner side of the granuloma is lined with epithelium derived from the remains of the epithelium of the cement. The granulation tissue may become converted into a firm fibrous capsule forming the cyst wall, the root of the tooth projecting into the cavity of the cyst. Proliferation of the epithelium lining the cyst may lead to appearances similar to those of dermoid cysts. More frequently the cysts contain a clear, mucoid, or thick brown fluid. They occur most frequently in the upper jaw. Carcinoma may take its rise from the epithelium of the cyst wall. The *multilocular cystomata* of the jaw are very rare tumors, taking their rise from the follicle; epithelial proliferations from the follicle forming alveolar or gland-like structures, which become cystic. The cyst walls are usually very thin. The growths may reach a large size, and cause great destruction of the jaw bone. Though seldom becoming carcinomatous the cysts cause great enlargement and atrophy of the bone, the bony layer over the cysts being sometimes as thin as paper, or in other cases the bone may entirely disappear, leaving the cyst covered only by periosteum.

Sutton ("Tumors Innocent and Malignant") defines the odontoma as a tumor composed of dental tissues in varying proportions and different stages of development, arising from teeth germs, or from teeth still in the process of growth. He classes them, according to the part of the tooth germ concerned in their formation, as follows: (1) *Epithelial Odontoma*, from the enamel organ; (2) *Follicular Odontoma*; (3) *Fibrous Odontoma*; (4) *Cementoma*; (5) *Compound Follicular Odontoma*, all from the tooth follicle; (6) *Radicular Odontoma*, from the papilla; (7) *Composite Odontoma* from the whole germ. For a description of these varieties and for illustrations of cases the reader is referred to this work.

Aldred Scott Warthin.

ŒDEMA.—(Hydrops, dropsy.) An increase in the amount of lymph within the tissue spaces or serous cavities is known as *œdema* or *dropsy*. The fluid itself is often called a *transudate*; but at the present time the distinctions formerly held between œdema and inflammatory exudate, and transudate and exudate, are no longer emphasized, inasmuch as the essential etiological factors are common to both. Various specific terms are employed to denote the portion of the body affected by the condition of œdema, as, for example, *hydrops* is usually limited to the collection of fluid within the body cavities, *œdema* to the collection of fluid within the lymph spaces of the connective tissue or parenchymatous organs, *anasarca* or *hydrosarca* to an œdematous condition of the skin or subcutaneous tissues, *ascites* to the collection of fluid within the peritoneal cavity; while *hydrothorax, hydropericardium, hydrocele, hydrophthalmos, hydrocephalus internus, hydrarthros, hydrops bursarum*, etc., are used to designate the collection of fluid in the pleural cavity, pericardium, scrotum, eye, cerebral ventricles, joints, bursæ, etc., respectively. Localizations of œdema of great importance clinically are designated as *œdema of the lungs, œdema of the glottis*, etc. The œdematous swelling of the presenting portion of the fœtal head is known as *caput succedaneum*. Œdematous conditions of the conjunctiva are termed *chemosis serosa*. The term *dropsy* in strict use should be confined to the collection of fluid within the body cavities, but is applied in a loose way to any œdema or collection of fluid of such extent as to be evident by the ordinary methods of physical examination.

Lymph.—Since œdema is a pathological increase of the lymph, it follows that the production of the former must depend upon a disturbance of the normal mode of lymph production. The clear watery fluid which permeates the intercellular spaces of the tissues and bathes the serous surfaces is known as the lymph. Its chief source is the blood, and its constituents are passed through the walls of the blood-vessels by processes of diffusion, filtration, and specific secretory activity of the cells of the vessel walls. Under certain conditions the fluid of the cells and other constituents of the tissues may also pass into the free fluid of the tissue spaces. According to Heidenhain the lymph is composed of fluid derived from the blood, the lymph of the organ under consideration, and the water contained in the tissue cells and fibres. The ultimate source is, of course, the blood. Formerly regarded as a passive filtration from the blood-vessels, the formation of lymph is now considered by the majority of investigators to be of the nature of a secretion of the cells forming the capillary walls. In support of the view of the selective action of the blood-vessel walls are the facts that the composition of the lymph differs greatly from that of the blood plasma, and differs also in its composition in different parts of the body; further, under certain conditions it may contain more salts and extractives (urea and sugar) than the blood. The rapid passage of crystalloid substances from the capillaries into the lymph is also a strong point in favor of the view that the proc-

Digitized by Microsoft®

ess is not one of mere diffusion, but is the result of a force inherent in the cells of the vessel walls. According to Heidenhain the specific function of the capillary walls plays a controlling part in the formation of lymph. Certain substances injected into the blood-vessels increase the production of lymph (extracts of leeches, mussels, crabs, peptone, etc.), and it is also possible that the capillary secretion is directly under nerve influence. It is very probable that certain œdematous conditions of the skin (urticaria, herpes zoster, etc.) are partly intoxications and in part due to nervous disturbances. The function of the lymph is the conveyance of nutrition to the cells and the removal of their waste products. From the lymph spaces the fluid is gathered into the lymph vessels passing to the lymph nodes, from which it is passed on to the veins by the larger lymph trunks. Not all the lymph is returned in this manner; a portion is undoubtedly taken up directly into the blood-vessels; or at least in some of the lymph nodes a portion is taken up by the capillaries of the lymphoid tissue.

www.libtool.com.cn

Etiology of Œdema.—It follows that as œdema is the result of an increase in the amount of lymph, such an increase may be brought about either by an increase in the amount of fluid passed out of the capillaries, or by some obstruction to the outflow of lymph through the lymphatics. In general, the causes of œdema are the various pathological conditions which may influence the process of lymph formation. The increased production of lymph may be due to an increase of the vascular secretion, or to an increased permeability of the vessel wall. These conditions may be brought about by increase of blood pressure, by pathological alterations in the vessel walls, or by the direct action of certain substances either upon the cells of the vessel walls or upon the nerves governing these, stimulating the capillaries to increased secretion. Within certain limits an increase in lymph production is equalized by an increase in lymph absorption through the lymphatics and also through the blood-vessels. Beyond this limit there arises a more or less permanent over-saturation of the tissues with lymph, and the condition of œdema is established.

According to etiology four general classes of œdema may be distinguished: *œdema from stagnation of the blood*, that resulting from *obstruction to the outflow of lymph*, that caused by *disturbance of capillary secretion*, and *œdema ex vacuo*. Clinically, a great number of varieties may be recognized: *toxic, thermal, traumatic, inflammatory, cachectic, infectious, hydræmic, anæmic, neuropathic*, etc., but all of these fall within the four etiological classes above named, the great majority belonging to the third class, namely, that produced by disturbance of the capillary secretion through alterations in the vessel walls.

Etiological Varieties of Œdema.—*Œdema of Stagnation.*—Following an obstruction to the onward flow of the blood, resulting from ligation or occlusion of the main venous trunks, or in general venous congestion, due to insufficiency of the heart, the capillary pressure rises and an abnormal secretion of lymph takes place. That the œdema is due directly to the increased blood pressure within the capillary cannot be said to have been definitely proved. It is probable that as a result of the increased pressure the cells of the capillary walls are stimulated to increased secretory activity. It is also probable that degenerative changes in the endothelium result from the distention of the vessel, so that as a consequence of an increased permeability of the wall serous transudation occurs. The fact that in many cases no changes in the vessel walls of an œdematous area can be found favors the theory of increased secretion. In chronic congestion the occurrence of œdema is also favored by the resulting loss of elasticity of the tissues about the vessels. An increase of arterial pressure does not give rise to œdema so long as the venous return is unimpeded, but in all cases of passive congestion there is an increased formation of lymph. This may be compensated for by an increased flow of lymph, but beyond a certain limit the fluid collects in the tissues. In cases of general passive congestion the œdema first shows itself in the most dependent parts of the body, the influence of gravity favoring the greatest increase of pressure in the vessels of these parts. As in general passive congestion there is some obstruction to the discharge of the large lymph trunks into the veins, the lymph of the tissues is not removed so rapidly as normally. Local passive congestion gives rise to local œdema; thrombosis of the femoral vein causing œdema of the lower extremity, occlusion of the portal circulation being followed by ascites, etc. The fluid in œdema of stagnation always contains but a slight amount of albumin. With increase of pressure the amount rises, and a varying number of red cells may escape from the vessels into the lymph.

Œdema Caused by Obstruction to the Lymph Circulation.—It has been shown by a number of investigators that obstruction to the current in the lymph vessels is not as a rule followed by œdema, on account of the numerous and universal collateral anastomoses, and also for the reason that the lymph may be reabsorbed by the blood-vessels. An actual obstruction to the lymphatic circulation can, therefore, hardly occur except in the case of the main lymphatic trunks. Even in these cases, if the production of the lymph remains normal, collateral channels may be developed, sufficient to carry off the lymph without causing œdema. According to Baldaert the total occlusion of all the lymph vessels of a part may give rise to a pure lymphatic œdema, which in the case of increased formation of lymph may develop into a tissue œdema. Obstruction of the thoracic duct by tumors, aneurisms, etc., is usually followed by chylous ascites. Even in this event a collateral circulation may be set up; but in other cases the rupture of the receptaculum chyli gives rise to a chronic chylorrhœa into the peritoneal cavity. In the case of œdema caused by stagnation lymphatic obstruction causes a great increase in the degree of the œdema present.

Œdema Caused by Disturbances of Capillary Secretion.—As the result of chemical changes in the blood, imperfect oxygenation, anæmia, infections, intoxications, long-continued passive congestion, trauma, effects of low or high temperatures, etc., certain pathological alterations in the walls of the vessels may be produced, of such a nature as to cause an increase in the secretion of the vessel walls and give rise to œdema. The exact nature of the changes we are at present unable to state; in some cases the endothelial cells appear granular, cloudy, and are exfoliated; in other cases no changes in the cells can be discovered. It is also possible that alteration of the cement substance between the cells favors an increased transudation of fluid. The forms of œdema produced by the above-named factors are known clinically as toxic, infectious, neuropathic, inflammatory, etc.

Œdema ex Vacuo.—After degeneration or necrosis of portions of the tissue of brain or spinal cord the necrosed material is absorbed and the defect becomes filled with fluid of a very low specific gravity and containing but a small amount of albumin. In atrophy of the brain and cord the subarachnoidal space and the ventricles may become enlarged and filled with a similar fluid. This process may be regarded as being of the nature of a compensatory attempt to restore the normal tension of the part.

Nature of the Transudate.—The fluid of œdema is usually colorless or pale yellow, clear, and of alkaline reaction. A few leucocytes and red cells are usually present. In cases with accompanying icterus the fluid may be yellow or even brownish. An excessive number of red cells may give it a reddish tinge. The collections of fluid in the serous cavities are more likely to vary in color in a noticeable degree, and usually contain flakes of fibrin. Occasionally they may contain large numbers of desquamated endothelial cells, leucocytes, or fat droplets. After rupture of chyle vessels the admixture of chyle with the fluid of an existing ascites may produce a milky turbidity of the ascitic fluid. In other cases the milky appearance of transudates may be caused by a precipitation of albumin. The chemical composition of transudates is closely related to that of the blood plasma.

Digitized by Microsoft®

The amount of proteids, salts, and extractives is a varying one, and is usually less than that of the blood. Under certain conditions the salts and extractives may occur in greater amounts than in the blood, but the amount of albumin is always much less. The fibrin forming elements may be absent or present in small amount. Mucin is occasionally present. The proportion of albumin in pure transudates varies greatly in different parts of the body. According to Reuss, the proportion of albumin in pleural transudations is 22.5 *per mille*, in pericardial 18.3, in peritoneal 11.1, in the fluid of subcutaneous œdema 5.8, in that of cerebral and spinal cavities 1.4.

The following table of the specific gravity and albumin content of certain transudates is given by Thoma:

	Specific gravity.	Per cent. of albumin.
Ascitic fluid in nephritis	1.006	0.56
Ascitic fluid in portal obstruction (cirrhosis)	1.008	.97
Ascitic fluid in general venous congestion	1.012	1.96
Pleural effusion in nephritis	1.007	
Pleural effusion in general venous congestion	1.012	1.30
Transudates of varying origin	1.007-1.011	0.05-1.1

As a rule the specific gravity of a pure transudate rarely reaches 1.010, usually falling below, 1.006–1.008. In inflammatory œdema the specific gravity may reach 1.016–1.020. In inflammatory œdema the amount of albumin is much greater than in pure transudates. The presence of abnormal substances in the blood plasma (sugar, uric acid, bile pigments, potassium iodide, phenol, etc.) leads to the presence of the same in the fluids of the tissues and body cavities.

General Morbid Anatomy.—Œdematous tissues are usually pale, swollen, and as the result of the deficient circulation colder than normal. The degree of change varies with the part involved and the structure of the tissue. The skin and subcutaneous tissue may take up an enormous amount of fluid; the skin may become greatly stretched, and an extremity may swell to many times its normal size. As a result of the extreme distention the skin at first becomes greatly thinned, smooth, and shining, later presents linear lines of rupture from which spontaneous oozing of fluid may occur; in chronic œdema the skin usually becomes thickened, rough, scaly, and pigmented, and may show numerous lineæ albicantiæ. The most characteristic physical sign of œdema is that of pitting on pressure, indentations made with the fingers in œdematous tissues persisting for some time, because of the diminished elasticity of the tissues. The lymph spaces of the skin and subcutaneous tissues may become so dilated that incision into these allows the fluid to escape in a constant stream. The appearance of the incised tissue is that of a partial liquefaction, so great may be the saturation with fluid. Œdema of the skin usually appears first over the ankles and beneath the eyes. The loose integument of the penis and scrotum may show the most extreme degree of saturation.

Collections of fluid in the body cavities, when extreme and long continued, cause dilatation of the cavity and compression of neighboring organs. The serous surfaces become grayish and more opaque and usually present more or less desquamation. In œdema of mucous membranes the mucosa becomes swollen, pale, grayish, more or less translucent, and of boggy consistence. In the case of the lung the alveolar spaces become filled with fluid, the presence of the fluid causes a loss of elasticity and a partial atelectasis. On section a more or less abundant frothy fluid escapes from the cut surface. In marked pulmonary œdema the volume and weight of the organ may both be greatly increased. Solid organs like the liver and kidney from the nature of their structure rarely show a marked condition of œdema. When present, the cut surface of the organ is moist and glistening.

The microscopical examination of œdematous tissues shows enlargement of the tissue spaces, separation of the connective-tissue fibrillæ, vacuolization of cells and nuclei, and the presence of fine albumin granules in the spaces occupied by the fluid. In the alveolar spaces of the lungs large numbers of desquamated epithelial cells are also found. In chronic œdema hydropic degeneration of some of the constituents of the tissue may take place. As a result of the lowered resistance of œdematous tissues, and the mechanical injury caused by stretching, distention, etc., secondary inflammatory changes are of frequent occurrence in and about œdematous tissues.

Clinical Varieties of Œdema.—*Inflammatory Œdema.*—The œdema associated with inflammatory processes is not of the nature of a pure transudate, but is usually classed under the head of exudates. Its etiology is, however, to be sought in alterations of the vessel wall similar to those which give rise to transudates, though of a more marked character. It occurs as circumscribed or diffuse swelling of tissues, or as effusions into the body cavities. It differs from transudates in the character of its fluid, which contains much more albumin and greater numbers of red cells and leucocytes, and a much greater proportion of fibrin-forming elements. It may be caused by any of the factors—infectious, toxic, traumatic, thermal, etc.—that give rise to inflammation. The œdema often seen in the neighborhood of inflammations is known as *collateral œdema*. Inflammatory œdema is regarded by some writers as representing the transition stage between the vascular changes that give rise to pure transudates or œdema, and those which lead to inflammatory exudation.

Toxic.—Heidenhain found that intravascular injections of the enzymes of the salivary, pancreatic, and gastric secretions, peptone, egg albumen, decoctions of the muscles of crabs and crayfish, etc., produced a marked increase in the production of lymph. He explained this phenomenon as due to the stimulation by these substances of the secretory functions of the cells of the vessel walls. According to Hamburger bacterial products circulating in the blood may either increase the permeability of the capillary wall or stimulate the endothelial cells to an increased or abnormal secretory function. A changed chemical condition of the blood may have a similar action. It has been suggested that œdema may be caused by a lack of oxygen, the resulting chemical changes in the blood or tissues causing an increase in osmotic pressure in favor of the tissues over the blood or lymph. The œdemas formerly regarded as *cachectic* or *hydræmic* are most probably caused by the altered functional activity of the endothelium due to changes in the composition of the blood. The œdema of chronic nephritis is probably to be explained in the same way. The acute œdematous conditions of the skin, such as urticaria, are also due wholly or in part to intoxication. The injection of certain protective or curative serums (plague serum) may be followed by extensive urticaria, or even by a more generalized œdema.

Hydræmic or Cachectic Œdema.—It was formerly held that a hydræmic condition of the blood, due either to a diminution of the solids of the blood or to a retention of water, could be a direct cause of an increased transudation through the vessel walls. The latter were believed to behave as dead animal membranes, and the process of œdema formation to be one of pure osmosis. It was shown by Cohnheim that hydræmia was not the direct cause of œdema. Even when the blood is replaced to the extent of one half its volume by decinormal salt solution, so that there is produced a marked hypoalbuminosis, no œdema is caused. In extreme hydræmic plethora, œdema may supervene when the amount of water in the blood becomes very great; but it does not develop in the same regions where œdema ordinarily is found. Further, the occurrence of one-sided hydrothorax, or of bilateral hydrothorax with unequal amounts of fluid in the two pleural cavities, must be taken as strong evidence of differences in the structure and function of the capillary walls in the two sacs. In general it may be said that hydræmia does not produce œdema, but only favors its occurrence. The œdemas which occur in chronic anæmia, cachexias, chronic nephritis, etc., are, therefore, to be regarded as due to changes produced in the vessel walls

Digitized by Microsoft®

www.libtool.com.cn

by the altered condition of the blood or by poisons circulating in the blood. By Thoma and other writers it is believed that cachectic and hydræmic œdemas are due to sclerotic changes in the vessel walls (*angiosclerotic œdema*). A loss of elasticity of the tissues may also favor the formation of œdema in these conditions. The fluid of hydræmic or cachectic œdema contains but a small amount of albumin as compared to inflammatory œdema.

Neuropathic Œdema. Angioneurotic Œdema.—If the production of lymph is dependent upon a secretory function of the vessel walls it is very probable that such function is under nervous control, and that under certain nervous disturbances an œdema may arise which may properly be designated as neuropathic. This is borne out by many clinical observations. In hysterical individuals and in persons who have been hypnotized localized œdemas may occur that admit of no other explanation. In epilepsy pale or red areas of angioneurotic œdema are not infrequently seen, in the shape of wheals, general urticaria, etc. In Basedow's disease urticaria not infrequently occurs, as well as circumscribed, unilateral œdema localized in the hands or legs. Erythema nodosum and herpes zoster are also regarded as partly toxic and partly neuropathic. Œdema also occurs after spinal paralysis; and in hemiplegia the affected side shows a more or less well-marked œdema. According to Janowski the severing of the vaso-motor nerves in conditions of œdema is followed by a great increase in the amount of the exudate. Vaso-motor disturbances in myelitis, tabes, sciatica, etc., are also associated with the production of œdema. Toxic, thermal, or traumatic irritation of the nerves may also lead directly to œdema. It must be borne in mind, however, that many writers hold that the existence of a purely neuropathic œdema has not yet been proved.

Œdema Fugax.—Transitory œdema is designated by this term. The majority of the so-called neuropathic œdemas are of this nature. Transitory œdema is of not infrequent occurrence in Basedow's disease, chlorosis, severe anæmia, hysteria, etc. Such œdemas usually appear during the day and disappear after a night's rest.

False Dropsy (*Hydropsia Spuria*).—The distention of cavities, chiefly those of glands, following stenosis or obliteration of the gland duct. The fluid usually results from the retention of secretions; it may be a thin serous or a thickened mucous fluid. In this class belong hydronephros, hydrosalpinx, hydrops cystidis felleæ, hydrometra, hydrops processus vermiformis, hydrops sacci lacrymalis, etc.

Œdema Intermittens.—Intermittent œdema has been described in cases of malaria, and in febris intermittens larvata. The whole body surface may be involved, but often the œdema is confined to the extremities, thorax, etc. Intermittent ascites and intermittent hydrarthros have also been observed.

Œdema Neonatorum (*Sclerema* or *Scleroma Neonatorum*).—A condition of the skin of the new-born characterized by an infiltration of serum into the subcutaneous tissue, hardening of the skin, and lowering of the skin temperature. Many theories have been adduced in explanation of this condition, but it is probable that scleroma represents a symptom complex and not an independent disease. The majority of children affected are those born prematurely. The affection begins usually on the second to the fourth day. After the eighth day it is very rare. Congenital cases have been observed. In the majority of cases the condition is fatal. The œdema has not been satisfactorily explained, but is probably due to changes in the blood following cardiac insufficiency, deficient oxygenation, and changed chemical nature of the blood in some cases due to intestinal intoxication. D'Agata is of the opinion that the condition is of the nature of a vaso-motor and trophic vagus neurosis.

Occurrence of Œdema.—Œdema is of most frequent occurrence in all forms of cardiac insufficiency, especially failure of compensation in valvular disease, chronic nephritis, cirrhosis of the liver, chronic anæmias, and cachexia, conditions in the lungs favoring venous stasis, thrombosis of large veins, or obstruction of these by tumors. In cases of hæmophilia after repeated hemorrhages œdema often occurs. Myelitis with decubitus is often associated with œdema of the lower extremities. Mediastinal tumors, or growths arising in the lungs or bronchial glands, or aneurism may cause œdema of one-half the body through pressure upon the large veins. In chronic chloral poisoning general œdema of the skin occurs, and in chronic morphinism œdema of the face has been observed. In both acute and chronic rheumatism circumscribed or diffuse œdema often appears in various parts of the body; in chronic rheumatism it is not infrequently associated with arteriosclerosis, particularly of the arteries of the foot and of the tibialis posticus. Œdema is also often associated with arteriosclerosis dependent upon other causes, vessel walls which show sclerotic changes being more permeable than normal vessels. In cases of cancer and ulcer of the stomach œdema may occur after severe hemorrhages. In chronic tuberculosis it is of less common occurrence. In this disease it is more often confined to one of the lower extremities, usually the left, as the result of marantic thrombi in the crural vein or some of its branches. When double-sided the œdema is due to cardiac insufficiency or to the changed condition of the blood. The development of amyloid disease or tuberculous peritonitis usually leads to extensive or general œdema.

Œdema of the larynx occurs in laryngitis, nephritis, malaria, cardiac insufficiency, enlargements of the thyroid, aortic aneurism, pressure of tumors upon the jugular veins and their branches, after the use of potassium iodide, inhalation of hot air, in acute infections, variola, typhoid, etc., in leukæmia, and in tuberculosis, syphilis, and carcinoma of the larynx, etc. Œdema of the pharynx occurs in the same conditions, but most frequently in scarlet fever and in chronic nephritis. The œdematous mucosa is swollen, translucent, and pale, these changes being most marked over the soft palate and uvula. The latter organ may be greatly increased in length and thickness and may cause serious disturbances of respiration. Œdema of the lung occurs especially in cardiac insufficiency, chronic nephritis, in connection with inflammatory conditions of the lung, and also in association with cerebral disease. Marked œdema of the penis and scrotum is very common in cases of extensive general œdema. Local œdema of these parts occurs in cases of stricture, traumatic injury of the urethra, bladder and seminal ducts, in infiltrations of urine, in syphilis, and after operations upon the bladder or rectum as one of the first signs of a phlebitis in the plexus prostaticus. There appears also to be an idiopathic form of œdema of the penis. In chronic œdema of this organ there often results a marked phimosis and a thickening of the mucous membrane of the external meatus. Œdema of the external female genitalia occurs after difficult labor, in cases of ovarian or uterine tumors, in abnormal position of the uterus, prolapse, etc.

In cases of infection with the bacillus of *malignant œdema* there develops very rapidly a general subcutaneous œdema, in the fluid of which many bacilli are found. Only a few cases have been reported in man, some of these following the injection of musk in the course of typhoid fever, others occurring during the puerperium, and others arising apparently without external injury. It is very probable that some of the conditions reported under this head were not in reality cases of infection by this bacillus.

Prognosis.—The consequences of œdema vary with the etiology, location, and extent of the process. Collections of fluid in the body cavities may cause compression of important organs, lungs, brain, etc. As a result of œdema of the nerves, degenerations and loss of function may take place. Œdema of the glottis may cause sudden death from suffocation. Œdema of the lungs is very frequently the immediate cause of death in cardiac insufficiency, chronic nephritis, etc. Fatal intracranial pressure may be caused by acute transudation into the cerebral ventricles and submeningeal spaces. Serious in-

Digitized by Microsoft®

terference with respiration and circulation may be produced by pressure upon the lungs or diaphragm or by pleural or peritoneal dropsies. In general it may be said that the prognosis in œdema is serious because of the important pathological conditions underlying its appearance.

www.libtool.com.cn

TREATMENT.—In general this is directed to the condition which gives rise to the œdema. Extreme distention of œdematous skin may be relieved by puncture and continuous drainage. Collections of fluid within the body cavities may also be removed by aspiration (see also *Ascites*). *Aldred Scott Warthin.*

ŒDEMA NEONATORUM, or œdema of the new-born, was long confounded with "scleroma neonatorum"—a distinct affection. Œdema may occur in infants prematurely born or in those born at term but of poor vitality; it differs in these subjects in no respect from œdema in older patients, and can hardly be considered more than a symptom, associated as it is with many different conditions of the body. As with œdema in general the parts are soft, waxy white, pit on pressure, and in the more dependent areas the swelling is greatest. Bad feeding, defective hygiene, exposure to severe cold soon after birth, feeble heart action, and atelectasis of the lungs are all causes tending toward the production of the symptom of œdema in new-born infants. The treatment is that of the general condition and should be directed toward the underlying causes. Artificial heat to maintain the body temperature is an important adjunct. *Charles Townshend Dade.*

ŒNANTHE. See *Poisonous Plants.*

ŒSOPHAGUS, PATHOLOGY OF.—The wall of the œsophagus consists of a mucosa, submucosa, inner circular and outer longitudinal muscular coats, and an external fibrous tunic. The mucosa is covered with stratified squamous epithelium, and contains sparsely scattered mucous glands and few lymph follicles. In the upper portion striped muscle is also present in the wall, in the lower portion only unstriped. The poor blood supply, the lack of mucous glands and lymph follicles, and the thick covering of stratified squamous epithelium render the œsophagus less liable to disease than the closely associated structures, the pharynx and the stomach. The independent part played by the œsophagus in affections of these organs is often strikingly shown in the sharply limited borders of inflammatory processes in the pharynx, the inflammation ceasing abruptly at the beginning of the œsophagus. Though œsophageal disease is relatively rare, it is nevertheless of very great clinical importance, not only from the fact that disease of the œsophagus may interfere with the proper passage of food into the stomach, and thus give rise to general impairment of nutrition, but also because of the proximity of this organ to such important structures as the trachea, lungs, and aorta. Further, the examination of the œsophagus is relatively difficult, and possible only through the use of special instruments or apparatus. (For methods of examination see *Stomach, Surgery of the.*)

CONGENITAL MALFORMATIONS.—Though relatively rare, these conditions are of practical interest, inasmuch as children so affected may live for some time after birth, or even reach adult age. The malformations may exist alone or in connection with other defects. The following forms have been described:

1. *Œsophago-tracheal Fistula.*—Abnormal communications between œsophagus and trachea may occur. The most common form is that in which the œsophagus at the upper third ends in a blind tube, while the lower portion opens at its upper end into the trachea or bronchus. The upper and lower ends of the obliterated œsophagus may be connected by a muscular band or a firm fibrous cord. This malformation may be due to primary disturbances of development, or may be acquired during intra-uterine life as a result of suppurative processes in the glands lying between the œsophagus and the trachea. The upper part of the œsophagus may be closed in this way by cicatricial contraction, while the lower part may be connected with the lumen of the trachea, or the reverse condition may occur. Children showing this malformation may be otherwise well developed; they die shortly after birth from inanition or aspiration pneumonia. In this connection should be mentioned also the rare occurrence of cysts lined with ciliated columnar epithelium, lying between the œsophagus and the bifurcation of the trachea. These cysts represent remains of the communicating canal between œsophagus and trachea. They may reach such a size as to cause compression of the œsophagus and secondary dilatations of the same, and are therefore of clinical importance. In other cases they may be discovered only accidentally, having given rise to no symptoms.

2. *Stenosis.*—Partial obliterations or narrowing of the lumen may occur as congenital malformations of either the upper or the lower portion of the œsophagus. The lower end of the upper portion may open into the trachea, or may form a blind sac. In other cases the œsophagus may be open as far as the level of the bifurcation of the trachea, at which point complete obliteration of the lumen may be found. In a few cases a membranous stenosis or obliteration has been observed, or the lumen has been closed by a ring-like fold of mucosa. Those cases of obliteration in which the continuity of the œsophagus has been completely broken have been explained by the development of the trachea and bronchi at the cost of the œsophagus; while those cases in which the continuity is not wholly lost, but in which the two portions of the œsophagus are connected by a muscular band, have been explained as the result of a fœtal pressure-atrophy. The conditions are rare; only the partial stenoses have clinical significance.

3. *Total absence* of the œsophagus is without clinical significance and is found only in acardiac monsters.

4. A *reduplication* of the œsophagus (*diœsophagus*) has also been very rarely observed. The reduplication may be complete or partial, and occurs in different degrees of double monsters. It is likewise without practical significance.

5. *Congenital Dilatations.* In very rare cases there has been observed just above the cardiac orifice a peripheral dilatation of limited extent, the so-called "fore-stomach" or "antrum cardiacum." Children presenting this anomaly usually show the clinical symptom of rumination.

CIRCULATORY DISTURBANCES.—*Active hyperæmia* occurs in the early stages of inflammatory conditions. It may be due also to the irritation of certain foods or drinks. *Passive congestion* occurs in all cases of general passive congestion, particularly in chronic heart and lung diseases, cirrhosis of the liver, etc. In chronic passive hyperæmia the mucosa of the œsophagus is dark bluish-red; the epithelium often shows plaques of thickening (leukoplakia). Local dilatations of the veins occur, the so-called *œsophageal hemorrhoids* or *varices* (see Fig. 3615). In the upper part of the œsophagus they are relatively frequent, forming small blue nodules or saccular elevations; these possess no clinical significance. In the lower portion of the œsophagus they occur even more frequently, particularly in the region of the cardiac orifice, or a few centimetres above this. The enlarged veins project above the level of the mucosa, and may form saccular papillomatous masses resembling rectal hemorrhoids. The dilated tortuous veins may be as thick as a lead pencil or even larger. They represent vicarious enlargements of the collateral branches connecting the portal circulation (through the vena coronaria ventriculi) with the vena azygos. They occur particularly in portal obstruction (cirrhosis, syphilitic hepatitis, pressure atrophy of the liver, obstruction or thrombosis of the portal vein), as well as in chronic passive congestion due to cardiac insufficiency. They are found in the majority of cases in connection with rectal hemorrhoids. Their presence is revealed clinically by hemorrhage, which may be fatal. As an early diagnostic symptom in cirrhosis of the liver bleeding from œsophageal hemorrhoids is of great im-

Digitized by Microsoft®

portance. Preceding the hemorrhage there may be observed pain in the stomach, swelling of the spleen, and distention of the abdomen, severe pain radiating from the stomach region to the shoulders or extremities—these symptoms are followed by sudden hemorrhage from the œsophagus. Similar symptoms are often seen preceding hemorrhages from piles. The cause of the œsophageal hemorrhage may be due to increase of venous pressure or to ulcerative changes in the mucosa over the varices. Rupture of the varix has followed coughing, severe muscular exertion, dyspnœa, etc. In other cases no direct cause for the hemorrhage can be found. Repeated hemorrhages of small size may lead to severe anæmia. The relative frequency of hemorrhage from œsophageal varices makes the condition a dangerous one.

Œsophageal hemorrhages may be caused also by injury, ulceration, new growths, etc. The hemorrhages very often arise from the large vessels in the neighborhood of the œsophagus, rather than from its own vessels. Bleeding from the latter occurs particularly in cancer of the mucosa. An aortic aneurism may erode the wall of the œsophagus and rupture into the lumen; or, on the other hand, the œsophagus as a result of ulcerative or carcinomatous changes may break into the aorta, carotid, left auricle, etc. Such an event is most likely to happen in cases of œsophageal carcinoma. In whatever way produced, the entrance of arterial blood into the œsophagus makes itself known by the appearance of the blood vomited up, providing the hemorrhage is of sufficient volume to cause immediate vomiting. There may, however, be a continuous slight oozing from an eroded artery or arterial aneurism, and the blood passing into the stomach may be so changed that its arterial character is lost before vomiting takes place. In some cases the blood may be digested and passed on into the intestines.

Retrograde Changes.—*Œsophagomalacia* is in the great majority of cases a post-mortem digestion of the mucosa of the œsophagus by stomach fluids which have passed, after or during death, through the cardia into the œsophagus. The epithelium is macerated, desquamated, or liquefied; the musculature may also be liquefied and perforated, the stomach juices passing into the pleural cavity. In the lightest grades, which are present in the majority of cadavers, the mucosa of the organ shows longitudinal stripes of desquamation corresponding to the longitudinal folds of the contracted mucosa. An intravital œsophagomalacia is of very rare occurrence, but has been described as the *round* or *peptic ulcer* of the œsophagus, which corresponds in all particulars to the round ulcer of the stomach. An *agonal* œsophagomalacia has been observed in severe cases of cerebral disease.

Atrophy of the œsophagus wall occurs in cachexia. *Degenerations* of the œsophagus wall are of very rare occurrence and have been studied but little. *Necrosis* is the most important retrograde process found in this organ. The most common cause is pressure, either from foreign bodies lodged within the lumen or from the pressure of an aneurism or tumor from without. As a result of the local anæmia caused by the pressure there occur necrosis and ulceration. The *peptic ulcer* has been mentioned. *Decubital* ulcers may be found in advanced stages of severe cachexias. *Noma* of the cheek or pharynx, gangrenous tonsillitis, or gangrene of the lung may be associated with *gangrene* of the œsophagus. Corrosive poisons may cause more or less extensive necrosis of the œsophageal mucosa associated with inflammatory changes. Gangrenous œsophagitis occurs also in severe infections as a rare complication.

Inflammation.—*Acute catarrhal œsophagitis* is the most common form. It is caused chiefly by irritating foods or drinks, through extension of inflammation from the pharynx or stomach, or as a secondary phenomenon in some of the acute infections (measles, scarlatina, typhoid fever, variola). As a result of the small number of glands in the mucosa there is often but little secretion. The epithelium may be desquamated, and the mucosa beneath hyperæmic, or cloudy white, or yellowish. Small ulcers may be formed over the surface of the folds, and these may heal with the formation of small longitudinal scars. In the case of foreign bodies deeper ulcers may be produced. The symptoms of acute catarrhal œsophagitis are, pain in swallowing, regurgitation, thirst, raising of

Fig. 3615.—Esophageal Varices. (After Kraus.)

secretion, pain on moving the neck, tenderness on pressure in the deep cervical region. Spastic contractions of the œsophagus may also occur.

Chronic catarrhal œsophagitis occurs chiefly in smokers and drinkers, as well as in individuals suffering from chronic pharyngitis or, more rarely, gastritis. The condition is often secondary to the chronic passive congestion caused by cardiac or pulmonary disease. It is found also in the portion of the œsophagus above a stenosis. It may be associated with diverticula. In cases of chronic gastritis characterized by frequent eructations of irritating substances or by frequent vomiting of the same, there may be produced a chronic œsophagitis, which may be of a purulent or ulcerative character. This condition is not infrequently found in old men.

Chronic œsophagitis may not always give rise to symptoms. In severe cases there may be pain and discomfort in swallowing. The pain has usually the character of pressure, more rarely it is stinging or burning; when it is severe, spastic contractions and regurgitation may occur. Moderate quantities of mucus may be expectorated; this may occasionally contain streaks of blood. The differential diagnosis from the accompanying affections of pharynx or stomach is often very difficult. The symptom of dysphagia, less marked in the case of fluids than in the swallowing of solid substances, is the most constant and characteristic symptom. Examination with œsophagoscope or sound is usually difficult, but is necessary for the exact determination of the condition. This is of great importance, inasmuch as the symptoms of chronic œsophagitis and beginning carcinoma of the œsophagus are the same; and the differential diagnosis can be made only by means of the œsophagoscope.

In chronic œsophagitis the mucosa is deep reddish-blue in color, and is thickened, often showing polypoid or papillomatous hyperplasias, or flattened plaque-like areas of epithelial hyperplasia (leukoplakia) (see Fig. 3616). The muscular coats are often hypertrophic. Over

www.libtool.com.cn

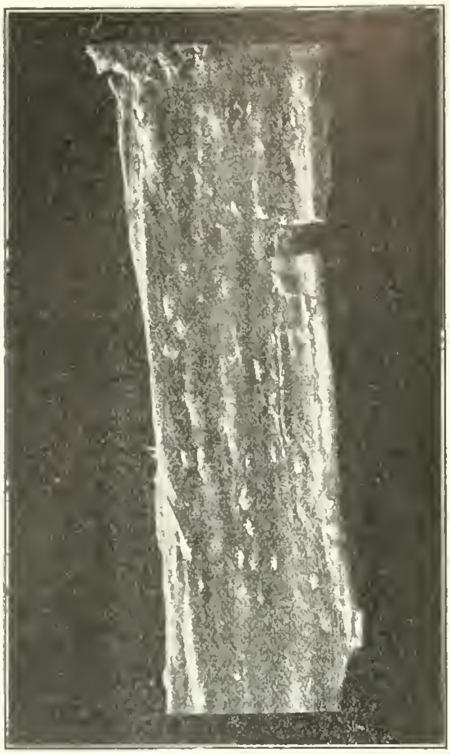

FIG. 3616. Leukoplakia of the Œsophagus. (After Kraus.)

the mucosa lies a layer of thin or thick, often very tenacious mucus, which at times is muco-purulent in character. Small or large erosions or ulcerations may also be present. The lumen is usually dilated, but may be narrowed either symmetrically or irregularly.

Abscesses may form in either acute or chronic œsophagitis, but are rare. In these cases the local symptoms are severe, chills and fever occur, blood or bloody purulent material may be expectorated. The course is usually prolonged; dysphagia may exist for many months. In very severe cases death may occur; but milder cases usually end in recovery after several weeks or months.

Follicular œsophagitis occurs when the glands of the mucosa become involved. The gland ducts are obstructed, there is extensive mucus formation, the gland lumen is dilated, and cysts filled with mucus are in this way produced. These rarely reach the size of a pea. About the cystic glands there is a small-celled infiltration; this may lead to suppuration and formation of ulcers. Occasionally a phlegmonous œsophagitis may be associated with the follicular form.

Phlegmonous œsophagitis is of rare occurrence. It may be caused by the presence of foreign bodies or corrosive poisons, but the most frequent cause is an extension from periœsophageal abscesses (purulent lymphadenitis, perichondritis cricoidea, spinal abscesses) or from phlegmonous processes in the pharynx, or more rarely in the stomach. It may also follow a follicular œsophagitis; through the confluence of the small follicular abscesses a diffuse purulent process may be produced. In advanced cases of pulmonary tuberculosis diffuse purulent œsophagitis or abscess formation in the œsophagus wall may occur without other evident cause.

Phlegmonous œsophagitis begins as a purulent infiltration of the submucosa, followed by a liquefaction of the tissue and the formation of circumscribed or extensive collections of pus. The mucosa may be extensively undermined; at the same time it may be reddened, and may present throughout its reddened surface numerous sieve-like yellowish apertures through which pus exudes. Large circumscribed collections of pus may cause bulgings of the mucosa into the lumen. The tissues about the œsophagus may be involved (periœsophagitis phlegmonosa), and the abscesses may rupture into the larynx and trachea, or more rarely into the mediastinum and pleura.

The symptoms of phlegmonous œsophagitis are usully obscure and offer few characteristics sufficiently striking to make the diagnosis from other conditions certain. Fever, chills, and dysphagia are the most constant symptoms. Pain may be felt behind the sternum or larynx; pressure upon the epigastrium may occasionally give rise to violent pain. Dyspnœa may be caused by pressure of an abscess upon the trachea or upon the bronchi. The dysphagia may increase to such an extent that fluids can no longer be swallowed. If the rupture of a large abscess into the œsophagus be followed by expectoration or regurgitation of pus, the diagnosis of phlegmonous œsophagitis is rendered more probable; but even in the event of such regurgitation the pus may come from an abscess in the neighborhood of the œsophagus, which has ruptured into its lumen. Only when foreign bodies are known to be lodged in the œsophagus can the diagnosis of phlegmonous œsophagitis be made with certainty. In the event of fistulous communication between the œsophagus and respiratory tract purulent pneumonia or gangrene of the lung usually results quickly. The prognosis is doubtful. Recovery may take place, the formation of cicatricial tissue in the submucosa and mucosa may give rise to stenosis, or in other cases intraparietal diverticula may be formed, the abscess cavities beneath the mucosa healing at the base but remaining open and communicating with the lumen of the œsophagus by wide openings in the mucosa having sharply cut undermined edges.

In connection with phlegmonous œsophagitis may be considered also the *periœsophageal abscess*. This has its origin most frequently in tuberculous lymph glands situated in the neighborhood of the œsophagus or in tuberculous caries of the vertebral column, or it arises in the course of a pyæmia. Further, purulent processes of the parotid or submaxillary may extend to the connective tissue about the œsophagus. Involvement of the œsophagus wall or rupture into the lumen of this organ may set up a phlegmonous œsophagitis. Rupture into the respiratory tract, pericardium, or pleura may occur. The periœsophageal abscess may reach a very large size, though often it is small. It is usually found between the fourth and seventh cervical vertebræ. The abscess arising in tuberculous lymph glands or tuberculous vertebræ is found most often in children, and its location is ordinarily between the vertebræ named. The symptoms are those of phlegmonous œsophagitis: fever, chills, dysphagia, pain on turning the neck, dyspnœa, etc. Children frequently become comatose; convulsions may occur; and finally the diagnosis may be made clear by the appearance of a swelling in the neck. In the case of tuberculous caries of the vertebræ the abscess may develop very slowly with few or no symptoms. The sound may be passed into the stomach without difficulty, but usually with more or less pain.

Œsophagitis pustulosa is the designation given to the changes in the œsophageal mucosa which occur in smallpox. Papules develop throughout the mucosa, these become cloudy and purulent, the epithelium over them is cloudy, thickened, and finally undergoes desquamation, leaving small ulcers.

Membranous Œsophagitis (*Œsophagitis Fibrinosa or Diphtheritica*).—True diphtheria of the œsophagus is rare; only in exceptional cases is there an extension from the pharynx into the œsophagus. Cases have been ob-

Digitized by Microsoft®

served in which the œsophagus remained free when both pharynx and stomach were attacked; the œsophagus may, therefore, be said to possess a certain immunity in respect to diphtheria. A membranous or fibrinous œsophagitis accompanied by diphtheritic necrosis is of relatively frequent occurrence as a secondary condition in severe cases of smallpox, scarlet fever, measles, pyæmia, cholera, typhus fever, typhoid, chronic Bright's disease, pneumonia, tuberculosis, and in children as a frequent complication in intestinal catarrh. The process is rarely diffuse, but is circumscribed, and usually localized on the highest parts of the folds of the mucosa. Small ulcers may be formed at these places. Usually the symptoms of diphtheritic œsophagitis cannot be separated from the accompanying disease, but in certain cases the disease may manifest itself through hemorrhage or discharge of pseudomembranes from the œsophagus. The prognosis is very grave. When recovery takes place cicatrization of the diphtheritic ulcers may lead to stenosis of the lumen.

www.libtool.com.cn

Œsophagitis corrosiva is produced by the action of corrosive agents, acids, or the caustic alkalies, most commonly by concentrated lye, which have been swallowed either purposely or accidentally. (See Fig. 3617.) The change produced by the corrosive agent is of the nature of a necrotic inflammation; its severity depends upon the strength or concentration of the poison. In mild cases the superficial epithelium is necrosed, and is desquamated in grayish shreds resembling a croupous membrane. Alkalies may cause the cells to swell and form a soap-like mass. A more severe action of a corrosive agent may convert the entire mucosa into a dirty gray or black eschar; the vessels are injected; the submucosa contains numerous ecchymoses, and there is a line of demarcation separating the dead tissue from the inflamed tissues of the submucosa. Active suppuration occurs and the necrotic mucosa is desquamated. If healing results, the lumen may become greatly narrowed or gradually completely occluded. In the most severe cases the deeper layers of the œsophagus may be affected. The symptoms are severe burning pain beneath the sternum, dysphagia, intense thirst, hemorrhage, and collapse. Portions of the eschar, or masses of bloody mucus may be expectorated. In the mild cases the pain ceases after twenty-four hours, the dysphagia becomes less from day to day, until the symptoms finally disappear altogether. If much scar tissue is formed, difficulty in swallowing may be experienced again after several weeks. Severe cases may be immediately fatal from shock or from hemorrhage, or from perforation; in rare cases the covrse is prolonged, abscess formation, mediastinitis, pyopneumothorax, etc., occurring as complications. Patients recovering from severe corrosive poisoning are sure to suffer from cicatricial contraction of the lumen.

The diagnosis in the majority of instances is revealed by the history of the case and the evidences of corrosive action in the mouth and pharynx. It is of importance to discover the nature of the poison in those cases which are seen shortly after the poisoning has occurred. Litmus paper may be applied to the mucosa of the mouth or pharynx as a rough method of diagnosis as to whether acid or alkali had been used, in case the facts cannot otherwise be ascertained. The majority of such cases are caused by concentrated lye or sulphuric acid. According to von Hacker one-fourth of the cases of poisoning with concentrated lye are fatal as the direct result of the poisoning; in the case of sulphuric acid, about one-half. Of those living after poisoning with concentrated lye about one-half acquire severe stricture of the œsophagus; of those living after sulphuric-acid poisoning about a third show contraction of the lumen.

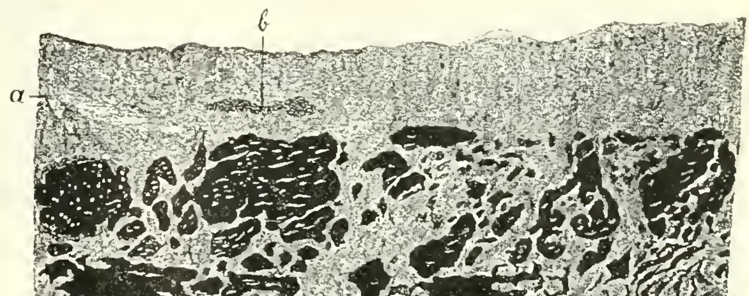

FIG. 3617.—Œsophagitis Corrosiva (after swallowing concentrated lye). *a*, The necrotic mucosa; *b*, bacteria embedded in *a*; *c*, upper portion of submucosa, infiltrated with homogeneous deeply staining masses (fibrin?); *d*, blood-vessel with necrotic wall; *e*, deeper portion of submucosa infiltrated with fibrinous network and leucocytes. (After Weichselbaum.)

Œsophagitis gangrænosa is of rare occurrence. It may follow the action of corrosive poisons, pressure of foreign bodies within the œsophagus or of tumors, aortic aneurism, etc., from without, or it may occur as an extension from gangrenous tonsillitis, pulmonary gangrene, etc. Decubital ulcers may occur in the upper part of the œsophagus or in the lowest portion of the pharynx. (See Fig. 3618.) Two small ulcers, one on the anterior wall, the other on the posterior wall, corresponding in position, shape, and size to each other, occur coincidently, so that one ulcer appears as the impress of the other. The condition occurs only in extremely cachectic individuals who have been confined to bed for a long time; it is due to the pressure of the larynx upon the œsophagus. The ulcers appear shortly before the death of the affected individual and cause difficulty in swallowing, in this way hastening the end.

Œsophagitis exfoliativa (Œsophagitis Desiccans Superficialis).—A number of cases of acute inflammation of the œsophagus, characterized by a rapid desquamation of the entire mucosa, have been described. The desquamated epithelium may form a hollow tube, 15–25 cm. long. The desquamation may be caused by subepithelial inflammation, action of chemicals, etc., but the exact nature of the disease is unknown. The majority of the patients were neurotic or hysterical.

Acute œsophagitis of young children occurs in nurslings as a result of a poor quality of mother's milk, soreness of the nipple, etc. It may be associated with gastro-intestinal irritation. Attempts at nursing are interrupted after a few seconds, the child cries, is restless, and regurgitates the greater part of the milk taken. Pressure upon

Digitized by Microsoft®

the lower part of the sternum is apparently painful, the child often crying out. The disease is important in that it may pass over into an ulcerative or gangrenous inflammation.

Ulcus Pepticum Œsophagi.—Ulcers in all respects similar to the round ulcer of the stomach may occur in the lower portion of the œsophagus, and are regarded as due to the same causes: viz., a digestion by the gastric juice. In cases in which the resistance of the œsophageal mucosa is lowered, the repeated entrance of the stomach fluids into the œsophagus may be followed by the development of one or more round or oval ulcers. These vary in size and depth, their edges are smooth; and the bottom of the ulcer is covered with stringy brownish black masses. Occasionally the ulcers are very large and circular, extending ring like about the lumen. They all show a marked tendency to cicatrization, and lead to strictures, stenosis, or the formation of diverticula. Ulcers extending deeply into the œsophagus wall may perforate, and, following this, pyopneumothorax, mediastinitis, pulmonary gangrene, pericarditis, erosion of the aorta or other large vessels, liver abscess, etc., may result. Carcinoma may develop in the scar, as is frequently the case in the stomach. Not infrequently the round ulcer of the stomach and that of the œsophagus are coincident.

The symptoms caused by round ulcer of the œsophagus are chiefly burning pain and a sensation of pressure behind the lower part of the sternum during the act of swallowing. As a rule, the pain is more severe when solid food is taken than when fluid diet is given. At other times severe cardialgia may be present; also nausea, acid regurgitations, vomiting, and hemorrhage, bloody stools, etc. These symptoms cannot be separated from those of round ulcer of the stomach, which is frequently coincident. The absolute diagnosis may be made only by means of the œsophagoscope. Ulcers of slight extent may heal without complication; after cicatrization new symptoms may appear as the result of the narrowing of the lumen. Severe cases are very danger-

FIG. 3618.—Decubital Ulcers in the Upper Part of the Œsophagus (lower part of pharynx). (After Kraus.)

ous because of the important complications which may follow, and on account of the accompanying rapid emaciation and anæmia.

SPECIFIC INFECTIOUS DISEASES.—*Tuberculosis* occurs as a secondary process in severe tuberculosis of other organs, particularly of the larynx and lungs and the neighboring lymph glands. Primary œsophageal tuberculosis has not yet been reported. The infection of the œsophagus may take place by direct extension from neighboring organs, most frequently from the rupture, into its lumen, of caseating lymph glands; or from the swallowing of sputum in cases of pulmonary tuberculosis, and very rarely from the metastasis of tubercle bacilli in acute miliary tuberculosis. It has been noted that infection does not occur in case of rupture of vertebral abscess into the œsophagus. Infection is made more likely by preceding affections of the œsophageal mucosa, ulcerations, etc. The tuberculous ulcers are usually superficial, but may lead to perforation. The edges are covered by hyperplastic epithelium, scattered through which small yellowish or gray nodules are seen; the bottom of the ulcer is either smooth or papillomatous. Tuberculosis of the œsophagus may exist without any symptoms; when symptoms referable to the œsophagus occur, they consist in dysphagia and pain behind the sternum during the act of deglutition. Thrush may exist coincidently with tuberculosis of the œsophagus, but it is to be remembered that in cases of pulmonary tuberculosis thrush or carcinoma may be found in the œsophagus as an independent affection. The use of the œsophagoscope is necessary for the absolute diagnosis.

Syphilis.—Ulcerations of the mucosa of the œsophagus may be present during either the secondary or the tertiary stage, but on the whole they are rarely observed. They have been seen also in cases of congenital syphilis. The most frequent syphilitic lesion of the œsophagus is the gumma. This may lead to ulceration, perforation, cicatricial stenosis, hypertrophy of the œsophagus wall, etc. Difficulty in swallowing is the chief symptom. The differential diagnosis rests chiefly upon the anamnesis, evidences of syphilis elsewhere, therapeutic test, etc.

Actinomycosis.—A number of cases of primary actinomycosis of the œsophagus have been reported. Inasmuch as the entrance of infection in this disease is usually through the air passages, the œsophagus may be involved by extension from the peribronchial lymph glands or from the lungs, mouth, pharynx, etc. In a given case it may be difficult to decide whether the œsophageal condition is primary or secondary; but in the majority of cases it is likely that the primary seat is in the mouth. It is also probable that, for the infection of the mucosa of the œsophagus, some other lesion (erosion, ulcer, etc.) must be present as a factor favoring the entrance of the organism. The diagnosis of œsophageal actinomycosis rests entirely upon the finding of the parasite in the material expectorated or removed by means of the sound or œsophagoscope.

Thrush.—This is the most common and important parasitic disease of the œsophagus. It may be primary or may extend from the mouth and pharynx. It is most commonly found in poorly nourished children, and in adults suffering from continued fevers, particularly typhoid and sepsis, from chronic cachexias, and from chronic tuberculosis, nephritis, and diabetes, in their last stages. (See Fig. 3619.) Healthy children and adults may be occasionally affected; but the disease is by far most common in cachectic children suffering from chronic digestive disturbances. As a rule, the pharynx and mouth are affected at the same time. The appearance of the parasite upon the mucosa of the mouth, tongue, or pharynx is very characteristic and the diagnosis is easily made. The parasite develops in the upper layer of the mucosa, its filaments forming a dense feltwork among the epithelial cells. Slightly elevated whitish or grayish patches, which can be easily scraped off, leaving a bleeding or ulcerated surface, are seen over the mucosa. In the œsophagus small white, flattened, or nodular patches may be scattered over the mucosa, or the patches may be arranged longitudinally, corresponding to the folds of the mucosa. In other cases a more diffuse growth may be seen, the œsophageal lumen to a large extent or throughout being lined by the growth. In very severe cases the growth may be so extensive as to form thick-walled casts of the lumen or even

Digitized by Microsoft®

solid cylinders. The growth may penetrate into the submucosa or even reach the muscle coats. Penetration into the blood-vessels may occur and metastasis of the parasite result. The reactive inflammation of the œsophageal wall is usually in proportion to the amount of infiltration, by the parasite, of the mucosa and underlying structures.

www.libtool.com.cn

FIG. 3619.—Lower Portion of Œsophagus Showing the Presence of Both Thrush and Tuberculosis. (After Kraus.)

Thrush of the œsophagus rarely gives rise to independent symptoms, except when the growth is extensive. Dysphagia followed by aphagia is the chief symptom, especially in the case of children. Occasionally hollow or solid cylindrical casts of the œsophagus may be regurgitated. In those cases in which the masses of the growth are firmly adherent to the mucosa death may result from the complete obstruction of the lumen of the œsophagus.

ANIMAL PARASITES.—In general trichinosis the encysted worms may be found in the striped muscle of the œsophagus wall. Their presence may be regarded as explaining the painful deglutition occurring in the course of trichina infection. Round worms (ascaris lumbricoides) may wander into the œsophagus from the stomach; and may be found occasionally in œsophageal diverticula. From the œsophagus they may reach the respiratory passages, and entering the larynx may cause severe or even fatal obstruction to respiration. Occasionally other forms of animal life may gain accidental entrance to the œsophagus (flies, bees, wasps, leeches, hair-worms, etc.); in the majority of cases no symptoms are produced, the intruder acting as a simple foreign body, except in the case of leeches and stinging insects. In the case of the former hemorrhage may be produced; and the sting of the latter may give rise to a severe œsophagitis.

PROGRESSIVE CHANGES.—*Hypertrophy* of the wall of the œsophagus occurs above a stenosis of a portion of the lumen or of the cardiac opening. In the latter case the lumen throughout its entire length may be greatly dilated.

TUMORS.—New growths of the œsophagus are on the whole not frequent. Metastatic growths are of rare occurrence. Of the primary tumors carcinoma is by far the most common. Benign tumors causing symptoms during life are very rare. The great majority of benign growths are small and clinically unimportant. Of these the most common are small *papillomatous warts* (œsophageal warts, verrucæ) (see Fig. 3620). These are usually about the size of a pinhead or bean, rarely larger, projecting above the mucosa, and are often multiple or confluent. They are found especially in old individuals. In structure these little growths consist of hyperplastic papillæ, covered with thickened epithelium resembling the condylomata. They rarely ulcerate, and only exceptionally may they offer slight obstruction to the passage of food. They are usually discovered only at autopsy, but their presence in the œsophagus could be revealed during life by means of the œsophagoscope, should they reach such a size as to cause symptoms.

Next in frequency occur *fibromata*, which usually take their rise in the connective tissue outside of the œsophageal wall, but, through pressure, are finally forced to occupy a position in the mucosa of this organ. The prevertebral fascia, the periosteum of the vertebræ, the perichondrium, the periœsophageal connective tissue, and less frequently the connective tissue of the muscle and submucosa of the œsophagus wall form the points of origin

FIG. 3620.—Papillomata of the Œsophagus. (After Kraus.)

Digitized by Microsoft®

for these growths. They are usually diffuse thickenings, but may be polypoid or sharply circumscribed. The last is usually of very small size. Microscopically, the œsophageal fibromata present the appearance of a *fibroma molle* and are usually well supplied with blood-vessels. Their consistency is soft and elastic. The polypoid fibroma may reach a large size and may, during efforts at vomiting, present itself in the pharynx or mouth, where the tumor may be felt or seen. If the growth possesses a long pedicle it may, when situated in the upper part of the œsophagus, be caught at the entrance to the œsophagus, and pressing upon the epiglottis give rise to severe symptoms of dyspnœa and dysphagia. Large growths may more or less completely block the œsophagus and cause pressure upon the trachea. In these cases there is a constant feeling of pressure behind the sternum, increased on eating, progressive dysphagia, pain radiating to the shoulder blades, dyspnœa, etc. The growth is very likely to ulcerate and a spontaneous cure may result in rare cases from such ulceration, or from the twisting or tearing of its pedicle. The diagnosis of œsophageal fibroma is made certain by means of the œsophagoscope, by removal of a portion of tissue from the growth, and by microscopical examination. The prognosis is on the whole unfavorable. The patient usually dies of inanition or suffocation.

FIG. 3621.—Carcinoma of the Œsophagus. (After Kraus.)

Lipomata of the œsophagus occur very rarely in the form of sharply circumscribed or polypoid growths arising in the submucous connective tissue, most frequently in the neighborhood of the laryngeal and tracheal cartilages.

Myxoma of the œsophageal wall has been observed in the form of a polypoid tumor of small size.

Myomata of the œsophagus have been observed a number of times. They are usually leiomyomata, but a few cases of rhabdomyoma have been described. The former may develop from the muscularis mucosæ or from the muscular coats; these growths may be circumscribed or polypoid and occur most frequently in the lower portions of the œsophagus in the neighborhood of the cardia. They are found at any period of life, are usually small, and do not give rise to symptoms. In the one case of rhabdomyoma which has been carefully described, the microscopical appearances were those of a rhabdomyosarcoma; metastasis into the neighboring lymph glands had occurred.

Primary sarcoma of the œsophagus is very rare. Alveolar, spindle-cell, and round-cell forms have been observed in the upper part of the organ, less frequently near the bifurcation, apparently arising from the tissues of the œsophagus wall. In the majority of cases of sarcoma involving the œsophagus, the tumor has extended from some one of the neighboring structures. Lymphosarcoma of the bronchial lymph glands may thus compress and invade the œsophagus. Finally, a widespread lymphosarcomatosis of the œsophagus wall may occur as the result of such extension. Ulceration, hemorrhage, etc., may follow. The ulcer may be covered by a growth of thrush; secondary infection and gangrene may result. Only one case of primary lymphosarcoma of the œsophagus has been reported. The diagnosis of sarcoma of this organ rests upon the presence of symptoms of œsophageal obstruction, the use of the œsophagoscope, and the removal of a portion of tissue for microscopical examination.

Dermoid cysts are very rare. They have been observed in the upper portion of the œsophagus or lower part of the pharynx. The *congenital cysts* lined with columnar cells, which have been observed in the œsophagus wall, are to be classed as *simple teratoid cysts* due to anomalies of development. They represent remains of the original communication between œsophagus and trachea.

Carcinoma.—This is the most common and important of the œsophageal neoplasms. It is almost always squamous-celled in character (*epithelioma, cancroid*), arising from the squamous cells of the mucosa, and exhibiting more or less horny change and formation of epithelial pearls, as is the case with the epithelioma of the skin. Only in rare cases is the primary cancer of the œsophagus of the columnar-celled type (adenocarcinoma). In such cases the growth takes its origin from the cells of the mucous glands, or from congenital cysts lined by columnar cells and lying in the walls of the œsophagus. Occasionally the cancer arising from the gland cells may take on the appearance of a carcinoma simplex, a carcinoma medullare, or a scirrhous carcinoma, etc., but these forms are very rare.

Œsophageal epithelioma (Fig. 3621) is not an infrequent disease. It is found more often in males than in females. The level of the bifurcation is most often involved. It has a tendency to grow in ring shape about the lumen, and in this way gradually to cause stenosis. As the cancer increases in size it quickly ulcerates. In this way a large part of the tumor may be lost and the stricture reduced. About the ulceration, the mucosa shows carcinomatous infiltrations and small secondary nodules, which may also ulcerate. In other cases the edges of the primary ulcer may be nodular, greatly thickened, and firm, causing marked stenosis. The œsopha-

Digitized by Microsoft®

geal wall above the cancer is usually hypertrophic and the lumen dilated. Proliferation of connective tissue about the ulcer may lead to the appearance of a scirrhous cancer. Very frequently a portion of the growth is soft, rapidly growing, and necrotic, while the remaining portion is very hard, composed largely of scar tissue. The greater the connective tissue formation the more marked the stenosis. In the majority of cases only one cancerous nodule of large size is present; only rarely are there multiple cancerous foci. The œsophageal mucosa about the cancer, and particularly the mucosa of that portion of the lumen which is situated above the stenosis, usually shows a marked chronic congestion or inflammation.

Œsophageal cancer occurs most often between the ages of fifty and sixty years. Cases have been observed in young individuals. The etiological factors are no better known than are those of carcinoma elsewhere. It is significant that the most common seat of the growth is at the narrowest portion of the lumen. The condition is more common in smokers and drinkers, and it is probable that chronic irritation here, as elsewhere, favors the development of the neoplasm. Foreign bodies, burns, healed ulcers, etc., have been regarded as etiological factors. The course of the disease usually extends over one year, often over a shorter period. Death takes place usually from inanition due to the stenosis, to a perforation or to hemorrhage, or from fatal complications due to metastasis or extension of the tumor.

Beginning in the mucosa from a proliferation of the epithelium the carcinoma cells infiltrate the submucosa and musculature as far as the outer fibrous covering. The wall first becomes thickened, its original elements undergo atrophy, and the affected portion of the wall is replaced by carcinoma tissue. Necrosis of the carcinoma cells follows, ulceration of the surface occurs, and there is a greater or less formation of scar tissue. As a result of the ulceration perforation into the trachea, bronchi, lung, mediastinum, pleura, pericardium, or large blood-vessels may occur. Erosion of the vertebral column may be produced. Perforation into the trachea, bronchi, or lung is of most frequent occurrence, death resulting from gangrene or purulent pneumonia. Occasionally the carcinomatous infiltration may involve the trachea and bronchi, or even the heart. Erosion of the aorta, carotids, or pulmonary vessels may cause fatal hemorrhages.

In many cases the cervical lymph glands and the connective tissue of this region show extensive carcinomatous infiltration, and the neighboring structures may suffer greatly from pressure. As a result of pressure upon one or both of the recurrent laryngeals, either by the primary tumor or by enlarged carcinomatous lymph glands, paralysis of one or both vocal cords may result. The changed character of the voice, in connection with obstruction to the passage of food through the œsophagus, is an important diagnostic symptom.

Metastases in distant organs occur first in the liver, lungs, and bones. Except in rare cases local metastases in the bronchial, tracheal, and epigastric lymph glands are always present.

The most extensive carcinomatous infiltration of the œsophagus wall may exist without the occurrence of symptoms directly referable to this organ. In some cases the only symptom is progressive emaciation and weakness. In the majority of cases the earliest symptom is dysphagia, which progresses rapidly so that the patient soon becomes emaciated. Regurgitation of food takes place immediately after swallowing if the cancer is situated in the upper portion of the lumen; after some time has elapsed, when the growth is in the lower part, particularly if the lumen above the stenosis is much dilated. The regurgitated food may contain pus, blood, or portions of necrotic cancer tissue. Pain may be constantly present or entirely absent; or present only when food is taken. It may be very severe, of a burning character, or there may be simply a dull pressure, located behind the lower part of the sternum, and radiating to the shoulder blades. Marked dyspnœa may result from the pressure upon the respiratory passages. The enlargement of the cervical lymph glands may occur early and indicate the nature of the disease. Pressure upon the recurrent laryngeals, causing paralysis of the vocal cords, is not infrequent. Disturbance of the sympathetic may cause oculo-pupillary symptoms (miosis, retraction of the lids, narrowing of the palpebral fissure, etc.). Erosion of the cervical vertebræ, pressure upon the brachial plexus, etc., may give rise to paralyses of the upper extremity. The occurrence of perforation into the respiratory tract, pleura, etc., is followed by characteristic symptoms on the part of the region involved. Emphysema of the skin of the cervical region and of the mediastinal tissue may occur. Trophic disturbances in the skin and nails have been observed. The urine usually contains albumin, indican, and phenol; in the late stages of the disease acetone, aceto-acetic acid, and oxybutyric acid.

FIG. 3622.—Spindle-Form Dilatation of the Œsophagus Above a Scirrhous Carcinoma. (After Kraus.)

The diagnosis rests chiefly upon the case history and the demonstration of a stenosis of the œsophagus. If in an individual past the age of forty years there occurs without evident cause a stenosis of the œsophageal lumen, with progressive emaciation, carcinoma is usually indicated. Cicatricial stricture or the presence of foreign bodies may be excluded by the history. Pressure from without, due to aneurisms or neighboring growths, must be eliminated. Carcinoma of the œsophagus has sometimes been mistaken for spasmodic stricture. The writer has seen two such cases, and was able to make the diagnosis of cancer in each case from bits of cancer tissue found adhering to the bougies used in dilating the stricture. In doubtful cases in which the stenosis is slight, the œsophagoscope should be used, and a bit of tissue removed for microscopical examination. The use of sounds, etc., should be attended with great care, from the possible danger of perforation. Auscultation of the œsophagus may also aid in the diagnosis. Gurgling sounds arising at the stenosis may sometimes be heard at a distance from the patient. The constant absence of the sound caused by the passage of food or drink through the cardia may be taken as evidence of the existence of a pathological process interfering with

www.libtool.com.cn
Digitized by Microsoft®

the normal function of the musculature of the cardia. In complete stenosis the food passed into the œsophagus may gradually accumulate above the stenosis and be regurgitated later. The absence of hydrochloric acid, pepsin, peptone, etc., may be taken as evidence that the food had not entered the stomach. The prognosis in all cases is hopeless. Death may be postponed by operative measures.

Fig. 3623. – Diverticulum of the Lower Third of the Œsophagus, with Dilatation. (After Kraus.)

Alterations in the Lumen. — *Dilatation* is usually secondary to stenosis. Primary dilatation of the œsophageal lumen is very rare. The dilatation in the acquired cases may be *general* or *partial*, either the entire œsophagus or only a portion of it, above the stenosis, being enlarged. The dilatation of a localized portion of the wall and not the entire circumference, is known as a *diverticulum*. *Primary or congenital* dilatation is usually general—the so-called spindle form. This may also be acquired, usually in chronic œsophagitis, or œsophagitis secondary to spastic contraction of the cardia. The musculature is usually thickened, and often shows fibroid areas. The ectasia may be enormous, the lumen measuring as much as 30 cm. or more in circumference—as large as a man's arm. At the same time the length is increased, and the organ becomes tortuous. *Secondary* dilatations develop above strictures, but are not present in all cases. (See Fig. 3622.) The dilatation may be fusiform or cylindrical. The muscular coats are usually hypertrophic in the dilated portion. Regurgitation is the chief symptom of œsophageal dilatation. Dyspnœa may be produced by pressure.

Diverticula are of two forms: *pressure diverticula* and *traction diverticula*. The first arises from pressure within the lumen, the latter from external traction pulling out the wall. Pressure diverticula are rare. They are found most frequently at the junction of the pharynx and œsophagus, on the posterior wall. They are also called *dorsal diverticula* in contrast to the *lateral diverticula* of the pharyngeal wall. They are rarely very long, and extend downward between the œsophagus and the vertebræ. The muscular wall is weakest normally at the point where these diverticula occur. Local bulging is first brought about by trauma, swallowing of large and firm pieces of food, etc. The bulging is increased by pressure of food, and gradually there is formed a saccular pouch, the mucosa and submucosa bulging out between the muscle bundles of the inferior constrictor of the pharynx (pharyngocele). In some cases muscle fibres have been found in the wall of the sac, and the condition has been regarded as an ectasia due to a disturbance in the closure of the fœtal cleft at this point. The latter view is probably more generally accepted than the former. In case the diverticulum becomes filled with food there may result difficulty in swallowing, gagging, and vomiting. Decomposition of the contents of the sac may take place, followed by maceration of the epithelium lining it, secondary infection, ulceration, and phlegmonous œsophagitis or periœsophagitis. If the sound is passed when the sac is filled, it is very likely to enter the dilated sac; when the sac is empty, the sound may pass by the opening of the sac without entering it. When passed down against the posterior wall, the sound is more likely to enter the sac.

Traction diverticula are not rare. They occur usually in the anterior wall, in the neighborhood of the bifurcation, rarely higher or lower. (See Fig. 3623.) They result from the extension of an inflammation of neighboring lymph glands with adhesion to the œsophageal wall and subsequent cicatricial contraction, pulling out the wall at the point of adhesion. The sac is usually short; at its tip the remains of a diseased gland are always to be found. The lumen of the diverticulum may point downward, horizontally, or upward. It communicates with the œsophageal lumen by a round, oval, or longitudinal opening of varying size. The mucosa about the opening is often puckered. Several diverticula may exist coincidently. In the majority of cases the lymph glands attached to the diverticula are tuberculous. The condition may have its origin in childhood. Usually traction diverticula exist without symptoms. Through perforation of the sac chronic purulent periœsophagitis may be set up, with extension to pleura, pericardium, lungs, etc. In this way the most severe symptoms may arise and the case reach a fatal termination.

Stenosis of the œsophagus may be *congenital* or *acquired*. In the latter case partial or complete obstruction of the lumen may result from foreign bodies, inflammatory swellings, phlegmon, growths of thrush, tumors; or cicatricial contraction of the wall following corrosive poisoning, syphilis, diphtheritic inflammation, trauma, etc.; or from changes in the neighborhood of the œsophagus, such as enlarged lymph glands, aneurisms, tumors of the lung or pleura, etc. A number of cases of œsophageal stricture following ulceration of the œsophagus in typhoid fever have been observed. The characteristic symptoms in all cases are dysphagia and regurgitation of food.

Rupture of Œsophagus.—This condition is rare. It may be due to trauma or to excessive internal pressure. It is reported as occurring in the healthy œsophagus as a result of prolonged vomiting; usually after a full meal, or in a condition of intoxication. It is probable that in some of these cases some pathological weakening of the wall was present. The condition is invariably fatal.

Foreign Bodies.—Among the foreign bodies reported as gaining entrance to the œsophagus are bones, leeches, needles, false teeth, etc. Needles may pass out through the wall and be found in other parts of the body. Sharp-pointed or rough bodies are most dangerous, as they may enter the wall of the organ and give rise to a phlegmonous œsophagitis, which may extend to the lungs, pleura, or pericardium. In other cases the foreign body may lead to erosion of the large vessels. Complete obstruction of the lumen may be caused by false teeth. Gangrene due to pressure usually results. The entrance of foreign bodies into diverticula may lead to perforation. The fungus of actinomycosis may gain entrance through the lodgment of bits of straw, chaff, etc., in the œsopha-

OJAI HOT SULPHUR SPRINGS.—Ventura County, California. Access.—Viâ Southern Pacific Railroad to Ventura, thence fifteen miles by stage to springs.

This resort is beautifully situated in Waterfall Canyon, about five miles from the thriving village of Nordhoff. The altitude of this location is about one thousand feet above the sea level. The surrounding scenery is very fine, and the vicinity affords excellent hunting and fishing. The springs flow about fifty thousand gallons per hour, and have a temperature ranging from 60° to 104° F. Several of the springs are carbonated, and others are sulphureted. Among the well-known springs are the Fountain of Life, St. Jacob's Well, and the Mother of Eve Springs. These Ojai waters contain the carbonates and sulphates of sodium, potassium, and magnesium, the carbonates of iron and lime, silicates, and carbonic acid and sulphureted hydrogen gases. Many stiff-jointed, rheumatic, and gouty persons repair to these springs for relief, and it is stated that a fair percentage of them are not disappointed in their quest. Good accommodations are provided for visitors.

James K. Crook.

OJAI VALLEY, SOUTHERN CALIFORNIA.—This little valley, said to be one of the most beautiful spots in Southern California, is situated in Ventura County, about sixty miles northwest of Los Angeles, and about fifteen miles from the coast. It has an average elevation of from nine hundred to twelve hundred feet, the upper part of the valley being the highest.

It is about fifteen miles in length, and from two to four miles wide. It is "entirely surrounded by the San Rafael and Santa Inez ranges, which rise on the east to a height of six thousand feet. It is thus well sheltered from harsh winds and partly also from the sea fogs" (Solly).

Nordhoff is the principal town with a population of eight hundred or more, and is the terminus of a branch railroad from San Buena Ventura. The upper Ojai is noted for its orchards, while the lower Ojai is devoted to beans and grain. Fruits of various kinds also thrive here. The opportunities for camping and shooting are abundant, deer, quail, and other small game being plentiful. The horseback rides are very attractive in this "country of beautiful views."

The following table, compiled from data given by Solly ("Medical Climatology"), will indicate the character of the climate:

Climate of Ojai Valley, taken at or Near Nordhoff.

	Jan.	Feb.	March.	April.	May.	Dec.	Winter.	Spring.	Year.
Temperature for 1892. Average (degrees F.) mean.	52°	53°	54°	56°	62°	50°	1893. 51°	1893. 54°	1893. 58°
Average mean	...	...	...	...	....	...	1895. 52	1895. 57	1895.
Maximum for 1892	78	79	85	82	100	77	85	95	
Minimum for 1892	27	...	28	31	34	25	26	32	
Humidity— Mean relative (January and February)	...	...	...	...	....	...	66%	65%	
Fogs, mornings	...	...	...	...	....	...	4	28	
Rainfall, inches	...	...	...	...	....	...	12.82	9.23	27.84
Rainy days	...	...	...	...	....	...	11	8	

The climate, it will be seen, is a very mild, equable one in the winter and spring, with a comparatively dry air, and slight rainfall; in brief, it represents the well-known characteristics of the Southern California climate for resorts situated some distance from the sea, and, in addition, the modifications produced by the peculiar situation of the valley, shut in as it is by mountains.

This climate is said to be especially favorable for asthmatics, and is also to be recommended for cases of pulmonary tuberculosis, chronic bronchitis, chronic diarrhœa, and nephritis.

The accommodations are only moderate. According to Solly there are pleasant boarding-houses and cottages. Such a locality as the Ojai Valley is rather suited to those who are well enough to take up a permanent residence there, and occupy themselves with the various pursuits of an outdoor life.

Edward O. Otis.

OJO CALIENTE.—Taos County, New Mexico. Post-Office.—Ojo Caliente. Hotel.

Access.—Take Denver and Rio Grande Railroad to Barrancas Station; thence twelve miles by stage to springs.

These celebrated hot springs are located at an elevation of about six thousand feet above the sea level in the region of the ancient cliff dwellers, twenty-five miles west of Taos and fifty miles north of Santa Fé. There is now a commodious hotel at the resort, having accommodations for about one hundred guests. The surrounding country is broken and mountainous, and the climate of the usual delightful New Mexico variety. The hottest summer day recorded at the springs in recent times was 93° F., and the coldest winter day 20° F. The resort is kept open all the year round. The springs are fifteen in number, and vary in temperature from 90° F. to 122° F. Their flow has not been measured, but it is estimated by Congressman Antonio Joseph, the proprietor, at about forty-two hundred gallons hourly. The following analysis was made by Prof. O. C. Marsh:

One United States Gallon Contains:

Solids.	Grains.
Sodium carbonate	91.52
Magnesium carbonate	1.26
Iron carbonate	5.90
Lithium carbonate	.12
Sodium chloride	22.18
Calcium carbonate	2.42
Potassium sulphate	3.00
Sodium sulphate	7.92
Silica	1.22
Total	135.54

An analysis, made in 1892, of the "New Spring" by W. T. Hillebrand, acting chief chemist of the United States Geological Survey, showed the presence of large quantities of carbonate of sodium, besides salts of lithium, potassium, strontium, barium, magnesium, and iron, with a considerable proportion of carbonic acid gas. The waters here have a great reputation in the treatment of advanced syphilis, chronic induration of the lymphatic glands, gout, and rheumatism.

James K. Crook.

OLD AGE. See *Senility*, and *Death, Physiological Theories of.*

OLD POINT COMFORT, NEWPORT NEWS, AND VIRGINIA BEACH.—Old Point Comfort, Va., is situated at the southeastern extremity of Yorktown Peninsula, at the entrance to Hampton Roads, through which the James River empties into Chesapeake Bay. Situated thus it commands a view directly out to sea between Cape Charles and Cape Henry. Directly south of Old Point Comfort, at a distance of about eleven miles, is the city of Norfolk, Va. In a westerly direction from Old Point, seven miles distant, as one passes up through Hampton Roads to enter the James River, is situated Newport News. "All vessels coming down the James River from Richmond and Petersburg, and those entering and leaving the harbor of Norfolk (and the Portsmouth Navy Yard there situated) must pass close to Old

Digitized by Microsoft®

Point Comfort, while the entire sea-going commerce of Chesapeake Bay passes it at no great distance on its way to and from the ports of Baltimore, Annapolis, and Alexandria."

Old Point Comfort is a government reservation, and here is situated the famous fortification of Fort Monroe, the largest of its kind in America, commanding the entrance to Hampton Roads and the approach to the navy yard at Norfolk. The very extensive marine view, the attractions of a large military garrison, combined with a mild climate a considerable portion of the year, render this resort one of the most popular ones in the country. Moreover, it is very easily and comfortably reached from the North, and affords excellent accommodations, though expensive.

The accompanying climatic table based upon observations taken at Norfolk, will serve also to illustrate the climate of Old Point and Newport News, for the three places are so near one another that there can be but little difference in their climatic elements.

www.libtool.com.cn

stable climatic conditions of a Northern spring during these months. One will find at this resort a large amount of sunshine, a comparatively mild temperature, no great amount of rain, and less wind than at Atlantic City. When one considers the ready accessibility of "Old Point" from the North, and its favorable climatic features, its value as a health resort must be regarded as very considerable. The sources of amusement and diversion are also many, and greatly enhance the value of the resort. They are the ever-shifting panorama of the ocean with the constant passing of various craft; the fascination of the military life, such a predominant feature here; the frequent visits of warships; the Normal and Agricultural Institute for colored people and Indians at Hampton, two and a quarter miles distant; and the National Soldiers' Home at the same place; the various shorter or longer excursions by water to Norfolk, Richmond, Virginia Beach, the York River, etc. The Hampton Golf Club and the Country Club are accessible to the guests of the hotels, and are said to be kept in excellent

Climate of Norfolk, Va., Latitude, 36° 51'; Longitude, 76° 17'. Period of Observation, Thirteen Years.

Like Atlantic City, Old Point Comfort is an all-year-round resort, frequented during the colder seasons of the year more especially by visitors from the North and during the summer by those from the South. As has been said, and as is the case with Atlantic City, the season of February, March, and April is the popular one for Northern visitors and invalids who desire to escape the unstable climatic conditions...

the great advantage of the beach as a playground for children. Such a climate and such a resort are especially to be recommended for those who with difficulty endure the rigors of a Northern winter, and at the approach of spring find themselves in a depressed condition, physically and mentally, without being seriously ill. It is also to be recommended for convalescents from various acute diseases,

Digitized by Microsoft®

for those who are recovering from the effects of an operation, and for scrofulous children. For the aged, the feeble, the neurasthenic, and for weakly children it offers, for a portion of the year at least, a mild and pleasant asylum. It is said to be immune from malaria. It can hardly be recommended for those suffering from any serious disease of the respiratory organs or from renal disease.

www.libtool.com.cn

As a half-way station between the North and the more Southern resorts in Florida, Georgia, and South Carolina, "Old Point" proves serviceable in the late autumn and in the spring.

There are two large and well-appointed hotels at "Old Point," the "Chamberlain" and the "Hygeia," with enclosed sun piazzas, affording excellent accommodations the year round. It is probable, also, that in the vicinity private boarding-houses and cottages can be found for those desiring less expensive accommodations than these luxurious hotels offer. The methods of reaching this resort are many and good. One can go by rail to Cape Charles and from there by steamer across the bay, or by rail all the way viâ Richmond; or one can make the trip from Boston, New York, Baltimore, and Washington by water.

Newport News, while possessing a similar climate, has less in the way of attractions to offer than Old Point, and is not so popular a resort, though it possesses much of historic interest. Here is located an extensive ship-building plant, with an immense dry-dock. It is also a port of importance. The Hotel Warwick offers good accommodations, and for one who desires a quieter existence than that at Old Point, Newport News would appear to be the more attractive of the two. It is reached by boat from Norfolk.

Virginia Beach is situated eighteen miles east of Norfolk, with which it is connected by rail, and six miles south of Cape Henry. It has a fine and extensive beach, affording good surf bathing, and is protected landward by extensive pine forests. The average winter temperature is 54° F, and the extremes for the year 34° F.

The climate is equable and mild and the soil dry. The Princess Anne Hotel is well appointed and offers excellent accommodations and food. The attractions are boating, bathing, fishing, shooting, and horseback riding. This climate and resort "are adapted for cases of chronic nephritis, bronchitis, overwork, and neurasthenia." (Hinsdale.) *Edward O. Otis.*

OLD SWEET SPRINGS.—Monroe County, West Virginia. Post-Office.—Old Sweet Springs. Hotel.

Access.—Viâ Chesapeake and Ohio Railroad to Alleghany Station, where Concord coaches meet all passengers for the springs. The location of Sweet Springs is more open than is generally the rule in mountain districts. They issue up in a valley of great loveliness, but are surrounded by mountain scenery of surpassing grandeur. The elevation is two thousand feet above the sea level, and the climate during the summer months is of the usual delightful character found in this region. The buildings at the springs are of brick and of a very substantial character, and at the height of the season the place resembles a miniature city. Eight hundred guests are easily entertained at one time. The main building is about three hundred feet in length, and no expense has been spared to make it one of the best summer hotels in the country. The hotel property embraces a grass farm of two thousand acres, which guarantees an abundant supply of dairy products, while neighboring farms furnish the best of poultry, mutton, etc. The water of the Sweet Springs is not unpleasant to the taste, but its temperature (79° F.) renders it rather warm for general use in drinking. For bathing, however, it is very agreeable. Two pools have been provided—one for men, the other for women,—each seventy-five feet long, twenty-five feet wide, and from three to five feet deep. The water is so clear that moss-covered stones on the bottom are distinctly visible. There are also warm and hot steam baths of both mineral and freestone water. The following analysis of the mineral water here was made by Prof. William B. Rogers:

One United States Gallon Contains:

Solids.	Grains.
Calcium sulphate	13.16
Magnesium sulphate	9.37
Sodium sulphate	6.32
Calcium carbonate	30.05
Magnesium carbonate	.80
Calcium chloride	.15
Sodium chloride	.14
Magnesium chloride	.31
Iron peroxide	.15
Silica	.17
Earthy phosphates	Trace.
Iodine	Trace.
Total	60.62
Gases.	**Cu. in.**
Carbonic acid	85.86
Nitrogen	4.31
Sulphureted hydrogen	Trace.
Oxygen	Trace.

This is a very good alkaline-calcic water possessing tonic, diuretic, alterative, and mild cathartic properties. It is valuable in functional disorders of the stomach, and is said to be employed with signal benefit in chronic diarrhœa and dysentery. It has also produced good results in rheumatism and in some forms of neuralgia, as well as in renal and urinary disorders. *James K. Crook.*

OLEIC ACID.—Oleic acid ($HC_{18}H_{33}O_2$) is the acid product of the decomposition of olein, the fluid constituent of natural oils and fats. Under the title, *Acidum Oleicum*, Oleic Acid, the United States Pharmacopœia recognizes the acid "prepared in a sufficiently pure condition by cooling commercial oleic acid to about 5° C. (41° F.), then separating and preserving the liquid portion." Such grade of acid is an oily liquid, yellow or brownish-yellow in color, and having an odor and taste as of lard. On exposure to air it absorbs oxygen and darkens in color. Its specific gravity is about 0.900 at ordinary temperatures. It is insoluble in water, but dissolves completely in alcohol, chloroform, benzol, benzin, oil of turpentine, and the fixed oils. On cooling the acid first becomes semi-solid, and at 4° C. (39.2° F.) congeals to a whitish, crystalline mass.

The medicinally valuable property of oleic acid is that while retaining the physical properties of a fixed oil, the acid is yet of high diffusive power, and, accordingly, upon inunction passes through the unbroken skin into the general circulation, and leaves behind a smooth, soft, and supple, but not greasy condition of the integument. Being an acid it forms salts with salifiable bases, many of which salts are soluble in excess of oleic acid. Such solutions of oleates in oleic acid are found to permeate the skin as readily as the simple acid, and for this reason such solutions form a class of medicines defined as "oleates," and devised as means of medicating the general circulation through the unbroken skin. Oleic acid is used exclusively for the manufacture of these pharmaceutical "oleates." *Edward Curtis.*

OLFACTORY NERVE.—I. Anatomical Part.—The olfactory nerve is the simplest of the nerves of special sense; indeed in its peripheral relations it is in some respects the simplest and most primitive nerve of the body. Its central relations, on the other hand, are most intricate and cannot be understood without reference to its evolutionary history. In the larva of the lowest vertebrate, the amphioxus (Fig. 3624), the anterior end of the tubular central nervous system opens freely to the outer body surface by a distinct neuropore on the dorso-median surface of the head. In the adult this pore becomes closed, but there persists a pit like de-

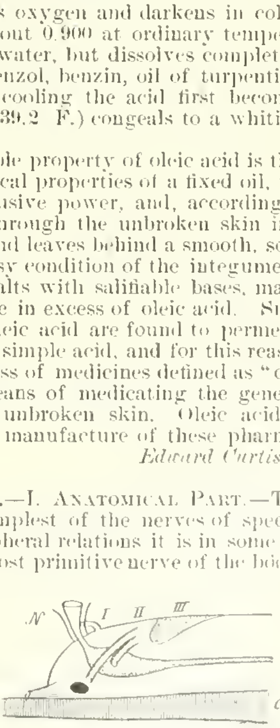

Fig. 3624.—Longitudinal Section Through the Brain of the Larval Amphioxus. *ch*, Notochord; *N*, neuropore, or sensory pit.

Digitized by Microsoft®

pression of the outer skin, reaching in to rest in contact with the surface of the brain. This pit is lined with ciliated epithelium and at this stage of life it is displaced so that it lies on one side of the median line. The appearance of this structure, which is known as the "olfactory pit," is shown in the accompanying figure (Fig. 3625). From this simple beginning the entire olfactory apparatus of higher animals has been developed. The neuropore in embryos of other vertebrates does not actually open to the surface, but its position can sometimes be determined by the appearance of a pit-like forward projection of the brain wall in its most cephalic boundary at a point corresponding to the lamina terminalis of the adult (the lobus olfactorius impar of von Kupffer) (see Fig. 3626). Here, too, there is an invagination from the outer skin in the corresponding region. From this invagination there is produced not only the nasal fossa and the contained sensory epithelium, but also the hypophysis, the latter rotating ventrally through an arc represented by the arrow in the figure.

www.libtool.com.cn

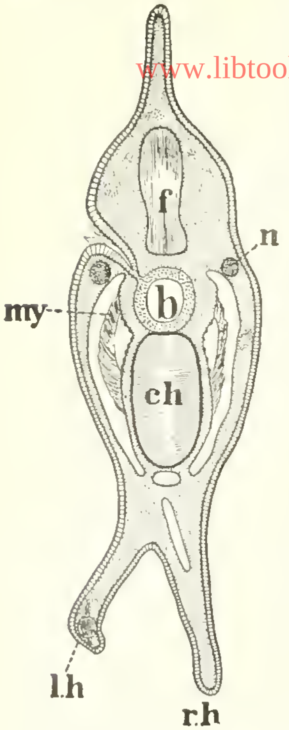

FIG. 3625.—Transverse Section Through Region of Olfactory Pit of Adult Amphioxus. (After Lankester.) The olfactory pit is seen as an ectodermic invagination at the left of the brain. *b*; *ch*, notochord; *f*, lymph space; *my*, first myotom; *n*, second cranial nerve.

The fact that the olfactory sensory thickening appears in the olfactory depression at a very early stage in its invagination has led to many attempts to homologize the olfactory organ with other sensory organs of ectodermal origin. In some of the fishes the adult olfactory mucosa is broken up into sensory patches resembling superficially the taste buds, and Blaue has assumed that these "olfactory buds" are the derivatives of one of the lateral line series of sense organs which has wandered into the olfactory fossa and there proliferated. In spite of the inherent improbability of this from theoretical grounds, his view has found its way into many of the current text-books of embryology. As a matter of fact, however, Blaue was ignorant of the development of the olfactory organ of these fishes, and the embryological history disproves his theory, for the olfactory sensory epithelium does not exhibit the "olfactory buds" until a very late stage in the ontogeny, showing that these are of secondary rather than primary significance. The truth is, that the phylogenetic origin and relationships of the olfactory organ must be left for future research to determine.

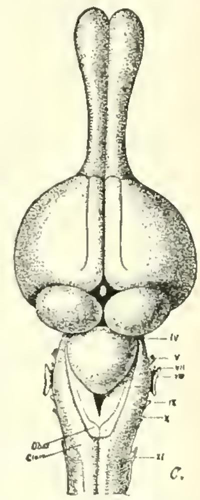

FIG. 3627.—Dorsal View of the Brain of a Young Alligator. (After C. L. Herrick.)

The later phylogenetic history is fortunately much clearer, and it is moreover of fundamental importance to our theories of the origin of the cerebrum, for the whole of the secondary prosencephalon in the lowest vertebrates seems to be related to this olfactory organ. As the optic lobes, geniculata, etc., have been evolved in response to the requirements of the organ of vision, so the olfactory bulbs and the earliest cerebral cortex seem to have been called forth by the necessities of the olfactory sense. Then later in the evolutionary process the prosencephalic roof, or pallium, became the seat of secondary connections for other nerve systems, until in man and other microsmatic mammals the olfactory function has been quite overshadowed by these secondarily acquired functions of a higher order. The distinction between the rhinencephalon and the remainder of the prosencephalon becomes more and more marked as we ascend the animal series.

Edinger and others have brought forth anatomical evidence to show that the first truly functional cortex, or pallium, to appear in the phylogenetic scale is the hippocampus, which is connected chiefly with the olfactory sense. With this is to be correlated the fact that the olfactory conduction path becomes medullated earlier in the development of the human cerebrum than that of any other special sense. Since the psychic functions in higher animals are associated, mainly, if not exclusively, with the cerebral cortex, it follows with great probability that the olfactory group of sensations was among the first to emerge into clearly defined consciousness. This olfactory cortex appears first in the Amphibia as a crescent of superficial nerve cells in the caudal and lateral border of the cerebrum. In the reptiles there is true cortex over the whole of the forebrain in addition to a simple but typical hippocampal formation. In these forms the olfactory nerve is the largest in the body and the whole system is enormous. It is, moreover, laid down according to the same general plan as in higher animals. The relations between olfactory bulbs and cerebrum in the reptiles are indicated by the accompanying figure of the brain of the alligator (Fig. 3627) and by the diagram of the olfactory connections in the lizard (Fig. 3628). This latter scheme applies also with no important changes save in the relative size of the parts, to all vertebrates above the reptiles in the zoological scale. In man, however, the sense of smell is relatively so unimportant and the higher cortical centres are so highly developed that it has proven a matter of the greatest difficulty to unravel the olfactory connections.

www.libtool.com.cn

Anatomically the olfactory nerve differs from all of the other nerves of the body in that its fibres arise from perikaryons, or cell bodies, lying in the sensory epithelium (Fig. 3629). In other words, the root ganglion for this nerve does not lie adjacent to the central nervous system, but its cells are in the periphery, diffusely scattered among the indifferent supporting cells of the sensory mucosa of the nasal organ. This condition we find in the case of no other nerve among the higher vertebrates, but it appears to be a survival of a primitive invertebrate condition. (See *Cranial Nerves*.)

The specific olfactory cells are distributed over a relatively small area of the nasal mucosa (about 2.5 sq. cm.) in the upper narrow part of the nasal sinus, partly on the superior turbinated bone, and partly on the nasal septum adjacent. Unlike the remainder of the nasal mucosa this portion is non-ciliated. It is yellowish in color and exceedingly vascular. The specific olfactory cells are commonly described as ending in a short stiff bristle.

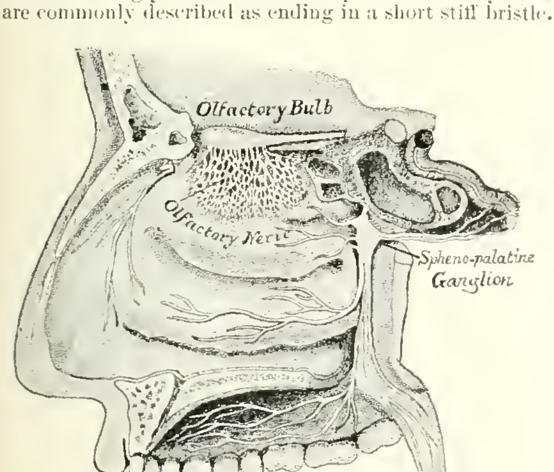

FIG. 3630.—The Right Olfactory Nerve on the Outer Wall of the Nasal Fossa. (Adapted from Hirschfeld.)

Recently Jagodowski has found (*Anat. Anzeiger*, vol. xix., p. 257) in the fishes that each of these cells is provided with a single long thread-like filament which projects outward into the mucus of the nose and which may be

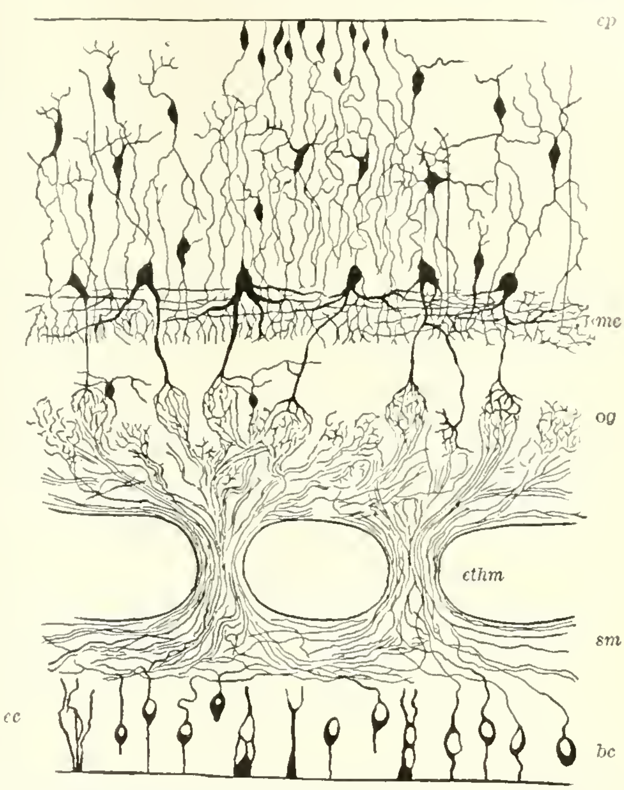

FIG. 3631.—Structure of the Olfactory Filaments and Bulb. (After Ramón y Cajal.) *bc*, Bipolar cells of the olfactory mucous membrane; *sm*, submucosa; *ethm*, cribriform plate of the ethmoid; *og*, olfactory glomeruli; *mc*, mitral cells; *cp*, epithelium of the olfactory ventricle; *cc*, epithelial cells of the olfactory membrane.

more than twice the length of the cell body from which it springs. The appearance of the fila olfactoria arising from these cells is indicated in Fig. 3630. These fibres passing from the olfactory mucosa to the olfactory bulb are commonly called the olfactory nerves, but it is evident that if the so-called specific cells from which they spring really correspond to the root ganglion cells of the other nerves, then the fila olfactoria correspond rather to root fibres. These fibres are non-medullated and are gathered into about twenty bundles, which enter the cranium by separate apertures in the cribriform plate of the ethmoid bone. The several strands enter the olfactory bulb and here terminate in peculiar arborizations in the glomeruli (Fig. 3631).

Jacobson's organ (a peculiar diverticle of the nasal sac) in some animals receives a special twig of the olfactory nerve, which rarely, as in Amblystoma, arises from the brain farther back (caudad) than the rest of the nerve and pursues a distinct course to its terminus.

The comprehension of the central relations of the olfactory nerves is greatly impeded by a confused and very inconsistent nomenclature. The term rhinencephalon was first used in neurology by Owen as a name for the olfactory bulb and its peduncle. It has since been extended by different writers to include various parts of the cerebrum which are concerned in the olfactory function, with, however, no uniformity in the extent of this application. The only logical course is (as pointed out by G. Elliot Smith, *Jour. Anat. and Physiol.*, xv., 1901) either to retain Owen's limited application of the term or

Digitized by Microsoft®

to extend it to include all parts of the forebrain, which are directly connected with the olfactory function, viz., the olfactory bulb, tract (or peduncle), tuber, the area perforata, "paraterminal body" (a term introduced by Elliot Smith for the area extending backward from the olfactory peduncle, the gyrus subcallosus, paraterminalis and upward to fill the space between the callosum and the hippocampal commissure), and the whole pyriform lobe and hippocampal formation. This usage will doubtless commend itself to the majority of working neurologists, in spite of the fact that a part of that which is commonly reckoned as pallium is here included in the rhinencephalon. This difficulty is in large measure obviated by Elliot Smith in the paper cited above, by a reconsideration of the phylogeny of the pallium, from which he concludes that the olfactory portions of the pallium should be separated morphologically from the remainder of the cortex, which is of more recent origin and hence may be termed the "neopallium."

The classification of the rhinencephalon, according to Retzius, has been tabulated by Barker as follows:

1. *Bulbus olfactorius.*
2. *Tractus olfactorius.*

3. *Trigonum olfactorium* (gyrus tuberis olfactorii).	Stria olfactoria lateralis to gyrus olfactorius lateralis. Stria olfactoria medialis to gyrus olfactorius medialis.
4. *Gyrus olfactorius medialis.*	Area parolfactoria Brocæ.
5. *Gyrus olfactorius lateralis.*	Pars anterior—Eberstaller's gyrus transversus insulæ and the limen insulæ. Pars posterior. Extends from angulus lateralis to anterior extremity of gyrus hippocampi and terminates in the gyrus semilunaris rhinencephali and the gyrus ambiens.
6. *Gyrus perforatus (seu intermedius) rhinencephali.*	Anterior, much perforated, part of substantia perforata anterior.
7. *Gyrus diagonalis rhinencephali.*	Posterior, less perforated, part of substantia perforata anterior. Corresponds to the diagonal band of Broca, which extends from the gyrus subcallosus to the anterior end of gyrus hippocampi.

8. *Other portions of rhinencephalon.*
   (*a*) *Gyrus hippocampi.*
   (*b*) *Uncus*
   (*c*) *Gyrus dentatus.*
   (*d*) *Gyrus intralimbicus.*
   (*e*) *Gyrus fascioloris*
   (*f*) *Gyri Andreæ Retzii*
   (*g*) *Indusium griseum* (including the *striæ longitudinalis medialis et lateralis*).
   (*h*) *Gyri subcallosi.*

Reference to Fig. 3631 will render unnecessary a detailed exposition of the primary olfactory connections. The glomeruli are entangled knots of fibres, partly the terminal arborizations of the fila olfactoria and partly the dendritic tips of the neurones of the second order, whose nuclei lie in the zone of mitral cells. Each mitral cell usually sends a dendrite (in man) to but one glomerulus, where it receives the terminal arborizations of many fila olfactoria. The structures within the olfactory bulb are stratified, the following layers being encountered as we pass inward. First, a layer of fila olfactoria bounded within by the glomeruli arranged in a single series. Then, after an interval containing chiefly nerve fibres constituting the so-called molecular layer, are the mitral cells, arranged in a thin layer typically but one cell deep. Within this is the granular layer containing very many cell bodies of the olfactory granules. These are minute cells with feebly developed dendrites directed toward the ventricular surface, and much branched neurites passing out between the bodies of the mitral cells to arborize just within the zone of glomeruli. Their functional significance is unknown. Within this layer is the zone of nerve fibres, containing the tracts directed toward the cortex and composed chiefly of neurites of the mitral cells. Olfactory impressions entering by the fila olfactoria are transferred to the dendrites of the mitral cells and by the neurites of these neurones (the mitral cells constituting the primary intracranial centre) are carried to their secondary centres viâ the olfactory tracts. These secondary connections, which are very diverse and intricate, can be briefly summarized as follows:

The olfactory tract connecting the bulb with the secondary centres contains three sets of fibres, the lateral and mesial olfactory striæ superficially placed, and the deep, or ental, or precommissural tract. On their way part of the latter fibres terminate in the gray matter distributed along its course, while others run to the anterior commissure, forming its anterior or olfactory part, and terminate in various parts of the rhinencephalon of the opposite side. The mesial olfactory stria terminates in the area parolfactoria and other gray centres near the median line at the attachment of the crus olfactorius, effecting secondary connections with the hippocampus through the indusium griseum of the callosum and by other paths. Others of these fibres pass into the septum pellucidum and ultimately reach the hippocampus viâ the fornix. The larger portion of the secondary olfactory fibres pass back in the lateral olfactory stria to terminate in the cortex of the uncus, giving off collaterals on the way to adjacent gray centres.

The reflex connections between the cortical olfactory centres in the hippocampus and the lower regions of the brain are too complicated to be summarized here. The fornix is the chief pathway for these fibres, and their most important connections are the mammillary bodies (by way of the corpus fornicis, the *Tr. Cort. mammillaris* of Fig. 3628), and the nucleus habenulæ (by way of the stria medullaris thalami, marked *Cort. habenularis* on Fig. 3628). For the general relations of these tracts consult Fig. 3632.

One is at once struck by the peculiar way in which these olfactory tracts are distributed by widely divergent paths to secondary centres, which are far separated in space (though morphologically related). Upon comparison with the connections within the reptilian brain (Fig. 3628) the explanation is plain. There practically the entire forebrain is devoted to olfactory connections, and the cortical additions of higher types have been intercalated in such a way as to separate tracts and centres which were primarily juxtaposed.

II. Physiological Part.—The sense of smell in human beings, as compared with many of the lower animals, is very feebly developed, as will be made clear by even a cursory examination of the comparative anatomy and physiology of the organ. Animals are classified with reference to this sense as osmatic and anosmatic, and the former group is subdivided into macrosmatic and microsmatic divisions, depending upon whether the sense is highly developed or but feebly so. Man belongs to the microsmatic group, this sense playing a very subordinate rôle, either physiological or psychological, in our vital economy. Its unimportance is, however, more apparent than real and is to be explained, as Zwaardemaker points out, on psychological grounds.

As a matter of fact, olfactory sensations are always with us and our daily actions are profoundly influenced by them, though this influence is largely unrecognized as such. For these sensations are, in the case of human beings, intimately connected with the somatic and organic functions, and have a strong emotional content which obscures the process of ideation. This imperfect comprehension of olfactory impressions is reflected in our language, for our vocabulary of olfactory sensations is very limited and almost all borrowed from that of other senses. For our knowledge of the outer world we depend chiefly upon the other special senses, particularly sight. With the macrosmatic animals, on the other hand,

Digitized by Microsoft®

the sense of smell is undoubtedly in some cases more potent in the elaboration of knowledge of the outer world than any other sense.

The physiology of the sense of smell is less perfectly known than that of any of the other special senses, and the same remark holds true of its psychology. While our knowledge of the anatomical arrangements of the paths of olfactory conduction to and within the brain has been greatly extended of late, we are yet ignorant of the means even by which the olfactory nerve termini are stimulated by the odorous substances. In particular, the physiological process underlying the difference between smell and taste is obscure. It is commonly stated that we taste substances in solution or in liquid form, while only gases are perceived by the sense of smell. While this is in general true, it nevertheless must be remembered that the odorous gases do not come into direct contact as such with the sensory end organs in the nose, either in fishes, where the nasal cavities are filled with water, or in air-breathing vertebrates, whose olfactory mucous membranes are always bathed with mucus in which the odorous substance must always be dissolved before it can irritate the sensory endings. Again, some sapid substances, such as hydrochloric acid, are also solutions of gases, and some solids in a state of fine division seem to give rise to distinct olfactory impressions. The fact that when the nostrils are filled with water carrying an odorous substance in solution the odor cannot be perceived does not necessarily imply that the failure is due to the fact that the substance is in solution, but rather to an irritating effect of the liquid upon the olfactory organ. This is indicated by two facts: First, that all olfactory sensation may be temporarily enfeebled or even entirely abolished for some time after the close of the experiment; and second, that if normal salt solution instead of water be used as a solvent, then the dissolved substance can in some cases still be smelled.

Tyndall discovered that odorous vapors have a considerable capacity for absorbing heat, and that very minute quantities of the odorous substance in the air experimented upon would produce surprising effects. At the close of a table giving the absorptive powers of different odorous vapors, he remarks: "We find that the least energetic in the list produces thirty times the effect of air, whilst the most energetic produces one hundred and nine times the same effect." The significance of these facts is still obscure. We certainly are not able to affirm as yet, with Ramsay, that the sense of smell is excited by vibrations of a lower period than those which give rise to the sense of light or heat, though it may well be that characteristic molecular vibrations give to various substances their distinctive odors. But in any case these movements seem to be incapable of transference to the receptive sense organ by the medium of ethereal vibrations, and direct contact of the odorous particles with the nervous organ seems indispensable. The ultimate stimulus is probably electro-chemical—a matter of ions.

Olfactory sensations are aroused with difficulty or not at all by irritation of the peripheral end organ by thermal, electrical, mechanical, or other stimuli than the normal gaseous media, though tumors or other irritants of the central olfactory apparatus may call forth vivid sensations of smell. It is hardly true, as often stated, that air containing odorous particles must be in motion in order to stimulate the olfactory organ. The truth is that in ordinary respiration the air currents do not strike the sensory surface directly, and hence olfactory impressions are called forth by such particles only as diffuse themselves upward from the respiratory portion into the olfactory fossa, while in sniffing the direction of the air currents is altered so as to pass more directly over the specific sensory area.

We are not as yet able to give a natural classification of smells, nor have we any secure basis for such a classification. Even the division into agreeable and disagreeable is subject to so great variation from one individual to another that it would be of small value, even if it were admissible on other grounds. Accordingly, the names of smells are usually taken from the objects which give rise to them, with little attempt at classification or correlation of similars.

The number of smell qualities is very large. Some of those commonly recognized are compound, though authorities differ as to the extent to which such mixture is possible, or whether it is possible at all. If two distinct odors are mingled under experimental conditions, there often results, not a fusion of the two into a blended odor, as occurs with tastes, colors, and tones, but the stronger will supplant the other completely, or there will be an oscillation between the two. With some odors, again, there appears to be a true compensation. Thus, if two different olfactory stimuli of unequal strength are applied simultaneously, one will usually overpower the other completely; but if the stronger scent be diminished

www.tlptool.com.cn
Digitized by Microsoft®

while the weaker is strengthened, a point may be found where the two blend into a single mixed odor. In other cases, however, a point is found where there is no sensation, *i.e.*, the odors are perfectly compensated. An increase of either stimulus results in the sensation appropriate to it and there is no mixture whatever. The olfactory organ is easily fatigued, more so by some odors than by others, and it is found that when completely fatigued for one odor it may be insensible to some other odors, partially so to another group and wholly unaffected in its sensibility with reference to still another group.

Such experiments suggest points of departure for the study of olfactory qualities, and enough progress has already been made to suggest that the modalities of smell can be grouped into several graded series. The number of such groups will quite certainly be greater than those known for taste, where we have simply the four primary qualities, sweet, sour, salty, and bitter. Zwaardemaker's nine smell classes are as follows:

(1) Ethereal scents: Fruit odors.

(2) Aromatic scents: Camphor and spicy smells, anise, lavender, etc.

(3) Balsamic scents: Flower odors, vanilla, gum benzoin, etc.

(4) Ambrosiac scents: Amber, musk.

(5) Alliaceous scents: Garlic, ichthyol, vulcanized rubber, asafœtida, bromine, chlorine, etc.

(6) Empyreumatic scents: Toast, tobacco smoke, naphtha, etc.

(7) Valeric, or hircine scents: Cheese, sweat, etc.

(8) Narcotic, or virulent scents: Opium, cimicine, etc.

(9) Nauseous scents, or stenches: Decaying animal matter, fæces, etc.

The ability to discriminate different intensities of odors is not highly developed; in general, the least observable difference between two smell intensities of the same substance amounts to about one-third of the original stimulus. On the other hand, the olfactory organ is sensitive to exceedingly small amounts of the irritating substance, or as Ladd states it: "The sense has a great degree of 'sharpness,' or power to be excited by small quantities of stimulus, as distinguished from 'fineness,' or power to distinguish minute variations in the sensations." There are many familiar illustrations of this "sharpness." It is stated, for example, that in a litre of air 0.000005 gm. of musk can be perceived, 0.000001 gm. of sulphureted hydrogen and 0.000000005 gm. of oil of peppermint. The sense is more delicate if the air containing the odorous substance is warmed.

It is learned by suitable tests that the sensibility of the organ of smell is much more acute than the perception of odors. It was found in one series of tests, for example, that upon the average 9 parts of camphor dissolved in 100,000 parts of water could be sensed by the nose, but without the perception of a definite odor, it requiring a solution of more than four times this strength before the specific odor could be recognized. Experiments made to determine the relative sensitiveness of men and women in this respect have thus far yielded conflicting results. With children it has been found that the sensibility (in the sense used above) increases up to the age of six years and then progressively diminishes. The delicacy of perception, on the other hand, measured by graded solutions of camphor, increases progressively with advancing age.

One source of perplexity in the classification of odors is the fact that some substances which have powerful odors in a state of great dilution are less effective in a state of high concentration. For some perfumes there appears to be an optimum vapor density below or above which the excitation is less strong. It has also been suggested that for unknown phylogenetic reasons some odors may have greater affective values than others, or it may be that fatigue of the sense of smell is *cæteribus paribus* less for those odors which have an element of utility to the species.

It must not be forgotten that some odorous substances affect the terminals of the trigeminus nerve in the respiratory part of the nasal passages, giving rise to tactile or other general sensation which may be combined with the olfactory sensations. This can be proven by plugging the olfactory sinus, when the trigeminal stimulus alone is perceived. Classification is further impeded by the universal confusion of tastes and odors. We say a substance "smells sweet," when as a matter of fact experiment shows that the modality sweetness can be perceived only by the sense of taste; and conversely most of the tastes of common experience are greatly affected by odors simultaneously sensed.

In the majority of persons (Toulouse and Vaschide) the left side of the nose is more sensitive than the right. With most of the other senses, on the other hand, there is an asymmetry in one-fifth of the cases in favor of the right side (van Biervliet). The difference is explained by the fact that the left side of the brain is more highly developed (in right-handed persons) and that the central olfactory tract does not cross before reaching its cortical centres, while those for the other senses do cross.

The measurement of olfactory sensations cannot easily be done absolutely in terms of the strength of the stimulus, though examples of the results of some attempts at the measurement of the threshold for smell in absolute terms are given above. To arrive at a relative measurement of olfactory values there are two methods chiefly in use. According to the method of Passy a number of flasks of equal size are provided and into each is put a measured quantity of the odorous substance, the quantities being arranged in a graded series. The substance may be allowed merely to diffuse itself through the air within the flask (which must be kept stoppered when not in use), or it may be dissolved in water or some other inodorous medium. By the use of a sufficiently extensive series, threshold values of different odorous substances may be determined and various other researches carried out.

The method of Passy is very laborious and for most purposes, particularly in clinical work, the olfactometer of Zwaardemaker is more convenient. In its simplest form it consists of a glass tube, curved at one end for insertion in the nostril and bearing a scale (preferably in centimetres), which slides with easy friction into a slightly larger tube which is lined with the odorous substance to be tested. The inner tube passes through a screen near its curved end. Now, when the outer tube is slipped completely over the inner tube so that its odorous lining is wholly covered by the latter, air drawn into the nostril through the inner tube will carry no odorous particles. If, however, the outer tube is slowly slipped off from the inner tube, the air current will pass over more and more of the exposed surface of the odorous substance before entering the inner tube, until a point will be reached at which the substance is just perceivable to the sense of smell. In this way the normal threshold can be determined for various substances and numerous tests of physiological and pathological interest carried out.

This simple apparatus has been modified in various ways. A very simple instrument which has the advantage of relative permanence of adjustment can be constructed by using a section of ordinary red rubber tubing for the outer tube. This should be slipped inside of a larger glass tube to prevent the odor from escaping from the outer side of the rubber, and the odor given off from the inner surface of the rubber tubing will remain quite constant for many months. For other odors the outer cylinder may be made of porous earthenware, whose pores may be filled with a solution of the odorous substance. Commonly the olfactometer is made double with a separate cylinder and breathing tube for each nostril, and for the study of the compensation of odors Zwaardemaker has constructed a very elaborate apparatus with two separate cylinders (one for each of the odors to be employed) connected with a single breathing tube and so adjusted that the amount of odorous surface exposed in each tube may be easily varied during the

Digitized by Microsoft®
www.libtool.com.cn

experiment. With the varying adjustments one odor or the other appears in consciousness alone until the proper compensation point is reached, when both odors vanish. The apparatus is provided with self-registering apparatus for recording on the kymograph the force of respiration in each cylinder and other data of the experiment.

www.libtool.com.cn

The unit in all of these experiments is the "olfactie," or the stimulus necessary to produce the least perceivable sensation. The position on the scale of the olfactometer having been determined for this minimal value, this value is taken as the unit, or olfactie, and other stimuli are measured in multiples of this.

For the fuller consideration of the subject of this article, see the work by H. Zwaardemaker, "Die Physiologie des Geruchs" (Leipsic, 1895), and the article by the same author entitled, "Les sensations olfactives, leurs combinations et leurs compensations," in *L'Année Psychologique*, vol. v., 1899, pp. 202–225. A complete bibliography of the organ and sense of smell up to January, 1901, has been compiled by Bawden, in *The Journal of Comparative Neurology*, vol. xi., No. 1, April, 1901.

C. Judson Herrick.

OLIBANUM.—*Frankincense. Thus. Gummi, resina olibani.*—A gum resin obtained from *Boswellia Carterii* Birdw. and other species of *Boswellia* (fam. *Burseraceæ*).

Olibanum is collected in northeastern Africa, chiefly by the Somali natives, and is mostly exported viâ India. It is produced by small trees similar to those which yield myrrh, and is chiefly obtained from incisions made for the purpose. It exudes as a thick milky juice, hardening into the tears described below, which preserve their white color much longer than those of other similar substances.

Olibanum occurs in irregularly oval or subglobular tears, separate, or occasionally somewhat agglutinated in the poorer grades, usually 1.25 cm. (0.5 in.) or less in diameter, from almost pure white to yellowish-white, occasionally reddish-brown when long kept, the surface powdery; breaking readily with a nearly flat, waxy, lustrous surface, translucent in thin fragments; odor balsamic, slightly like turpentine; softening between the teeth, aromatic and somewhat bitter. Triturated with water, it forms a white emulsion and is almost wholly soluble in alcohol. When burned, it emits a very strong and pleasant odor, on account of which it is used as incense.

Olibanum consists principally of resin, usually from 60 to 70 per cent., or occasionally 75 per cent., with from 30 to 35 per cent. of gum and from 3 to 8 per cent. of volatile oil. Its bitter principle has not been examined. The volatile oil, which is an article of commerce for perfuming purposes, combines a slight lemon-like odor with that of the drug, and is of complex composition. The resin is divisible into two portions, namely, *Boswellic* or *Boswellinic acid* and *olibano-resin*. The gum is more like acacia than like tragacanth.

From a medicinal point of view, the uses of olibanum are quite unimportant. It is no longer official in any leading pharmacopœia and is but little used in professional medicine.

Owing to its fragrant properties, it is with some a favorite ingredient of plasters and ointments, and it is elsewhere used for odorizing purposes. It has mild counter-irritant and disinfectant properties, leading to its use as a vulnerary. Internally, it possesses the ordinary stimulating diuretic and expectorant properties of the oleoresins, and it also has a considerable use, especially among the laity, based chiefly on religious fancy, as an emmenagogue. The dose is from 1 to 3 gm. (gr. xv.–xlv.). It is used chiefly, perhaps, in the form of the emulsion, although the tincture is to be preferred.

Henry H. Rusby.

OLIGÆMIA.—A decrease in the total mass of the blood. The term is often used incorrectly as a synonym for anæmia. The latter term is used to indicate a deficient supply of blood to a part, or a deficiency in the total amount of blood within the body, or, most commonly, to designate a decrease in the number of the red cells or a diminution of the hæmoglobin. The expression *general anæmia* may, therefore, be regarded as expressing the same idea as that conveyed in oligæmia. The decrease in the total mass of blood may be due to a number of causes, and the following varieties may be distinguished:

Oligæmia Vera.—True oligæmia is due to a sudden loss of blood through hemorrhage. A loss of half of the total mass of the blood is invariably fatal, and hemorrhages of even less degree may cause death. The red cells may drop after a single large hemorrhage as low as two million. After such a loss of blood there is a rapid fall in blood pressure, the pulse becoming very small, frequent, and irregular. In cases of hemorrhage of slight degree, but continued through a long period of time, the deficiency is partly made up by an increase in the fluids of the blood, the true oligæmia becoming thus converted into a hydræmic oligæmia.

Oligæmia Hydræmica or Serosa.—An oligæmia with increase of water in the blood, the red cells and albumin being diminished, occurs after all hemorrhages, particularly in the case of oft-repeated or prolonged hemorrhages of slight degree, as in bleeding piles, excessive menstruation, etc., also in conditions characterized by loss of albumin, as in chronic nephritis, dysentery, chronic suppurations, prolonged lactation, tumor cachexias, scurvy, malaria, etc. The hydræmic condition of the blood leads to pathological changes in the blood-vessel walls, favoring the passage of fluids and the increased production of lymph (œdema). Hydræmia is, however, not the direct factor in the production of œdema, but only a favoring one.

Oligæmia Sicca (Inspissatio Sanguinis, Anhydræmia).—A thickening of the blood through loss of water may lead to a decrease of the total mass. Such a condition may occur in cholera, dysentery, severe diarrhœas, excessive sweating, insufficient supply of water, etc. The highest degree of oligæmia sicca occurs in Asiatic cholera. As a result of the circulatory disturbances thus produced, and an insufficient supply of blood to the nervous centres, the characteristic symptoms of severe anæmia may arise, although the total number of red cells and total amount of salts and albumin in the blood are not decreased. The thickened blood becomes tea-like, the blood serum is richer in albumin and in salts. The body tissues become very dry, and non-encapsulated serous exudates are resorbed.

Oligæmia Oligocythæmica.—A decrease in the total blood mass due to a diminution in the number of red cells (see *Oligocythæmia*).

Oligæmia Hypalbuminosa.—A decrease of the blood mass due to a decrease in the albumin of the blood. As a result of such loss of albumin the blood becomes more watery; the condition is therefore practically a form of oligæmia hydræmica. (See also *Blood, Anæmia, etc.*)

Aldred Scott Warthin.

OLIGOCHROMÆMIA.—A decrease in the amount of hæmoglobin in the blood. This is one of the commonest changes in the blood, and may occur either when the red cells are normal in number or in association with an oligocythæmia. A simple loss of hæmoglobin is the chief change in chlorosis and the secondary anæmias. In chlorosis the number of the red blood cells may be nearly normal, while the hæmoglobin may be greatly reduced, even to twenty or twenty-five per cent. or less. In the secondary anæmias the number of red cells is also diminished, but the hæmoglobin is reduced to a relatively greater extent; thus, for example, if the number of red cells be diminished to 2,500,000, the hæmoglobin is usually found to be lower than fifty per cent. The individual red cells are, therefore, deficient in hæmoglobin. This is shown microscopically by the presence of a central clear area in the red cell. This area may be of varying size and shape; in severe cases the hæmoglobin-containing portion of the cell may be reduced to a narrow ring, enclosing a clear and transparent central area. In very extreme cases some cells may contain no hæmoglobin at all

Digitized by Microsoft®

(the so-called blood shadows). In other cases the central clear area may not be enlarged, but small vacuoles occur throughout the cell protoplasm; the hæmoglobin may be preserved in the central part, and around this there may be a clear ring of varying width. Often the central portion stains very dark with eosin, and such cells are sometimes mistaken by inexperienced observers for nucleated red cells. Inasmuch as the darker central area takes the eosin and not the nuclear stain the mistake is inexcusable. In still other cases no definite vacuoles or clear spaces are seen within the cells, but their deficiency in hæmoglobin is shown by their lighter color and lighter staining. On the other hand, in pernicious anæmia the amount of hæmoglobin is relatively higher than the red cells; as, for example, if the red cells are 2,500,000 the hæmoglobin is fifty per cent. or higher. As a rule, however, both red cells and hæmoglobin are greatly decreased in this disease. The explanation of the relatively high hæmoglobin content is found in the presence of numerous large red cells (macrocytes) containing more hæmoglobin than the normal red cell. This may be regarded as of a compensatory nature. A pathological oligochromæmia occurs in all forms of anæmia, whether due to hæmolysis or deficient blood formation. In the latter case the individual red cells may contain a normal amount of hæmoglobin, or even a greater amount. In severe anæmias the hæmoglobin may be reduced to ten per cent. or less, but it must be borne in mind that the estimation of the low percentages is attended by a greater or less error. A physiological oligochromæmia occurs in the new-born during the nursing period, in the mature female after menstruation, and in the later months of pregnancy and the post-partum period. (See also *Anæmia*, etc.)

Aldred Scott Warthin.

OLIGOCYTHÆMIA.—A diminution in the number of the red blood cells, due either to lessened production or to an increased destruction of the same. The condition is of very frequent occurrence and may be due to a great variety of causes.

A physiological oligocythæmia occurs in hibernating animals during the winter sleep; observations made upon the marmot showed a diminution of the red cells from 7,000,000 to 2,000,000 during the period from November to February. There is also, according to some observers, a slight physiological variation in man, the number of red cells becoming slightly lower toward evening. According to Vierordt, Limbeck, and others, the red cells begin to diminish within one-half to one hour after the ingestion of a full meal, the number being reduced between 250,000 and 750,000 per cubic millimetre, remaining so for a short time, and after two to four hours gradually reaching normal again. The diminution is more marked after the ingestion of large quantities of fluids, and is therefore regarded as due to the dilution of the blood resulting from the absorption of fluid. According to some observers the red cells are increased in number during fasting or starvation, but Raum and Grawitz noted a definite diminution of red cells in healthy fasting men. Normal menstruation does not reduce the number of the red cells. After delivery there is usually found a diminution of red cells lasting for from ten to fourteen days. Under ordinary conditions the post-partum oligocythæmia is slight.

Pathological oligocythæmia occurs after hemorrhage, and in many infections and intoxications. It is found constantly in prolonged fevers, in leukæmia, cachectic conditions, malaria, syphilis, poisoning with mercury or lead, and in carcinoma, particularly of the stomach. A condition of oligocythæmia may also be produced by many poisons, the most important of which are: aniline, nitrobenzole, pyrogallic acid, toluylenediamine, potassium chlorate, amyl nitrite, phallin, helvellic acid, muscarin, arsenic, antimony, picric acid, carbon disulphide, sulphuric acid, glycerin, abrin, ricin, etc. In icterus the presence of the salts of the bile acids in the blood gives rise to oligocythæmia. The venom of poisonous snakes causes extensive destruction of the red cells. In yellow fever there is also a very marked destruction of red cells. Pernicious anæmia is characterized by marked oligocythæmia resulting from the destruction of the red cells by some poison as yet unknown. It is not improbable that the disintegration of red cells and the setting free of hæmoglobin may give rise to certain bodies or ferments having a hæmolytic action. In the oligocythæmia associated with infectious processes the specific poisons produced by the infecting organs have in the great majority of cases a decided hæmolytic action. In certain conditions of the bone marrow the formation of red cells may fall below the normal, hæmatopoiesis not keeping pace with hæmolysis. On the other hand, in cases of increased hæmolysis the bone marrow may present evidences of increased blood formation, and in very rare cases there is a probable similar compensation on the part of the spleen and lymph nodes. The diminution of red cells in the blood of man may be so great as a reduction to 500,000 or less per cubic millimetre. Such severe oligocythæmia is characteristic of the later stages of pernicious anæmia, but may be caused by poisons. (See also *Anæmia*, *Hæmolysis*, etc.)

Aldred Scott Warthin.

OLIVE OIL.—Oleum Olivæ. *Sweet Oil. Salad Oil.* —"A fixed oil expressed from the ripe fruit of *Olea Europæa* L. (fam. *Oleaceæ*)," U. S. P.

The olive is a small or medium-sized tree, with a much-branched trunk and numerous slender branches. The bark is gray, the wood compact, rather hard, agreeably scented, and susceptible of a high polish. Its fine yellow color, variegated with brown, in addition to the above qualities, make it a favorite material for small wooden ornaments and pieces of furniture.

The leaves of the olive tree are white underneath with a layer of stellate hairs. The fruit, the well-known olive, is an oval, pointed drupe, about 2 or 3 cm. (1 in.) long, consisting of a firm, very oily mesocarp, and a spindle-shaped, hard putamen, containing a single long and narrow, also oily, seed. Its color when ripe is dull blue or purple, its taste bitterish and oily.

This valuable tree is a native of Asia Minor, Palestine, and other parts of the Levant, where its cultivation is of the greatest antiquity, as the Old Testament and numerous ancient records show. It was introduced into the Mediterranean countries of Europe and Africa also at an early date, and has become thoroughly naturalized in some of them. In the course of time it appeared in the warmer parts of South America and elsewhere in the tropics, as well as in California in this country.

The fruit of the olive has been improved in form and size, as well as flavor, by cultivation, and there are several well-distinguished varieties. The olive is one of the most important products of Spain and Italy.

For the table, olives are gathered while still green, but fully grown, soaked in water or sometimes in lye to remove their natural bitterness, and finally pickled in a simple or sometimes flavored brine. For the oil they are allowed to ripen, and then are ground and subjected to pressure.

The quality of the product depends upon nicety in every stage of the operation; for the best table oil, fine fruits of good varieties must be taken, and the pressing done at once, without heat; this yields a moderate quantity of very clear, light-colored, generally slightly greenish, pleasant-flavored oil, generally called "Virgin Oil," which is sold for table use. The remaining cake is then broken up and heated or mixed with boiling water and more strongly pressed, when a further product of darker and stronger tasting oil is obtained. This grade of oil, which is called "foots," can be used for cooking or for fuel. An easy way, finally, for obtaining a large yield of oil is to lay the olives in heaps until decomposition begins, when a very strong-smelling oil (*huile fermentée*) results.

Composition.—No other fruit contains so large a proportion of fixed oil as this; it amounts generally to over one-half, and in good qualities to almost three-fourths. Besides, the fruit contains considerable *mannit*, diminish-

Digitized by Microsoft®

ing as it ripens and the oil increases. Olive oil of the quality required for medicinal purposes is thus described: "A pale yellow, or light greenish-yellow, oily liquid, almost devoid of odor, having a nutty, oleaginous taste, with a faintly acrid after-taste, and a neutral reaction. Specific gravity, 0.915–0.918. Slightly soluble in alcohol, but readily soluble in ether. When cooled to about 10° C. (50° F.), it begins to be somewhat cloudy from the separation of crystalline particles, and, at about 5° C. (41° F.), it begins to deposit a white, granular sediment; below 2° C. (35.6° F.), it forms a whitish, granular mass." The principal part, more than two-thirds, of olive oil is the liquid fat *olein*, or triolein; nearly all the rest is *palmitin*, with a little *stearin*, *butin*, and perhaps also *cholesterin*. Of the so-called "olive oils" in the American market the cheaper ones, even bottled and labelled in French as "Pure Olive Oil from Nice," etc., are at present almost entirely better grades of cotton-seed oil, and some of the more expensive sorts are said to be adulterated with it. This oil and other cheaper ones are also used abroad extensively as substitutes for or adulterants of this delicious and much-prized substance.

Action and Use.—This can be disposed of quite briefly, so far as its medical use is considered. Given internally, it is chiefly a fatty food, and is emulsified and absorbed as other fats are. It is slightly, only very slightly, laxative, and has no other physiological action. Locally applied it is a neutral protective from the atmosphere, as are other fats; but in this application it has given place somewhat to cheaper ones—suet, lard, cotton-seed oil, etc.,—and especially to the various *petrolatum* products.

It is rather frequently given as an injection, but *castor oil* is preferable for this purpose. Like most other fixed oils, it is destructive to insect life, and rectal injections and applications are often efficient in the treatment of ascarides. Many reports have been published of the efficacy of large quantities of olive oil, two to four gills at a dose, in favoring the removal of gall stones. A little cocaine may be added if there is a tendency to reject it. Its most extensive employment in medicine is perhaps in the composition of several liniments and of the pharmaceutical soaps; in this field it has also of late been replaced in this country by the cheaper oil from cotton seed.

Administration.—As a laxative, three or four tablespoonfuls are required,—a dose that is apt to disturb the stomach of one unaccustomed to oils. This, as stated above, may often be prevented by the use of gr. ¼ of cocaine, given just before the administration of the oil. As an injection, one or two teacupfuls, injected warm, and retained an hour or so and then followed by soapsuds, make a very efficient composition for relieving an overloaded rectum.

W. P. Bolles.

OLIVER SPRINGS.—Anderson County, Tennessee. Post-Office.—Oliver Springs. Hotel.

Access.—From Knoxville viâ Southern Railroad (formerly East Tennessee, Virginia, and Georgia Railroad), thirty-five miles northwest to springs.

The Oliver Springs and the small village of the same name are situated on the southern slope of the Cumberland range of mountains, where the counties of Anderson, Roam, and Morgan join their boundary lines. The surroundings of the resort are very pleasing, and the climate is of a genial, attractive character. The average summer temperature at the springs is 72° F., and of the winter 38° F., showing an unusually low variation. It is said that malaria has never been known to exist in the vicinity. There are nine mineral springs within the ten acres occupied by the hotel grounds. They have not been fully analyzed, but are said to contain iron, manganese, lithia, magnesia, and sulphur. They are used considerably for medicinal purposes, and, joined with the beautiful scenery, the pleasant climate, and a comfortable, new hotel, they serve to render this location a very attractive one for the health or recreation seeker.

James K. Crook.

OLYMPIAN SPRINGS.—Bath County, Kentucky. Post-Office.—Olympian Springs.

Access.—Viâ Lexington and Big Sandy Railroad to Mount Sterling, thence by stage.

These springs are ten in number, and are of the saline-sulphureted variety. The waters are promptly diuretic in their action. Analysis was made by Dr. Robert Peter in 1858, and again in 1887. Following is the result of the former analysis of the salt sulphur spring:

One United States Gallon Contains:

Solids.	Grains.
Magnesium carbonate	7.20
Iron carbonate	Trace.
Lime carbonate	13.93
Potassium chloride	10.67
Sodium chloride	166.01
Magnesium chloride	55.39
Lime sulphate	Trace.
Iron and bromide	Trace.
Alumina	Trace.
Silica	1.04
Water and loss	78.60
Total	332.84

Gases: Carbonic acid, sulphureted hydrogen, not estimated.

A re-examination of the waters in 1877 showed essentially the same results. The following additional ingredients were found in minute quantities:

Baryta carbonate.	Sodium iodide.
Strontium carbonate.	Sodium sulphide.
Sodium carbonate.	Boric acid.
Calcium chloride.	Phosphoric acid.
Lithium chloride.	Manganese carbonate.
Sodium bromide.	

Examination of the two other springs showed the presence of sodium carbonate in the proportion of twenty grains per gallon. One of them contains a little less than two grains of iron carbonate to the gallon.

James K. Crook.

OMENTUM, PATHOLOGY OF.—The term omentum (epiploön) is applied to the folds of peritoneum which connect the stomach with its neighboring organs, the liver, colon, and spleen. In structure similar to the mesentery, each omentum may be regarded as a special mesentery connecting the stomach with the organs named. They are usually designated respectively as: *gastro-hepatic* or *lesser omentum* (*omentum minus*); *gastro-colic* or *great omentum* (*omentum majus or epiploön*); and the *gastro-splenic* omentum.

The *gastro-hepatic* (stomach-liver) *omentum*, or small omentum, extends from the lesser curvature of the stomach and the adjacent first part of the duodenum to the portal fissure of the liver, enclosing between its two layers the hepatic artery, portal vein, bile duct, and associated structures, bound together by loose connective tissue.

The *gastro-colic* (stomach-colon) *omentum*, or great omentum, connects the greater curvature of the stomach and the adjacent first part of the duodenum with the transverse colon. It is the largest of all the peritoneal duplications, and is composed of four layers of peritoneum; it is much more voluminous than is necessary for the mere connection of the stomach and colon, and hangs down in front of the small intestines like an apron.

The *gastro-splenic* (stomach-spleen) *omentum* is a double fold of peritoneum passing from the dorsal surface of the stomach, near its left border, backward to the hilum of the spleen. It runs below into the gastro colic omentum. It is often called the gastro-splenic ligament. It contains the splenic vessels.

In structure the omental folds are composed of either two or four layers of the peritoneal membrane, a basement structure of very loose connective tissue, containing a remarkable number of blood-vessels and lymphatics, and more or less adipose tissue, the whole being covered with endothelium. Small lymph nodes are not infrequently found in the great omentum, less frequently in

Digitized by Microsoft®

the gastro-splenic, but are almost constantly present in the lesser omentum. These usually show the structure of ordinary lymphatic glands, but hæmolymph glands also occur. Accessory spleens are of common occurrence in the gastro-splenic omentum.

www.libtool.com.cn

The great omentum is by far the most important, both physiologically and pathologically considered. That its function is of great importance, in so far as the protection of the peritoneal cavity is concerned, cannot be doubted. It usually contains a large amount of fat tissue, and this fact, taken in connection with its "coverlet" investiture of the small intestines, has led to the view, advanced by both Aristotle and Galen, and commonly accepted even to-day, that the organ is of service in preserving the heat of the body and protecting the intestines against chilling. Such function, doubtful as it appears, is of slight importance compared with the protective function of the omentum against intraperitoneal infection. The remarkable richness of the organ in blood-vessels and lymphatics—far in excess of the needs of the structure itself, if intended only for a protective covering—is structural evidence of the chief omental function. The vessels form a rich plexus throughout the connective tissue beneath the endothelial covering, the vessels themselves in many cases being separated from the peritoneal cavity by the endothelium alone. Numerous clinical observations tend to show that the transudation of lymph into the abdominal cavity or the absorption of lymph from the cavity is an important function of the omentum. Many writers hold that the omentum is a modified lymphatic ganglion. It has been shown experimentally that, after the removal of the omentum, animals are much more susceptible to intraperitoneal injections of micro-organisms than control animals whose omentums have not been removed. The inference may be drawn that micro-organisms obtaining entrance to the peritoneal cavity are taken up by the omentum and there rendered harmless or are killed.

In local traumatism, or after operations involving the peritoneum, in beginning peritoneal infection, local peritonitis from whatever cause, etc., the omentum is quite commonly found attached to the affected area, entirely surrounding it and shutting it off from the remainder of the peritoneal cavity. This occurs particularly in appendiceal and tubal disease, following the beginning of a local peritonitis, but it is also of very frequent occurrence over the surface of liver, spleen, intestines, etc. It would appear that the omentum is attracted to the diseased area; the location of such adhesions deep in the pelvis or in parts of the peritoneal cavity not usually occupied by the omentum would indicate such a movement of the omentum to the affected part. The slightest irritation in any part of the peritoneum is apparently sufficient to cause the omentum to attach itself to the affected area, and to shut off the focus of infection from the remainder of the peritoneal cavity. Even when microscopic changes are not visible, alterations of the intestinal wall permitting the passage of germs or of their products, are sufficient to cause such adhesions. The plastic exudate thrown out by the omentum at the point of lesion no doubt offers some purely mechanical protection against the spread of infection; it is also probable that the secretion poured out from the omental vessels has some bactericidal or antitoxic action. Furthermore, the bacteria received into the lymphatics of the omentum are either rendered less virulent or are destroyed

Malformations.—The great omentum may be entirely absent, or only incompletely developed. Variations in size and shape are common; partial defects of large size are not infrequent. Misplacements of portions of the organ are found in connection with congenital hernias. Congenital cysts of the omentum are of very rare occurrence.

Circulatory Disturbances.—The vascular relations of the omentum are such as to make the circulatory conditions of this organ dependent upon that of the neighboring structures. Inflammations of the gastro intestinal tract, hernias, obstructions, tumors, disturbances of the portal circulation affect the vessels of the omentum to a more or less marked degree.

Active hyperæmia of the omentum occurs in the early stages of epiploitis, also after the sudden diminution of abdominal pressure after the removal of ascitic fluid or of a tumor of large size.

General passive congestion of the omental vessels follows portal obstruction, either as the result of hepatic disease or of pulmonary or cardiac affections. The vessels of the great omentum may be markedly congested in advanced stages of cirrhosis, or in failure of compensation in valvular disease of the heart. In such cases the congested omentum plays a large part in the production of the associated ascites.

Advantage has been taken of the dilated condition of the omental vessels in cirrhosis of the liver, and of the fact that the omentum readily forms adhesions with other structures, by an attempt to set up a collateral circulation between the portal and the systemic veins by means of "*Morrison's operation.*" This consists in the establishment of an anastomosis between the vessels of the omentum and those of the anterior abdominal wall through artificially induced adhesions. The peritoneum is first rubbed, and the omentum sutured to the area so treated. It is at present too early to speak of the value of this procedure; but very favorable results have been reported. In a case operated upon by Lens, venous channels were demonstrable in the adhesions that had formed between omentum and peritoneum. Animal experimentation shows the possibility of the establishment of such a collateral anastomosis. Similar results may be obtained by adhesions formed between the diaphragm and the liver or spleen.

Hemorrhage.—Small ecchymoses occur into the omental tissues in extreme active or passive congestion, in severe cases of the acute infections, in sepsis, in epiploitis, fat necrosis, secondary carcinoma, hæmophilia, etc. Large hæmatomata are rare; they may occur in association with fat necrosis in cases of acute pancreatitis, or in severe epiploitis associated with appendicitis or salpingitis, or very rarely in hæmophilia.

Infarction.—Incarceration or torsion of the omentum may, by shutting off the blood supply, give rise to an anæmic necrosis. Ligation or thrombosis of the epiploic artery will produce the same result. In cases of resection of the omentum in herniotomy a thrombosis may be induced in the omental vessels which may extend to the gastric arteries. In cases in which the ligations are near the epiploic artery, anæmic ulceration of the stomach or hepatic infarction may occur, as the result of the extension of thrombosis into the gastric and hepatic vessels.

Œdema of the omentum is of frequent occurrence. It may be due to general or local passive congestion, obstruction of the portal circulation, epiploitis, etc. In acute epiploitis associated with general peritonitis and ascites the omentum may be very much swollen. As a rule, œdema of the omentum is manifest in the resulting ascites; the free interchange of fluid between the lymph spaces of the omentum and the peritoneal cavity relieves the omentum, so that it does not become swollen through the accumulation of fluid in its tissue spaces, until the collection of ascitic fluid in the peritoneal cavity reaches a certain degree of tension.

Ascites.—The omental function of lymph production and lymph absorption is directly connected with the development of ascites. All conditions favoring an increased formation of lymph by the omentum, as well as those preventing the absorption of peritoneal fluids, lead directly to ascites. Malpighi was perhaps the first to suggest that ascites may be caused by a pouring out of fluid from the omental vessels. In a case reported by Landgraf, an ascites intractable after fourteen tappings disappeared after the sloughing of a part of the great omentum which presented itself in an omental hernia. Similar cases have been observed. Eitel reports an interesting case of marked ascites which had been repeatedly tapped. A large tumor was found to be present in the upper part of the abdomen. On operation this was dis-

Digitized by Microsoft®

covered to be the great omentum tightly rolled upon itself, its veins constricted and its circulation impeded. It was unrolled and the ascites was cured. The cause was attributed to the fact that the patient, a worker in a quartz mill, was in the habit of carrying a heavy box of mill product pressed against his abdomen. Other cases of a similar nature point to the omentum as a direct factor in the production of ascites.

www.libtool.com.cn

Hydrops Omenti.—The collection of fluid between the layers of the great omentum is so designated. This condition occurs more frequently in cases of ascites in children than in old individuals.

Chylous Ascites.—In cases of secondary carcinoma of the omentum or in chronic fibroid omentitis, the ascitic fluid may be white or milky, due to fat or albumin in suspension. The presence of these substances may be due to the fatty degeneration of desquamated endothelium or tumor cells, or may result from the obstruction of chyle vessels. In the former case, when little fat is present in the fluid, the condition may be designated as *pseudochylous ascites.*

Retrograde Changes.—Atrophy of the omentum, as shown by total or marked disappearance of its adipose tissue, occurs in cachexias and wasting diseases as a part of the general marasmus. Atrophy of the fibrous trabeculæ may also occur. Cases have been observed in which the atrophy of portions of the organ gives rise to large open spaces between its coarser trabeculæ.

Necrosis of the omentum may be caused by incarceration or torsion, by ligation or thrombosis of omental vessels, or it may be associated with gangrenous conditions of the intestines.

Fat necrosis of the omentum occurs in acute pancreatitis, in pancreatic carcinoma, and in association with fat necrosis of the abdominal fat elsewhere. The necrosed areas are yellowish-white, slightly elevated and opaque, and usually circular in outline. The omentum may look as if it had been touched with a hot iron. The necrotic areas may be hemorrhagic. In cases of longer standing lime salts may be deposited in the necrosed cells.

Amyloid has been reported as occurring in the walls of the omental blood-vessels.

Hyaline change of the walls of the omental arteries is found in chronic fibroid omentitis, in association with omental tuberculosis, in the neighborhood of inflammatory adhesions, etc.

Calcification may follow fat necrosis, or occur in old tubercles. In two cases of splenic anæmia associated with hepatic cirrhosis (Banti's disease) numerous small nodules of calcification were found by the writer throughout the abdominal fat.

Inflammation (*Omentitis* or *Epiploitis*).—Inflammation of the omentum is essentially a part of a more or less general peritonitis in the great majority of cases; but in certain instances the omental inflammation preponderates, or appears to be primary; and further, as mentioned above, localized peritonitis is almost always associated with a localized epiploitis, the omentum adhering to and shutting off the inflammatory process (see *Peritonitis*). The character of the epiploitis is the same as that of the general or local peritonitis with which it is associated, viz., *fibrinous, purulent, gangrenous,* etc. The omental process is, however, in all cases characterized by a greater tendency to proliferation and formation of granulation tissue than is the case with the other portions of the peritoneum. This is especially true of the localized forms of epiploitis with adhesion; the inflammatory process is essentially plastic in character (omentitis adhæsiva). As a result of very active inflammations there may be formed such large masses of granulation tissue in the omentum as to produce tumors which may be mistaken clinically for neoplasms.

Inflammatory Tumors of the Omentum.—As the result of such excessive production of granulation tissue in the inflamed omentum, there is not infrequently found a tumor-like thickening of the omental tissues. This may occur in any part of the abdomen, but is most frequent in the appendix region. The thickening of the omentum may be diffuse or nodular, often limited to the portion adherent to the peritoneum about the primary focus. In other cases the omentum may be rolled up tightly above the level of the umbilicus, forming a firm cylindrical mass extending across the abdomen. The tumor mass may develop very rapidly in acute processes, but more gradually in chronic inflammations. After the inflammation has subsided the tumor may disappear through the resorption of exudates and the contraction of the granulation tissue, and the omentum may become detached. In other cases, after the inflammation has disappeared, the tumor remains and the omental adhesions become hard and organized. In purulent cases the inflammation may persist, and a chronic tumor then remains, composed of an inflammatory focus (abscess) surrounded by thick omental adhesions of granulation tissue. In other cases, after the termination of the inflammation, the omentum becomes detached, the granulation tissue is converted into fibrous tissue, and the omentum is greatly changed in form by the production of diffuse or nodular fibroid thickenings (omentitis fibrosa). If there is much retraction of portions of the new fibrous tissue the omental tumor may be very small and irregular (omentitis fibrosa retrahens).

Inflammatory tumors of the omentum also follow laparotomy, in which either the normal or the inflamed omentum has been ligated and in part removed. Torsion of the omentum may also give rise to an omental tumor. In some cases, after an operation for strangulated hernia, the omentum has become inflamed, though not involved in the strangulation. In all these cases the inflammatory tumor develops slowly; in one-half of the recorded cases the period of development varied from one to four months, and in some cases the interval was much longer. The tumor is usually on the same side of the body as that upon which the operation was performed, its location depending upon the amount of omentum removed. It may or may not be adherent to the abdominal wall. The tumor is usually about the size of an orange, but may be much larger. When adherent to the wall the tumor is immovable; if non-adherent it may be moved upward or laterally, but not downward. The surface of the mass is usually smooth, the consistence firm. It is tender on pressure. It usually does not move with respiration, or only slightly. Percussion gives a dull tympanitic note, often completely dull. In the centre of the tumor may be found the ligatures used to tie off the omentum, and it is believed by some that the use of silk ligatures in such operations plays an important part in the development of the tumor.

Clinically, the inflammatory tumors of the omentum may be mistaken for ovarian tumors, misplaced liver or spleen, malignant growth of the intestines, etc. In certain cases they have been regarded as malignant neoplasms (sarcoma) even after microscopical examination. Coley mentions a case in which a portion of the omentum had been excised on account of its presence in a left inguinal hernia. The stump became inflamed, withdrew, and gave rise to a mass in the region of the splenic flexure. Malignant disease was suspected, the abdomen was opened, and a portion of tissue removed for examination. The diagnosis was "probable spindle-celled sarcoma." The patient died after a radical operation. The autopsy showed that the inflamed omental stump had become attached to the splenic flexure, and the section for microscopical examination had been cut from the very abundant inflammatory tissue.

In two cases in the writer's experience there were found, in the region of the appendix, large tumor masses that clinically presented characteristics of malignancy. Microscopical examination of tissue removed for diagnosis showed a very cellular granulation tissue, rich in blood-vessels, having relatively thick walls. In one case the diagnosis of "omental granulation tissue" was given. The patient recovered, and the tumor completely disappeared. In the other cases the first sections examined were prepared by a quick method for immediate diagnosis. The

Digitized by Microsoft®

section showed a sarcomatous-like structure of round and spindle cells grouped around blood-vessels, suggesting an endothelioma. Study of the sections showed large numbers of plasma cells present, and the fact that all of the blood-vessels had relatively thick walls. A diagnosis of omental granulation tissue was then given. A year afterward the tumor was reported as having entirely disappeared. There can be but little doubt that some of the so-called disappearing malignant tumors of the abdomen belong to this class. The microscopical appearances of small bits of tissue removed for diagnosis may on first glance strongly suggest a sarcomatous growth. In the relatively thick sections obtained by means of the freezing microtome or by quick embedding methods the finer points necessary to a differential diagnosis are usually not sufficiently clear for a safe diagnosis, and it is from such sections that the diagnosis of sarcoma is usually made. The writer holds that in carefully prepared sections the differential diagnosis between such forms of richly cellular granulation tissue and sarcoma may be made without great difficulty. The presence of numerous plasma cells, the prominence of the small vessels, both in number and in size, their relatively thick walls, the hypertrophic character of their endothelium, the marked endothelial proliferation, the typical character of the mitosis, the presence of fibrin and small pus collections, are all points establishing the diagnosis of subacute or chronic development of granulation tissue. The presence of adipose tissue and coarse trabeculæ of fibrous tissue are also of service in fixing the origin as omental.

Omental Abscess.—An acute omental abscess may develop without the association of a general peritonitis or of any discoverable local change. In the majority of cases, however, the appendix is the seat of primary infection. Omental abscess may be associated with salpingitis, and very frequently follows laparotomies or herniotomy. In those cases in which the omental abscess is apparently of cryptogenic origin, or overshadows the primary lesion, it may be inferred that the resistance of the omental tissues had been lowered, or that the organ, through circulatory disturbances or for other reasons, has been unable to overcome the virulence of the bacteria taken up. The abscess may be found in any part of the abdominal cavity, but as the omentum is commonly rolled up, it lies usually above the level of the umbilicus. It may develop around ligatures which are used in tying off the omentum. The organ is reddened, thickened, and is usually adherent to the abdominal wall by a fibrinous exudate, which is most marked over the abscess. The latter not infrequently forms an encapsulated pocket of pus between the omentum and the anterior abdominal wall, and may extend into the tissues of the latter. The clinical symptoms are those of sepsis, with local pain and tumor. In many cases the abscess becomes chronic, a large amount of fibrous tissue is formed about the encapsulated area, the adhesions become hard and firm, and a gradual healing of the abscess may take place. A more or less generalized peritonitis may accompany the abscess. Occasionally the pus may break through into the intestine and recovery follow. Rupture into the peritoneal cavity may cause a severe general peritonitis which may be fatal.

Sequelæ of Omental Inflammation.—As a result of inflammatory conditions of the omentum there may arise adhesions between the organ and the various abdominal viscera; these may cause stenosis, or snaring off of portions of the bowel, obstruction of the ureter, pressure upon the common duct or pylorus, abnormal position of the pelvic organs, etc.

Progressive Changes.—Either fibrous or fatty *hyperplasia* of the omentum may occur in the portion of the organ included in hernial sacs. The hyperplasia may take on the character of a lipomatous growth. Cases have been reported of such hyperplasias in hernial sacs which reached half-way to the knees.

The remarkable capacity for *proliferation* possessed by the omentum has been taken advantage of in plastic operations in the abdomen. (For further details in regard to this part of the subject, the reader should consult the article next beyond this.)

Tumors.—Primary neoplasms of the omentum are rare. *Fibroma* and *lipoma* have been described. In the former class of cases the actual disease may in reality have been a localized fibroid thickening resulting from an inflammatory omental tumor. The so-called lipomatous growths have been, in the majority of cases, localized or diffuse fatty hyperplasias.

Of the primary malignant tumors reported as occurring in the omentum *endothelioma* and *myxosarcoma* are the forms whose origin in this organ is supported by observation; but it must be observed that the rarity of such cases, and the imperfect descriptions given, leave us very much in ignorance as to the occurrence and nature of primary omental tumors. In the older literature there are occasional reports of "*primary cancer*" of the omentum, "scirrhus of the omentum," and "primary colloid disease," "vesicular degeneration," "hydatid disease," etc. The exact nature of this peculiar growth of the omentum, apparently primary in some cases, cannot at present be stated. Primary epithelial growths (carcinoma) of the omentum of course do not occur. In some cases the growth may have been secondary to colloid carcinoma of the stomach or intestine, or to cystocarcinoma of the testis or ovary. In typical cases the omentum is greatly thickened; its surface is uneven, flocculent, and shreddy, this appearance being due to the projection of rounded villus-like masses of gelatinous material attached by shreds of tissue. The appearance strongly suggests hydatid disease of the placenta. On microscopical examination the mass of the omentum has a finely spongy texture of connective tissue enclosing masses of gelatinous material. Swollen cells are occasionally found in the spaces. If we exclude the cases of true *colloid cancer* or *cystocarcinoma, secondary* to primary tumors in other organs, there still appears to be a peculiar myxomatous growth of the omentum, which according to the most careful reports (Eve and others) must be classed as a *myxoma* or *myxosarcoma.* No proof of its endothelial origin exists. Matas has reported a case of primary myxosarcoma of the omentum with secondaries in peritoneum and accompanied by a mucoid ascites.

The flat or warty growths, originating from endothelium, may be primary in the omentum as well as in the peritoneum. Microscopically, the primary endotheliomata of the peritoneum consist of cords or strands of cells in the connective tissue beneath the endothelial covering. The cords of cells appear to follow the lymph vessels. The growth may originate from the superficial layer, or from the endothelium of the lymph vessels.

Omental *cysts* have also been reported, and have been interpreted as "*simple serous cysts*," "*distended lymph vessels*," "*congenital multilocular cystoma*," etc. It is not improbable that the latter variety was a primary tumor of the ovary, which after becoming adherent to the omentum, had been freed from its original attachments. Such a process has undoubtedly occurred in the case of the so reported *dermoid cysts of the omentum.* Though primary dermoids of the omentum may occur, it is highly probable that those observed have originated from primary ovarian dermoids in the manner described.

Secondary malignant growths of the omentum are of very common occurrence; they represent most frequently carcinoma metastases from primary growths in stomach, intestine, gall-bladder, pancreas, ovaries, testis, uterus, and prostate. A number of cases of melanotic sarcoma of the omentum have been reported. While the growth, in several of these instances, was regarded as primary, it undoubtedly was metastatic from primaries in the skin or choroid.

Pseudomyxoma.—The omentum as well as the general peritoneal surface may be involved in the process known by this name. It is due to rupture of an ovarian cystoma, the discharge of mucoid or colloid material into the peritoneal cavity, and the organization of the latter by proliferation of the peritoneal tissues.

Parasites.—*Echinococcus* of the omentum has been re-

Digitized by Microsoft®

ported. After rupture of a primary hydatid cyst into the peritoneal cavity the omentum may be secondarily involved in connection with the remainder of the peritoneum.

Tuberculosis of the omentum is of relatively common occurrence. In many cases the infection of the peritoneum appears to be primary in the omentum. The thickened omentum may be tightly rolled up, forming a tumor-like mass which may be mistaken for a neoplasm. In primary tuberculosis of the female genital tract, large tubercles may be found in the omentum. (See also *Peritonitis, Septic and Tuberculous.*)

Syphilis.—A fibroid omentitis has been observed in congenital syphilis, and in connection with syphilitic cirrhosis and fibroid splenitis.

Foreign Body.—A case is reported of an encysted needle being found in the omentum. Gauze, sponges, ligatures, or foreign bodies left in the peritoneal cavity during laparotomy may become included in omental adhesions.

Aldred Scott Warthin.

OMENTUM, SURGERY OF.—The omentum is composed of two layers of peritoneum which are derived from the anterior and posterior walls of the stomach. They pass downward in front of the abdominal organs into the hypogastric region, and are reflected backward upon themselves and pass upward until they reach the transverse colon. There they separate, and after covering this portion of the intestine they come into contact behind it, forming the transverse mesocolon. Thus the omentum is really made up of four layers, but in adult life the layers cannot be wholly separated, although this construction gives to the omentum a very loose and lobular character. In almost all persons the omentum contains a good deal of fat, and in individuals who are very stout the quantity of fat is proportionally large.

The function of the omentum under normal conditions seems to be to afford protection to the underlying coils of small intestine, and also to facilitate their movements. Under pathological conditions it has the further function of applying itself to any wounded surface of the peritoneum within reach, so that it may even be able to occlude a perforation and prevent fatal escape of intestinal contents. By reason of its large serous surface it doubtless aids materially in the resorption of extravasated fluids from the peritoneal cavity.

The lesions of the omentum which are of surgical importance are traumatic, inflammatory, parasitic, and neoplastic.

Traumatisms.—If the abdominal cavity is opened, for example, by a stab, the omentum will often be found presenting itself in the wound. It frequently serves a useful purpose by protecting other more important organs from exposure to infection and traumatism in an open wound. It may even protrude through a stab wound which opens both the lower part of the pleural cavity and the peritoneal cavity through the diaphragm. It is the most common content of a hernial sac. The omentum which is thus prolapsed into a wound may be uninjured, or some of its vessels may have been opened by the traumatism, or it may become inflamed, or it may become gangrenous either on account of the traumatism or secondarily through its becoming strangulated in the wound.

Intraperitoneal hemorrhage from a larger omental vessel may prove fatal because the thin walls of its vessels favor long-continued bleeding. In excising prolapsed or injured or adherent portions of omentum the surgeon should be careful to see that every bleeding vessel is secured by a ligature. If the omentum which presents itself in a wound is uninjured and the wound itself is clean, the omentum may be cleansed and replaced; otherwise it should be cut away.

Inflammation.—The simplest form of inflammation which can affect the omentum is of a traumatic character. This is most frequently seen in connection with an omental hernia, where repeated slight traumatisms give rise to local fibrinous peritonitis with the formation of adhesions. The hernia will then become partly or wholly irreducible and the omentum will be still more exposed to slight injuries. This condition is often seen in inguinal and umbilical herniæ. In operating upon such herniæ, it is customary to excise portions of omentum which are badly matted together by adhesions, or whose surfaces are deprived of their peritoneum when the omentum is torn loose from the hernial ring. The removal of more or less of the omentum does the patient no harm, but the stump of the omentum may give rise to serious trouble. It sometimes retracts, and becomes adherent to the abdominal wall or some portion of the intestine, while adhesions take place about it to such an extent that a mass is formed that has more than once been mistaken for a tumor. In one case within the knowledge of the writer a section of this new-formed fibrous tissue was removed and was pronounced by a well-known pathologist to be a spindle-celled sarcoma. In consequence an extensive resection of the descending colon, to which the omentum was adherent, was performed, and from the indirect effects of this operation the patient died. Such an inflammatory tumor in the omental stump will, like all ciatricial tissue, decrease in size in the course of time, but it may give the patient a great deal of trouble during the process, and the adhesions produced by it may continue to give trouble long after the inflammation has subsided.

Suppurative inflammation may develop in the omental stump, usually as the result of an infected ligature. If general peritonitis is avoided, an abscess may be produced within the omentum. The omentum under such circumstances will attach itself to the surrounding parts, including the anterior abdominal wall, so that it may be possible to open the abscess without entering the general peritoneal cavity.

The more chronic inflammations, such as syphilis, tuberculosis, and actinomycosis, may involve the omentum, usually in common with other portions of the abdominal cavity. Omental echinococcus is also known, and in very rare instances an echinococcus cyst of the omentum reaches a great size, although the lesions in other portions of the peritoneum are insignificant.

Tumors.—A few primary tumors of the omentum have been reported. They are for the most part lipomata, sarcomata, or cystic tumors of congenital origin. Dermoid cysts and teratomata are thus explained. There are also acquired cysts of the omentum of a serous or hemorrhagic character, the latter being secondary to hæmatoma. Thus the tumors of the omentum are similar to those of the mesentery.

In addition to these primary tumors of the omentum secondary nodules may develop on its surface and within it in case of malignant disease of other abdominal organs, while tumors of the transverse colon may grow downward into the omentum so that they simulate omental tumors. A careful examination after the abdomen is opened will usually show the starting-point of such a tumor.

An omental tumor is characterized by a great range of mobility as long as adhesions do not exist. For this reason a small cyst may easily be mistaken for a solid tumor. As tumors of the mesentery often have a great mobility, it will scarcely be possible to differentiate them from omental tumors before the abdomen is opened.

The removal of an omental tumor requires no special technique. On account of the thin walls of the vessels all bleeding should be stopped by ligature before the abdomen is closed. Mass ligatures cannot well be avoided, but the amount of tissue included in each ligature should be small. It is also worth while to approximate the peritoneal surfaces of the omentum by a continuous catgut suture so as to prevent the formation of extensive adhesions. If an echinococcus or epithelial cyst cannot be removed *in toto*, it should be sutured into the abdominal wound and drained.

Omental Grafts.—The omentum has occasionally been used to cover a defect in the peritoneum which could not be closed by direct suture or as an additional safeguard

Digitized by Microsoft®

to cover a weak suture of the stomach or intestine. It is especially adapted for such a purpose because of its extensive peritoneal surface, its great mobility, and its free blood sepply. Furthermore, the omentum can be sacrificed without especial injury. The advantage of covering all wounded surfaces within the abdominal cavity with peritoneum has not been generally recognized, yet when this is done repair is hastened and the risk of sepsis is lessened as truly as is the case in covering wounded surfaces of the body with skin, while within the abdominal cavity a raw surface has a third disadvantage not possessed by external raw surfaces in that it gives rise to adhesions more or less dangerous, according to their situation. Such adhesions can be partly or wholly avoided if the raw surface is covered with peritoneum. The omentum has been used with success to supply peritoneal grafts, which may remain attached to the omentum, or may be wholly cut from it and stitched over the wounded surface like a skin graft over a raw external wound. The wound in the omentum itself should of course be closed by suturing the cut edges of the peritoneum.

Edward Milton Foote.

ONYCHIA. See *Hands and Fingers, etc.*

OPEN-AIR TREATMENT OF PULMONARY TUBERCULOSIS.—The so-called "open-air" treatment of pulmonary tuberculosis has been adverted to frequently in this Handbook, notably under *Falkenstein*, *Goerbersdorf*, and *Health Resorts*. It is the established treatment of pulmonary tuberculosis at the present day, and is most completely exhibited in the sanatoria. In a word, it consists in affording the patient pure outdoor air to breathe continuously, both night and day, keeping him out of doors by day and having his bedroom windows open by night, or in many cases and places having him sleep also out of doors. It is hardly necessary to add that at the same time due attention should be paid to diet, rest, hydrotherapy, and to all that pertains to the hygienic well being of the patient; hence this method is also, and perhaps more correctly, termed the "hygienic-dietetic" treatment. This treatment has been brought to such a degree of perfection that it may almost be said to be independent of climate, that is, it can be successfully carried out wherever there are pure air free from dust, protection from wind, and a moderate amount of sunshine—climatic conditions which are obtainable almost everywhere outside of large centres of population. It seems a very simple matter to conduct such a treatment, but experience has shown that constant supervision is necessary, aided by the example of others, in order to keep the patient up, day after day, summer and winter, to this treatment in all its strenuousness; hence the great value of sanatoria and their constant and rapid increase in number. Even though this treatment is in a measure independent of climate, it is not to be asserted that all climates are equally valuable, for it is obvious that the greater the number of favoring climatic elements, the more perfectly the treatment can be conducted, and the more successful it will be. Hence such resorts as Davos, Colorado Springs, Idylwild (California), Asheville, Aiken, and many others of superior climatic excellence are especially favorable for this mode of treatment, provided the other essential factors, such as diet, etc., are at hand. It may be thought that this treatment can be accomplished by simply instructing the patient to keep out of doors; nothing could be more fallacious than this. In the first place, the patient will not keep out of doors all day of his own volition. If he is out for a few hours each day, he is prone to think that he is fulfilling his instructions. Further, he is too often left to himself to determine whether he shall remain at rest or take exercise while in the open; generally he does the latter, sometimes from ignorance, sometimes for the want of any proper place where he can remain at rest. Here, again, comes in the value of the sanatorium where all these details are carefully looked after.

The theory of the outdoor treatment is, of course, evident; the object is so to improve the nutrition of the pulmonary tissue and general system, and so to harden the patient and thereby increase his resisting power that he will no longer present a favorable soil for the tubercle bacillus. It is also claimed for this treatment that it will increase tissue metabolism, so that fibroid transformation of tuberculous lung tissue may be hastened, or the encapsulation of caseous areas effected.

Are all cases of pulmonary tuberculosis suitable for the open-air treatment? Obviously not, for all cases are not susceptible of an arrest or improvement; and the object of this treatment is to *cure*. Although it is difficult, if not impossible, in many cases and in the various stages of the disease, to form a probable prognosis, still in general it may be said that advanced cases with mixed infection and septic symptoms—cases of very extensive disease, those in which the tuberculous process is accompanied by acute symptoms, or those in which the recuperative power seems to be lacking, and the whole system appears to have collapsed—are unfavorable cases and unfitted for the severe régime of the open-air treatment. Fresh air, of course, should be afforded all cases, as to everybody else, sick or well; but this can be done in a well-ventilated room, where the patient is made comfortable and kept at rest. If some of these apparently hopeless cases later exhibit more favorable symptoms and develop greater recuperative power, they then can more properly be subjected to the open-air treatment.

Lest there may be some misunderstanding, it is well again to state what may seem self evident, viz., that the open-air treatment in all its rigorousness means practically a continuous outdoor existence. Day after day in all kinds of weather one must be exposed to the open air, and the windows of his sleeping-room must be kept open day and night, summer and winter. This does not mean that one shall sit out in a rain or snow storm, but on a veranda for example, which affords shelter from the storm and wind and yet is open to the air. The writer, for example, had a patient at Rutland, Mass., who, during a New England winter, spent eight hours daily out of doors, always slept in a cool room, with open windows, and bathed his chest every morning with cold water.

In Colorado Springs it is quite generally the custom for consumptives to sleep out of doors, even in winter, with face and body well protected. This is more readily done in warmer climates, as in Phœnix, Arizona, for example, where the practice is quite general. It is also a practice, with some, to sleep with the head out of doors, well protected, while the body is within. As a rule, the vitality and bodily vigor of a consumptive are low, and hence the greater part of the time out of doors is spent at rest, best on a reclining or ship's chair. One of the common sights at the German sanatoria is the "Liegehalle" or piazza, where are long rows of patients in reclining chairs. Dettweiler insists upon almost complete rest in the open air, while other phthisio-therapeutists permit their patients who have no fever to take a limited amount of exercise. As has been said above, a well-equipped sanatorium affords the best opportunity for taking the open-air treatment, and medical supervision is always at hand to insist upon it; at the same time it is practicable, in very many cases, to devise at the home of the patient an arrangement for this treatment. A properly protected veranda, preferably facing the south; a tent with a wooden floor; a country barn with the large doors open; a shed or wooden chalet simply and cheaply constructed, serving also as a sleeping-room by night;—all of these afford opportunities for the "treatment." If the physician is at all ingenious he will readily invent some way by which this can be accomplished, for there is almost always something in or about the patient's house that can be utilized for this purpose.

It is hardly necessary to say that a patient used to an indoor life, as the great majority of them are, must be somewhat gradually accustomed to a constant open-air exposure, but it is marvellous how perfectly they establish the habit, and how complete is the endurance which they attain. Knopf ("Prophylaxis and Treatment of

www.libtool.com.cn
Digitized by Microsoft®

Pulmonary Tuberculosis") quotes Andvoid, of Tonsaasen, Norway, as saying that he leaves his patients on their chairs, wrapped in furs, for from five to nine hours a day at a temperature of 25° C. (– 13° F.).

The number of hours during which the patient remains out of doors depends largely upon the location and latitude of the resort. At Davos, for example, the sun rises late and sets early, on account of the surrounding mountains, so that a winter's day is only about four or five hours long. In Falkenstein the patients remain out of doors for from seven to ten hours a day all the year through; at Rutland, Mass., for about eight hours; at Colorado Springs for from seven to eight.

The effects upon the patient of this prolonged stay in the open air are striking. Appetite and weight increase; cough and expectoration diminish; and if there is any rise of temperature at any part of the day, this is likely soon to disappear. The patient also experiences a sense of well-being and invigoration, together with mental exhilaration. After a course of open-air treatment one is no longer content to live indoors or sleep with closed windows.

It may be pertinently asked if patients do not catch cold under this constant open-air exposure. On the contrary, experience has proved that they are less likely to do so than when they live under constant protection with the consequent unavoidable exposure to impure air. The constant exposure to pure germless air, however cold, when one is properly clad, does not render one susceptible to catching cold, as Nansen so strikingly proved on his Arctic expedition.

In conclusion, it is well to reiterate that the open-air treatment is not the whole treatment of pulmonary tuberculosis. In addition, there must be an abundance of nutritious and properly prepared food; rest; a most careful avoidance of over-exertion either mental or physical; moderate exercise under careful supervision, and in suitable cases; and due attention to the skin by the use of various hydrotherapeutic measures. In brief, all the hygienic measures conducive to the invigoration of the general system, must be adopted. *Edward O. Otis.*

OPHTHALMIA, PURULENT. See *Conjunctiva, Affections of.*

OPHTHALMOMETER.*—An instrument for measuring the curvature of the refracting surfaces of the eye.

Thomas Young (1801)[1] was the first investigator to attempt accurate measurements of the curvature of the cornea in the living eye. By measuring the diameter and the prominence of the cornea, he found the chord and versed-sine of an arc of a corneal meridian; from these data he calculated the radius of curvature. Young's estimate of the curvature of the cornea agrees very closely with the results which have since been obtained by more refined methods.

Kohlrausch (1840)[2] measured the image of a distant object viewed by reflection at the anterior surface of the cornea, as in a convex mirror, and thus laid the foundation of ophthalmometry in the modern sense. The object used by Kohlrausch was a pair of candle flames placed behind small openings in an opaque screen. The images of the two bright points were viewed through a small astronomical telescope, constructed for observing at a distance of from two to three feet, and their positions marked by two adjustable spider lines in the eyepiece. The length of the image (distance separating the images of the two points of light) was then read, through the telescope, on a finely divided scale placed as nearly as possible at the distance at which the image had been observed.

Now the object and the image lie at conjugate foci of the cornea, considered as a convex mirror, and the relations of the two focal distances is expressed by the equation

$$\frac{1}{f'} - \frac{1}{f} = \frac{2}{r};$$

or

$$r = 2f \cdot \frac{f'}{f - f'}; \qquad (1)$$

in which

r = the radius of curvature of the cornea;

f = the distance of the object from the surface of the cornea;

f' = the distance of the image from the surface of the cornea.

As the observing distance is taken at between two and three feet, and the object is stationed at as great or at a greater distance, f is quite large in comparison with f'; it is admissible, therefore, without sensibly affecting the accuracy of the equation, to disregard f' in the denominator of (1) and to write the equation in the simplified form:

$$r = 2f \cdot \frac{f'}{f} = 2f'.* \qquad (2)$$

Again, the length of the object is to the length of the image in the ratio of their respective distances from the centre of curvature of the convex mirror (cornea).

Designating these distances by g and g' respectively, we have

$$\frac{g'}{g} = \frac{\text{length of image}}{\text{length of object}}.$$

But $$g' = r - f'$$

and $$g = r + f'$$

whence $$\frac{r - f'}{r + f} = \frac{\text{length of image}}{\text{length of object}};$$

or $$r - f' = (r + f) \cdot \frac{\text{length of image}}{\text{length of object}}. \qquad (3)$$

In the right-hand member of (3) neglecting r, which is small compared with f, and in the left-hand member of (3) substituting for f' its value $\frac{1}{2}r$ derived from (2), we have, as a sufficiently close approximation, the simplified equation

$$r = 2f \cdot \frac{\text{length of image}}{\text{length of object}}.\dagger \qquad (4)$$

* The writer desires particularly to acknowledge his indebtedness to Dr. John Green, of St. Louis, for assistance most kindly rendered in revising the present article for the press.

* To test the error involved in the use of this simplified equation, compare the values of r derived from (1) and (2) in a special case. For example:

Let $f = 0.8$ metre = 800 millimetres,
Let $f' = 4$ millimetres,

then by (1)

$$r = 1600 \cdot \frac{f'}{796} = 2.01\,f';$$

and by (2)

$$r = 1600 \cdot \frac{f'}{800} = 2.00\,f'.$$

The value of r by (2) is therefore too small by $0.01\ f' = 0.01 \times 4$ millimetres = 0.04 millimetre, which is within the limit of error in observation.

† To test the error involved in the use of (4) compare the values of r derived from (3) and (4), in a special case. For example, as in the previous note:

Let $f = 0.8$ metre = 800 millimetres,
Let $f' = 4$ millimetres.

Then by (3) [using for r in the right-hand member and for f' in the left-hand member their values as given by (1).]

$$r - \frac{r}{2.01} = (800 + 8.04) \cdot \frac{\text{length of image}}{\text{length of object}} \text{ millimetres},$$

whence

$$r = 1608.08 \cdot \frac{\text{length of image}}{\text{length of object}} \text{ millimetres},$$

and by (4)

$$r = 1600 \cdot \frac{\text{length of image}}{\text{length of object}} \text{ millimetres}$$

The value of r by (4) is therefore too small by

$$\frac{8.08}{1600} = 0.005 = \text{about } \tfrac{1}{2} \text{ per cent}$$

It should be further remarked that the use of the equation

$$\frac{1}{f'} - \frac{1}{f} = \frac{2}{r}$$

is permissible only on the assumption that the diameter of the convex surface at which rays are reflected to form the virtual image is small

Digitized by Microsoft®

The results obtained by Kohlrausch, also by Senff (1846),[3] who carried the investigation somewhat further, correspond very closely with measurements which are now generally accepted. The later development of ophthalmometry has been in the direction of perfecting the instrument for purposes of scientific investigation, and of adapting it to clinical use.

www.tlbtool.com.cn

The ophthalmometer was perfected, as an instrument of scientific research, by Helmholtz (1854).[4] With the addition of a large graduated circle, arranged to carry lamps, it was employed by Donders and Middelburg to measure the curvature of the cornea in different meridians.

The ophthalmometer of Helmholtz is essentially an adaptation of the heliometer of Clausen (1841).[5] A divided plate of thick glass with parallel surfaces is mounted in a cubical box fixed in front of the objective of a small astronomical telescope constructed for observing at a distance of from 0.5 metre to 1 meter, so that each half of the glass plate covers half of the objective. The two halves of the divided plate are arranged to turn in opposite directions on a common axis at right angles to the axis of the telescope, and the amount of rotation is read to tenths of a degree on a graduated disc fitted with a vernier. So long as the two halves of the glass plate are in the same plane, perpendicular to the axis of the instrument, an object seen through the telescope appears without displacement and single; but any rotation of either half of the plate gives rise to a displacement of the image formed by the corresponding half of the objective, and this displacement increases with the rotation. As the two halves of the plate are rotated simultaneously in opposite directions the displacement of the images is also in opposite directions, and the total displacement is double what it would be if either half of the plate were rotated separately through the same angle.

The object (three points of light disposed in a row) as seen by reflection at the surface of the cornea is focussed by the telescope through the glass plates in the zero position—*i.e.*, with both plates set at right angles to the line of vision. The graduated disc is then turned until the two images are seen touching each other, but not overlapping, in which position of the plates the displacement of each image is exactly equal to half the length of the image. The amount of displacement (x) of either image depends on the index of the refraction (n) of the glass of

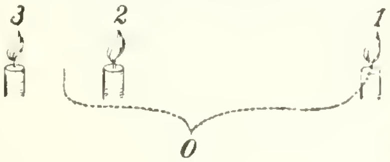

FIG. 3634.

which the plate is made, the thickness (h) of the glass plate, and the angle (ϕ) through which the plate has been rotated as expressed in the equation

$$x = h \cdot \frac{\sin(\phi - \phi')}{\cos\phi'},$$

the value of ϕ' being dependent on that of ϕ, as expressed in the equation

$$\sin\phi = n \cdot \sin\phi';$$

in comparison with the radius of the sphere. This implies that the image must be small in comparison with the radius of curvature of the cornea, or, what amounts to the same thing, that the object must be small in comparison with its distance from the observed eye.

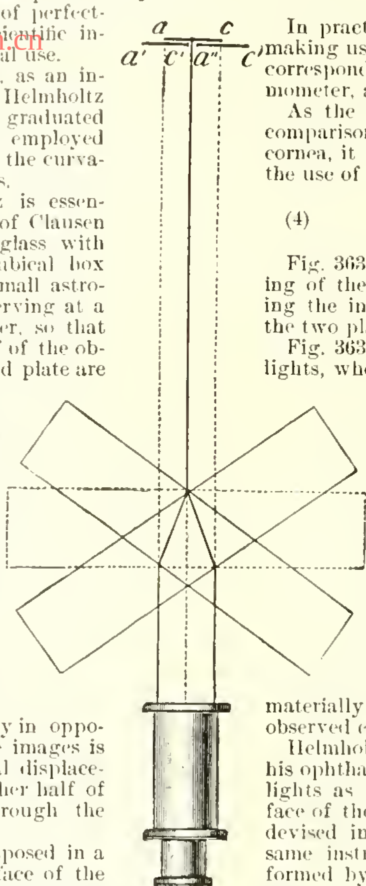

FIG. 3633.

as the displacement of each image is equal to half the length of the image, we have

$$\text{length of image} = 2x = 2h \cdot \frac{\sin(\phi - \phi')}{\cos\phi'}. \qquad (5)$$

In practice all calculation is dispensed with by making use of a table of successive values of $2x$ corresponding to different readings of the ophthalmometer, as ascertained by experiment.

As the distance of the object is quite large in comparison with the radius of curvature of the cornea, it is admissible to calculate the latter by the use of the simplified equation

$$(4) \qquad r = 2f, \frac{\text{length of image}}{\text{length of object}}.$$

Fig. 3633 shows the arrangement and the working of the glass plates, a' c' and a'' c'', representing the image a, c, as doubled by the rotation of the two plates in opposite directions.

Fig. 3634 shows the arrangement of the three lights, whose double images are viewed by reflection at the surface of the cornea; the image of 1 is brought by the rotation of the plates into a position midway between 2 and 3, as shown in Fig. 3634.

It will be seen from (5), also from inspection of Fig. 3633, that the size of the image is determined by the amount of rotation of the plates as indicated by the reading of the graduated disc, and is independent of the observing distance; also that, from the principle of construction of the ophthalmometer, the measurements may be made with great accuracy and without being materially impeded by slight movements of the observed eye.

Helmholtz also made direct measurements, with his ophthalmometer, of the real image of a pair of lights as seen by reflection at the posterior surface of the crystalline lens, and by an ingeniously devised indirect method he measured with the same instrument the much fainter virtual image formed by reflection at the anterior surface of the lens. By repeated measurements made upon the same eye in a state of accommodative relaxation and in accommodation for the near, he obtained the necessary data for calculating the radii of curvature of both surfaces of the lens in each of these two conditions. The measurements of Helmholtz were repeated with some modifications of the technique by H. Knapp (1860).[6] Knapp also measured the curvature of the cornea, mostly in the horizontal and vertical meridians, in a series of cases of astigmatism (1862).[7]

To adapt the ophthalmometer to the measurement of the curvature of the cornea in any required meridian,

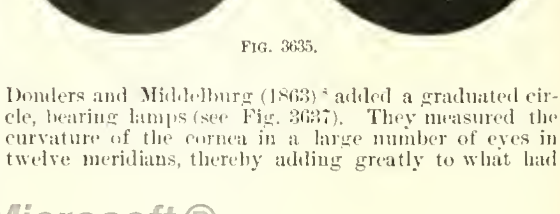

FIG. 3635.

Donders and Middelburg (1863)[8] added a graduated circle, bearing lamps (see Fig. 3637). They measured the curvature of the cornea in a large number of eyes in twelve meridians, thereby adding greatly to what had

Digitized by Microsoft®

been previously known regarding the different forms of astigmatism.

Coccius (1867)[9] substituted a fixed plate cut from a doubly refracting crystal of Iceland spar for the movable glass plates used by Helmholtz. The amount of displacement of the image formed by the extraordinarily refracted rays is determined by the thickness of the plate, and is constant; the size of the object (distance separating the lights) is therefore varied, until the two images are seen to touch each other without overlapping. The radius of curvature of the cornea is found from the simplified equation:

www.libtool.com.cn

$$(4) \qquad r = 2f \cdot \frac{\text{length of image}}{\text{length of object}}.$$

The ophthalmometer of Javal-Schiötz (1881)[10] is especially designed for the clinical investigation of the curvature of the cornea in all meridians, and is admirably adapted to its purpose. Two strongly illuminated targets (*mires*) of white enamel replace the lights, and the doubling of the image is effected by means of a doubly refracting prism of Iceland spar, which is achromatized, and at the same time a little more than neutralized for the ordinary rays by the addition of a prism of flint glass turned in the opposite direction. With this construction of the prism, the two images of the pair of targets, formed, the one by the ordinary and the other by the extraordinary rays, are displaced equally in opposite directions; the aggregate displacement of the images for the distance at which the eye is observed is 3 mm. The two targets (*M M*, Fig. 3637), are arranged to slide on a graduated arc of 0.35 metre radius, turning with the tube of the telescope. The head of the patient is supported by the head-rest, so that the centre of curvature of the cornea shall lie approximately at the centre of curvature of the arc. A more exact adjustment of the distance is then secured by moving the telescope, with its stand, until the doubled images of the two targets are seen sharply defined by reflection at the surface of the cornea; the telescope is constructed for distinct vision at the distance of the image, which is formed about 4 mm. behind the centre of the cornea. The doubly refracting prism is in the part of the tube marked *C W*, and the meridian in which the arc and targets stand is read on the graduated disc at *E*. The eye under examination is directed upon the end of the telescope; the other eye is covered by the pivoted screen *P*.

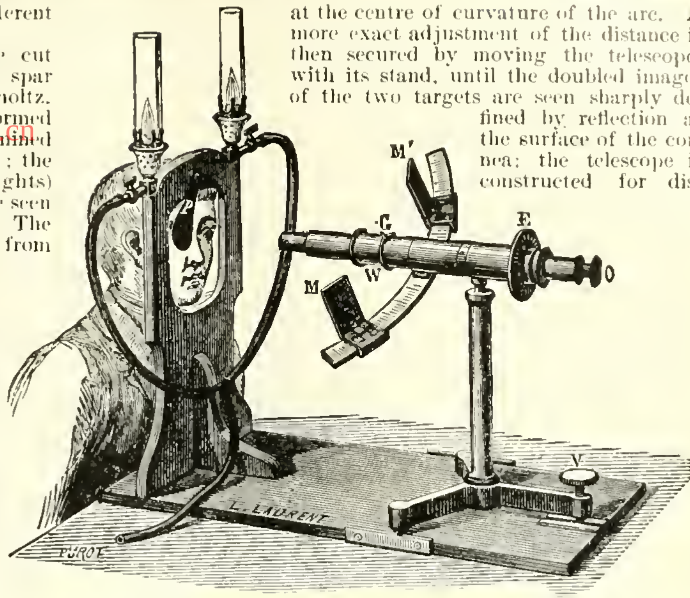

FIG. 3637.—Ophthalmometer of Javal-Schiötz, Original Model.

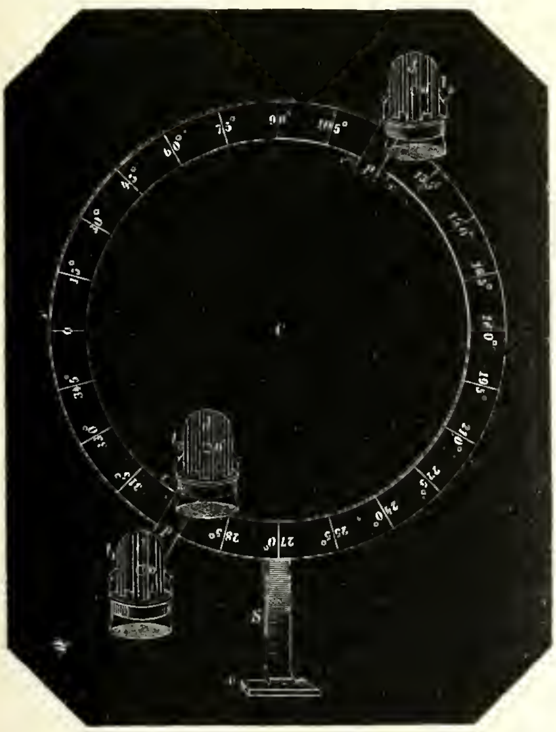

FIG. 3636.

As the effect of the doubly refracting prism (at the constant distance, $f = 0.35$ metre, of the targets from the eye) is to separate the two images exactly 3 mm., it is evident that when the length of the object (chord *M M*, separating the outer sides of the two targets) is so adjusted as to allow the two images to touch each other without overlapping, the length of the image must be just 3 mm. We have then, approximately,

$$(4) \qquad r = 2f \cdot \frac{\text{image}}{\text{object}} = 700 \cdot \frac{3}{\text{chord } M\,M} \text{ millimetres.} = \frac{2100}{\text{chord } M\,M} \text{ millimetres.*}$$

It will be observed that in this solution, $2f$ ($= 2 \times 0.35$ metre $= 700$ mm. and *image* ($= 3$ mm.) are constants.

* It will be remarked that, by the construction of the Javal-Schiötz ophthalmometer, the distance of the targets from the observed eye is rather small, and the image is rather large in comparison with the radius of curvature of the cornea (see page 363, footnote). In the use of equation (4) there is, therefore, a considerable margin of error, though not enough to detract from the usefulness of the instrument in clinical work.

It will be remarked that r, by this solution, is the radius of a circular arc whose chord measures 3 mm. which arc is assumed to be of the same curvature as a section of the corneal surface by a plane passed through the visual axis and the axis of the telescope. But the configuration of the cornea is approximately that of a segment of a prolate ellipsoid, and supposing the axis of this ellipsoid to coincide with the axis of the telescope, r will be the radius of a circle whose curvature is equal to that of the elliptical section of the cornea at the two points in which the direction of the reflecting surface determines the length of the image, *i.e.*, at two opposite points on the ellipsoid each 1.5 mm. distant from its axis. Under these conditions it is evident that r will be greater than the radius of curvature of the cornea at its centre.

As a rule, the visual axis does not coincide with the axis of the corneal ellipsoid, but makes an angle with it (angle α), which angle is sometimes as great as 12°. The axis of curvature of the cornea is, therefore, not ordinarily in a line with the axis of the telescope, and the two points in which the direction of the corneal surface determines the length of the image are not symmetrically placed with reference to the axis of the ellipsoid. As the curvature of the ellipsoid at these two unsymmetrical points is unequal, it cannot be represented by a spherical surface. In any case, however, the value of r by equation (4) is greater than the radius of curvature of the cornea at its centre.

Digitized by Microsoft®

consequently r (the radius of curvature of the cornea) is an inverse function of the chord $M M'$. The length of this chord is read from the graduation on the arc. The radius of curvature of the cornea in different meridians

www.libtool.com.cn

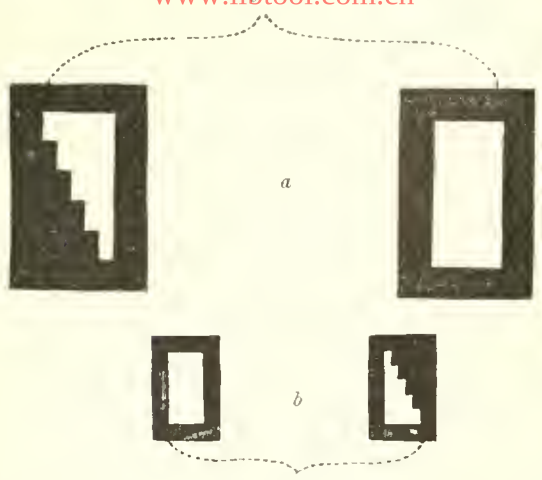

FIG. 3638.—*a*, The Targets; *b*, their corneal images as seen through the telescope without intervention of the prism of Iceland spar.

may be calculated from measurements of the chord $M M'$, made after turning the telescope, with the arc and targets, about its axis.

The great value of the Javal-Schiötz ophthalmometer is in its remarkable adaptation to the detection and measurement of corneal astigmatism, and for such examination it has won general recognition as indispensable to the ophthalmic practitioner. In astigmatism the essential thing to be considered is the difference in refraction in the two principal meridians, and it is for the measurement of such differences in the corneal curvature that the instrument has been especially designed. In the use of the ophthalmometer the length of the object (chord $M M'$) remains unchanged throughout the observation of the eye in its two principal meridians, and it is only the difference in the length of the image when the arc is adjusted successively for the corneal meridians of greatest and least curvature that is regarded. The observation consists in simply noting the amount of overlapping of the two images in the second position of the arc, after having first brought them into exact contact in the first position.

The device for reading the amount of overlapping of the images is shown in Fig. 3638, *a*. The outer side of one

FIG. 3639.—Corneal Images as Seen Through Telescope and Prism. Double images in touching position.

of the rectangular targets is cut in the form of steps of such width that each step approximately represents a difference of corneal curvature corresponding to 1 D of ocular refraction.* The number of overlapping steps is taken as the number of dioptries of astigmatism attributable to inequality of curvature of the cornea in its two principal meridians.

Fig. 3639 shows the doubled images of the targets in the position of contact; in Fig. 3640 the same images are shown with two steps overlapping, indicating 2 D of corneal astigmatism. It will be observed that in both these positions the images are rectangular, also that they lie exactly in the same line.

This rectangular form and linear direction of the images of the four targets is seen whenever the curvature of the cornea is symmetrical with reference to the plane of the arc. When the cornea is a surface of revolution, with its axis passing through the centre of the arc, this condition is fulfilled for all positions of the targets; but when the cornea is of a configuration approaching an ellipsoid of three unequal axes, the position of the arc

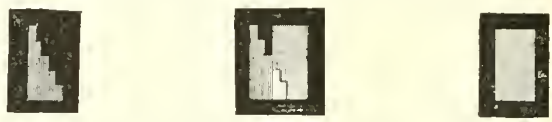

FIG. 3640.—Overlapping of Double Images — As = 2 D.

must be such that its plane shall bisect the ellipsoid in one or the other of its two principal planes. In all other positions of the arc the images of the four targets appear more or less distorted, and the images of the two pairs of targets are not in the same line (see Fig. 3641).*

This distortion and oblique displacement of the two images, in all but two positions of the arc, reveals at a glance the presence of corneal astigmatism. To find the meridian of greatest corneal curvature, the arc is turned until the images are seen in a line and most widely separated.† The two targets are then moved inward or outward on the arc until the images are brought into the position of contact. Lastly, the arc is turned through an angle of 90°, or until the images are again seen in a line, and the number of overlapping steps, which repre-

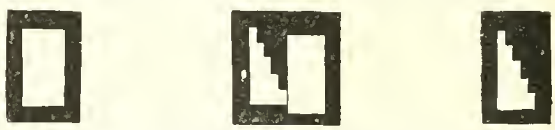

FIG. 3641.—Double Images not on a Level—Astigmatism Present. Arc not in a principal meridian.

sents the number of dioptries of corneal astigmatism, is noted. The examination of the two eyes need not consume more than two or three minutes.

The measurements of corneal astigmatism as made with the ophthalmometer agree remarkably, in most cases, with the results obtained by the use of methods which show the total astigmatism of the eye. The agreement in the direction of the principal meridians is especially close, so that in by far the greater number of cases the direction of the axis of the correcting cylindrical glass may be taken directly from the reading of the instru-

* Inasmuch as different eyes present considerable variation in corneal curvature, necessitating a corresponding variation in the separation of the targets in order to bring their images into exact contact, it is evident that a step on the target does not always represent the same fractional part of the chord $M M'$. In the case of a relatively flat cornea the targets must be set nearer together, and each step will then represent a larger fractional part of the chord $M M'$; conversely, when the cornea is of greater than average curvature the targets must be set wider apart, and each step will then represent a smaller fractional part of the same chord. It follows that in the former case each overlapping step in the image must represent somewhat more, and in the latter case, somewhat less, than 1 D of corneal astigmatism. It is well, therefore, always to note the length of the chord $M M'$, so that a correction can be made for it if deemed necessary.

* For an analysis of the phenomenon of distortion of the image formed by a mirror of asymmetrical curvature, also of the same phenomenon as it occurs in the case of a lens of asymmetrical refraction, see a paper by the writer: "Ein Beitrag zur Theorie der Cylinderlinsen," Graefe's Archiv, 1887.

† By interchanging the targets the images may be brought into the position of contact when the arc is set in the meridian of least corneal curvature, and the overlapping steps counted in the second position of the arc; in practice this is found to be more convenient, for the reason that the meridian of least curvature is, as a rule, approximately horizontal, and it is easier to adjust the targets in the horizontal and to observe the overlapping of the images in the vertical meridian.

Digitized by Microsoft®

ment. In respect to the grade of astigmatism the agreement is less exact, for the reason that the observed corneal astigmatism is often modified by an astigmatism attributable to an oblique position of the crystalline lens, As a rule, the meridian of greatest corneal curvature is

www.libtool.com.cn

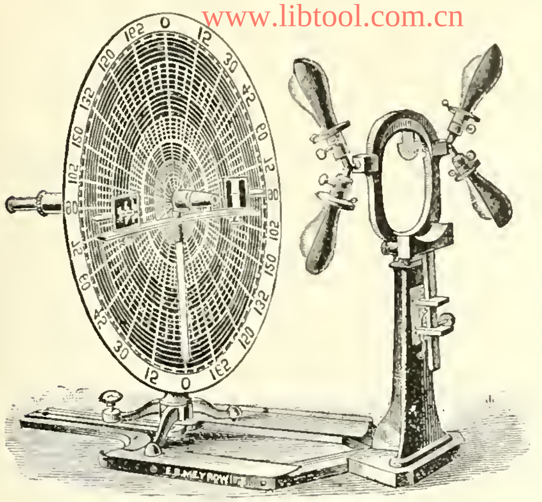

Fig. 3642.—Javal's Ophthalmometer with Attachment for Electrical Illumination of the Targets.

approximately vertical, and the meridian of greatest lenticular refraction is approximately horizontal; the total astigmatism is therefore generally somewhat less than the corneal astigmatism when the meridian of greatest corneal curvature is approximately vertical, and greater when, contrary to the rule, it is approximately horizontal.

In a comparatively small number of instances the total astigmatism is found to vary very widely from the corneal. For example, a relatively high grade of lenticular astigmatism may so far dominate a corneal astigmatism as largely to control both the direction of the principal meridians and the grade of the total astigmatism. Again, it is not uncommon to find a low grade of astigmatism, oftenest with the meridian of greatest refraction horizontal or nearly horizontal, in the absence of corneal asymmetry. Lastly, the ophthalmometer occasionally reveals an anomalous condition in which the corneal meridians of greatest and least curvatures are not at right angles to each other.

Not only has the Javal-Schiötz ophthalmometer greatly advanced our knowledge of astigmatism, but it affords, also, most important special information in every case of investigation of the refraction of the eye.

The instrument-maker Kagenaar (Utrecht, 1887)[11] has somewhat cheapened the original Javal-Schiötz ophthalmometer by substituting a pair of weak glass prisms, turned in opposite directions, for the doubly refracting prism of Iceland spar. Leroy and Dubois (1888)[12] have also produced a low-priced ophthalmometer, in which the doubling of the image is effected by means of two plates of thick glass as used by Helmholtz. In a second and newer model[13] (see Fig. 3642) the shape of the targets has been somewhat altered; and the direction of the meridians of greatest and least corneal curvature is read on the reflected image of the large disc which now constitutes the most conspicuous feature of the instrument.

OPHTHALMOSCOPE; OPHTHALMOSCOPY.—from ὀφθαλμός, eye, and σκοπέω, to view. The ophthalmoscope, German, *der Augenspiegel*, is an optical device by means of which the interior of the eyeball is rendered visible.

Ophthalmoscopy, in its wider meaning, includes whatever pertains to the objective examination of the eye; in a narrower sense, it is restricted to the examination of the interior of the eye by the aid of the ophthalmoscope.

The anterior segment of the eyeball, comprising the cornea, the anterior chamber filled with the aqueous humor, the front of the iris, and so much of the anterior capsule of the crystalline lens as corresponds to the area of the pupil, is accessible to direct inspection by the naked eye, or through a magnifying glass. Even when the pupil is strongly contracted, a central opacity of the

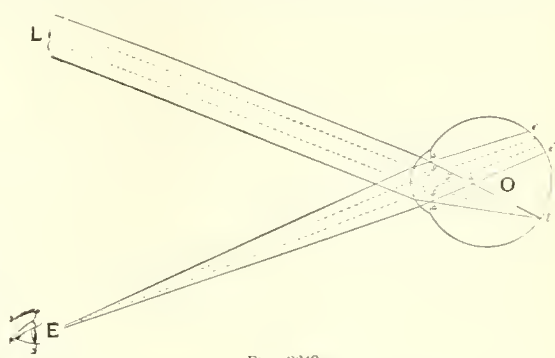

Fig. 3643.

lens capsule or of the immediately subjacent lens substance reveals itself by a characteristic white or gray appearance. When the pupil is widely dilated, we may look deeply into or through the crystalline, and may obtain glimpses of a detached and displaced portion of the

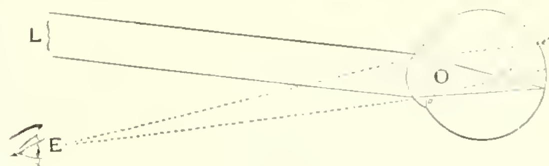

Fig. 3644.

retina, of a blood clot or other large foreign body in the vitreous, or of the surface of a very prominent tumor arising from the retina or choroid.

Let *L* (Fig. 3643) represent a pencil of parallel rays emanating from a distant source of light and entering the dilated pupil *a a* of the eye *O*, so as to light up a

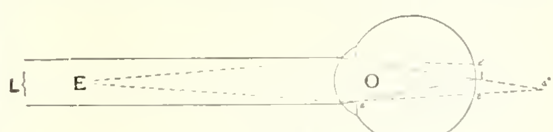

Fig. 3645.

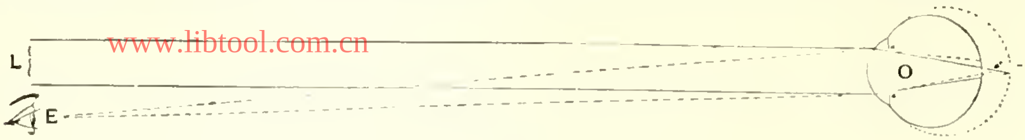
path through the vitreous, indicated by the cone *a a l*. The eye of an observer at *E* will receive rays from any object which may happen to lie within that portion of this cone, near its base, which is bounded by the line *a a′′*. Outside of the limits *a a′ a′′*, the whole interior of the eye is either in comparative darkness or is shut off from view by the iris at *a, a*. If the pupil is contracted

Digitized by Microsoft®

to the diameter *b b'*, only such part of the pencil *L* as is included within the dotted lines can enter the eye, and only such objects as happen to lie within the smaller



www.libtool.com.cn

FIG. 3646.

cone *b b' l* will be illuminated; of this smaller cone the greater portion is shut off from view by the iris at *b*, *b*, so that nothing can be seen outside the narrow limits *b b' b'*. If we take the angle *L O E* smaller (Fig. 3644), the point *a'* will fall farther back in the vitreous, and it will be possible to see more deeply into the eye.

When the angle *L O E* is taken very small, approaching zero (Fig. 3645), the illuminated point *l* falls within the area *e e*, which represents the field of view commanded by the eye of an observer at *E*; luminous rays from *l* will then enter the eye *E*, and the pupil of the eye *O* will be seen lighted up—*das Augenleuchten*. The particular case indicated in Fig. 3645 is, however, impossible, for the reason that, in the assumed position of the observer's eye, his head is necessarily interposed between the source of light and the observed eye. For this reason, when two persons look each into the eyes of the other, the pupils of all four eyes appear black.

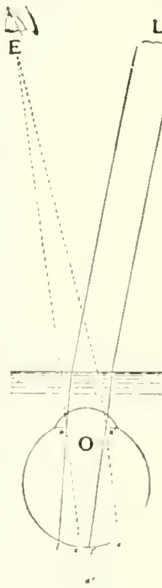


FIG. 3647.

When the refraction of the observed eye *O* is hypermetropic, the illuminating pencil is cut by the retina before reaching a focus (Fig. 3646), thus lighting up an area at the fundus which will be larger or smaller according as the pupil is more or less dilated and the pencil is cut by the retina at a greater or less distance from its focus. An observer looking into the eye, at a very small angle to the axis of the illuminating pencil, may receive rays of light from this illuminated area, and will then see the pupil of the observed eye illuminated. To develop this phenomenon by daylight, the pupil of the observed eye must be somewhat widely dilated, in order both that the illuminated area may be as large as possible, and that the iris at *a*, *a'* may cut off as little as may be of the view into the eye. The appearance of a shining pupil is best produced when the observer, with his back to a window, looks into the face of another person, a few feet away, whose eyes are directed toward a strongly illuminated surface, such as a bright cloud in the sky. Shining of the pupils is also very conspicuous, under particular conditions, in animals with eyes of hypermetropic construction whose fundus is clothed by a strongly reflecting layer—the tapetum. A familiar instance is the glowing of the eyes of the cat, when the gaze of the animal, with pupils widely dilated, is encountered by a person entering a dark room with a lighted lamp. In persons with congenital or acquired absence of the iris—*aniridia*, *irideremia*—the eyes may similarly be seen to shine by lamplight. The vivid red color of the pupils of albinos is independent of the refractive condition of the eye, and is a result of the lighting up of the whole interior of the eyeball through the unpigmented and abnormally translucent iris and choroid; when the eye of an albino is shaded by an opaque card, the pupil, viewed through a hole in the card, appears black, as in a normally pigmented eye (Donders).*

If we annul the refraction at the cornea by plunging the head of an animal under water (Fig. 3647), the eyes will be rendered very strongly hypermetropic, and the pupils may be seen to shine brightly by ordinary daylight. In this experiment it is also possible to see some of the details of the fundus through the widely dilated pupil.*

If the observed eye is strongly myopic, the illuminating pencil will converge to a focus (Fig. 3648) at some point in the vitreous humor, and, continuing on its course, will light up an area *l' l* where it is cut by the retina. As in the case of the hypermetropic eye, a portion, *e' l*, of this illuminated area will fall within the field of view commanded by the eye of an observer at *E*, who will then see the pupil of *O* lighted up.

If we take as the source of light a small incandescent electric lamp *L* (Fig. 3649), darkened at the back and sides, the retina of the (unaccommodated) emmetropic eye *O* will intercept the illuminating pencil before it reaches its focus, and a small area, *l l*, of the fundus will be lighted up. In this case, as in the cases assumed in Figs. 3646 and 3647, a considerable portion, *e l*, of the illuminated area, *l l*, falls within the region *e e*, from which rays of light can enter the eye of an observer at *E*, behind and a little to one side of the lamp. Under these conditions the pupil of *O* is seen strongly illuminated.†

If we move the lamp *L* nearer to the eye *O*, the angle *L O E* will become larger and larger, and the portion *e l'* of the illuminated area *l l'*, falling within the field *e e'*, will become smaller and smaller; whenever the angle *L O E* becomes so large that no part of *l l'* coincides with any part of *e e'*, the pupil will cease to appear luminous. If, however, we fit a small refracting prism *P*, to the incandescent lamp (Fig. 3650), we may so change the direction of the illuminating pencil as to turn it upon the eye *O*, as if emanating from *L'*, thus permitting an observer to look into the eye from *E*, at a very small angle to the axis of the illuminating pencil, even though he approach to a distance of only a few centimetres from the cornea of the observed eye.

The most convenient and effective way of lighting up the fundus of the eye is by making use of a reflector. This reflector may be made of unsilvered transparent glass, in which case it may be set at an angle of about forty-five degrees to the direction of the axis of the illuminating pencil (Fig. 3651). Of the incident rays, some are

* The shining of the eyes of certain animals in the dark was, for a long time, attributed to a supposed power of generating light. Prevost (1810) showed that the phenomenon is observed only when the eyes are illuminated by light falling directly upon them. Rudolphi (1810) called attention to the fact that it is necessary to look into the eye in a particular direction. In aniridia in the human eye Beer (1839) saw the pupils red and shining when he looked at the eyes in nearly the direction from which the light fell upon them; W. Cumming (1846) and Brücke (1847) discovered, independently of each other, that the pupils of the unmutilated human eye may be made to shine under the same conditions of illumination and inspection (cited from Helmholtz: "Handbuch der physiologischen Optik," first edition, S. 189).

* Mery (1704) first described this experiment, in which probably the first view of the blood-vessels of the retina of a living animal (cat) was obtained. The visibility of the details of the fundus in this experiment was correctly ascribed by La Hire (1709) to the alteration in the conditions of refraction, of which, however, he failed to give an exact explanation (cited from Helmholtz, *op. cit.*, S. 190). By the aid of the orthoscope of Czermak, a little trough of glass, fixed to the cheek and nose with wax, and filled with water, the observation of Mery may be repeated upon the human eye.

† This arrangement of the light represents essentially that employed by Brücke (1847). Brücke used a lamp or a candle as the source of light, and shut off the light from the eye of the observer by means of a small opaque screen.

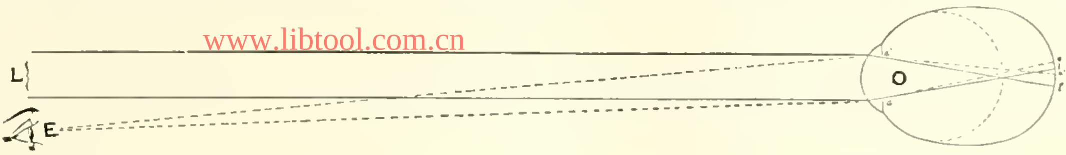

FIG. 3648.

L'. So, also, in the case of the efferent pencils, some of the rays are lost by reflection in the direction of the light *L*, while others are transmitted by the glass, to be re-

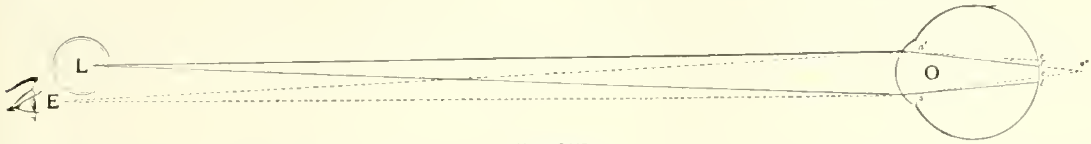

FIG. 3649.

ceived by the eye of an observer looking through the transparent mirror directly in the axis of the illuminating pencil.*

A plane mirror of silvered glass, or of polished metal,

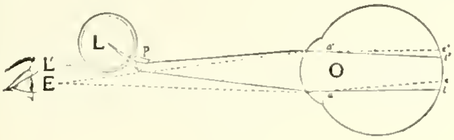

FIG. 3650.

may be substituted for the mirror of transparent glass, with the double advantage of reflecting a much stronger light into the eye and of permitting the lamp to be placed by the side of and at any required distance behind the patient's head (Fig. 3652). An observer looking past the side of the mirror, or, more conveniently, through a small central perforation, sees the pupil of the eye *O* more strongly illuminated than when an unsilvered glass mirror is used. The farther the plane mirror is held from the observed eye the smaller is the portion of its reflecting surface from which rays of light can enter the pupil and the weaker the illumination (Fig. 3653).

By making use of a concave mirror held near the eye, we may reproduce very nearly the same conditions of illumination as when the plane mirror is used (Fig. 3654), or, increasing the distance of the mirror or of the lamp, we may throw at will a parallel (Fig. 3655) or a convergent pencil (Fig. 3656) into the eye. If we increase still further the distance at which the mirror is held from the eye, and from the lamp (Fig. 3657), a very large convergent pencil, reflected from the entire surface of the mirror, may be thrown into the observed eye, and when the lamp and the pupil of the eye, *O*, come to lie in conjugate foci of the mirror (Fig. 3658), the size of the illuminating pencil is limited only by the diameter of the mirror, and the illumination at the fundus is correspondingly intense. A concave mirror of very thin, silvered glass, of a diameter of 33 mm. and a focal length of about 23 cm., with a central perforation of about 3.5 mm. diameter, is found to be, on the whole, most convenient, as serving both for such examinations as are required to be made with the mirror held near the eye (Figs. 3654 and 3656) and for those in which it is required to reflect a

large convergent pencil from a greater distance (Figs. 3657 and 3658).

If the illuminating pencil is made to pass through a strong convex lens held in front of and at somewhat less than its principal focal distance from the cornea of the observed eye, a very large convergent pencil may be thrown into the eye and focussed at any desired distance behind the cornea. With a convex lens of about 20 dioptries (5 cm. focus), held at a distance of about 4.5 cm. in front of the cornea (Fig. 3659), the focus will lie in the vicinity of the nodal point of the eye, and a large area of the fundus, limited only by the angular diameter of the convex lens, will be strongly illuminated.

If a weaker lens is employed, or if the lens of 5 cm. focus is held nearer to the observed eye (Fig. 3660), the focus of the illuminating pencil will lie at some point in the vitreous humor, and the illuminated area at the fundus will be larger or smaller according as the focus lies farther from or nearer to the retina. When the focus lies at a certain depth in the eye the diameter of the illuminated area is further limited by the size of the pupil, so that only a part of the illuminating pencil, corresponding to a larger or smaller central portion of the convex lens, can gain entrance into the eye.

If a stronger convex lens is used, or if the lens of 5 cm. focus is removed to a little more than its focal distance from the observed eye (Fig. 3661), the focus of the illuminating pencil will lie a little in front of the cornea, and the fundus will be illuminated in an area which, as in the case assumed in Fig. 3659, is limited only by the angular diameter of the convex lens.

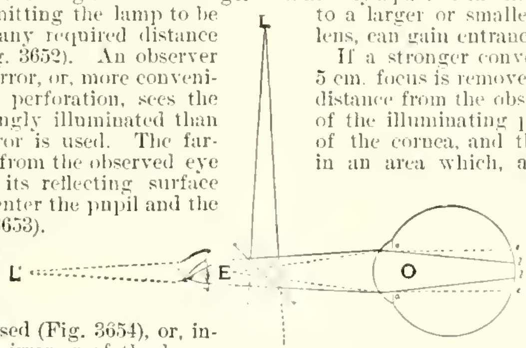

FIG. 3651.

In all three positions, as shown in Figs. 3659 to 3661, nearly the whole of the illuminated area of the fundus falls within the field of view commanded by the eye of an observer at *E*, so that rays emanating from a large area at the fundus may enter the eye of the observer.

By combining the perforated concave mirror, of about 23 cm. focus, with a convex lens of 5 to 6 cm. focus (Fig.

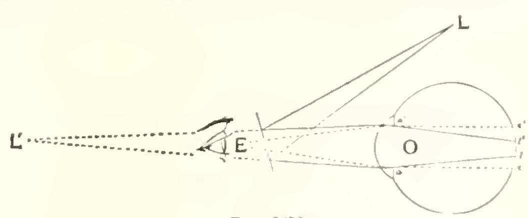

FIG. 3652.

3662), the maximum useful degree of illumination is attained, together with the ability to regulate the diameter of the illuminated area at the fundus by varying the dis-

tance at which the lens is held from the eye. The observer looking through the central perforation in the mirror, directly in the axis of the illuminating pencil, is also in the most favorable position for receiving rays from the illuminated area at the fundus.*

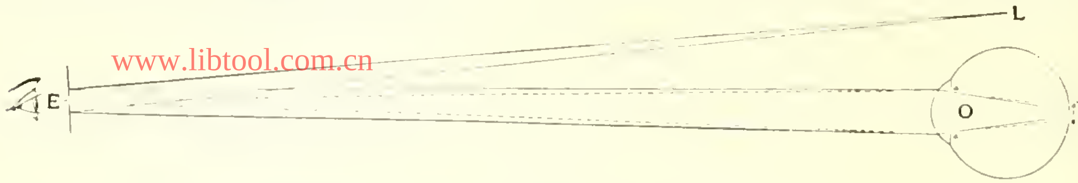

FIG. 3653.

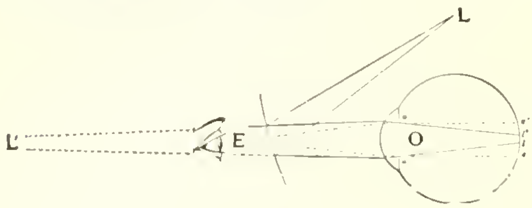

FIG. 3654.

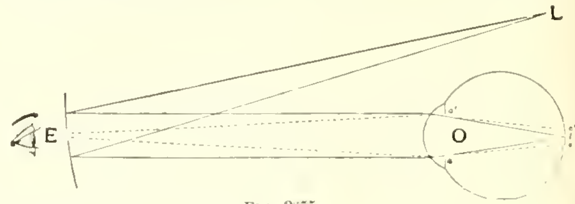

FIG. 3655.

We have thus far, for simplicity of demonstration, considered the source of light as a luminous point, which we have taken either at an infinite distance (Figs. 3643–3648), or at some short distance, as indicated by the position of the small electric lamp (Figs. 3649–3662). In practice, however, we ordinarily make use of an oil lamp or gas burner, in which case the area of illumination at the fundus corresponds to the inverted image of the flame (Fig. 3663). The maximum intensity of illumination is attained when the illuminating pencils are focussed exactly in the retinal image and the pupil is widely dilated.

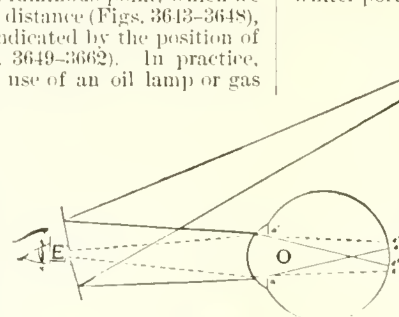

FIG. 3656.

The lamp ordinarily used in ophthalmoscopic work is an Argand oil lamp (the so-called student's lamp—Figs. 3675–3677), or an Argand gas burner, with some arrangement for adjusting it to the height of the patient's head. A petroleum lamp with a broad flame, or a bat-wing gas jet, may also be used. There is some advantage in surrounding the flame by an opaque screen, of metal or of asbestos, with an opening

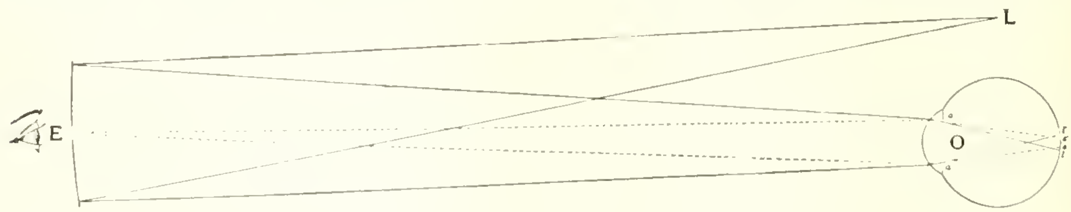

FIG. 3657.

of 2.5 or 3 cm. diameter. Many attempts have been made to utilize different forms of electric lamps as substitutes for oil or gas burners; a rather powerful incandescent lamp with the bulb of ground glass, fitted with a special rheostat for controlling the intensity of the light, has found favor with some good observers. Other inventors have employed a very small electric bulb and mirror, both attached to the handle of the ophthalmoscope, or have suppressed the illuminating mirror altogether.

A minor disadvantage in using oil or gas illumination is the yellow color of the flame, which imparts to the whiter portions of the fundus a somewhat unnatural tint. The true color of the fundus is best observed by indirect sunlight, either from a bright cloud or admitted into the darkened room through a hole in the window shutter which may be glazed with ground glass or covered with thin white paper. Direct sunlight is by far too intense to be safely thrown into the eye, even when reflected from an unsilvered glass mirror; the light of the full moon is insufficient, unless it be concentrated by reflection from a very large concave mirror.

The size of the bright image of the flame is in an inverse ratio to the distance (*LO*, *L'O*, *L''O*, Fig. 3663) of the lamp from the nodal point of the observed eye, or, when the plane mirror is used, to the distance $LE + EO$ (Figs. 3651–3653); when the illuminating pencils are imperfectly focussed, the image is spread out, at its borders, in a width equal to the radius of the circle of confusion in which any single pencil is cut by the retina. When a concave mirror is used, and the distance from the observed eye is large (Figs. 3657 and 3658), the illuminated area is practically the image of the mirror.

The extent of the area at the fundus, which falls within the field of view of the observer in the direct method of examination—*i.e.*, without the interposition of the convex lens—varies directly as the size of the pupil of the observed eye, and inversely as the distance from the eye at which the observer is stationed; a fairly large pupil and a near point of observation are therefore essential to the enjoyment of an ample field. To secure a near

* The illumination by means of the perforated concave mirror, conjoined with the employment of the convex lens to form an inverted image of the fundus at or near its anterior focus (Ruete, 1852), constitutes an invention second only in practical importance to that of Helmholtz. Figs. 3659 to 3661 illustrate a development of Brücke's experiment, by Helmholtz (1852).

Digitized by Microsoft®

point of observation, we hold the ophthalmoscopic mirror as near as possible to the observed eye, and to prevent contraction of the pupil under the stimulus of the light reflected into the eye, we may instil a drop of a weak mydriatic solution, or we may make use of a mirror which reflects light of the minimum intensity compatible with sufficient illumination. If we employ a mydriatic we choose, by preference, a solution of cocaine (1 to 50), of euphthalmin (1 to 50), or of cocaine and euphthalmin (1 to 100 each), either of which will sufficiently dilate the pupil in the course of from ten to twenty minutes, without subjecting the patient to the inconvenience incident to the prolonged mydriasis which follows the instillation of a strong solution of atropine, duboisine, or hyoscyamine. To reflect a weak light into the eye, we may use a perforated plane or convex mirror made of darkly tinted glass, or, still better, the original form of mirror devised by Helmholtz, which is made up of three or more plates of thin, unsilvered glass. This compound mirror reflects more light than a single plate of glass, and also polarizes the reflected pencils; by its action as an analyzer, it also extinguishes most of the rays reflected from the surface of the cornea, which often interfere with the view of the parts within the eye.

www.libtool.com.cn

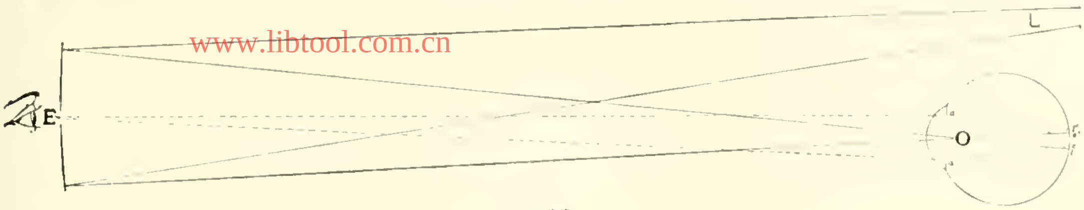

Fig. 3658.

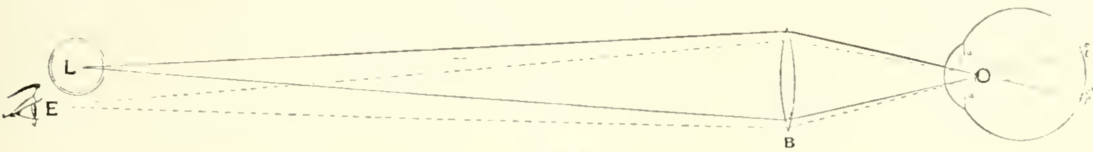

Fig. 3659.

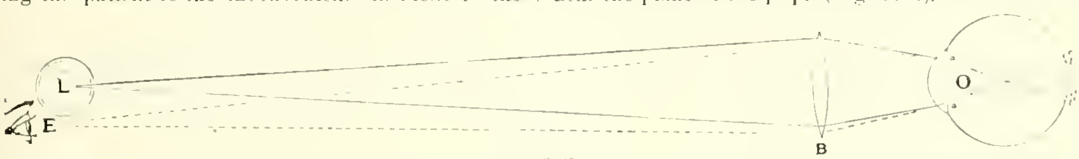

Fig. 3660.

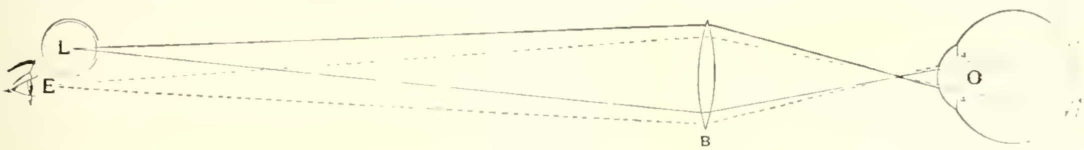

Fig. 3661.

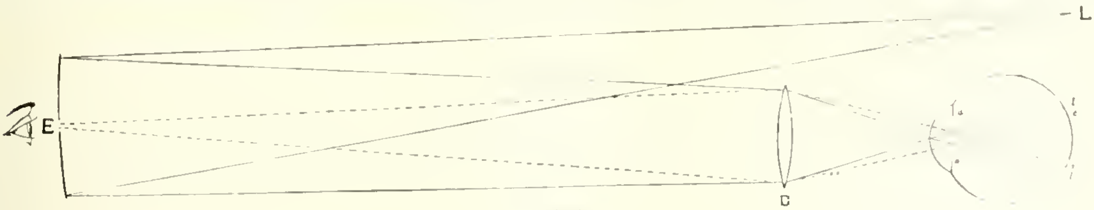

Fig. 3662.

In the indirect method of examination—*i.e.*, by the use of the convex lens of about 5 cm. focus held at about its focal distance in front of the observed eye—the size of the pupil plays a much less important part than in the examination by the direct method, and in certain positions of the lens it is almost completely eliminated as a factor in determining the intensity of the illumination and the amplitude of the field of view. This is practically the case whenever both the focus of the illuminating pencils and the intersection, within the eye, of the lines which defined the limits of the field of view lie in or very near the plane of the pupil (Fig. 3662).

Whenever the inverted image of the flame, at the fundus of the observed eye, is smaller than and lies wholly within the field of view commanded by the eye of the observer, the form of the image may be seen more or less distinctly outlined, according as it is itself sharply defined and as the refractive condition of the observed eye is such as to admit of the efferent pencils being accurately focussed upon the retina of the observer. Outside of the limits of this bright image, the fundus appears dark by contrast, although in fact dimly lighted through the faint general illumination of the interior of the eye by the bright image

Digitized by Microsoft®

itself, and also by a little light reflected from the face of the observer.

When the image of the flame is larger than, and includes the field of view, the entire visible area of the fundus appears strongly illuminated.

When the (plane) mirror is slightly rotated, in any direction, the inverted image of the flame moves across the

www.libtool.com.cn

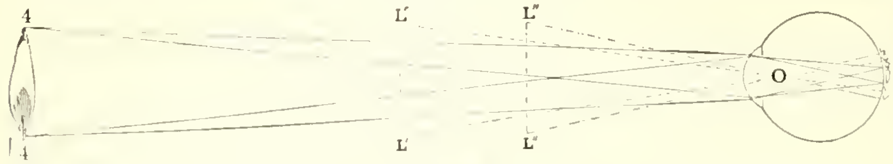

FIG. 3663.

fundus of the observed eye in the same direction. When the observed eye is hypermetropic, or is focussed for a distance greater than that of the eye of the observer, the apparent motion of the image is in the same direction as its real motion; but when the observed eye is focussed for a distance notably less than that of the eye of the observer, the image appears to move in the opposite direction. Upon the observation of the direction of the apparent motion of the illuminated area at the fundus, is

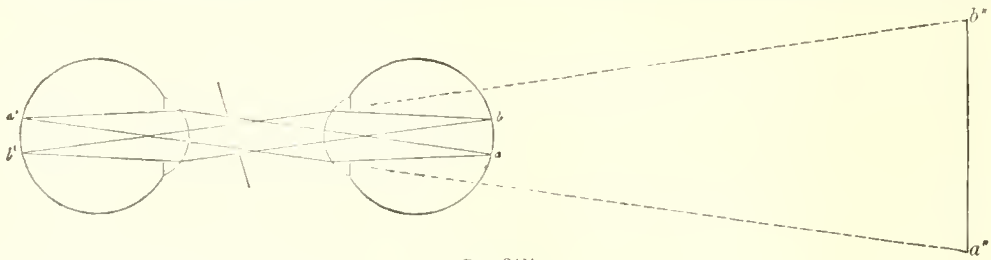

FIG. 3664.

based a ready and very useful method for the diagnosis and measurement of ametropia (see *Shadow-Test*).

In the living human eye the fundus appears ordinarily of a vivid red color, which is the expression of the color of the blood of the choroidal circulation showing through and more or less modified by the layer of hexagonal pigment cells.* This color is most intense in albinos, very bright in persons of blond complexion and light blue eyes, conspicuously darker in brunettes with deeply pigmented eyes, and least intense of all in the black races, in whom the illumination of the fundus is often so faint as to give off but little light, except from the white disc of the optic nerve and from the blood-filled vessels of the retina. Under normal conditions the red color is almost wholly due to the blood circulating in the capillary layer of the choroid, immediately underlying the layer of hexagonal pigment cells and hiding the more deeply seated choroidal arteries and veins. On this red background, which appears of a finely granulated texture, the retinal arteries and veins show conspicuously, branching from the central artery and vein on the nearly white optic disc (Pl. XLVII.).

Under favoring conditions of refraction in the observed and in the observing eye, the minuter details of the fundus are distinctly visible, both directly, in the erect

* After death the red color of the human fundus is lost.

image, and indirectly, in the inverted image. In the direct method of examination the eye of the observer is brought very near to the observed eye, in order that the field of view, as determined by the area of the pupil, may be as large as possible (Figs. 3651, 3652, 3654, and 3656; *cf.* Figs. 3653, 3655, 3657, and 3658). In the indirect method the observer is necessarily stationed at a much greater distance, say 20 cm. or more, beyond the position of the inverted aërial image (Figs. 3667–3672).

In the direct method of examination the visibility of the details of the fundus is affected in different ways according as the refraction of the observed eye is normal (emmetropic) or abnormal (myopic or hypermetropic). These three principal cases must be considered in order, the observing eye being assumed to be emmetropic.

(*a*) The observed eye is emmetropic, and with relaxed accommodation (Fig. 3664). Let *a* and *b* represent the origins of two efferent pencils, at two points within the illuminated area at the fundus of the observed eye. As both eyes are assumed to be emmetropic, the rays composing these pencils become parallel after refraction at the cornea of the observed eye and, entering the eye of the observer, are focussed at *a'* and *b'* upon its retina, where they form an inverted image *b' a'*, equal in size to *a b*. The observer looking through the pupil of the observed eye sees the portion *a b* of its illuminated fundus in the erect position, and magnified as indicated by the dotted lines drawn toward *a"* and *b"*.

(*b*) The observed eye is myopic (Fig. 3665). Let *a* and

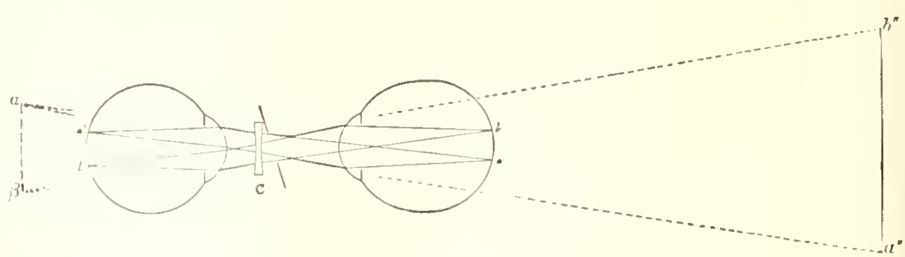

FIG. 3665.

b again represent the origins of two efferent pencils. As the observed eye is myopic, the rays composing these pencils become convergent after refraction at its cornea and would, if continued, converge to foci at *α* and *β*. Entering the eye of the observer they take on increased convergence, to cross at focal points in the vitreous, from which they again diverge to be cut by the retina as circles of confusion, thus forming a blurred image. By the interposition of the concave lens *C*, of a negative focal length equal to the distance *a C*, the convergent pencils are rendered parallel before they enter the observer's eye, so that they can be focussed accurately in the points

a' and *b'* at its retina to form a sharply defined image, somewhat larger than the object *a b*. The concave lens *C*, placed at the anterior focus of the observed eye—about 13 mm. in front of its cornea—exactly corrects its remains adjusted for parallel rays, we may interpose the convex lens *C*, of a focal length equal to the distance *a C*, and thus render the divergent rays parallel before they reach the eye. The convex lens *C*, placed at the anterior

www.libtool.com.cn

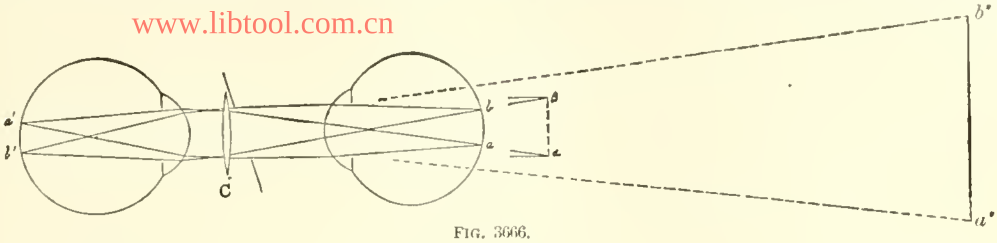

FIG. 3666.

myopia, and is, therefore, equal to the concave spectacle glass needed in distant vision. If the lens *C* is held a centimetre or more in front of the principal anterior focus of the observed eye, as is generally the case in ophthalmoscopic examinations, the negative focal length of the concave lens thus selected will be less than that of the required spectacle glass, by just its distance from the anterior focus of the eye. In low grades of myopia the error arising from a variation of 2 or 3 cm. in the distance of the concave lens is inappreciable, but in the higher grades (of 4 dioptries or more) the distance of the concave lens from the anterior focus must be added to its focus of the hypermetropic observed eye, exactly corrects its hypermetropia; if placed at a greater distance from the eye than its anterior focus, this excess of distance must be subtracted from the focal length of the convex lens. In low grades of hypermetropia small variations in the distance of the convex lens from the eye may be neglected.*

The details of the fundus of the hypermetropic eye, viewed through a convex lens placed behind the ophthalmoscopic mirror, are seen somewhat less magnified than in the case of the emmetropic eye.

In viewing the details of the fundus in the erect image

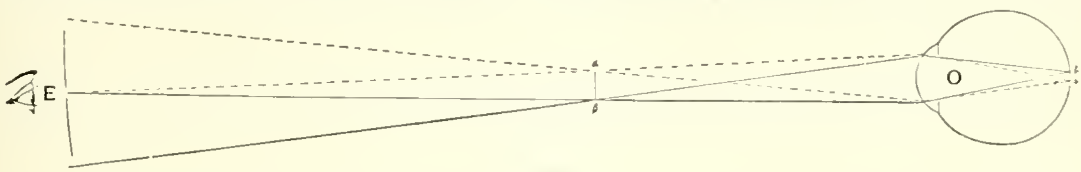

FIG. 3667.

(negative) focal length, in order to insure the highest degree of accuracy of which this method of examination is capable.*

The details of the fundus of the myopic eye, viewed through a concave lens placed behind the ophthalmoscopic mirror, are seen somewhat more magnified than in the case of the emmetropic eye.

(*c*) The observed eye is hypermetropic, and with relaxed accommodation (Fig. 3666). Let *a* and *b* again represent the origins of two efferent pencils. As the observed eye is hypermetropic, the rays composing these pencils emerge from the eye divergent, as if emanating from points *α* and *β* behind the eye, and, entering the eye of the observer, are rendered convergent, but not the cornea and lens of the observed eye perform the function of a simple microscope. If we adopt the conventional rule of referring the magnified virtual image to a distance of 8 Paris inches (about 217 mm.), the enlargement will be represented very nearly by the ratio 217 : 15, or about 14.5 diameters, in the case of an emmetropic eye of average dimensions (Helmholtz).

Ametropia in the eye of the observer plays an important part in affecting the distinctness of the view of the fundus in the erect image. Thus a myope who, with the unaided eye, can focus only divergent rays upon his retina, does not see the details of the fundus unless the observed eye is hypermetropic to a degree equivalent to or somewhat in excess of the measure of his own myopia.

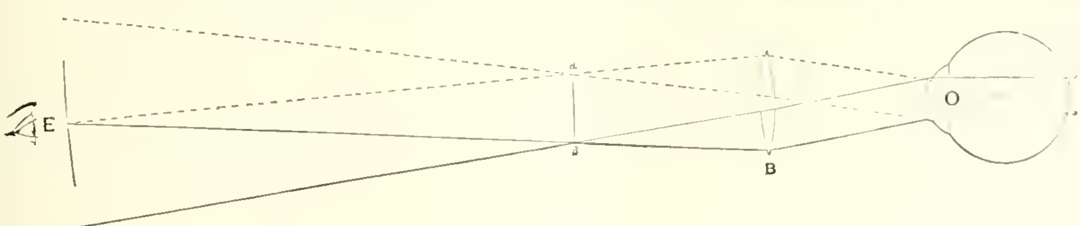

FIG. 3668.

sufficiently to focus them at its retina. An imperfectly defined image is therefore formed at *b' a'* of somewhat smaller size than the object *a b*. Here, however, the accommodation of the observer's eye may come into action, consciously or unconsciously, to focus the image upon its retina, and thus a distinct view of the fundus at *a b* may be obtained. Assuming that the eye of the observer A hypermetrope, on the other hand, can, with relaxed accommodation, obtain a clear view of the fundus of a

* The use of a concave lens behind the mirror, of a negative power sufficient to correct, or somewhat to overcorrect, the sum of the myopia of the observed and the observing eye, is a part of the original invention of Helmholtz (1851).

* The principle underlying the method of measuring the refractive condition of any eye, by means of a concave or convex lens placed behind the ophthalmoscopic mirror, is clearly set forth in the first publication of Helmholtz (1851), but the practical employment of the method on an extensive scale began with E. Jaeger (1856). It was also early cultivated by Donders, and especially by Mauthner (1867). Its general adoption, as a part of the daily work of the ophthalmic practitioner, dates from the introduction, by Loring (1869), of an instrument provided with a series of especially selected correcting lenses arranged to admit of easy and rapid changes.

www.libtool.com.cn

myopic eye in which the myopia does not exceed the measure of his own hypermetropia, and, by exerting his accommodation, he may be able to see the fundus of an emmetropic or even of a hypermetropic eye. A hypermetropic observer enjoys, therefore, a certain advantage in respect of the facility with which he can adjust his accommodation so as to see clearly under different refractive conditions of the observed eye, but he labors under a special disadvantage when he attempts to measure its refraction, and this for the reason that it is generally impossible for him either to estimate the degree to which he exerts his accommodation, or to control its exercise so perfectly as to hold it with even approximate accuracy at the point required to make him virtually emmetropic. To obtain trustworthy measurements of the refraction by means of the ophthalmoscope by the direct method, the hypermetropic observer should first neutralize his manifest hypermetropia by means of the appropriate convex glass, or else should subtract a quantity equal to the measure of his Hm from the value of the strongest convex glass, or add the same quantity to the value of the weakest concave glass through which he is able to see the details of the fundus distinctly. Similarly, the myopic observer should first correct his myopia by means of a neutralizing concave glass, or else should subtract a quantity equal to the measure of his myopia from the value of the weakest concave glass, or add the same quantity to the value of the strongest convex glass, through which he is able to see the details of the fundus. If the observer is astigmatic in any notable degree, he will see the fundus in the erect image under the same imperfect definition as if astigmatism were present in the observed eye. It is, therefore, essential to the highest accuracy, in measuring the refraction by this method, that the observer correct any astigmatism that may exist in his own eye by means of the appropriate cylindrical glass.

In the indirect method of examination the observer does not view the fundus itself, but an inverted aërial image of the fundus. The myopic eye forms such an image at its far-point (*punctum remotissimum, r*). Let *a* and *b* (Fig. 3667) represent two points taken within the illuminated area of a strongly myopic eye, and within the field of view of the observing eye at *E*. Inasmuch as the points *a* and *b* lie behind the principal posterior focus of the observed eye, the pencils originating from these points emerge, respectively, from the eye as pencils of convergent rays, to be focussed at the distance of the far point *r*, where they enter into the formation of an inverted real image *β a*. An observer stationed at *E*, about 20 cm. beyond *β a*, may accommodate for this real image, and see the finest details of the fundus sharply defined and magnified, but in the inverted position. The practical application of this method is greatly restricted by the fact that it is adapted only to cases of myopia of high grade, and that, at the best, the field of view is very small. Moreover, the image is seen under very different degrees of enlargement, according as the myopia is of a lower or a higher grade.

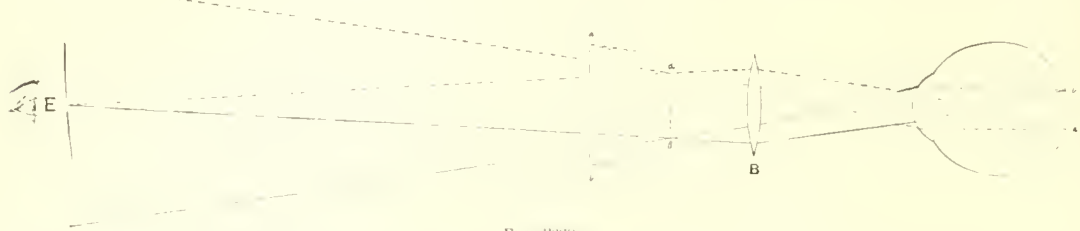

FIG. 3669.

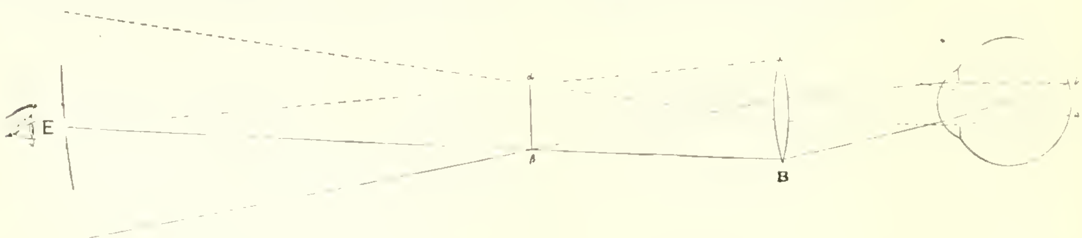

FIG. 3670.

The indirect method is extended to the examination of all eyes, irrespective of the state of the refraction, by making both the illuminating and the efferent pencils pass through a strong convex lens, placed at about its principal focal distance in front of the observed eye (Figs. 3668 to 3670; *cf.* Figs. 3659 to 3662). The efferent pencils, whether parallel (Fig. 3668), convergent (Fig. 3669), or divergent (Fig. 3670), are focussed by the convex lens either at its principal focus (in emmetropia), a little within the principal focus (in myopia), or a little beyond the principal focus (in hypermetropia). An inverted image is thus formed at or near the principal focus of the convex lens, and may be viewed from a station *E*, taken at a distance of from 20 to 25 cm. beyond the position of the principal focus.

The degree of enlargement of the picture of the fundus in the inverted real image, when the convex lens is placed at exactly its principal focal length in front of the nodal point of the observed eye, is found by dividing the focal length of the lens by the distance of the nodal point of the eye from its retina (= 1.5 cm. in the emmetropic eye). With a lens of 4 cm. focus the amplification is, therefore, 4 : 1.5 = 2.6; with a lens of 5 cm. focus it is 5 : 1.5 = 3.3; with a lens of 6 cm. focus it is 6 : 1.5 = 4; and with a lens of 8 cm. focus it is 8 : 1.5 = 5.3. In ametropia of the observed eye the second term in these several ratios is either greater (in myopia) or less (in hypermetropia) than the normal measure of 1.5 cm., so that the amplification of the inverted image is less in myopia, and greater in hypermetropia, than it is in emmetropia.

In very high grades of myopia, in which an inverted image of its fundus is formed by the eye at a very short distance in front of its cornea, the convex lens must be held very near the observed eye in order that it may take part in the formation of the image. This implies the use either of an excessively strong lens, in which case the details of the fundus will appear but little magnified in the inverted image, or of a weaker lens, held at a distance notably less than its focal length from the observed eye,

Digitized by Microsoft®

Ophthalmoscope.

in which case the boundaries of the field of view will be greatly narrowed. In the highest grades of myopia a modification of the indirect method of examination is, therefore, to be preferred.

Fig. 3671 shows a greatly elongated eye, representing a myopia of about 25 dioptries, and, therefore, forming an inverted image of its fundus at a distance of about 4 cm. in front of its nodal point. A convex lens of about 10 dioptries power (= 10 cm. focus) is held at about its principal focal length in front of the observed eye, and, therefore, at a distance greater than that of the inverted image. The observer, at *E*, views the image *β a* through the convex lens, and consequently sees it magnified by the lens. In this position of the convex lens neither the intensity of the illumination nor the extent of the field of view is materially influenced by the size of the pupil. A convex lens of a focal length a few centimetres greater than the distance of the image from the nodal point of the observed eye, held at about its principal focal distance in front of the cornea, gives a fairly ample field of view, together with a convenient enlargement of the inverted image. If the lens is moved nearer to the observed eye —*i.e.*, nearer to the place of the image—the field of view will be more extensive and the amplification less; if, on the other hand, the lens is moved farther from the eye, the field of view will be less extensive and the amplification greater.

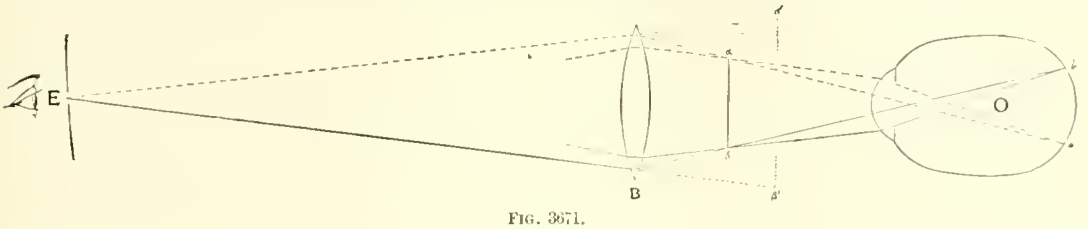

FIG. 3671.

In emmetropia of the observed eye the efferent pencils, of parallel rays, are focussed by the convex lens at its principal focus, irrespective of the distance at which the lens is held in front of the eye. The amplification of the image remains, therefore, constant for any particular lens, whether the distance of the lens from the eye be taken greater or less than its principal focal length. Only the size of the illuminated area at the fundus and the extent of the field of view are affected by the change in the position of the lens.

In ametropia, on the other hand, any change in the distance of the convex lens from the observed eye is attended, also, with some change both in the distance at which the inverted image is formed in front of the lens and in the amplification of the image. In hypermetropia, if we move the lens farther from the eye, the amplification of the image will be somewhat diminished. Conversely, in myopia, any increase in the distance of the convex lens from the eye is attended with some increase in the amplification of the image.

This change in the size of the inverted image in ametropia gives rise to a characteristic phenomenon in astigmatism, namely, a change in the apparent form of the disc of the optic nerve, according as the convex lens is held at a greater or less distance in front of the observed eye. In mixed astigmatism (Ahm or Amh) the eye is virtually myopic in the principal meridian of greatest refraction, and hypermetropic in the principal meridian at right angles to this meridian. It follows that, in moving the convex lens farther from the eye, the size of the inverted image increases in the direction corresponding to the ocular meridian of greatest refraction, and diminishes in the direction of the meridian of least refraction, so that the optic disc is seen as an oval of progressively varying form. In simple hypermetropic astigmatism (Ah) and in simple myopic astigmatism (Am) the change in the form of the inverted image of the disc is the same as in mixed astigmatism, but the variation is confined to the direction corresponding to the ametropic meridian. In compound hypermetropic astigmatism (H + Ah) and in compound myopic astigmatism (M + Am) the same change in form is observed as a result of unequal increase or decrease in the two principal meridians.

This change in the apparent form of the inverted image of the optic disc in astigmatism is necessarily attended with some indistinctness of outline, but this practically adds to, rather than detracts from, the conspicuousness of the phenomenon. In the case of the retinal vessels, the definition varies according as they happen to lie approximately in the direction of one or the other of the principal diameters of the oval. Both the distortion of the inverted image of the disc, and the inequality in the definition of the vessels which lie in the direction of the two principal meridians, may be made to disappear by the simple expedient of rendering the convex lens itself astigmatic by holding it more or less obliquely to the visual axis, according to the grade of astigmatism to be overcome.

The ample field of view, conjoined with as strong an illumination as can be utilized, the convenient degree of enlargement of the retinal picture, the fact that the conditions of visibility of the fundus are not materially affected by hypermetropia, or by any but the highest grades of myopia, and the facility with which the disturbing influence of astigmatism may be annulled by giving an oblique position to the lens, all combine to render the indirect method particularly available whenever we wish to obtain a general view of a large area of the fundus. On the other hand, for the examination of the details of the fundus under a greater magnifying power, and especially for measuring the refraction of the observed eye, the direct method offers advantages which are entirely its own. The two methods are, therefore, to be cultivated side by side, each supplementing the other; the two together affording the means of studying the fundus with a thoroughness not so perfectly attainable by the use of either method alone.

In order to be able to use both methods equally well, so as to obtain from each the best service of which it is capable, it is of the first importance that the observer eliminate any sources of error growing out of the uncontrolled exercise of his own accommodation. This can be

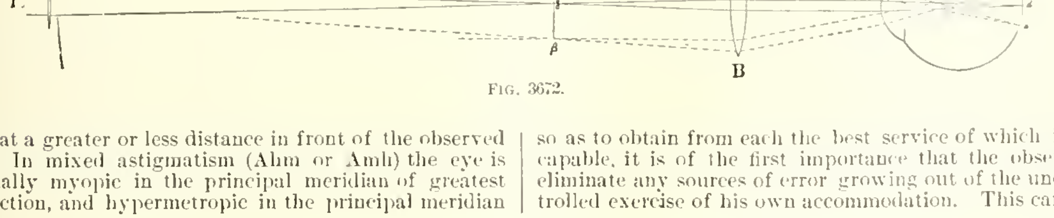

FIG. 3672.

Digitized by Microsoft®

attained only by the observer training himself to make all examinations, as well by the indirect as by the direct method, under the uniform condition of complete accommodative relaxation. And here the learner has, first of all, to suppress an instinctive tendency to accommodate for the short distance at which he knows that the object,

www.libtool.com.cn

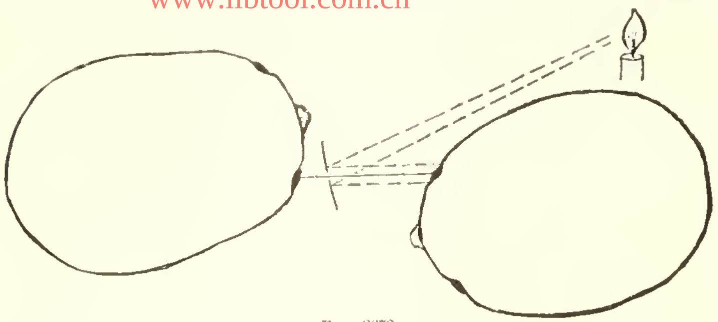

Fig. 3673.

or its image, actually lies. Hence, in practising the direct method, the learner should be made to feel that he must look not so much into the observed eye as through it, as if viewing an object lying far away. If myopic, he should accustom himself always to use the weakest concave correcting glass, or if hypermetropic, to use the strongest convex correcting glass through which he can obtain a distinct view of the details of the fundus; if emmetropic, he should learn to observe the fundus of an emmetropic eye without a correcting glass, and, in examining a myopic or a hypermetropic eye, to find and make use of the particular concave or convex correcting glass which exactly measures its myopia or hypermetropia. In practising the indirect method the learner should also acquire the habit of viewing the inverted image with relaxed accommodation, which he will accomplish, if emmetropic, by looking through a convex lens of about 5 dioptries power (20 cm. focus) placed immediately behind the hole in the mirror; or, if hypermetropic, by substituting for this lens such other lens, of greater power, as shall, in addition, correct his manifest hypermetropia; if myopic, he should similarly employ the convex or concave lens which accurately adjusts his own far point (r) for the distance of 20 cm.; and only in the particular case in which his far point lies at this distance (M = 5 dioptries) should he practise the indirect method without a correcting glass.

The use of a convex correcting glass in the indirect method of examination is shown in Fig. 3672; for the use of a concave or convex correcting glass in the direct method of examination see Figs. 3665 and 3666.

A fairly large pupil is always desirable in ophthalmoscopic examination, and in employing the direct method it is often indispensable. Nevertheless, it is not always either necessary or advisable to make use of a mydriatic. As the pupils contract both under the stimulus of strong light and in connection with the exercise of the accommodation, it is best to conduct all ophthalmoscopic examinations in a completely darkened room of considerable size, and preferably with walls of a dark color. The general darkness of the room is favorable to the dilatation of the pupils, and the consciousness that he is in a room of some size makes it easier for the patient to relax his accommodation when he is asked to direct his gaze toward a large and faintly lighted object upon the opposite wall. By observing these precautions the causes which incite to contraction of the pupils are in a great measure eliminated, with the exception of the direct influence of the light reflected into the eye by the mirror. The light of a student's lamp, reflected from the concave mirror of silvered glass and concentrated upon the region of the optic disc, ordinarily excites but little pupillary contraction, and, in fact, most of the routine examinations by the direct method may be made by the aid of this mirror without having recourse to artificial mydriasis. In searching for minute changes in the region of the macula lutea it is, however, not infrequently advisable to make use of a weak mydriatic, such as cocaine or euphthalmin. If, for any reason, it is judged inexpedient to instil a mydriatic solution into the eye, the plane mirror of Helmholtz, made up of several layers of unsilvered glass, may often be made to render excellent service.

In order to permit the patient to direct his gaze upon a somewhat distant large object, it is important that his view, with the eye not under examination, be not cut off by the head of the observer. Hence the very useful rule, of general application, that the observer accustom himself always to use his right eye in examining the right, and his left in examining the left eye (Figs. 3673 and 3674).

The ophthalmoscopic armamentarium, in its simplest effective form, includes (1) a perforated concave mirror, of about 33 mm. diameter and 23 cm. focus, mounted on a handle of about 13 cm. length, and fitted with a rotating disc or other mechanism by which any required concave or convex correcting glass may be easily brought into place behind the hole in the mirror; (2) a convex lens, of a diameter of about 3.5 cm. and a focal length of 5 or 6 cm.; and (3) a good lamp, which should be so mounted as to admit of the easy adjustment of the flame to about the height of the observed and of the observer's eye. This simple apparatus, used in a well darkened room, affords the means of exploring the eye, from the anterior epithelium of the cornea back to the retina and optic disc.

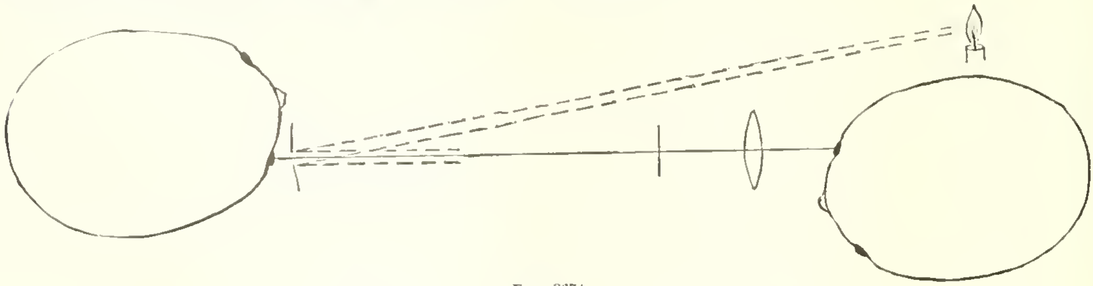

Fig. 3674.

If we place the lamp a little in front of the plane of the patient's face, and concentrate a cone of light upon the cornea by means of the convex lens (Fig. 3675), the conditions of illumination are very favorable to the detection and observation of any slight irregularities or opacities in the cornea, whether superficial or more deeply seated, and also of finely punctate deposits such as often occur in or upon the lining membrane of the cornea (membrane of Descemet). If we change very slightly the

Digitized by Microsoft®

position of the lens, so that the cone of light shall fall upon the iris, we may note slight changes in its texture, and also any irregularities in the contour and pigmentation of the pupillary margin. By concentrating the light upon the region of the pupil, we may similarly detect thin deposits of lymph obscuring the anterior capsule of the crystalline lens in the pupillary field, specks of brown pigment detached from the posterior surface of the iris and adherent to the lens capsule, and also such opacities as have their seat in the capsule or in the anterior layers of the crystalline. If we have previously brought the

www.libtool.com.cn

FIG. 3675.

eye under the influence of a mydriatic, we may detect and carefully study any adhesions (synechiæ) which may have been formed between any part of the pupillary border and the lens capsule, whether recent or of indefinitely long standing. If the pupil is widely dilated, we may look deeply into the crystalline lens (*cf.* Fig. 3643) and thus detect and observe the various forms of opacity incident to different types of cataract, or we may even look through the crystalline into the vitreous, and obtain glimpses of a mass of effused blood or lymph, or of a very prominent tumor growing from the fundus. In many cases it is desirable to make use of a magnifying glass in connection with this lateral or oblique focal illumination, for which purpose there is nothing better than an ordinary doublet of about 3.5 cm. focal length. By the method of lateral illumination all objects are seen by the light which they reflect from their surface, and, therefore, in their actual color.

In using the mirror, the lamp is placed a little behind the plane of the patient's face, and, preferably, on the same side as the eye to be examined. Having placed a convex glass of about 5 dioptries (20 cm. focus) behind the mirror, we throw the light upon the eye from a distance somewhat less than the focal length of the lens. Looking through the mirror, we see the field of the pupil brightly illuminated, and of a vivid red color, whenever the media are of unimpaired transparency and the fundus is of its normal hue. In the presence of diffuse clouding of the cornea or crystalline lens, or a turbid condition of the aqueous or vitreous humor, the red color of the pupil may appear conspicuously dulled, or may not be seen at all. A circumscribed opacity, on the other hand, whether in the cornea, on the anterior lens capsule, or in the substance of the crystalline, appears black against the red background of the fundus. Motes and shreds in the vitreous appear, also, as a rule, under the aspect of black specks or threads, intercepting the red light from the fundus, but in rare instances, as in the case of crystals of cholesterin, they may reflect so much light as to sparkle brilliantly (*synchysis scintillans*). If a fixed opacity has its seat at or very near the centre of rotation of the eyeball (about 13.5 mm. behind the vertex of the cornea), it will undergo little or no change of position when the observed eye is turned in different directions; if in front of this centre, it will move in the direction in which the eye is turned; if behind the centre, it will move in the opposite direction. The greater the distance at which the body lies in front of or behind the centre of rotation, the greater will be the range of its excursions. Thus a spot in the cornea will move through a larger arc than an opacity at the depth of the anterior lens capsule, and this in turn will move through a larger arc than one situated at or near the posterior capsule. Inasmuch as the pupil and the anterior lens capsule lie at the same depth within the eye, an opacity situated at the front of the lens maintains a nearly constant position with reference to the bright field of the pupil, while a spot on the cornea, or in the deeper layers of the lens,

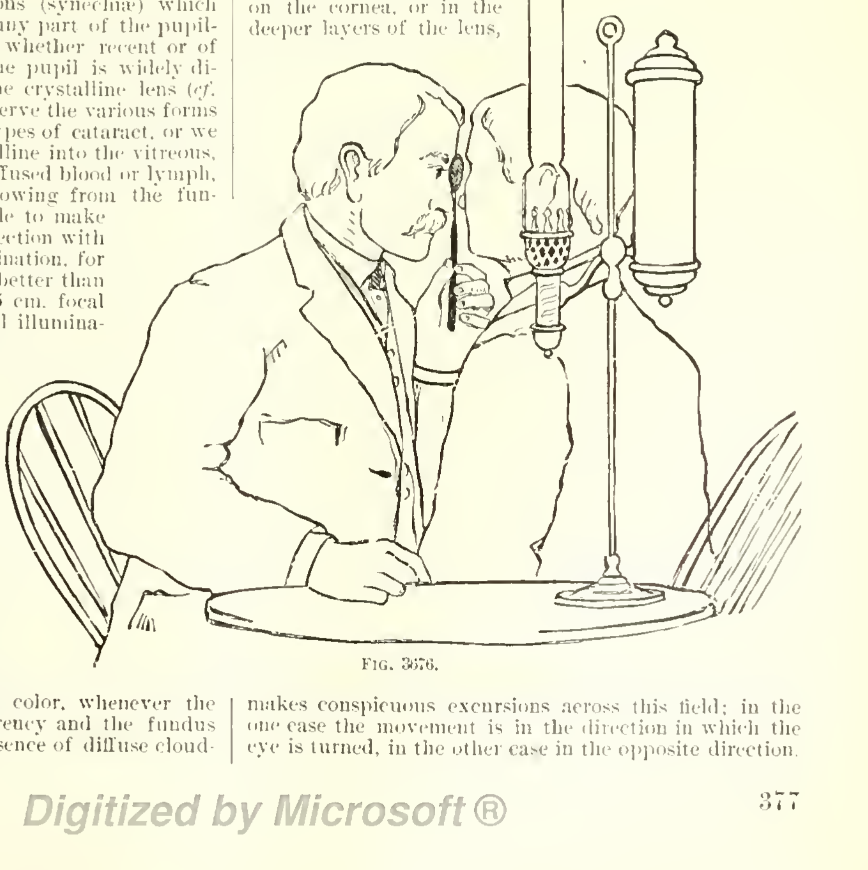

FIG. 3676.

makes conspicuous excursions across this field; in the one case the movement is in the direction in which the eye is turned, in the other case in the opposite direction.

Digitized by Microsoft®

Another point to which the motion of a visible body within the eyeball may be referred is the bright image of the flame as seen reflected at the front of the cornea. This bright reflex is always seen at the point on the cornea which lies nearest to the eye of the observer, and affords, therefore, an approximately fixed point of reference.

www.fhbtool.com.cn

Still holding the mirror at a distance of about 20 cm. from the observed eye, it may happen that we obtain a distinct view of the details of some part of its fundus. This can occur only in myopia of a very high grade, in which the observed eye forms an inverted image of its fundus at some point within a few inches of its cornea, or in a somewhat high grade of hypermetropia. In such a case we may make a slight rotary movement of the handle of the mirror, and so change the position of the image of the flame at the fundus; as this image passes across the field of view in the direction in which the mirror is turned, its inverted image, in front of the eye (in myopia), will move, across the pupil, in the opposite direction; in hypermetropia the movement of the virtual image of the flame will be in the direction in which the mirror is rotated. If, while looking at the inverted image, we bring the mirror nearer to the eye, we presently reach a point at which the details of the picture are lost. We next advance the mirror to the usual position for the observation of the fundus in the erect image, about 5 cm. from the observed eye (Figs. 3673 and 3676). At this short distance the field of view is much enlarged (see Figs. 3651, 3652, and 3654; *cf.* Fig. 3653), and the conditions are at the best for the detection and observation of fixed or floating opacities lying deep in the vitreous, as well as for the observation of a detached retina, or a tumor growing from the fundus. It may also happen that on approaching the observed eye the details of its fundus are seen sharply defined, indicating the presence of hypermetropia of a grade in excess of the power of the convex glass behind the hole in the mirror. In such a case we may at once measure the degree of hypermetropia, by bringing progressively stronger convex glasses into position behind the mirror. If, on approaching the eye, the details of the fundus are not seen, or are seen but indistinctly, through the convex glass of 5 dioptries, we may change to successively weaker convex glasses, or to concave glasses of progressively increasing power, until, by noting the particular glass which first affords a perfectly distinct view, we have obtained a definite measurement of the refraction. If, in the course of successive observations with glasses of different power, we at first get a distinct view of only such of the retinal vessels as correspond in direction to one of the ocular meridians, and with some other glass we obtain an equally distinct view of the vessels corresponding in direction to the meridian at right angles to the former, we have both established the presence of regular astigmatism and obtained the data for the determination of its type and the measurement of its grade. If, as sometimes happens, we see the same vessels, or parts of vessels, under different degrees of definition, according as we view them through different parts of the cornea, we have to do with a case of irregular refraction (irregular astigmatism) dependent probably upon some irregularity in the contour of the cornea. In such a case the bright reflex from the cornea may show variations in size and in shape, dependent on differences in the contour of the reflecting surface. In keratoconus (conical cornea), of even low grades, the distortion of the retinal picture and the changes in the form and size of the corneal reflex are especially characteristic.

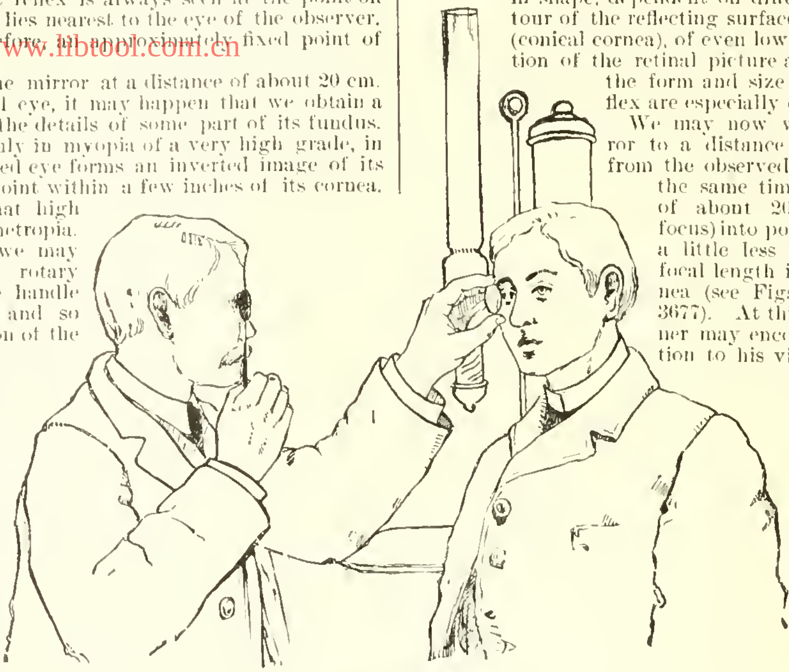

FIG. 3677.

We may now withdraw the mirror to a distance of about 40 cm. from the observed eye, bringing at the same time the convex lens of about 20 dioptries (5 cm. focus) into position at a distance a little less than its principal focal length in front of the cornea (see Figs. 3672, 3674, and 3677). At this stage the beginner may encounter an obstruction to his view of the interior of the eye arising from the bright reflex images of the flame or mirror formed by the two surfaces of the convex lens, the one virtual, behind the lens, the other real, in front of the lens. When the lens is held exactly concentric with, and at right angles to, a line connecting the pupils of the observing and the observed eye, the two reflex images lie also in this line, and may thus completely cut off the view into the eye. Both images are, however, easily got out of the way, either by moving the convex lens a little to one side, or by slightly rotating the lens so as to displace the two images in opposite directions. The strong convex lens, held at somewhat less than its focal distance in front of the eye, considerably magnifies a spot in the cornea, or in the field of the pupil, as seen from behind the hole in the mirror, and the conditions are favorable, generally, to the inspection of these parts

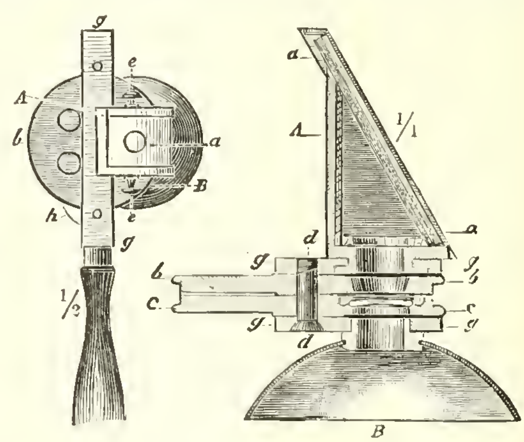

FIG. 3678.

of the eye. We may next turn our attention to the details of the fundus as seen in the inverted image, at about the position of the anterior principal focus of the convex lens, looking at it, for reasons already given, through the

Digitized by Microsoft®

convex glass of about 5 dioptries (20 cm. focus), placed behind the hole in the mirror. Having got rid of the two reflex images formed by the convex lens, either by moving it a little to one side or by turning it a little obliquely to the line of sight, we may encounter a further obstacle in the reflex image formed by the anterior surface of the cornea. This will, however, give no serious trouble, except in the particular case in which the vertex of the cornea of the observed eye is directed exactly toward the hole in the mirror; a slight turning of the eye in any direction sufficing to displace the bright reflex from the central region of the pupil. Inasmuch as the inspection of the region of the macula involves the turning of the observed eye exactly in the direction of the eye of the observer, the indirect method is not favorable to obtaining a good view of this part of the fundus. Nevertheless, we may often succeed in eliminating much of the disturbance from the corneal reflex by making lateral movements of the convex lens in different directions.*

www.libtool.com.cn

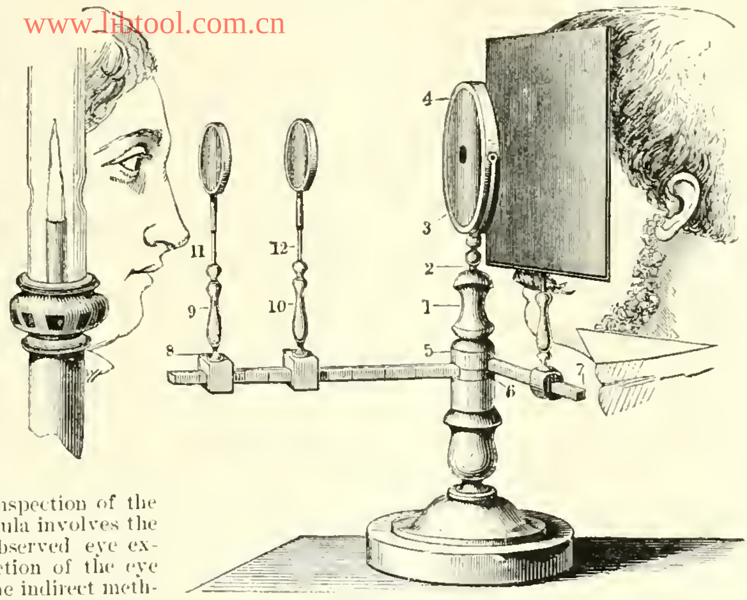

FIG. 3679.

It happens not infrequently that in moving the convex lens in a lateral direction a loop of a retinal blood-vessel appears to change in form. This is an effect of parallax, and is dependent on the fact that, by the lateral movement of the lens, the line of sight is considerably deflected, so that we see the vessel as from a different point of view. A loop of a retinal artery or vein, lying in a plane perpendicular to the general surface of the fundus, may thus appear as a straight line when viewed directly from in front, but will show something of its actual curvature when viewed from either side; the amount of the apparent curvature depending on the actual height of the loop and the extent of the lateral excursions of the lens.

For the inspection of the fundus generally, in the inverted image, including the disc of the optic nerve, the conditions are altogether favorable. To see the optic disc, which is situated to the nasal side of and a little below the posterior pole of the eye, the patient must turn his eye in the same direction, which he will most easily and surely accomplish by looking a little to the temporal side and slightly downward with the eye not under examination. To obtain a view of the peripheral regions of the fundus, the patient must turn his eye in the direction corresponding to the part to be examined, the details of which, as seen in the inverted image, will appear to move in the same direction.

If the concave ophthalmoscopic mirror is taken of very long focus (about 75 cm.), and held at a distance from the lamp and from the observed eye about equal to its radius of curvature (1.5 metres), the illuminating flame and the observed eye will be nearly at conjugate foci of the mirror, and the pupil of the latter will appear strongly illuminated. If, now, the observed eye is myopic in any degree in excess of one dioptrie, it will form an inverted aërial image of its fundus at a distance of 1 metre or less and some details of this image will be visible to an observer looking through the hole in the mirror. Inasmuch as, at the great distance of the mirror, the visible portion of the fundus is very small the patient may have to turn his eye slightly in different directions in order to bring one of the retinal vessels into view. The observer looking through a convex lens of 5 dioptries (20 cm. focus), placed behind the hole in the mirror, may calculate pretty accurately the distance of the image from the observed eye by noting the distance at which he sees the blood-vessel sharply defined. In simple myopic astigmatism (Am) and in mixed astigmatism (Amh or Ahm), only those retinal vessels whose direction is approximately at right angles to the principal ocular meridian of greatest refraction are visible in the inverted image; in hypermetropia (H), and in simple or compound hypermetropic astigmatism (Ah or H + Ah), the image is virtual, and the method is inapplicable.[1]

A plane mirror, at the distance of 1 metre, gives but a very small image of the flame at the fundus, and the field of view is also very small (see Fig. 3653). Neglecting entirely the details of the fundus, and regarding only the image of the flame, the distinction between hypermetropia and myopia may be made by simply observing the direction in which the image appears to move when the direction of the illuminating beam is changed by slightly rotating the mirror. This test turns on the fact that in hypermetropia the image which we see is virtual, and is situated behind the observed eye, while in myopia it is a real image, and is situated in front of the observed eye. Hence, in hypermetropia the image is seen to move into, across, and out of the field of view in the direction in which the (plane) mirror is rotated; in myopia the apparent movement is in the opposite direction. As the details of the image are disregarded, it is unnecessary to use a correcting glass behind the mirror, unless it be needed to correct a very high grade of ametropia in the eye of the ob-

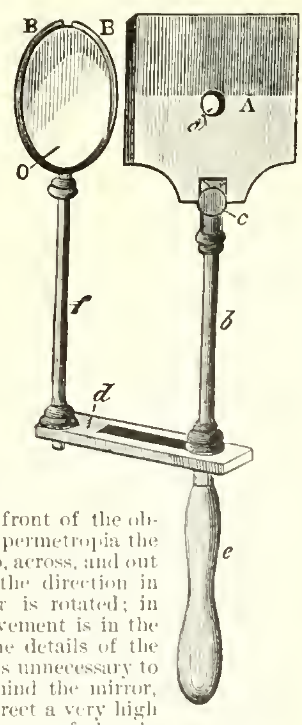

FIG. 3680.

* The geometrical axis of the cornea does not exactly coincide with the line of sight, the latter cutting the cornea a little to the nasal side of its vertex. Hence the corneal reflex does not, as a rule, exactly cover the image of the fovea. The angle which the axis of the cornea makes to the line of sight is known as the angle α (Donders); it is greatest in hypermetropic eyes, and least, sometimes even negative, in myopic eyes.

Digitized by Microsoft®

server. In this test it amounts practically to the same thing whether we speak of the movements of the bright image, or of the border of the unilluminated area surrounding it. It happens, however, that the writers who have especially cultivated this method have directed attention rather to the dark border (shadow) than to the image of the flame; hence the name, *shadow-test*, by which this method is commonly designated (see *Shadow-Test*).

www.libtool.com.cn

As a rule, an eye under ophthalmoscopic examination relaxes its accommodation. Hence measurements made with the ophthalmoscope not infrequently show a somewhat higher grade of hypermetropia, or lower grade of myopia, than is revealed by subjective tests made with test letters without the resort to artificial mydriasis. In the case of certain careless or obstinate patients, of some illiterate persons, and especially of young children, the ophthalmoscope is indispensable in the diagnosis of ametropia in all its forms.

Two principal types of the ophthalmoscope are to be distinguished, namely, those adapted to the examination of the fundus by the direct method, and those in which an inverted real image of the fundus is formed by the aid of a convex lens. The former type appears in a practically perfect form, in the original invention of Helmholtz (1851); the latter type was evolved in its essential features by Ruete, in the course of the following year. The invention of Helmholtz consists essentially in the discovery of the fundamental fact that the fundus can be seen by looking through a mirror from which light is reflected into the eye; Ruete, by the combination of a concave mirror and a convex lens or lenses, demonstrated the practicability of viewing the fundus in a strongly illuminated real image. Helmholtz, in turn, by a development of the experiment of Brücke (see Figs. 3659 to 3661), showed that it was possible to see the details of the fundus, in the inverted image, by direct illumination, and with no other apparatus than a screened lamp or candle and a convex lens. The subsequent development of the ophthalmoscope has been confined essentially to changes in details, and to modifications designed to facilitate certain special uses.

It is entirely practicable to illuminate the fundus by direct light, and view its reflected image in the mirror. Thus in the arrangement shown in Fig. 3651, it is possible, though less convenient, to place the lamp at L', and to view the image, as reflected on the mirror, from L. With the lamp (preferably a small electric incandescent bulb) at L or at L', it is possible for two observers, sta-

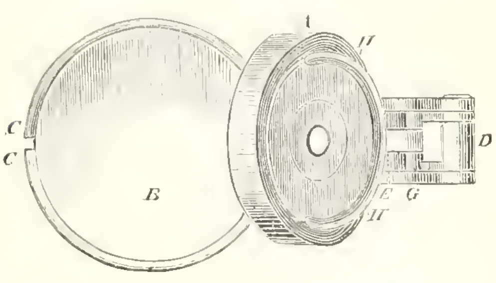

FIG. 3681.

tioned at L' and L, to view the fundus of O at the same time. Demonstrating ophthalmoscopes for two observers are based on this principle.*

Again, the efferent pencils emanating from different parts of the illuminated area at the fundus may be severally divided behind the mirror, so that each half, after two reflections, shall enter the corresponding eye of the observer. The binocular ophthalmoscope, like the binocular microscope, gives some degree of stereoscopic effect.*

Fixed ophthalmoscopes, as distinguished from ophthalmoscopes in which the mirror and the convex lens are held each in the hand, have been devised in considerable number; they have been used in measuring the details of the fundus, in making drawings of the fundus in normal and pathological states, and, especially, in demonstrating the ophthalmoscopic picture to a number of persons in succession.† Their prototype is to be found in the original ophthalmoscope of Ruete (Fig. 3679). The camera lucida may be used with any fixed ophthalmoscope.‡

Ophthalmoscopes have also been constructed with a combination of mirrors, by means of which an observer may, with one eye, see the fundus of his other eye. By a different arrangement of mirrors an image of the optic

---

* In every reflecting ophthalmoscope there are two points of view at which the eye of an observer may be stationed so as to receive rays of light from the illuminated fundus, namely, the usual and most favorable position immediately behind the mirror, and a less favorable position close by the side of the lamp. The use of an electric lamp makes it possible to see the details of the fundus from a station in its immediate vicinity whenever the efferent rays reflected from the mirror are parallel or divergent, as is ordinarily the case when a plane or a slightly convex mirror is used. With a concave mirror of a focal length less than its distance from the place of the inverted image, a twice inverted (*i.e.*, erect) image of the fundus may be seen at some point between the mirror and the lamp. A third point of view may be obtained by deflecting a part of the efferent rays at some point between the observed eye and the mirror. This is effected in the "ghost" ophthalmoscope of Laurence ("Klinische Monatsblätter für Augenheilkunde," S. 534, 1863) by interposing a sheet of polished transparent glass, set at an angle of 45°, in the path of the illuminating and the efferent rays; the latter are in part transmitted by the sheet of glass, and in part reflected at right angles to their original course. Some of the rays which have entered into the formation of the inverted image may be deflected to one side by reflection from a small plane mirror in front of and partially covering the central opening of the illuminating mirror; or some part of the same rays may be similarly deflected by a small reflector, preferably a totally reflecting right prism, placed just behind the illuminating mirror. Demonstrating ophthalmoscopes of this construction have been devised by De Wecker and Roger ("Bulletin de l'Académie des Sciences," 1870), and by Sichel *fils* (Annales d'Oculistique, 1872). By slightly separating the two totally reflecting glass rhombs in the binocular ophthalmoscope of Giraud-Teulon, and cutting them off square at their ends, an ophthalmoscope for three observers has been constructed (Monoyer: Revue médicale de Nancy, 1874); a fourth observer may see the fundus reflected on the illuminating mirror in the direction of the light.

* Coccius was probably the first to construct a binocular ophthalmoscope; a small perforated plane mirror, set, at an angle of 45°, behind the hole in the illuminating mirror, deflected a part of the efferent rays in a direction at right angles to the line of sight, and a second plane mirror, parallel to and about six 6 cm. distant from the other, reflected these rays into the second eye of the observer. The two retinal pictures were necessarily of unequal size, but notwithstanding this defect, the instrument is said to have given a somewhat better view than when but one eye was used (Snellen und Landolt; Graefe-Saemisch, "Handbuch der gesammten Augenheilkunde," iii., i., S. 160). The first binocular ophthalmoscope of good construction is that of Giraud-Teulon, in which the rays which have traversed the right half of the hole in the mirror are reflected to the right, and the other half to the left, and both are again reflected, at right angles, to enter the two eyes of the observer. All this is very simply accomplished by total reflection at the two obliquely cut ends of two rhombohedra of glass enclosed within a small metallic box behind the mirror (Annales d'Oculistique, xlv., 1861). By a slight change in the construction of this instrument, by Laurence and Heisch, it is made of a little lighter weight, although more fragile and more costly. A further modification, by Coccius, consists in the application of the principle of the common opera-glass, by which the image is seen considerably magnified (Report of the Fourth International Ophthalmological Congress, London, 1873). The latest change in this ophthalmoscope is by its inventor, who has notched the proximal ends of the two rhombohedra so as to make a small central opening, behind which he has placed a very small electric lamp, thus dispensing with the mirror (Giraud-Teulon: Annales d'Oculistique, xcvi., December, 1886).

† Th. Ruete: "Der Augenspiegel und das Optometer," Göttingen, 1852. The Epkens-Donders ophthalmoscope (1853) is a fixed ophthalmoscope designed for the measurement of the details of the fundus as seen in the erect image. Ulrich (Henle und Pfeuffer's Zeitschrift für rationelle Medicin, 1853) combined the mirror and object lens in a short metal tube, to the side of which a candle was attached. Hasner (Prager Vierteljahrsschrift, 1855) made the tube longer and used a separate lamp. R. Liebreich (Archiv für Ophthalmologie, 1855) constructed his larger ophthalmoscope by mounting an instrument essentially like Hasner's upon a standard and fixing the head of the patient by means of a special rest. With this ophthalmoscope he made the elaborate colored representations of the fundus figured in his "Atlas der Ophthalmoscopie" (Berlin, 1863). Burke ("Ophthalmoscope réflecteur," Havre, 1871) constructed a fixed ophthalmoscope in which a second concave mirror, of 19 cm. focus, was substituted for the usual object lens in examinations by the indirect method. Carter (Report of the Fourth International Ophthalmological Congress, London, 1873) mounted the several parts of the ordinary hand ophthalmoscope, all on an enlarged scale and with correspondingly increased radii of curvature, upon separate standards resting on a table four feet long.

‡ The camera lucida was used with the Epkens-Donders ophthalmoscope and with the large ophthalmoscope of Liebreich: Noyes (Transactions of the American Ophthalmological Society, 1873) also applied it to the fixed ophthalmoscope of Carter.

disc is formed at the macula of the same eye. These are curiosities of ophthalmoscopy.*

The ophthalmoscopes which have won a permanent place in the armamentarium of the ophthalmic practitioner are all based directly upon the simple reflecting ophthalmoscope of Helmholtz and the compound ophthalmoscope of Ruete. A few typical forms must be briefly noticed.

www.libtool.com.cn

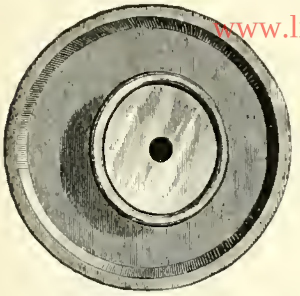

FIG. 3682.

The ophthalmoscope of Helmholtz (1851), perfected in some of its details by the instrument maker Rekoss, is shown in Fig. 3678. The two revolving discs, at the back of the mirror, have each five openings, in four of which are mounted concave glasses, giving twenty combinations ranging from — 3 dioptries to — 13 dioptries. The mirror, made up of three layers of very thin glass, is set at an angle of 56° to the plane of the revolving disc. The lamp is placed a little behind the plane of the observer's face, necessitating the use of a screen, to shade the observed eye from the direct light. The purpose of the concave glasses, in the two discs, is to permit the details of the fundus to be distinguished notwithstanding the presence of myopia of the observing or of the observed eye, and also to neutralize any disturbing effect arising from the possible exercise of the accommodation in either eye.[2]

The ophthalmoscope of Ruete (1852) consists of a perforated concave mirror and two vertical standards for holding lenses, all mounted in line on a fixed horizontal bar (Fig. 3679). With a convex lens of 4 cm. focus, mounted on the first standard at a distance of about 3 cm. in front of the cornea of the observed eye, an inverted image of its fundus, magnified about two and a half diameters, is formed about 4 cm. in front of the lens, and is viewed by the observer looking through the hole in the concave mirror. A second convex lens, mounted on the second standard at a distance somewhat beyond the position of the inverted image, affords the means of viewing this image under an increased amplification. A concave lens, mounted on one of the standards, is used in the examination by the direct method.[3]

FIG. 3683.

Coccius (1853) attached a convex lens to a plane mirror in such a position that the illuminating rays pass through the lens before impinging upon the mirror (Fig. 3680). The conjoined effect of the convex lens and plane mirror is essentially that of a concave mirror.[4]

Ruete's fixed ophthalmoscope becomes an ordinary hand ophthalmoscope when the mirror and the convex lens are dismounted, and are held in the two hands of the observer.

* Helmholtz ("Beschreibung eines Augenspiegels," Berlin, 1851) described a simple method by which an observer may, by looking in a mirror, see the illuminated pupil of one of his own eyes with the other eye. Coccius ("Ueber Glaukom, Entzündung und die Autopsie mit dem Augenspiegel," Leipzig, 1859) devised an arrangement of light and mirror by which an eye may receive a defined picture of its own optic disc. Heymann ("Die Autoskopie des Auges," Leipzig, 1863) combined a perforated plane mirror, a reflecting prism, and three convex lenses in such a manner that with one eye a view is obtained of the fundus of the other eye in a twice-inverted (*i.e.*, erect) picture. Similar arrangements have been devised by Giraud-Teulon (Annales d'Oculistique, xlix., 1863) and by Coccius.

Zehender (1854) substituted a convex mirror of 16 cm. radius of curvature for the plane mirror in the instrument of Coccius, thus making it possible to obtain from a single convex mirror the effect also of a plane, or of a concave, mirror (Fig. 3681).[5]

A convex mirror offers a slight theoretical advantage over a plane mirror, as does the latter over a concave mirror, in examinations by the direct method, and the instruments of Coccius and of Zehender have been especial favorites with some excellent observers. They are, however, more difficult to manage than the concave mirror, and are at present but little used. In practice the perforated concave mirror of 23 cm. focus suffices for most examinations, whether by the indirect or the direct method; in a few special cases the polarizing plane mirror of Helmholtz maintains its superiority over all rival inventions.

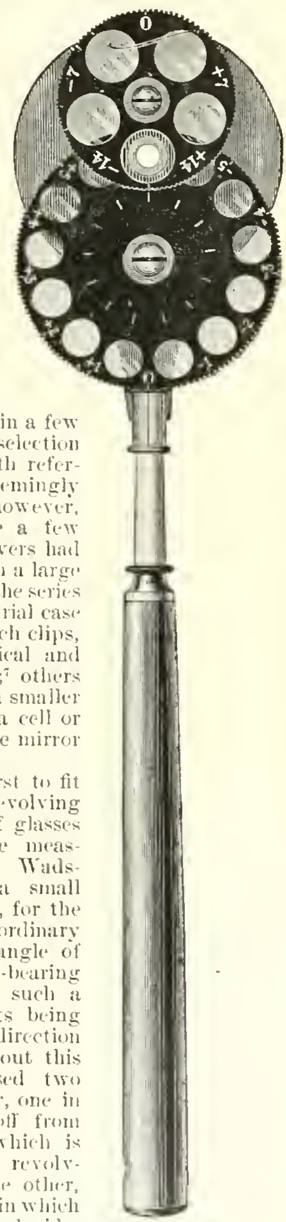

FIG. 3684.

The ophthalmoscope of Helmholtz, with the two Rekoss discs, includes all that is required for the convenient measurement of the refraction by the direct method, provided only that the discs are made larger, so as to contain a few more glasses, and that the selection of the glasses is made with reference to this use. This seemingly obvious development was, however, long deferred. Meanwhile a few exceptionally careful observers had ophthalmoscopes made with a large clip, to receive any one of the series of glasses in the oculist's trial case (Donders),[6] or with two such clips, intended to hold a spherical and a cylindrical glass (Noyes);[7] others contented themselves with a smaller series of glasses, fitted to a cell or small clip at the back of the mirror (Jaeger).[8]

Loring (1869) was the first to fit the ophthalmoscope with revolving discs containing a series of glasses sufficient for the accurate measurement of the refraction.[9] Wadsworth (1876) substituted a small mirror, of 15 mm. diameter, for the larger concave mirror in ordinary use, setting it at a fixed angle of 20° to the plane of the lens-bearing disc, and mounting it in such a manner as to admit of its being turned in any required direction (Fig. 3682).[10] Following out this suggestion, Loring devised two modifications of the mirror, one in which a segment is cut off from one side of the mirror, which is hinged at this border to a revolving setting (Fig. 3683); the other, the so-called tilting mirror, in which a segment is cut off from each side, and the mirror is swung on pivots at the two extremities of its vertical diameter (Fig. 3687).[11] The ophthalmoscope of Loring, as perfected by its inventor, is the type of a thoroughly good instrument for all practical uses; as made under his direction, by Mr. H. W. Hunter, of New York, it has not been surpassed as a model of good construction and fine workmanship.

Digitized by Microsoft®

The essential points in the construction of a good ophthalmoscope are few and simple. The best material for the concave mirror is silvered glass, which should be very thin, in order that the margin of the central perforation may encroach as little as possible upon the effective area of the opening when the mirror is turned obliquely to the line of sight; any excess of thickness above 0.3 mm. is both unnecessary and injurious. The central hole should be about 3.5 mm. in diameter,* and its unpolished margin should be coated with a dull black pigment; the alternative expedient of removing the silvering from a small central area of the mirror is not to be commended. A mirror made of polished metal is more difficult to keep in order, and, unless in very perfect condition, reflects much less light than a mirror of silvered glass. The focal length of the mirror should be about 23 cm.; this is a convenient focal length for examinations by the indirect method, and in the direct method the effect is not very different from that of a plane mirror (*cf.* Figs. 3652 and 3654). The mirror should be so mounted as to admit of its being inclined about 25°, to the plane of the correcting glass, and it is very desirable that it be so arranged that it can be turned in its cell. For the latter reason, and also because the mirror, when lying flat in its cell, is in closer proximity to the correcting glass, the writer prefers the hinged mirror of Loring (Fig. 3683) to his tilting mirror (Fig. 3687).

Fig. 3685.

Fig. 3686.

The correcting glasses should be so mounted as to admit of their automatic centration, and of the easiest possible change from one glass to another without interrupting the observation by removing the instrument from the eye. The series of lenses should be sufficiently large to include the entire range of hypermetropia and of myopia, with intervals as small as can be taken note of by the observer; a common interval of 1 dioptrie will suffice for most practitioners, others may be able to utilize an interval as small as 0.5 dioptrie. A combination of a larger and a smaller Rekoss disc, or of a full disc with a quadrant of another disc, is sufficient to meet these requirements; the glasses in the principal disc should be of somewhat greater diameter than the hole in the mirror (about 5 mm.); those in the second disc or quadrant should be a little larger (about 7 mm. in diameter). The two discs should be as thin as the curvature of the glasses will permit, and they should be mounted in the closest possible proximity to each other and to the back of the mirror.

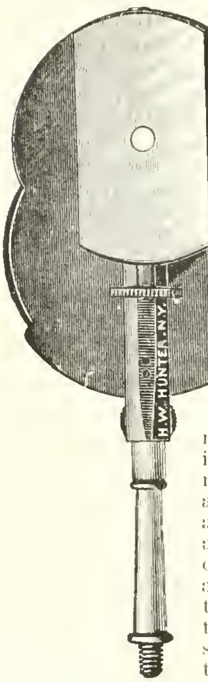

Fig. 3687.

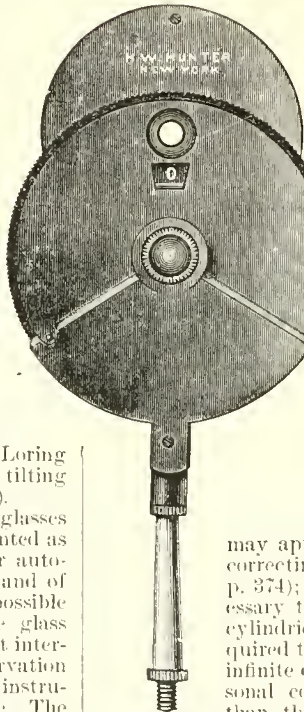
The handle of the ophthalmoscope should be not less than 14 or 15 cm. in length, measured from the centre of the mirror, and it should be large enough to admit of its being easily and firmly grasped by the hand. As, with this length of handle, it is somewhat difficult to reach the edge of the principal disc with the finger, a rack-and-pinion mechanism (Crétès), a cog-wheel (Loring), a train of cog-wheels (Noyes), or a cog and cam device (Meyrowitz), has been added; a very full series, of no less than seventy-four glasses, has been mounted, after the manner of an endless chain, in the place of the usual revolving disc (Couper);[12] a smaller series, similarly mounted, is used in the ophthalmoscope of Morton.

If the observer is simply hypermetropic or myopic, he may apply his personal correction to the correcting glass found by observation (see p. 374); if he is astigmatic, it may be necessary to add to the ophthalmoscope such cylindrical glass or glasses as may be required to correct his vision in either eye for infinite distance. The glasses for this personal correction should be a little larger than those in the second disc (about 9 mm. in diameter) and should be mounted immediately behind it; in astigmatism, of even as low a grade as 1 dioptrie, its correction adds appreciably both to the sharp definition of the picture and to the observer's quickness of perception.



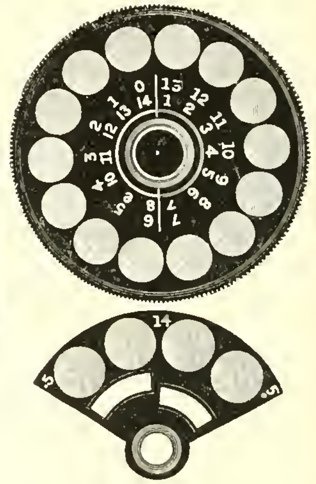


Fig. 3688.

Fig. 3684 shows the back of an ophthalmoscope made for the writer, in 1876, by Hunter.[13] It is, in fact, one of Loring's smaller ophthalmoscopes, with the addition of a second smaller disc—a construction adopted, a little later, by Badal, in France. Substituting + 13 and − 13 for + 14 and − 14, the order in which the glasses are brought into use becomes precisely the same as in the ophthalmoscope of Badal and in the later ophthalmoscopes of Loring; with +0.5 and −0.5 in the place of + 7 and − 7, as figured, an interpolation of 0.5 dioptrie may be made between the limits + 6.5 and − 6.5. A third disc, with two glasses, serving also as a cover to the smaller disc (Fig. 3685), or a setting of the form shown in Fig. 3686, affords the means of applying such correction as an astigmatic observer may find advantageous. The ophthalmoscope of Loring, with the tilting mirror, in the construction finally adopted by its author, is shown in Figs. 3687 and 3688.[14]

John Green.

* H. Knapp (Archives of Ophthalmology and Otology, iv., i., p. 41, 1874) made comparative trials of a number of mirrors with holes varying from 1 to 5 mm.; "the best illumination is obtained by an opening in the mirror of 3.5 or 3.75 mm. in diameter."

Plate XLVII., by Jaeger, shows the fundus of a normal eye as viewed by means of the ophthalmoscope.

OPIUM.—(U. S. P.; B. P.; P. G.) *Succus Thebaicus, Lachryma Papaveris, Extractum thebaicum, Meconium, Laudanum.*

Definition.—Officially considered, under the authority of the United States Pharmacopœia, opium is "the concrete milky exudation obtained by incising the unripe capsules of *Papaver somniferum* L. (*P. officinale* Gmel.; *P. album* Mill., fam. *Papaveraceæ*), and yielding, in its normal moist condition, not less than nine per cent. of crystallized morphine" when assayed by the United States Pharmacopœia process. This definition is to be read in connection with the description given below, which more closely delimits the article. It is also to be considered in connection with the provisions for *Opii Pulvis* (see the section on Preparations), which has a different alkaloidal standard, and with those for the alkaloidal standardization of the preparations made from the latter.

Fig. 3689.—The Opium Poppy (var. nigrum). Plant much reduced. (Baillon.)

The definitions of other pharmacopœias differ considerably from that of ours. The German requires, as ours formerly did, that opium be produced in Asia Minor; also that it contain from ten to twelve per cent. of morphine and not more than eight per cent. of moisture. The British Pharmacopœia requires different amounts of morphine for the opiums used in the different preparations; not less than seven and a half per cent. for the tincture and extract, and between nine and a half and ten and a half per cent. for other uses. For diluting a higher with a lower grade, the United States Pharmacopœia requires that the morphine percentage of the latter be between seven and a half and ten per cent. In view of the standardization of the preparations, it would at first thought appear superfluous to impose rigid standards for the drug, but important commercial and tariff considerations are involved, aside from the fact that large downward variations in morphine percentages are liable to be accompanied by important upward variations in the percentage of other, perhaps undesirable, alkaloids.

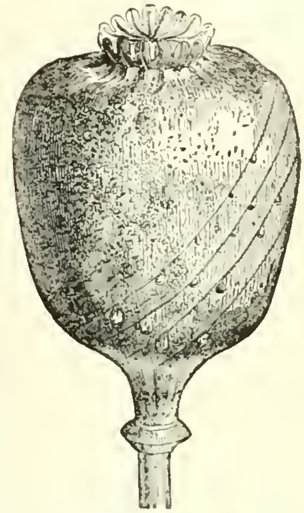

Fig. 3690.—White Poppy, showing the incisions made in the green capsule for the extraction of opium. (Baillon.)

Origin.—All opium is now regarded as the product of the one species named in our definition, though some botanists have been inclined to regard its varieties as distinct species. Although the plant grows abundantly in a wild state about the eastern Mediterranean, and in adjacent regions, opium is wholly the product of cultivated plants. Although the *var. glabrum*, having red flowers and usually dark seeds, is preferred and more largely grown in Turkey, and the *var. album*, with white flowers, is more commonly grown in Persia, such distinctions are not rigid, since flowers of all intermediate colors may usually be seen in a Turkish plantation. The opium plant here figured (Fig. 3689) is an annual herb, nearly a metre (a yard) high, somewhat branched above and bearing from five to twenty large flowers and capsules (see Fig. 3690). The latter is about as large as a small apple, and yields the opium by the process described below. (See section on Production.)

Almost every country possessing a suitable climate has yielded opium of fair to good quality, including Europe as far north as Sweden and North America as far north as New England, though most of these operations have been purely of an experimental character. Financial success in opium production requires a special combination of conditions affecting soil, climate, population, and cost of labor, and has been attained, to a noteworthy extent, only in Turkey, Persia, India, China, and Egypt. Of these products that only of Turkey answers perfectly to the official description, and it supplies practically the entire medical demand, except for purposes of morphine manufacture. For this, any product rich in morphine and easily worked is selected, the most of it, with the exception of Turkish opium, being Persian, so far as United States manufacturers are concerned. All other opium is consumed in the vicious practices of smoking and chewing. Of this, the Egyptian product is probably somewhat greater than the whole of the Turkish product, though smaller now than formerly. That of India is probably from ten to twenty times as great as that of Turkey, and that of China at least double that of the

Digitized by Microsoft®

rest of the world, including even the Indian. It will thus be seen that the vicious use of opium is about fifty times as great as its medicinal use, in connection with which it must be remembered that probably more than half of that usually classed as medicinal is in reality vicious.

www.libtool.com.cn

Production and Preparation.—The best climatic conditions for poppy culture are those which prevail in the warmer wheat-growing sections—conditions under which it is practicable to sow in September, to trust to a covering of snow for the protection of the young plants through the winter, and to gather in the crop late in the following summer. More precarious, and generally less successful, is the production of a crop during the summer of the same year, the sowing being done in February or March. The capsules are ready for incision when just beginning to turn yellow, at which time the dense network of milk tubes ramifying through the entire thickness of the pericarp is charged with a thick milky juice. In Turkey the incisions are made in a somewhat obliquely or spirally transverse direction (Fig. 3690), in India vertically. In both cases the knife possesses two or three blades set near to one another, and the incision is made as deeply as possible, care being taken that it shall not penetrate the central cavity. This work is performed in the late afternoon, *i.e.*, at a time when the sun will not interfere with the flow of juice. In the morning, the exudation will be found to have thickened sufficiently to admit of its collection. It is considered that the quality of the Indian product is injuriously affected by the prevalence of very heavy dews. The opium is removed by a blunt scraping instrument, to which it is prevented from adhering in a troublesome degree by various devices; in Turkey, by the use of the saliva of the collector, in Persia by the application of a small quantity of oil. Owing to slight differences in the use of the scraper, portions of the epidermis of the capsule may or may not be removed with the opium. The collection of the Smyrna product naturally adds from five to eight per cent. to the weight of the opium from this source, and this amount is usually very largely added to. (See section on Adulteration.) As gathered, the opium is transferred to a poppy leaf held in the left hand, and the mass, when of convenient size, is laid away in the shade for a day's drying, which, if it has not advanced too far, will permit of the moulding of the product. When sufficiently dry it is enwrapped in the poppy leaf, and such masses may then, without further modification, be packed in Rumex capsules, to prevent their adhesion to one another, and marketed. They may, on the other hand, be subjected to very varied processes for various purposes. Considerable of the Persian opium is subjected to a long-continued kneading or beating process, with exposure to the atmosphere, so as to cause it to assume a resemblance in appearance to Constantinople opium. The latter variety is said to be similarly beaten up, so as to make it of a more homogeneous and finer structure. Much of the high-grade Turkish opium, and almost all of that of similar grade of other countries, is beaten up with that of lower percentage, to increase its bulk and weight. It is even said that some medicinal Turkish opium has thus mixed with it that of other countries. None of the operations above considered, though designed to reduce the morphine strength, can be regarded as acts of adulteration, so long as they do not result in reducing the morphine strength below official standards. Persian and Indian opium, instead of being wrapped in the poppy leaf, are usually wrapped in paper, and, since they are designed chiefly for exportation to China, they frequently bear inscriptions in Chinese characters. The masses are of varied forms, being in squares, cakes, cylindrical sticks, balls, or in masses similar to those of the Turkish article. Instead of being packed, like the Turkish, in Rumex capsules, they are usually packed in "poppy-trash," consisting of the chopped, dried capsules and other parts of the plants.

Adulteration.—The dilution of a high-grade, by the addition of a low-grade opium has been already considered. That by the addition of an excessive amount of the epidermis of the capsule or of the chopped capsules, or possibly of other parts of the plant similarly chopped, sometimes amounting to a third of the weight of the opium, or of an extract of the capsules, or of starchy substances, all of which are in themselves practically inert, may be considered, when they do not reduce the morphine strength below the official standard, as on the borderland between dilution and adulteration. The use of an extract made from the herbage of the plant is clearly adulteration, and is rather common, as is that of various gummy substances of an extraneous nature, and of earthy substances, some of them effervescing with acids. The use of such heavy bodies as stones, nails, and bullets, now less common than formerly, scarcely requires mention. The custom still prevails, to a greater or less extent, of diluting opium, after arrival in this country, so that it barely meets the official requirement, the product being known as *Pudding* or *Boston Opium.*

DESCRIPTION.—In irregularly globular, usually more or less flattened masses, weighing from 250 to 1,000 gm. (½ to 2 lbs.), the surface marked with the impression of a poppy-leaf used for wrapping, and frequently bearing fragments of this, with some rumex fruits; of a chestnut-brown or reddish-brown, changing to dark or blackish-brown with long keeping; plastic and rather soft, or gradually hardening from without inward, with age; fractured surface exhibiting more or less tissue fragments, together with small tear-shaped particles of opium and, under the microscope, some acicular crystals, especially visible after moistening with benzene; of a heavy narcotic odor and taste, the latter disagreeable and bitter.

The required morphine percentage has been stated under Definition. Although the official definition would permit the employment of the higher grades of opium from any country, it will be seen that the description, in view of what has been said concerning the different methods of wrapping and packing, would exclude all but the Turkish variety. Persian opium is light-colored and characterized externally and internally by an oily appearance. Egyptian opium is packed much like the Turkish, but is dark-colored and is almost if not quite invariably below the official standard in morphine yield. Indian opium is also dark-colored, usually possesses a peculiar odor, said to be due to fermentation during the long process of curing required by the peculiar conditions to which it is subject, and is commonly encased in coverings made by glueing together poppy leaves or petals by a substance made partly from a dark-colored exudation from the curing opium and partly from an extract of the plant. Very little of it is exported, except to China (*Provision Opium*), and this small quantity is restricted almost wholly to the Patna product. Chinese opium is mostly of very low grade, though of late some of much better quality has been produced. It is not of interest in materia medica.

Since it is required that the determination of the morphine percentage be accomplished by the official method, it is important that this process be here given:

Assay of Opium.

Opium, in any condition to be valued.. 10 gm.
Ammonia water .... 3.5 c.c.
Alcohol,
Ether,
Water......... of each a sufficient quantity.

Introduce the opium (which if fresh should be in very small pieces, and if dry, in very fine powder) into a bottle having a capacity of about 300 c.c., add 100 c.c. of water, cork it well, and agitate frequently during twelve hours. Then pour the whole as evenly as possible upon a wetted filter having a diameter of 12 cm., and, when the liquid has been drained off, wash the residue with water, carefully dropped upon the edges of the filter and the contents, until 150 c.c. of filtrate are obtained. Then

Digitized by Microsoft®

carefully transfer the moist opium back to the bottle by means of a spatula, add 50 c.c. of water, agitate thoroughly and repeatedly during fifteen minutes, and return the whole to the filter. When the liquid has drained off, wash the residue as before until the second filtrate measures 150 c.c. and finally collect about 20 c.c. more of a third filtrate. The second filtrate, placed in a tared capsule, is first to be evaporated until it represents only a small volume; then to this is to be added the first filtrate; and, finally, after rinsing the vessel with the third filtrate, the evaporation is to be continued until the residue weighs 14 gm. Rotate the concentrated solution about in the capsule until the rings of extract are redissolved, pour the liquid into a tared Erlenmeyer flask having a capacity of about 100 c.c., and rinse the capsule with a few drops of water at a time, until the entire solution weighs 20 gm. Then add 10 gm. (or 12.2 c.c.) of alcohol, shake well, add 25 c.c. of ether, and shake again. Now add the ammonia water from a graduated pipette or burette, stopper the flask with a sound cork, shake it thoroughly during ten minutes, and then set it aside, in a moderately cool place, for at least six hours, or over night.

Remove the stopper carefully, and, should any crystals adhere to it, brush them into the flask. Place in a small funnel two rapidly acting filters, of a diameter of 7 cm., plainly folded, one within the other (the triple fold of the inner filter being laid against the single side of the outer filter), wet them well with ether, and decant the ethereal solution as completely as possible upon the inner filter. Add 10 c.c. of ether to the contents of the flask, rotate it, and again decant the ethereal layer upon the inner filter. Repeat this operation with another portion of 10 c.c. of ether. Then pour into the filter the liquid in the flask, in portions, in such a way as to transfer the greater portion of the crystals to the filter, and, when this has passed through, transfer the remaining crystals to the filter by washing the flask with several portions of water, using not more than about 10 c.c. in all. Allow the double filter to drain, then apply water to the crystals, drop by drop, until they are practically free from mother-water, and afterward wash them, drop by drop, from a pipette, with alcohol previously saturated with powdered morphine. When this has passed through, displace the remaining alcohol by ether, using about 10 c.c., or more if necessary. Allow the filter to dry in a moderately warm place, at a temperature not exceeding 60° C. (140° F.), until its weight remains constant, then carefully transfer the crystals to a tared watch-glass and weigh them.

The weight found, multiplied by ten, represents the percentage of crystallized morphine obtained from the opium.

Constituents.—Not all of the alkaloids of opium here described occur in all the varieties of opium, the presence or amount of some of them depending upon varying conditions of production or preparation. Of the twenty naturally occurring alkaloids, the identity of which has been established, morphine and codeine, as well as their derivatives, apomorphine and apocodeine, and also narcotine, are considered under those titles. Although several of the others are somewhat used in medicine, they are not sufficiently employed to be entitled to separate consideration, and they are briefly discussed here and in the section on Properties and Uses. Besides these, quite a number of alkaloids have been obtained artificially by treatment of the others.

Morphine occurs in opium of different kinds and grades in amounts varying from a small fraction of one per cent. up to nearly twenty-five per cent. Its ordinary percentage varies from six or seven to twelve or fourteen per cent. In the medicinal Turkish opium, probably as the result of manipulation with that object in view, it occurs almost uniformly in from nine and a half to ten and a half per cent. It occurs in the drug as a compound with sulphuric acid or as one with meconic acid. *Codeine*, which exists similarly, rarely if ever reaches one per cent. in amount and sometimes does not exceed one-fifth of one per cent.

Narceine ($C_{23}H_{29}NO_9 + 2H_2O$) resembles narcotine in appearance, though the crystals are finer and more slender and are slightly bitter. It melts at 145.2° C. (291.6° F.), is insoluble in ether, but is somewhat soluble in water and in alcohol. Nitric acid colors it yellow, though the color is evanescent; iodine, in small amount, gives it a blue color; Erdmann's reagent produces a deep yellow tint, becoming brownish, then orange; finally, Frohde's reagent produces a brownish green color which first turns yellow and then red. Like narcotine, narceine is but weakly basic. Its salts are crystallizable and are mostly incompatible with water, being precipitated or decomposed by it. Its hydrochloride is mostly employed and is strongly basic.

Thebaine ("paramorphine," $C_{19}H_{21}NO_3$) usually occurs in strongly lustrous scales, but sometimes in prismatic crystals. It is soluble in alcohol, benzene, and chloroform, and to a considerable extent in ether, and is insoluble in water. Its melting point is 193.4° C. Sulphuric acid colors it blood red, changing to yellow, nitric acid colors it red, Erdmann's reagent orange-red, Frohde's orange-yellow, slowly disappearing. It is decomposed quickly by diluted acids, with a production of the two isomeric uncrystallizable alkaloids *thebenine*, and *thebaicine*. It yields readily crystallizable salts.

Papaverine ($C_{20}H_{21}NO_4$) occurs in colorless acicular or prismatic crystals, soluble in hot alcohol, chloroform, and benzene, only slightly so in ether and cold alcohol, and insoluble in water. Its melting point is 147° C. (296.6° F.). It is colored purple or violet by warm sulphuric acid, violet-blue, becoming blue, yellowish, and colorless by Frohde's reagent. It yields salts readily and these are somewhat soluble in water.

The remaining alkaloids occur only in very minute amounts, and are merly objects of curiosity in materia medica. They are:

Codamine ($C_{20}H_{25}NO_4$), *Cryptopine* ($C_{21}H_{23}NO_5$), *Gnoscopine* ($C_{22}H_{23}NO_7$), *Hydrocotarnine* ($C_{12}H_{15}NO_3$), *Lanthropine* ($C_{23}H_{25}NO_4$), *Laudanine* ($C_{20}H_{25}NO_4$), *Laudanosine* ($C_{21}H_{27}NO_4$), *Meconidine* ($C_{21}H_{23}NO_4$,) *Oxynarcotine* ($C_{22}H_{23}NO_8$), *Protopine* ($C_{20}H_{19}NO_5$), *Pseudomorphine* ($C_{34}H_{36}N_2O_6$ "Phormine" or "Oxydimorphine"), *Rhoeadine* ($C_{21}H_{21}NO_6$), *Tritopine* ($C_{42}H_{54}N_2O_7$), and *Xanthaline* ($C_{37}H_{36}N_2O_9$).

Next to the alkaloids, the most important constituent of opium is about four per cent. of meconic acid ($C_7H_4O_7$), occurring free and in the alkaloidal salts. It can be extracted by the addition of lime, as calcium meconate. It occurs in colorless scales or prismatic crystals, soluble in alcohol and in hot water. It is colored deep red by ferric salts, the color not being destroyed by hydrochloric acid or by chloride of mercury or gold. It is tribasic and is decomposed, by boiling, into *comenic* and *pyrocomenic acids*.

A variable amount of lactic acid occurs in opium. *Meconin* and *Meconoisin* are neutral principles. The former ("opianyl") is in colorless, odorless, shining, bitter prismatic crystals, melting in the air at 110° C. (230° F.) and is soluble in alcohol and ether, slightly in water. It gives a green color when evaporated with sulphuric acid, with the addition of a little water. The latter has a somewhat higher melting point and yields a red, changing to a purple color, on similar treatment with sulphuric acid.

Among the less important constituents of opium neither starch nor tannin occurs. There is a varying amount of resin, a caoutchouc-like substance, gum, pectin, fixed oil, wax, glucose, coloring matter, and a volatile odorous principle.

Action and Uses.—A consideration of the actions of the more important constituents must precede those of opium. Those of morphine, codeine, and narcotine have already been considered under these titles. Of the minor constituents, the odorous principle of opium is often objectionable to the senses, and is removed in the *Opium Deodoratum* or *Deodorized Opium* (*Opium Denarcotisatum*, United States Pharmacopoeia, 1880) by repeatedly washing with ether, and adding to the dried residue enough

Digitized by Microsoft®

sugar of milk to restore the product to its original weight. This treatment is supposed to remove also the narcotine, and probably most of the thebaine, the latter result greatly affecting its physiological action.

Thebaine.—This alkaloid is to be regarded as the principal constituent antagonistic to morphine, and hence to the general action of opium. It is a powerfully poisonous irritant of the spinal centres, producing convulsions. Therapeutical uses for it have not been developed.

Narceine acts very similarly to morphine, but is much weaker; its employment is vaguely stated to be free from the disagreeable after-effects of the latter drug, while others regard it as practically inert. Probably much of that used has been contaminated with morphine, yet the use of its numerous salts with organic and inorganic acids, has fully demonstrated that it does possess activity. Its dose is about the same as that of codeine 0.025–0.05 gm. (gr. ⅓ to gr. ⅔). None of the other alkaloids is known to be of importance in medicine.

Meconic Acid, though of no importance physiologically, has been considerably employed in compounding salts of alkaloids, under the impression that these, being the natural forms of occurrence in opium, were more diffusible and active than other salts. In this view, it was long official in the British Pharmacopœia, but the idea has now been abandoned and the substance is little used.

Opium.—From the foregoing it would appear that the action of opium should be that of morphine, except for the slight modification due to the presence of its thebaine. In the main, this is true, yet practice demonstrates differences which cannot thus, nor in any positive way, be accounted for. Doubtless the difference is partly due to the substitution of primary effects, when used in one form, for secondary effects when used in the other. In opium, as in most nervines, such primary and secondary effects are more or less antagonistic, as specially exemplified in its effects upon intestinal excretion, where a dose, relatively very small or very large, in consideration of the condition of the patient, is liable to increase peristalsis and discharge, while the characteristic effect of a moderate dose is to constipate. That opium should be less promptly hypnotic, producing more of a preliminary excitation of the spinal and lower cerebral centres, commonly with irritable pulse, can be readily charged to the action of its thebaine. It is difficult, however, thus to explain its greater intestinal astringency or constipating effect or its peculiar diaphoretic properties.

From a therapeutical standpoint opium can be used for all the purposes for which morphine is employed, though the dose should be relatively somewhat larger; that is, a dose of opium should contain more morphine than would be employed as a salt for the same purpose. Even with this proviso opium is not to be selected in preference to morphine for ordinary somnifacient purposes, since its action cannot be so accurately estimated, nor is it so prompt. On the other hand, there are cases in which it is to be preferred, even for such uses, since its after-effects are not so disagreeable or lasting as those of morphine. For checking intestinal discharges, opium is greatly to be preferred, though its continued use is not so constipating as that of morphine; often, in fact, it tends to looseness of the bowels. When it is necessary to maintain for some time an equable analgesic effect, as in relieving abdominal pain in peritonitis, for instance, opium is usually to be preferred, though it is sometimes desirable first to get the patient under its influence by the use of morphine. Subject to the above modifications, the specific actions and uses of opium should be sought under *Morphine*.

Special Uses and Doses of the Preparations.—(It is to be remembered that the doses of opium and its preparations are subject to the same enormous special variations as are those of morphine.) Of opium itself there is but one official preparation, namely, the *Opii Pulvis* or powdered opium, from which all the other preparations are made. This discrimination is of practical importance, since powdered opium must contain between thirteen and fifteen per cent. of morphine, about a half more than the lowest allowable (and usual) content in opium. It is specified that powdered opium of too high a percentage may be reduced to the proper strength by mixing in due proportion with that of a lower grade. Whenever the dose of opium is stated, it is powdered opium, which is to be understood. For ordinary purposes, this is 0.066 gm. (gr. i.). The substance is often given without change, much oftener in the form of the pills (*Pilulæ Opii*), each containing the above mentioned amount, with a little soap, or in the deodorized form, mentioned at the beginning of our paragraph on Actions and Uses, its strength and dose being equal to those of powdered opium. Crude, undried opium is occasionally given in pill form when slow solution is desired, as in cases of relaxed intestine, diarrhœa of phthisis, and chronic dysentery. Old and hard pills are sometimes written for (and many apothecaries keep them on hand for the purpose), in the hope that they will pass the stomach undissolved and exert a local continuous influence upon the intestine. This result is, however, not exactly within control, and may be better attained by coating pills with keratin. More often still, when the effect of solid opium is desired, the extract (*Extractum Opii*) is given, its morphine strength being eighteen per cent., and the dose from half as large to as large as that of powdered opium. The above-named are favorite forms for the administration of opium when it is desired to produce a constipating effect, to restrain intestinal peristalsis and relieve the pain dependent thereon, to relieve irritation dependent upon extreme purgation and irritant poisoning, and to stay nearly all forms of abdominal inflammation. In these cases the grain of opium is often combined with three or four grains of lead acetate. In this connection, the external employment of the "lead and opium" wash must not be forgotten. Its effect in relieving pain and averting or reducing inflammation in and underneath the skin are sometimes magical. It is made by dissolving one hundred and twenty grains of lead acetate in about ten ounces of water, adding one-half a fluidounce of tincture of opium, and water enough to make sixteen fluidounces. It should be shaken well before using.

The simple liquid preparations are the tincture (*Tinctura Opii*), or laudanum, the deodorized tincture (*Tinctura Opii Deodorata*), the vinegar (*Acetum Opii*), and the wine (*Vinum Opii*), all containing ten per cent. of powdered opium and between 1.3 per cent. and 1.5 per cent. of morphine, and exhibiting no important difference in physiological action, the selection being based chiefly on the basis of odor and flavor, and the ordinary dose of each being ten minims. Laudanum contains its opium in a mixture of equal volumes of alcohol and water. The deodorized tincture bears the same relation to laudanum that deodorized opium does to powdered opium. It is made from powdered opium, the deodorizing process being part of its manufacture. The vinegar contains three per cent. of nutmeg and twenty per cent. of sugar in dilute acetic acid. The wine is made with a mixture of white wine and fifteen per cent. of alcohol, and contains one per cent. each of cloves and cassia cinnamon. The action and uses of laudanum may be taken as the type of those of this group. It is used in cases similar to those in which opium is itself employed, but where a more prompt effect is desired. It is a favorite preparation for relieving the convulsions of puerperal eclampsia, as much as a fluiddrachm being often given and repeated once or twice if necessary. In some forms of hemorrhage connected with pregnancy or delivery, large doses are also commonly employed. Laudanum constitutes a favorite addition to poultices, for relieving superficial pain, and it is frequently rubbed in with liniment or applied with lime liniment to relieve pain when not deeply seated. In spite of the fact that absorption of morphine by the skin is slight, such treatment is of undoubted value. Laudanum is very commonly applied on pledgets of cotton to aching teeth or ears, though the latter treatment is not always to be recommended.

There are several mixed preparations of opium which

Digitized by Microsoft®

are of great importance, paregoric (*Tinctura Opii Camphorata*) being perhaps the most so. This preparation contains only 0.4 per cent. of opium, with the same amount each of benzoic acid, camphor, and oil of anise, together with four per cent. of glycerin in diluted alcohol. It has no alkaloidal standard. Paregoric constitutes a most excellent combination of a carminative with an analgesic, and is of the greatest value in relieving abdominal pains which present such indications. It is pre-eminently the form of opium for administration to children; but it is to be borne in mind that its continued administration, through the inattention rather than the direction of the physician, has frequently been the means of leading to the formation of an opium habit. The dose of paregoric is 4–15 c.c. (fl. ʒ i.–iv.).

The brown mixture or compound mixture of liquorice (*Mistura Glycerrhizæ Composita*) contains twelve per cent. of the camphorated tincture of opium with six per cent. of wine of antimony, three per cent. each of the extract of liquorice and the spirit of nitrous ether, five per cent. of syrup, and ten per cent. of mucilage of acacia. The dose is about 16 c.c. (fl. ℥ ss.). This preparation is in its nature somewhat similar to the Dover's powder, being a much used expectorant and diaphoretic, with distinct diuretic properties also.

Dover's powder (*Pulvis Ipecacuanhæ et Opii*) contains ten per cent. each of powdered ipecac and powdered opium in sugar of milk, the dose being 0.66 gm. (gr. x.), and the corresponding liquid, often spoken of as liquid Dover's powder (*Tinctura Ipecacuanhæ et Opii*), consists of ten parts of the fluid extract of ipecac in one hundred parts of the deodorized tincture of opium (corresponding to ten per cent. of opium), the whole reduced by evaporation to one hundred parts; the dose is ten minims. The last-mentioned two preparations constitute a remarkably useful combination of a diaphoretic with an analgesic and somnifacient action. In this diaphoresis both elements play their own peculiar part. An approaching "cold" can frequently be averted by a full dose of either, with a few hours' rest. An irritable cough, preventing rest, is relieved by the hypnotic effect, while the condition itself is benefited by the diaphoresis. The troches of liquorice and opium (Trochisci Glycyrrhizæ et Opii) each contain 0.15 gm. (about gr. ij.) of extract of liquorice, 0.005 gm. (gr. $\frac{1}{12}$) of powdered opium, with sugar, acacia, and a little oil of anise to flavor. They are very useful in allaying throat irritation and mildly promote expectoration. By adding a little ipecac or tartar emetic the effect of Dover's powder may be simulated in mild degree.

The following table exhibits the preparations of our Pharmacopœia and the proportion of opium in each:

OPIUM (NOT LESS THAN NINE PER CENT. MORPHINE).

- Powdered opium (thirteen to fifteen per cent. morphine).
  - Deodorized opium (fourteen per cent. morphine).
  - Deodorized Tincture ($\frac{1}{10}$ P. opium).
    - Tincture of ipecac and opium ($\frac{9}{10}$ deod. tincture opium, $\frac{1}{10}$ fluid ex. ipecac).
  - Pills of opium (1 grain in each).
  - Camphorated tincture. ($\frac{4}{1000}$ P. opium, camphor, etc.).
    - Compound mixture of liquorice ($\frac{12}{100}$ camphor. tincture opium, $\frac{6}{100}$ wine antimony).
  - Tincture of opium ($\frac{1}{10}$ P. opium).
  - Wine of opium ($\frac{1}{10}$ P. opium and aromatics).
  - Vinegar of opium ($\frac{1}{10}$ P. opium and nutmeg).
  - Powder of ipecac and opium ($\frac{1}{10}$ P. opium, $\frac{1}{10}$ ipecac).
- Extract of opium (eighteen per cent. morphine).
  - Plaster of opium ($\frac{6}{100}$ ex. of opium).
  - Troches of liquorice and opium (ex. of opium, $\frac{1}{20}$ grain each).

Henry H. Rusby.

OPIUM HABIT. See *Insanity: Drug Habituation and Intoxication.*

OPIUM, POISONING BY.—The poisonous nature of opium, and of the poppy, was known to the ancients as early as the time of Nicander (185–135 B.C.), who gives a clear description of the toxic effects of a "drink prepared from the tears which exude from poppy heads." Dioscorides, three centuries later, refers to the lethal effects of the poppy, and describes the method by which opium was then obtained, a method which does not sensibly differ from that which is practised at present. Pliny (A.D. 70) speaks of the toxic powers of opium, and cites the instance of Post. Licinius Cæcina, who, disgusted with life, terminated his existence with opium—an instance which was by no means singular, as the narrative concludes with "item plerosque alios."

In modern times (since 1600) we can find mention of but twelve cases of homicidal poisoning by opium or its preparations or derivatives, of which two were by laudanum and the remainder by morphin. Suicidal and accidental poisonings by the opiates are of very frequent occurrence. Probably thirty to forty per cent. of non-homicidal poisonings in the United States and in Great Britain are caused by these poisons. The widespread use of "soothing syrups" and other similar nostrums containing opium is unquestionably a factor in the high percentage of infant mortality.

SYMPTOMS.—The symptoms produced by opium and its preparations, and by morphin—acute meconism—are practically the same, whatever preparation of opium or salt of morphin may have been used. Other things being equal, however, morphin and its salts are more rapid in their action than opium or the preparations made from the crude drug.

The *time* at which symptoms manifest themselves is usually from half an hour to one hour after the poison has been taken. Frequently this period is much shortened. In children who have received large doses the poison sometimes begins to produce its effects within a very few moments or almost immediately. When the poison has been introduced by hypodermic injection, it acts more rapidly than when taken by the stomach. Opium in solution acts more promptly than the same substance in the solid form, and the salts of morphin are more rapid in action than the alkaloid itself. Opiates administered by the rectum are more rapid in their action than when given by the stomach. The symptoms appear earlier when the poison is taken while fasting than when it is taken upon a full stomach. In exceptional cases the interval between the taking of the poison and the appearance of its effects is very much shortened even in adults. Thus, 45 c.c. of Liquor opii sedativus has caused total insensibility in fifteen minutes, and death in an hour and twenty minutes. Cases have also occurred in which the action of the poison has been much retarded, although taken in solution. Thus, instances are recorded in which no symptoms were produced in nine, twelve, fourteen, and eighteen hours by 45, 15, 60, and 45 c.c. of laudanum.

The clinical history of acute morphin or opium poisoning may be divided into three stages.

The first period, that of increased nervous excitability,

Digitized by Microsoft®

is usually of short duration in the acute form of poisoning, although cases are recorded in which it has lasted fourteen and eighteen hours. It is frequently entirely absent, when large doses have been taken. This stage is marked by restlessness, great physical activity, loquacity, greatly increased imaginative power, frequently to the extent of hallucinations, always of a pleasing character, and by increased cardiac action. In adult males priapism sometimes occurs during this stage. Vomiting is also of occasional occurrence and greatly improves the patient's chances of ultimate recovery.

The condition of excitation passes, sometimes rather suddenly, into an intermediate stage of diminished excitability. The patient becomes weary, incapable of physical exertion, dull, and drowsy. He complains of a sense of weight in the extremities and an irresistible desire for sleep, to which he finally yields if not kept awake. The sleep is at first seemingly normal, though profound. The pulse and respiration are normal. The patient may be roused and sometimes kept awake by shaking him, by the infliction of pain, or by loud talking. The face is pale, the lips are somewhat livid, the surface is covered with perspiration, and the pupils are contracted. During this period the patient frequently experiences a violent itching of the skin, which is sometimes followed by the appearance of an exanthem which may be papular, red, bluish, or almost colorless, or resembling those of urticaria or of scarlatina.

The condition of somnolence is of short duration, and passes quickly into the stage of narcosis. The patient can no longer be roused, even by the most violent means. He lies motionless and senseless, with eyelids closed or partly closed. The surface is bathed in profuse perspiration, which exhales the odor of opium in opium cases. The face is pale, the lips are blue, the lower jaw is dropped, and the muscles are completely relaxed. The pupils are insensible to light, and contracted to the size of pinheads until death occurs, when they dilate. A few cases are, however, recorded in which the pupils were said to be dilated. At first the superficial arteries, temporals, and carotids are seen to pulsate fully, strongly, and rapidly, while the respiration is slow and shallow (eighty pulsations in the minute to four respiratory movements have been observed). Later, the pulse becomes feeble, slow, irregular, and easily compressible. The respiration becomes slow, shallow, stertorous, and accompanied by mucous râles. Retention of urine occurs early in the history, and continues until death or recovery.

From this period, if the case do not yield to treatment, the poisoning usually proceeds rapidly to a fatal termination. The surface of the body and even the expired air become cold. The skin is cyanosed and covered with a cold clammy perspiration. The pulse becomes slower, more feeble, and gradually imperceptible. The respiration is more shallow and feeble, while the râles become more pronounced. Individual muscles, or groups of muscles, are agitated by short clonic twitchings, and occasionally convulsions and tetanus occur. Later, the muscles become completely paralyzed, the respiratory movements are made at longer intervals and finally cease; the circulation continues after the cessation of respiration. Finally, the action of the heart is arrested and the patient dies quietly. Sometimes epistaxis and other hemorrhages occur toward the end; and in some instances death results from cerebral hemorrhage.

Should recovery follow after the stage of narcosis, the respiration gradually becomes more frequent and more natural, the pulse becomes first perceptible and then gradually passes toward the normal, while the condition of coma passes into one of deep sleep, which may continue for from twenty-four to thirty-six hours longer, although the patient can be roused.

In the great majority of cases in which recovery has progressed so far that the patient may be roused it will be complete. Nevertheless, occasional instances are recorded in which the victim has relapsed into a deeply comatose condition and has finally died.

In cases of recovery the patient, on awakening, is weary, giddy, and uncertain in his movements. He may also suffer for some hours from nausea and headache, and for a longer time from loss of appetite and derangement of digestion. In two cases Dr. Edes (*British Medical and Surgical Journal*, 1881, cv., 251) has observed the presence of casts in the urine; in one case, accompanied by albumin.

Duration.—In cases of fatal poisoning by the opiates death usually follows in from twelve to eighteen hours after the poison has been taken. Of 48 fatal cases, death followed within twenty-four hours in 43; within eighteen hours in 39; within twelve hours in 26, and within nine hours in 20. The minimum duration of the poisoning was forty-five minutes; and the maximum, fifty six hours.

Cases are recorded in which the symptoms of narcotism have disappeared and the patient has died at a greater interval of time than the above maximum. In such cases, although the death may have been accelerated by the action of the poison, the fatal result is immediately due to other causes. Thus, in a case quoted by Taylor, a patient suffering from disease of the heart took, in four hours, two hundred drops of laudanum, and was bled to the extent of thirty ounces. On the sixth day he was sufficiently recovered to undertake a journey, and died on the eleventh day. In this case the cause of death was failure of cardiac action, aggravated at least as much by loss of blood as by opium.

In cases of death in which the patient has suffered from a disease whose symptoms resemble those of opium poisoning, and has also received a large dose of an opiate, the question of duration may become one of considerable medico-legal importance. In a case which came under the author's observation a physician had given a child of four months gtt. x. of the Tinct. opii deodorata by mistake for Tinct. opii camphorata. The patient suffered from well-marked symptoms of opium poisoning, but under immediate treatment improved, and in forty-eight hours had apparently recovered. Death followed, however, in ninety hours from acute hydrocephalus.

Obviously, the same causes which influence the rapidity of action of the poison, and those which modify the effects of unusually large or small doses, will also influence the duration of the case, whether it terminate in death or in recovery.

Lethal Dose.—As the action of the opiates is much modified by conditions, such as age, habit, state of health, form of administration, and idiosyncrasy, it is impossible to fix a lethal dose applicable to all conditions. It may be said, however, that 0.065 gm. or gr. i., of morphin, or 0.1 gm. or gr. vi. of opium, would cause symptoms of poisoning in an adult not habituated to the drug, and possibly would cause death. Several instances of death from 0.2 to 0.26 gm (gr. iij.-iv.) of morphin (or laudanum equivalent) are reported. In other cases death has followed after doses as small as 0.032 (gr. ss.), but in these other causes were also operative or the report is unsatisfactory (see Witthaus and Becker, "Medical Jurisprudence," iv., 730).

On the other hand, numerous cases are on record of persons, not addicted to the opium habit, who have recovered from very large doses. The largest quantity of morphin certainly thus recovered from was 3.89 gm. (gr. lx.) of the acetate (Wood, *Boston Med. and Surg. Journal*, 1876, 82). Although the relative immunity in these cases of very large dose may be ascribed in some degree to an idiosyncrasy of the patients, their escape has been probably more largely due either to non-absorption of the poison or to rejection of the major portion by vomiting.

Infants and children are peculiarly susceptible to the poisonous action of opiates, even in very minute doses. Cases of death from small doses of laudanum are cited as follows: Gtt. iv. (equivalent to gr. $\frac{1}{6}$, 0.011 gm., of opium) in a child of nine months; the same quantity in a child of five weeks; gtt. v. (= gr. $\frac{1}{5}$, 0.013 gm.) per rectum in a child of eighteen months; gtt. viij., during eighteen hours, in four doses (= gr. $\frac{1}{3}$, 0.022 gm.),

www.libtool.com.cn
Digitized by Microsoft®

in a child of six weeks; gtt. iij. (= gr. $\frac{1}{4}$, 0.008 gm.) in an infant of two weeks; ♏iss (= gr. $\frac{1}{10}$, 0.0065 gm.) in an infant of three days; gtt. ij. (= gr. $\frac{1}{12}$, 0.0054 gm.) in an infant of five days; the same quantity in another of four days, ♏ i. (= gr. $\frac{1}{13}$, 0.005 gm.) in an infant of seven days; and gtt. i. (= gr. $\frac{1}{25}$, 0.0026 gm.) in an infant of six days. A dose of gr. iv. pulv. ipecac. et opii (= gr. $\frac{2}{5}$, 0.026 gm., of opium) has caused the death of a child of four and a half years. Huseman and Taylor refer to a case (Edwards) in which the amount that caused the death of a four-weeks-old child was as low as 0.006 gm. (= gr. $\frac{1}{10}$) of opium, taken in the form of the camphorated tincture.

www.libtool.com.cn

Even during this early period of life occasional instances of recovery from relatively large doses are met with. A case is reported by Dr. Corbet, in the *Lancet*, August 29th, 1857, p. 220, in which an infant of one day received ♏ xxx. (= 2.3 grains, 0.15 gm. of opium), yet recovered within ten hours. This case is of interest, as the age of the infant precludes the possibility of its having become accustomed to the drug, as was probably the case with a child of six months who recovered from a dose of a teaspoonful of laudanum (= 4.6 grains, 0.298 gm. of opium) (Simmonds), although treatment was delayed for an hour; and with another of nine months who recovered from a dose of two teaspoonfuls (= 9.2 grains, 0.596 gm.) of the same tincture.

The dosing of infants and young children with officinal or proprietary preparations of opium by mothers and nurses is widely practised. One of the results of the practice is the large percentage of deaths from opiates among young children. A tabulation of 144 cases of opium poisoning, taken chiefly from English and American journals, gives this result:

	Total cases.	Children less than one year.	Children less than five years.	Children less than ten years.
Laudanum	79	24	25	26
Opium	18	9	10	11
Morphin	34	3	5	5
Patented opiates	13	10	12	12
Totals	144	46	52	54
Percentage of total		32	36	37.5

From which it appears that about one-third of the reported poisonings by the opiates occur in children less than one year old.

The poisonous action of the opiates is very greatly diminished by habit, probably more than that of any other poison. The amounts taken by adult opium-eaters, laudanum-drinkers, and morphin-injectors are sometimes enormous. Cases in which the consumption reaches 2 gm. (grs. xxx.) of opium, or one-half, one, or even two ounces of laudanum (= 0.5, 1, 2 gm.), in twenty-four hours are of by no means uncommon occurrence. Such cases sink into insignificance when compared with that of De Quincey, whose daily draught of laudanum at one time reached nearly nine fluidounces (= about 20 gm. of opium). Krüger-Hansen relates the case of a patient who consumed in one year over 300 gm. of opium, a daily average of over 0.8 gm. (about gr. xiij.). Zeviani cites the case of a woman who, in thirty-three years, had taken over 100 kgm. of opium, equivalent to a daily average allowance of 8 gm. (= nearly gr. cxxv.); and as the dose is gradually increased by opium-eaters, the daily consumption in this case must have been much greater in the later years. Headland and Myers refer to instances in which gr. xviij. (= 1.16 gm.) of morphin were taken daily; and the author met with the case of a young man of twenty, of profligate habits, who had reached the same quantity, when he terminated his career with a large dose of potassium cyanid.

It is not to be inferred from these large amounts that an opium-eater can take an unlimited quantity of the drug without experiencing its poisonous action. It is simply a question of quantity—a quantity necessarily varying in each case,—and instances are of frequent occurrence in which the opium-habitué has experienced the symptoms of acute poisoning, and has even died from the effects of an overdose.

The tolerance of opiates acquired by habit is not confined to adults; it is also produced in quite young children. A remarkable case in point was published by Dr. J. L. Little (*American Journal of Obstetrics*, 1878, xi.). A male infant, suffering from acute inflammation of the knee-joint, followed by an abscess, began at three weeks of age with small doses of paregoric, gradually increased to a teaspoonful. Subsequently Tinct. opii was substituted, and then Magendie's solution of morphin, in doses gradually increased, until, when nearly eight months of age, the child took in one day two fluidounces of Magendie's solution (equivalent to 2.07 gm., gr. xxxij.) of morphium sulfate.

Treatment.—The treatment in cases of acute opium poisoning should be directed, first, to removal of unabsorbed poison from the stomach; and, second, to prevention of death by coma and cessation of respiration, until the processes of elimination have removed that portion of the poison which has been absorbed.

In the earlier stages of the poisoning, emetics are of value—zinc sulfate or ipecacuanha; or, if the patient be an obstinate suicide, apomorphin, hypodermically. On no account should tartar emetic, or any antimonial, be used as an emetic in this or any other form of poisoning. Stomach lavage is to be preferred to the exhibition of an emetic; particularly in the later stages, when, the patient having lost the power of swallowing, a hypodermic injection of apomorphin usually fails to provoke emesis. The siphon is to be preferred to an emetic, not only on account of its more certain and rapid action, but also because its use does not tend to increase the cerebral congestion as does the exhibition of the emetics. On the other hand, in some exceptional cases, in which opium in substance has been taken, an emetic may be necessary to remove masses too large to enter the pipe. In cases likely to lead to litigation, the material removed by the siphon should be preserved. The stomach having been emptied of its contents, the viscus is next to be well washed out, preferably with a solution (1 to 1,000) of potassium permanganate, about 500 c.c. of which are finally left in the stomach. This procedure is to be followed even when the poison has been taken hypodermically, as it is eliminated by the stomach.

If the case be seen before the stage of sopor has been established, it should be prevented, if possible, by keeping the patient in motion—walking him between two sufficiently robust assistants, preferably in the open air, if location and weather permit, but not in the direct sunlight. This "ambulatory treatment" has been beneficially prolonged in some cases for from six to eighteen hours. Under its influence sometimes the action of an emetic which has remained inert is brought about.

If the patient be already in a lethargic condition, he is to be roused without delay. This is best accomplished by cold affusions to the head, the body being kept warm and dry, flagellation to the palms and soles, or to the back with damp towels, or the use of the faradic current. When roused, the patient is to be kept awake as above.

Should the respiration have ceased or become very slow, it may frequently be stimulated by the application of the induced current, the positive pole being applied to the root of the neck over the point where the phrenic nerve crosses the scalenus anticus muscle, while the negative pole is carried laterally over the anterior attachments of the diaphragm. If the faradic current be not obtainable, or if it fail, artificial respiration is to be performed. To be of service this must be persisted in, in some cases, for many hours, and until normal respiration is again established. Dr. W. F. Cheatham has published (*North Carolina Medical Journal*, 1886, 20) a case in which this was the sole method of treatment. The respiration had ceased and the pulse was barely perceptible. Artificial respiration was applied. In thirty-seven minutes

Digitized by Microsoft®

the patient made an effort of respiration; in an hour and forty minutes the respiration was five per minute, though stertorous. In nine hours consciousness returned, and recovery followed.

If the case be at all prolonged, distention of the bladder and possibility of reabsorption are to be prevented by the use of the catheter. If this be done in a case in which there is www.libtool.com.cn of litigation, the urine so removed should be carefully preserved.

Little can be said in favor of the different drugs that have been used as so-called physiological antidotes. Atropin, which is so frequently administered as an antidote to opium poisoning, unquestionably dilates the pupils, but has little, if any, effect upon the respiration. Cases are recorded in which, although atropin has been given until the pupils were widely dilated, the respiration has ceased, and the patient has subsequently recovered by means of artificial respiration (see paper of Dr. Cheatham, quoted above).

Tinctura belladonnæ, strong infusion of coffee by the stomach or subcutaneously, extract of coffee, caffein, brandy, digitalin, chloral hydrate, veratrum viride, and jaborandi have been used as antidotes. The last named, or pilocarpin, may be of value to increase the elimination, and thus lessen the duration of the poisoning.

Post Mortem Appearances.—The autopsy reveals no lesions which are characteristic of opium poisoning, except, possibly, the odor of the drug. Obviously, if morphin have been the substance taken, or if other more powerfully odorous substances be present, this will not be observed. The surface of the body is livid. Rigor mortis is said to be of shorter duration than usual, although an autopsy is reported by Tardieu at which rigor mortis was well marked sixty-two hours after death. Putrefaction is said to be more rapid than usual. The blood is fluid and dark. The vessels of the brain and meninges are gorged with blood, and the cut surfaces of the brain substance present numerous dark red spots. The veins of the scalp are also filled with blood. Serous effusions are frequently met with between the membranes, more rarely in the ventricles. The lungs are usually congested. The stomach and other viscera are normal, so far as the action of the poison is concerned. The bladder is generally full of urine.

The congestion of the cerebral vessels and of the lungs are the most noteworthy appearances. Yet, as they may be absent in opium poisoning, and may be present when death has resulted from other causes, they are only of value as confirmatory evidence of the cause of death.

Analysis.—To detect the presence of morphin in the viscera after death, or in articles of food, it is necessary to separate that alkaloid in a condition of as near purity as possible. In cases of opium poisoning it is further necessary to search for meconic acid, and, if possible, for other of the opium alkaloids.

If the facts of the case do not point very distinctly to opium or morphin as the poisonous agent, the process of Dragendorff should be followed for the separation of the alkaloids (Dragendorff, "Ermittl. v. Gitten." 4 Aufl., 1895, 149-153).

If the indications of opium or morphin poisoning be sufficiently direct, the following simplified method for the separation of morphin and of meconic acid may be followed. The substances, if solid, are finely hashed and extracted several times with water containing one per cent. of hydrochloric acid at the ordinary temperature (if the materials be alkaline, the proportion of acid is to be increased to such an extent that the liquid, when in contact with it, retains its acid reaction). The aqueous extracts are filtered and shaken with amyl alcohol three or four times, and oftener if necessary, until the amylic alcohol is no longer colored, and the alcoholic layers separated. If the substances under examination be liquid, they are to be rendered acid with hydrochloric acid, filtered, and the filtrate treated with amyl alcohol. The amylic solution now contains meconic acid, if present in the objects examined; and the watery solution, the alkaloids as chlorids. To separate meconic acid the amyl-alcohol solution is shaken with successive portions of water, which are separated, until the water is no longer colored. The alcohol is evaporated over the water-bath; the residue extracted with hot water; the solution filtered hot; the water evaporated over the water-bath; the residue extracted with alcohol; the solution filtered, and the alcohol evaporated. The tests for meconic acid are finally applied to a portion of the last residue. During this treatment a small portion of the meconic acid is converted into comenic acid, which does not, however, interfere with the tests.

To separate morphin from the aqueous liquid above mentioned, the hydrochloric acid is neutralized completely with ammonia, and the liquid rendered distinctly acid with acetic acid, and evaporated over the water-bath to the consistency of a syrup. The residue is extracted with four or five volumes of ninety-per-cent. alcohol and filtered. The filtrate is freed from alcohol by distillation. The residue, diluted with a small quantity of water, if thick, is heated to 50° to 60° C., an equal volume of amyl alcohol* is added and then sufficient ammonium-hydroxid solution to render the solution distinctly alkaline. The mixture is next strongly shaken at intervals for half an hour, the amylic alcohol separated, and the extraction of the aqueous liquid with amylic alcohol repeated three times. The united amylic solutions are evaporated to dryness; the residue is extracted several times with warm (not hot) water slightly acidulated with sulfuric acid, and the solution filtered. Upon the acid filtrate is floated a mixture of ten parts absolute ether and one part (ninety-five-per-cent.) alcohol; ammonium-hydroxid solution is added to alkaline reaction, and the whole strongly agitated. The ether-alcohol layer is separated; the extraction of the, now alkaline, aqueous liquid is similarly repeated several times, and the ether-alcohol evaporated in a number of small watch glasses. To portions of the residue so obtained, either dry or dissolved in a few drops of water, as the nature of the test may require, and now sufficiently freed from coloring and other foreign substances, the tests for morphin are to be applied.

Tests.—I. *Morphin.* 1. With the general reagents for the alkaloids, the morphium salts give reactions as follows, the fractions indicating the maximum of dilution in which the alkaloid is capable of reacting: With *phosphomolybdic acid*, yellowish, amorphous precipitate, $\frac{1}{5000}$; with *iodin in potassium-iodid solution*, red-brown, amorphous precipitate, $\frac{1}{5000}$; with *potassium and bismuth iodid*, amorphous precipitate, subsequently changing to silky needles, $\frac{1}{5000}$; with *auric chlorid*, lemon-yellow precipitate, becoming darker; with *phosphotungstic acid*, flocculent precipitate, $\frac{1}{1000}$; with *potassium iodhydrargyrate*, yellowish, amorphous precipitate, $\frac{1}{1000}$; with *platinic chlorid* slowly, yellow, crystalline precipitate, $\frac{1}{100}$; with *picric acid*, bright yellow, amorphous precipitate, $\frac{1}{100}$; and with *tannic acid*, a faint cloudiness, becoming somewhat thicker on standing. For the above tests the solutions of the alkaloidal residue are to be made with very dilute sulfuric acid, and the reagents should be as nearly neutral as their natures will permit.

2. Morphin dissolves in concentrated nitric acid with an orange-red color, which gradually changes to yellow. Addition of stannous chlorid solution does not change the color of the yellow solution to violet, as it does with the similar color obtained with brucin. Limit, 0.01 mgm.

3. Morphin dissolves in concentrated sulfuric acid, forming a colorless solution. If this solution be heated over the water-bath for an hour, and allowed to cool, or, preferably, if it be allowed to stand in a desiccator twenty-four hours, and then treated with a trace of nitric acid or a minute granule of saltpetre, a beautiful violet color is produced, which soon changes to purple-red, and then gradually fades. Limit, 0.001 mgm. (A. Husemann).

A further portion of the sulfuric-acid solution, if

* It is absolutely essential that the amylic alcohol used should be purified, *shortly before use*, by repeated redistillation, until a portion, on evaporation, yields no residue capable of reducing iodic acid.

Digitized by Microsoft®

treated, after warming and subsequent cooling as above, with a small fragment of potassium dichromate, assumes a mahogany-brown color (J. Otto).

4. A fragment of solid morphin moistened with a solution of ferric chlorid, as neutral as possible (best obtained by dissolving the chlorid obtained by the dry method in water), assumes a brilliant blue color.

For the success of this test it is essential that the morphin salt be as free from impurities as possible, that little or no free acid be present, and that but a small quantity of the reagent be used. The color gradually changes to green and brown (Robiquet). Limit, 0.1 mgm.

5. A fragment of morphin moistened with Fröhde's reagent (a freshly prepared and colorless solution of 5 mgm. sodium or ammonium molybdate in 1 c.c. sulfuric acid) colors the reagent violet in a short time. The color changes to blue, and then to dirty green, and, finally, to faint reddish. Addition of water discharges the color instantly. Limit, 0.005 mgm.

6. Dissolve a small quantity of iodic acid in a few drops of water, in a small test tube, and agitate with a few drops of chloroform; the latter must remain colorless. Add the solution to be tested, and again agitate. The chloroform, which settles to the bottom, has a violet color, in the presence of morphin, while the aqueous layer is yellowish. Now float upon the surface of the liquid dilute ammonium hydroxid, with as little mixing of the liquids as possible; a brown band is formed at the junction of the ammoniacal and aqueous liquids (Serullas, Duflos, Lefort). Limits: For the violet color of the chloroform, $\frac{1}{7000}$; for the dark band with ammonium hydrate, $\frac{1}{10000}$.

This reaction is also produced by reducing agents other than morphin.

7. Dissolve the solid in warm, concentrated hydrochloric acid containing a little concentrated sulfuric acid, and heat in an air oven at 110° to 120° C. In the presence of morphin a purple color is produced, still visible in the presence of the accompanying carbonized matter. After evaporation of the hydrochloric acid, a further quantity of the dilute acid is added, and the mixture neutralized with sodium bicarbonate in slight excess; a cherry red color is produced, which changes to a dirty-greenish hue as the point of neutrality is reached. On addition of a few drops of a dilute alcoholic solution of iodin, the color changes to green, and the pigmentary substance now dissolves in ether with a purple color (Pellagri).

The reaction is due to the formation of apomorphin, and is consequently also observed with codein.

Many other tests for morphin are in use; the above are, however, sufficient. No one of them is in itself characteristic.

II. *Narcotin.* The reactions of the alkaloids of opium other than morphin are at present of but little toxicological interest, as they are substances which are not commonly met with, and hence are unlikely to cause poisoning. For the purpose, however, of distinguishing between morphin and opium poisoning by analysis (a distinction which may be of medico-legal importance), the reactions of narcotin and of meconic acid (see below) are taken advantage of. Narcotin is chosen from among the other opium alkaloids for this purpose, partly because it is more abundant in opium, and partly because of the sharpness of its reaction with sulfuric acid.

If the Dragendorff method have been followed, narcotin should be searched for in the residue of evaporation of benzene from the alkaline solution.

1. Of the general reagents for the alkaloids, phosphomolybdic acid, potassium iodhydrargyrate, iodin in potassium iodid, and picric acid give precipitates in solutions of $\frac{1}{1000}$ to $\frac{1}{3000}$.

2. Moistened with concentrated sulfuric acid at the ordinary temperature, narcotin produces an intensely yellow solution, which, on gradual heating, changes to orange, then, beginning at the borders, blue-violet, and, when the heat has been raised to the point of volatilizing of the acid, dark red. The colors are presented more slowly, but more purely, by dissolving the residue in dilute sulfuric acid and evaporating quite slowly (Couerbe, Husemann). Limits: $\frac{1}{2000}$, very evident; $\frac{1}{10000}$, faint carmine only.

3. Dissolve in concentrated sulfuric acid, let stand an hour, and add a trace of nitric acid; a red color, which for some time increases in intensity.

III. *Meconic Acid.* 1. Crystallizes in white, glistening prisms, either single and large, or small and arranged in bundles, which at 100° C. lose their water of crystallization and become opaque. If heat have been applied to the solution in the presence of acids, the shorter, prismatic crystals of comenic acid will be also observed.

2. Meconic acid, or a meconate in solution, gives white or yellowish precipitates with lead acetate, silver nitrate, mercurous nitrate, and mercuric nitrate.

3. The characteristic reaction of meconic acid is the formation of an intense red color when the acid or one of its salts is moistened with a solution of ferric chlorid (Sertürner). The color does not disappear either on warming or on the addition of hydrochloric acid, or of auric chlorid, or of mercuric chlorid.

Comenic acid gives the same reaction. It can only be present as a product of decomposition of meconic acid. Acetic and thiocyanic acids and their salts also give a red color with ferric chlorid. The former may be present as a normal food constituent, and the latter is present in the saliva in quantity sufficient to give the reaction without any preliminary purification. The red color, however, produced by acetic acid is discharged by heat or by the addition of hydrochloric acid, and that due to the thiocyanate disappears instantly on addition of auric chlorid or of mercuric chlorid solution.

FAILURE OF DETECTION.—As morphin is oxidized to oxydimorphin in the body, more or less completely according to the magnitude of the dose, it is usually eliminated in cases of poisoning as a mixture of oxydimorphin and morphin, both of which respond to the reactions given above. This elimination is principally by the alimentary canal and only in traces by the urine, whatever may have been the channel of introduction. Therefore the stomach and intestinal contents, or the product of stomach lavage, are the situations in which the poison will most probably be detected, and we may expect to find it in the urine only when very large doses have been taken. It has also been detected in the liver and kidneys in several instances, but very rarely in the brain. The detection of morphin is by no means certain, and carefully conducted analysis may fail to show its presence in the cadaver after undoubted poisoning by it, even when the stomach has not been washed out and vomiting has not occurred.

Although morphin is more subject to decomposition than strychnin, it still withstands the influence of putrefaction quite well. In a case cited by Woodman and Tidy it was detected four months after death; and Stas gives an account of a case in which he detected morphin in all the organs of a body after thirteen months of burial.

In cases of long burial, caution is required that ptomaïns be not mistaken for morphin, as occurred in an Italian case, in which Selmi showed that what a careless analyst had taken for morphin was in reality a ptomaïn (Selmi, "Sulle Ptomaïne," 1878). Such a mistake is impossible, if the tests described above are carefully applied (see Witthaus and Becker, "Med. Jur.," iv., 760–769).

Rudolph A. Witthaus.

OPTIC NERVE. See *Eye.*

OPTOMETRY—from ὀπτ-, root of ὄψομαι, fut. of ὁράω, to see, and μέτρον, measure—signified, in its older use, the measurement of the range of vision (*die Gesichtsweite*). With the attainment of broader and more accurate knowledge of the physiology and pathology of vision, quantitative methods have been applied to the investigation of other visual functions, and we now recognize, as parts of one general subject, the measurement

FIG. 3691.

Eidoptometry—from εἶδος, form—deals with the measurement of the acuteness of the visual perception of form—*visus*, V.; German, *Sehschärfe*, S. Assuming an adequate illumination and a sharply defined retinal image, the physiological limit of the acuteness of vision is determined by the fineness of the mosaic formed by the cones of the retina at the fovea centralis. Let *d d* (Fig. 3691, *B*, from Helmholtz) represent the mosaic of retinal cones at the macula, and *a*, *b* and *c* the images of three vertical bars of a grating for which the eye is accurately accommodated. When the grating is removed to such a distance from the eye that the image of each bar does not much exceed the diameter of one of the retinal cones the several images appear more or less distorted or beaded, according as they happen to fall upon one or another, or perhaps upon two, of the cones lying nearest to their tracks. With the bars and interspaces of the grating each of a width of 0.4167 mm., the appearance shown at *A* begins to be manifest when the grating is removed to a distance of 1.1 to 1.2 metres (Helmholtz). This corresponds to a width of about 0.005 mm. in the retinal image for each bar of the grating, and to a visual angle of about 1.2′; it also indicates a very close approximation of the width of the image to the diameter of the retinal cones at the macula (0.0045 to 0.0054 mm.). Observations on the smallest angular distance at which two fixed stars of lesser magnitude (Hooke) or the bars of a grating (Helmholtz) can be positively distinguished by the naked eye, point also to an angle of about 1′ as the normal limit of distinct retinal perception.

The first serious attempt to apply a system of exact measurement to the clinical determination of the acuteness of vision was made by E. Jaeger. Jaeger's *Strichscale*[2] consists of a series of lines diminishing in length and in width from No. 1, with a width of 0.4597 Vienna inch, to No. 80, with a width of 0.0037 inch; the measure of the acuteness of visual perception is the narrowest line which can be positively distinguished at the distance at which the observation is made. Thus a normally acute eye sees No. 5 at 100 feet; No. 30 at 20 feet; No. 80 at 1 foot, etc. Unfortunately, the ratio of gradation adopted by Jaeger is such that the numbers do not indicate the relation of individual measurements to the normal. Moreover, the determination turns entirely on the unchecked statement of the person examined, that he sees the lines down to a certain place in the scale. The results of numerous and characteristically careful measurements made by Jaeger with this scale point to a visual angle of about 1′ as the limit of distinct recognition of the individual lines by a normal eye.

Snellen[3] was the first to work out a system of measurement adequate to the needs of the ophthalmic practitioner. Assuming a visual angle of 1′ as the average limit of distinct vision in the normal eye, Snellen constructed, upon this basis, a number of capital letters of sizes corresponding to seventeen different distances, ranging from 200 Paris feet (No. CC.) to 1 foot (No. I.). Each square letter, viewed from its appropriate distance, subtends a visual angle of 5′, and each letter is made up of lines subtending each an angle of 1′. The ultimate elements from which the several square letters are constructed are small squares, each subtending an angle of 1′; and twenty-five of these smaller squares are equal in area to the larger square in which the letter is inscribed. Only such letters are used as can be drawn approximately within the compass of a square, and even of these scarcely any two are of absolutely equal legibility; still, the difference is not so great as to impair the practical usefulness of the method, and the recognition of only a part of the letters in any line affords the means of making a finer discrimination than if only the more easily recognizable letters of the alphabet were used. Furthermore, certain of the letters often appear under characteristically modified forms when viewed by an astigmatic eye; D sometimes looking like B, O like the numeral 8 or like S, H like N, V like W, etc. The test of perfect recognition of form is the correct naming of all the letters at the distance corresponding to the number. Representing the greatest distance at which all the letters in any given line are recognized by *d*, and the greatest distance at which the same letters are seen by a normally acute eye by D, the measure of the acuteness of vision in any particular case is expressed in the fractional form $\frac{d}{D}$. The adoption of this simple and very convenient system was immediate and general; it remains the only method suited to the daily requirements of the practitioner.

The system of Snellen admits of but little further development; simple geometrical figures[3] and representations of familiar objects of characteristic outlines[4] are of use in examining children or illiterate persons. The substitution of a scale based on distances taken in metres instead of in Paris feet was made by Snellen in 1875.[5] The simpler form of letters known to printers and sign painters by the inappropriate name of "Gothic"[6] has been tried instead of the "block-letter" used by Snellen, and a regular ratio of gradation in geometrical progression[7] has been employed in the place of his somewhat arbitrarily selected series of numbers* (see Plate XLVIII.); a notation expressed in tenths of the normal, and therefore capable of being expressed in decimal form,[8] has also been somewhat extensively used.

For testing the perception of form at short distances, printed texts are in general use; such texts were first published by Jaeger[9] in a great number of different languages and in various kinds of type. Jaeger's smallest type (No. 1, = "gem" or "brilliant"), read fluently at a distance of one foot, is a pretty severe test of normally acute vision conjoined with good power of accommodation for the reading distance. Jaeger's numbers have no definite significance, beyond the fact that the higher numbers indicate the larger sizes of letters; still it is more convenient to employ even an arbitrary standard than to use the somewhat uncertain nomenclature of the type-founders.

Photoptometry—from φῶς, light—is comparatively little employed in the ordinary routine of ophthalmic practice, yet it is not without positive value in the diagnosis of impaired function of the retina. Two principal types of photoptometers have been used, each of which has its special applications.

A rapidly rotating disc, upon which a smaller or larger sector (Masson),[10] or a row of short lines arranged along a radius (Donders),[11] is depicted in black upon a white ground, or in white upon a black ground, presents the appearance of a shaded surface, or of a number of concentric shaded rings diminishing in intensity toward the periphery of the disc. Whenever the width of the black line is less than $\frac{1}{360}$ of the circumference of an imaginary

* The card of test-letters shown in Plate XLVIII. is constructed on the basis of a constant ratio of gradation, $\sqrt[3]{2} = 1.26$; the Arabic and Roman numerals denote, respectively, the distances in metres and in feet at which the letters should be distinguished by a normal eye. For convenience, the foot has been taken as equal to one-third metre, which is a little more than the Paris foot. In the arrangement here reproduced only a single letter is given for each number of the scale. The construction of the individual letters is slightly altered from that adopted by Snellen, with a view to somewhat more uniform legibility of the different letters.

Digitized by Microsoft®

circle drawn through it, the shaded ring is ordinarily so faint as to be no longer perceived by a normal eye in average daylight within doors (Helmholtz).[12] The acuteness of light perception, in any particular case, is indicated by the number of the concentric rings seen when the disc is rapidly rotated.

The photoptometer (*Lichtsinnmesser*) of Förster[13] is a closed box one foot long, eight inches wide, and six inches high; at one end are two openings for the eyes, and a window, about two inches square, covered with translucent white paper. Behind this paper diaphragm is a small lantern, enclosing a candle of standard illuminating power. The quantity of light which enters the box is determined by the area of the paper diaphragm, and this is regulated by means of two notched plates of metal sliding over each other so as always to leave a square opening whose area may be read off from a graduated scale. At the opposite end of the box is placed the test object, a card showing alternate black and white stripes of from 1 to 2 cm. in width. The measure of the acuteness of the perception of light (L) is the quotient of h, the smallest area of the window required for the recognition of the stripes by a normal eye, divided by H, the smallest area which suffices for the recognition of the same stripes by the eye under examination. According to Förster's observations, made with an instrument of the construction just described, $h = 2$ sq.mm., giving the value, $L = \frac{2}{H} = \frac{1}{\frac{1}{2}H}$.

Chromatoptometry—from χρῶμα, color—as applied to the diagnosis of defective color perception, has been discussed under the title *Color Perception*, Vol. III., pp. 208–217. Approximate measurements of the acuteness of color perception may be made with Snellen's test letters, printed in vivid colors on a black ground; or similar white letters on a black ground may be strongly illuminated by colored light.

The principle of simultaneous contrast may be utilized as a qualitative test of color perception. Thus the shadow cast by any small opaque object upon a white ground appears of a color complementary to that of the light. The test may be made in the dark room appropriated to ophthalmoscopical examinations, by placing a sheet of colored glass in front of the lamp and directing the attention of the patient to the color of the shadow cast by a pencil, or by a small opaque card, upon a white screen.

Perioptometry—from περί, around—is properly the measurement of the limits of the visual field in its several dimensions; it includes also the detection and measurement of defects in the field of vision (scotomata), wherever they may be situated. The simplest, and for many purposes the best, method of testing the central portions of the field, up to a distance of about 45° from the point of fixation, is by means of a blackboard or a large sheet either of dark or of white paper, upon which a central point of fixation is marked by a small cross, +. The patient is placed at a measured distance from the board (usually one foot), and is directed to look with one eye (the other being covered) at the central cross. A bit of chalk or crayon, fixed to the end of a short wand of the same color as the board or paper, is then moved from the periphery toward the centre of the field, until it reaches a point at which it is seen by the patient. The observation is repeated for other ocular meridians in succession, until the boundaries of the field have been determined at a number of points sufficient to admit of drawing a continuous outline through them.[14]

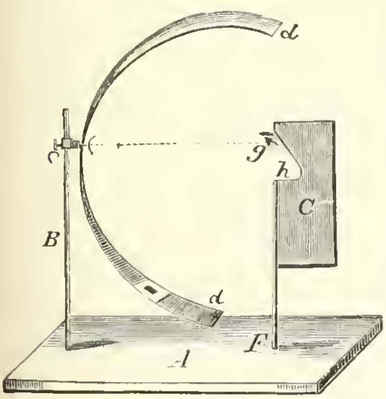

FIG. 3692.

For mapping the periphery of the field, when of nearly normal extent, a plane surface is insufficient, and

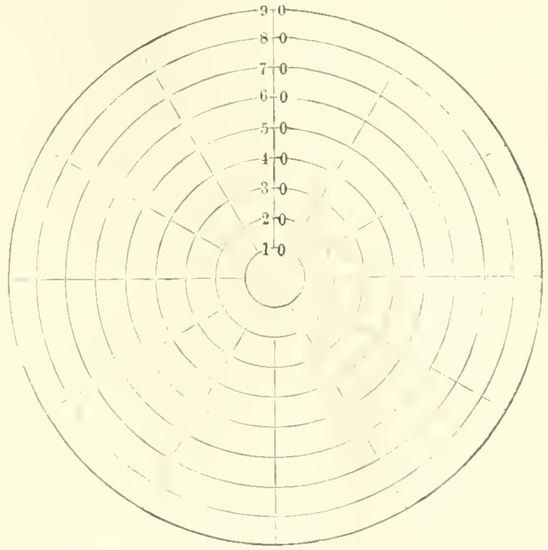

FIG. 3693.

for all distances greater than 45° from the point of fixation the distortion of the peripheral portions of the chart becomes excessive. For the projection of the entire field, with all its parts in due proportion, we require a hemispherical background instead of a plane surface; to this end we make use of the *perimeter*,[15] which is merely one-half of a broad blackened hoop, upon the inside of which the angular distance of any point of the fundus, lying in the meridian corresponding to the direction of the hoop, may be noted (Fig. 3692). By turning the hoop about a central pivot as an axis, it is brought into the necessary position for the observation of the extent of the field in different meridians; each point, as determined, is transferred to a blank chart printed, in concentric circles (Fig. 3693).

For the direct mapping of the visual field in its entire extent the perimeter of Scherk[16] has been devised; it consists of a hollow hemisphere, of one foot radius, blackened on the inside. The eye to be examined is placed at the centre of the sphere, and the limits of the field are marked with chalk in the same manner as when the blackboard is used. For greater convenience the hemisphere is made in separable halves, and the mapping is done for one-half of the field at a time.

Most of the perimeters, as found in the shops, have an arrangement of cords and pulleys, by means of which the test object is moved along the arc; this is a complication of at least doubtful advantage. A further complication consists in a self-registering apparatus, analogous to that employed in the "*conformateur*" used by hatters to prick a small diagrammatic outline of the shape of the head. For practical utility the arrangement in use at the Utrecht clinic is to be commended; it consists of a blackboard, about three feet square, to the centre of which is pivoted a removable half-hoop of one foot radius; the blackboard serves for the direct mapping of limitations of the field within the limits of 45° from the point of fixation, and the arc is used for peripheral measurements. The divisions of the arc between 0 and 45° are projected upon the board in circles whose radii are equal to the tangents of the respective angles.[17] The

www.libtool.com.cn
Digitized by Microsoft®

half-hoop of the perimeter is usually made of brass, and is rather heavy; one-half of a hoop of a cheese-box, stiffened at the back by a piece of thin board sawed to the proper curve, answers every purpose in practice; the points are determined by moving a bit of chalk or a small square of white cardboard along the blackened arc.

FIG. 3694.

Instead of the small square of cardboard a small electric lamp, the intensity of which may be regulated at will by means of a rheostat or by varying the internal resistance of the battery, may be used in determining the limits of the visual field in cases of cataract or other obscuration of the media; a candle may be used for the same purpose.

For testing the limits of the field for color perception, small pieces of colored cardboard, usually 1 cm. square, are used instead of the bit of chalk or square of white card. A small convex mirror of very short radius of curvature, such as the bulb of a thermometer, may also be used to reflect white or colored light from a lamp placed a little above and behind the patient's head.

The perception of form in the peripheral regions of the retina is tested by means of two small black squares on a white ground, with an interspace equal to one of the squares (Fig. 3694). These squares, of sizes corresponding to the thickness of the limbs of Snellen's test letters (Nos. XX. to C.), are moved along the arc of the perimeter toward the centre of the field, until the white interval is seen between the two black squares.

Dioptometry—from διά, through—has to do with the eye considered as an optical instrument, with especial reference to the detection and measurement of the different anomalies of refraction and accommodation. The detection, measurement, and correction of the several anomalies of refraction and accommodation are treated in this HANDBOOK under the titles, *Accommodation and Refraction*, *Astigmatism*, *Hypermetropia*, *Myopia*, and *Presbyopia*.

Dioptometry is either objective or subjective, according as the investigation turns upon observations made by the examiner or by the person examined. The objective methods are of the wider applicability, inasmuch as they may be employed in cases in which the patient is incapable either of making accurate observations or of accurately reporting his observations; subjective determinations have, on the other hand, the special advantage that they are the actual measurements of the function performed by the eye under examination. Objective examination affords, in many cases, the readiest means of discovering and of approximately measuring a refractive anomaly, and is often of service as a guide to the examiner in the conduct of such tests as require the active co-operation of the patient.

In objective examinations the chief dependence is upon the ophthalmoscope (see *Ophthalmoscope*, also *Shadow-Test*). A second method, based upon the observation of the images formed by reflection at the anterior surface of the cornea, and therefore suited to the detection of deviations from normal curvature of the first and most important of the refracting surfaces of the eye, demands notice in so far as it may be employed in clinical investigations.

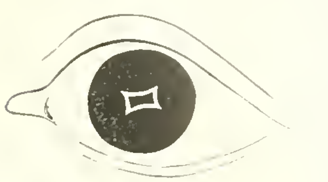

FIG. 3695.

The image of a luminous point or small flame, as it is seen mirrored by a cornea of irregular curvature, undergoes conspicuous changes of form according as the reflection is from one or another part of the corneal surface. This is especially noticeable in irregularity of contour resulting from the cicatrization of a corneal wound or ulcer, or from distention of the corneal tissue as a result of softening from disease. It is also very characteristic in keratoconus (conical cornea), in which affection the principal image remains nearly in one position, at the rounded vertex of the cone, whatever the direction from which the light is thrown upon it. When the light falls upon the cone from the side, two images are often seen, the one small and nearly central, corresponding to the vertex of the cone, the other lateral and distorted, formed by reflection on the side of the cone nearest the light. In regular astigmatism, in which asymmetry of the cornea is ordinarily the most important factor, the image of the point of light appears drawn out in a direction corresponding to one of the two principal meridians; when two lights are used, their images will be seen to be appreciably nearer together when they lie in the plane of the corneal meridian of greatest refraction than when they lie in the plane of the meridian of least refraction. Inasmuch as the distance which separates the two images is determined by the corneal curvature in the meridian in which they lie, it is possible, by measuring this distance, to obtain the necessary data for calculating the radius of curvature. The ophthalmometer of Helmholtz,[18] adapted by Donders and Middelburg[19] to the investigation of the curvature of the cornea in its different meridians, is an instrument by the aid of which such measurements may be made with almost the accuracy of an astronomical observation.

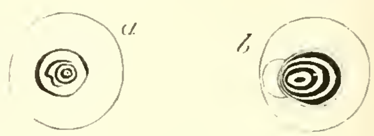

FIG. 3696.

If a rectangular white card is held at a distance of a few inches in front of an eye, the image, as seen reflected on the cornea, will appear more or less distorted whenever the corneal curvature is either irregular or asymmetrical. The most striking distortions are observed in conical cornea and in astigmatism; in the former condition the four straight sides of the card appear incurved in the direction of the vertex of the cone (Fig. 3695); in the latter condition a square card is reflected as a parallelogram, and a circular card as an oval.

This experiment is further developed in the keratoscopic disc of Placido,[20] a circular card or metal disc, about 23 cm. in diameter, with concentric rings painted in black and white upon the side turned toward the eye to be examined. The observer, looking through a central hole in the disc, sees an image formed by reflection on a large central area of the cornea; the effect of any asymmetry or distortion of the reflecting surface is revealed by a characteristic asymmetry or distortion of the image (Fig. 3696).

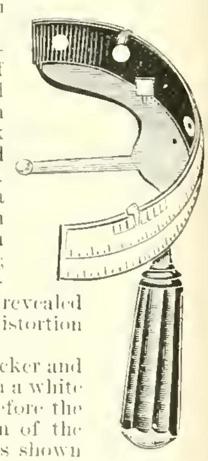

FIG. 3697.

In the "astigmometer" of De Wecker and Masselon[21] a square black card with a white border 1.5 cm. in width is held before the eye to be examined, and the form of the image of the white border noted, as shown in Fig. 3695.

The ophthalmometer of Javal and Schiötz[22] is a simplification of the Donders-Middelburg modification of the ophthalmometer of Helmholtz; instead of lights, special test objects (*mires*) of enamelled metal are used, and the images are viewed through a small telescope which contains a doubly refracting prism, by means of which the images are doubled and brought into such relation to each other that their mutual distance can be ascertained at a glance. The several parts of the instrument are so proportioned that the refraction for any meridian may be read off in dioptries without the trouble of making calculations (see *Ophthalmometer*).

In the ophthalmophakometer of Tscherning (1900), small adjustable electric lamps are carried on an arc like

www.libtool.com.cn
Digitized by Microsoft®

that of the Javal-Schiötz ophthalmometer. By means of this instrument Tscherning has succeeded in measuring the curvatures of the posterior surface of the cornea and of the two surfaces of the crystalline lens. The ophthalmophakometer, like the ophthalmometer of Helmholtz, is adapted rather to accurate research work in the physiological laboratory than to clinical use.

www.libtool.com.cn

FIG. 3698.

The *arc keratoscopique* of De Wecker and Masselon (Fig. 3697)[23] is a simplification of the ophthalmometer of Javal and Schiötz; a number of small white discs, arranged at equal distances upon a blackened arc like the arc of a perimeter, give reflections in which the interspaces are nearly equal when the curvature of the cornea is regular, but unequal when the curvature changes from the centre toward the periphery (Figs. 3698 and 3699). The instrument is especially adapted to the detection of conical cornea.

In subjective dioptometry we distinguish methods which turn upon the recognition of the forms of test objects, such as the test letters of Snellen, and methods in which the accurate recognition of form is not required.

In any case in which the acuteness of vision is normal, the detection and measurement of simple ametropia (H or M) may be made by means of trial glasses used in connection with the test letters of Snellen. Having placed the patient at a measured distance of 5 metres from the card of test letters, we note the smallest line of letters which he is able to read correctly with the unaided eye. If by this test we find V. = $\frac{5}{5}$, the presence of myopia of any grade in excess of 0.02 dioptrie is excluded, and the eye is either practically emmetropic or hypermetropic with accommodative power in excess of its hypermetropia (A > H). To decide between these two possible conditions we place a weak convex glass before the eye and note whether there is any falling off in the acuteness of vision at the distance of the test card. If we still find V = $\frac{5}{5}$, the presence of some degree of hypermetropia is established, and we exchange the convex glass for another of greater power, until we have hit upon the strongest convex glass through which V remains at the normal standard $\frac{5}{5}$. The value of this convex glass in dioptries* is the measure of the manifest hypermetropia.

Whenever, by the use of the test letters, we find V < $\frac{5}{5}$ we suspect the presence of myopia, and proceed at once to try the effect of a weak concave glass. If V is improved by this glass we try stronger glasses in succession, until we have found the weakest concave glass through which V = $\frac{5}{5}$. The value of this concave glass in dioptries† is the measure of the myopia (M), or possibly of the myopia augmented by some degree of abnormal tension of the accommodation.

In order to measure the total hypermetropia (Ht), and sometimes, also, to obtain the true measure of a myopia, it is necessary to bring the eye under the full influence of one of the stronger mydriatics, and to repeat the examination with the test-letters. The problem is so far simplified by the suppression of the accommodation that it is now only a question of what glass, whether convex or concave, raises V to its maximum at the distance of the test card.

If no glass suffices to raise V to the normal standard of $\frac{5}{5}$, and especially if the patient is in doubt as to which of several glasses of somewhat different power gives the best visual result, we may suspect the presence of astigmatism. The special methods used for the detection and measurement of astigmatism have been described under that title (see *Astigmatism*).

A large collection of trial lenses is an indispensable part of the armamentarium of the ophthalmic practitioner, and it is convenient to include in it the full range of numbers as found in commerce, or for which grinding tools are kept by the working opticians. With such a series of spherical lenses (in pairs), ranging (through zero) from + 20 to − 20 dioptries, and a full series of cylindrical lenses (in pairs), ranging from + 10 to − 10 dioptries, it is possible to correct almost any case of simple hypermetropia, myopia, or astigmatism by means of a single glass for each eye, and, similarly, to correct any case of compound or of mixed astigmatism by means of a combination of two glasses for each eye. The lenses of the trial case should be accurately centred, and set in brass cells turned with a thin projecting flange (like the wheels of a railway carriage) so that any two may be provisionally mounted, with the two flanges in contact, in a trial frame made with a single groove.[24] In the higher numbers of each series the lenses should be of the plano-convex and plano-concave form, and they should be so set in their cells as to bring their plane surfaces very nearly in contact when any two lenses are used in combination, thus making it possible to build up any desired double convex, double concave, or periscopic lens, or by combining a plano-spherical with a plano-cylindrical lens, to build up any required spherico-cylindrical lens with the same combination of surfaces as in the lens to be prescribed.*

The trial frames should be of the lightest practicable weight and of the simplest possible construction. For most purposes a single groove, made wide enough to receive the thin flanges of two lenses, is sufficient. A dozen or two of such frames, of different widths and height of bridge, costs no more than one or two of the complicated and less convenient trial frames shown in almost endless variety in the catalogues of the manufacturing opticians.

By enlarging the series of test letters through the addition of a few numbers, so as to extend its range to say 0.1 metre, the position of the near-point (p) may be approximately determined by direct observation. Oftener, however, we determine the position of p after having provisionally corrected the eye for distant vision by means of glasses; for practical purposes it is generally sufficient to measure the distance (P_2) of the binocular near-point (p_2) from the anterior nodal point of the eye (see *Accommodation and Refraction*).

It is possible to use the card of test letters for the direct determination of the grade of myopia, by noting the greatest distance at which the letters corresponding to that distance are distinctly recognized. In the lower grades of myopia good measurements may sometimes be made in this manner, but in the higher grades the convergence of the visual axes is apt to be attended with some exercise of the accommodation, so that the measurements are often somewhat in excess of the actual myopia.

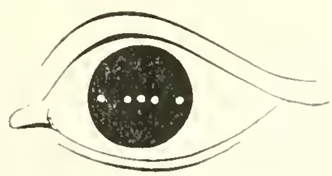

FIG. 3699.

* Less 0.2 dioptrie, as a correction for the distance of the test object.
† Plus 0.2 dioptrie, as a correction for the distance of the test object.

* The following specification of a series of trial lenses has been found satisfactory in practice:

Spherical lenses, in pairs: + 2.0 D, through 0, to − 2.0 D, with a common interval of 0.125 D (thirty-three pairs); + and − 2.25 D to + and − 7.0 D, with a common interval of 0.25 D (forty pairs); + and − 7.5 D to + and − 12 D, with a common interval of 0.5 D (twenty pairs); + and − 13.0 D to + and − 20.0 D, with a common interval of 1.0 D (sixteen pairs); + and − 22.0 D (two pairs); + and − 24 D (two pairs):—total, 113 pairs of spherical lenses.

Cylindrical lenses, in pairs: + and − 0.125 D to + and − 2.0 D, with a common interval of 0.125 D (thirty-two pairs); + and − 2.25 D to + and − 7.0 D, with a common interval of 0.25 D (forty pairs): + and − 7.5 D to + and − 10.0 D, with a common interval of 0.5 D (twelve pairs); + and − 11 D to + and − 14 D, with a common interval of 1.0 D (eight pairs):—total, 92 pairs of cylindrical lenses.

The entire collection of 205 pairs of lenses, together with a series of prisms, in pairs ranging from 1° to 12° angle, is contained in a box measuring 47 × 42 × 6.5 cm.; for convenience in keeping the case free from dust, the lenses are arranged in a bottomless tray which may be lifted out of the box.

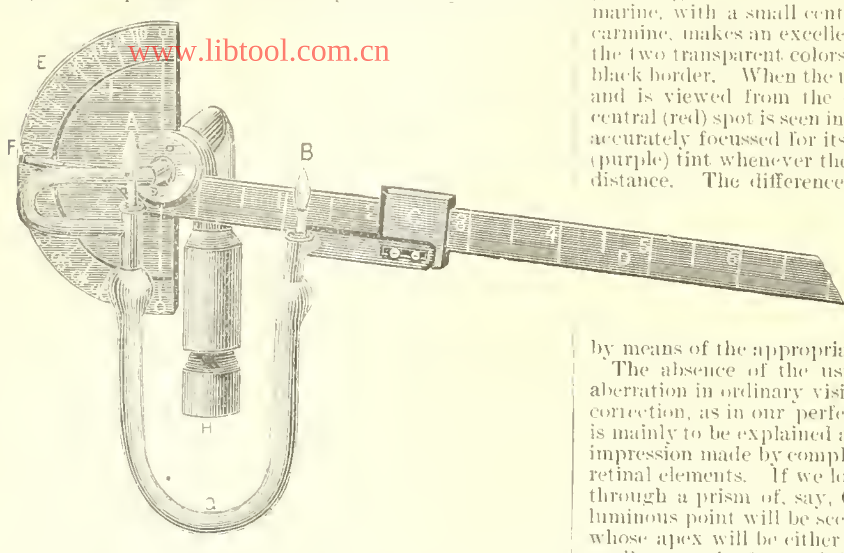
Optometry.

Optometers for the measurement of the refraction, and also of the range of accommodation, at some short distance, say, of one foot, have been made in a great variety of forms; they are, however, of much less value than might be expected, whether as regards saving of time in



www.libtool.com.cn

FIG. 3700.

observation or accuracy of results. The binocular optometer of Javal (see Vol. I., p. 594), especially devised for the measurement of astigmatism, probably still remains the best instrument of its class.

A point of light, such as the flame of a small taper or gas jet, viewed from a distance of 5 metres or more, is seen by an emmetropic eye as a bright point, with some indication of bright rays, as in the familiar picture of a star (see Vol. I., 596). The same distant bright point is seen by a myopic eye, or by a hypermetropic eye in a state of accommodative relaxation, as a bright spot (circle of confusion) of a greater or less diameter, dependent on the grade of ametropia and the size of the pupil. When the pupil is fully dilated by a mydriatic, the size of the circle of confusion is approximately proportionate to the degree of ametropia, so that a pretty exact measurement may be made by simply noting the distance at which two tapers must be placed, one from the other, in order that the two circles of confusion may touch each other. Thomson[25] has devised as apparatus (Fig. 3700) in which two small gas jets are so arranged as to admit both of varying the distance between the two lights and of altering their direction to correspond to different ocular meridians; the degree of ametropia is read off from a scale which forms a part of the instrument.

By making the effective area of the pupil very small, as in looking through a pinhole pricked in a blackened card, the circles of confusion may be so reduced in size as to admit of tolerably distinct vision even in high grades of ametropia. If two pinholes are pricked in the card, at a distance of, say, 4 mm. from each other, a pretty distinct image will be formed by the rays passing through each of the pinholes, but the two bundles of rays will fall upon different parts of the retina whenever the eye is adjusted for any distance other than that of the object (Fig. 3701). This experiment, first described by Scheiner,[26] has been utilized in the optometers of Porterfield[27] and Young,[28] and has been further developed in a method for the clinical investigation of ametropia by Thomson.[29]

When a colored test object, in a field of a contrasting color, is viewed by an eye adjusted for some distance other than that of the object, the circles of confusion, representing parts of the object and of the field adjacent to the line of demarcation of the two colors, overlap in the retinal image and form the combination color proper to the mixture. The experiment succeeds best when the test object and the contrasting field are in transparent colors and viewed by transmitted light. A sheet of ground glass coated with varnish colored blue by ultramarine, with a small central area similarly painted with carmine, makes an excellent test object for this purpose; the two transparent colors should be separated by a thin black border. When the test object is hung in a window, and is viewed from the opposite side of the room, the central (red) spot is seen in its actual color when the eye is accurately focussed for its distance, but in a combination (purple) tint whenever the eye is focussed for some other distance. The difference between the carmine-red and the combination-purple is especially striking in astigmatism, when the test object is made up of radiating lines of carmine, on a blue field[30] and the eye is corrected for one of its principal meridians by means of the appropriate spherical glass.

The absence of the usual phenomena of chromatic aberration in ordinary vision is not due to an achromatic correction, as in our perfected dioptric instruments, but is mainly to be explained as an effect of the simultaneous impression made by complementary colors upon the same retinal elements. If we look at a distant point of light, through a prism of, say, 60° angle, the spectrum of the luminous point will be seen under the form of a triangle, whose apex will be either in the red or in the violet, according as "the focus of the eye is adapted to collect the red or the blue rays to a point";[31] in other words, according as the eye is slightly myopic or hypermetropic. In emmetropia the spectrum is seen under the form of a double triangle in which the narrowest part lies in the very strongly luminous yellow region. The impression made by a point of white light upon any single cone of the retina is, therefore, compounded of the spectral yellow and a composite yellow, made up of red and green. This mixed yellow, superimposed as it is, upon a field of diffused violet, is further modified to approach white.

The chromatic aberration of the eye reveals itself very plainly in looking at a point of light of which all but the blue and red rays have been extinguished by the passage of the beam through a sheet of cobalt-blue glass.[32] Looking through such a glass an emmetropic eye, focussed for the distance of the light, sees it of a nearly uniform purplish-blue tint, with an inconspicuous halo of a clearer blue; a myopic eye sees the same light red, with a blue halo; and a hypermetropic eye, uncorrected by accommodation, sees it blue, with a red halo. To measure the grade of the ametropia it is sufficient to find the spherical (concave or convex) glass through which the light appears of a purplish-blue bordered by a clearer blue.

An emmetrope, looking at distant red and green lights, such as are carried by vessels and used as railway signals, sees the two lights of about the same magnitude; a myope sees the green light as an aggregation of circles of confusion, and therefore larger than the image of the red light; a hypermetrope, with imperfect accommoda-

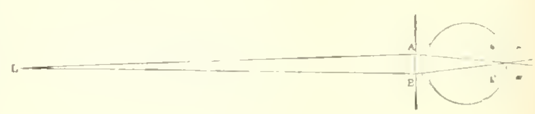


FIG. 3701.

tion, sees the red light larger than the green. When the vision is corrected for the distance of the lights they are seen in their normal relation of equality in size.[33] *

* The difference in the size and definition of the retinal image of a red and of a green light is quite sufficient to enable a hypermetropic or slightly myopic pilot, or railway employee, to utilize this difference as an aid to the discrimination of lantern signals, even though he be color-blind.

Optometry.

Ophthalmostatometry—from ὀφθαλμός, eye, and στα-, root of ἵστημι, to stand—is the measurement of the position of the eyes. The most important measurements are those which have to do with the two eyes in respect of their mutual distance and the relative direction of the visual axes.

www.libtool.com.cn

The distance between the two eyes may be roughly measured by looking the patient in the face and letting him direct his gaze alternately upon the two eyes of the observer, who in turn reads off the position of the fixing eye with his fixed eye upon a graduated rule held in the hand or mounted like a spectacle frame. The right or left corneal margins, or the right or left margins of the pupils, may be taken as fixed points whose mutual distance is an approximate measure of the true interocular distance. An inaccuracy of this, as of other objective methods of measuring the interocular distance, arises from the fact that the visual axis does not exactly coincide with the geometrical axis of the eye, but, as a rule, cuts the cornea a little to the inner (nasal) side of its vertex. The angle which the visual axis makes with the axis of the cornea (angle *a* of Donders)[34] averages about five degrees in the emmetropic eye; it is somewhat greater in hypermetropic and less in myopic eyes, and in very high grades of myopia it may even be negative, so that the visual axis may cut the cornea at, or a little to the outer (temporal) side of, its vertex. Objective measurements of the interocular distance are, therefore, ordinarily a little too large, though sufficiently accurate for most practical purposes.

If we place a diaphragm, with a central perforation of about 1 mm. in diameter, in each of the two clips of a trial spectacle frame, and adjust the distance of each from the median line of the nose so that a distant vertical line shall be seen bisecting the small circular field as defined by the margins of the perforation, the distance between the centres of the two perforations will be the true measure of the distance of the two (parallel) visual axes from each other.[35]

To measure any deviation of the optic axes from parallelism, when the patient fixes his gaze upon a distant object, a lighted candle may be held about a foot in front of the deviated eye and moved in different directions until its image, as seen reflected on the cornea, occupies a position central to the pupil when viewed from a station just behind the light. The angle at which the light must be held to one side of a line drawn from the observed eye to the (distant) point fixed by the other eye is the measure of the angular displacement of the deviated eye; it may be conveniently measured upon the arc of a perimeter, the eye whose deviation is to be measured being at the centre of curvature of the arc (Landolt).

Ophthalmotropometry—from ὀφθαλμός, eye, and τροπή, turning—is the measurement of the movements of the eyeballs. Most important, from a clinical standpoint, is the estimation of the interrelation of the recti interni and recti externi muscles.

In insufficiency of the recti interni, not amounting to strabismus divergens, the phenomenon of double vision (see *Diplopia*) does not ordinarily manifest itself so long as it is possible to maintain the fusion of the two retinal images through the forced exercise of the convergence; if, however, we displace one of the retinal images upward or downward, by means of a weak prism, any insufficiency of the interni immediately reveals itself by a crossing of the images, which then assume an oblique direction, one to the other, instead of the vertical direction proper to the action of the prism. The measure of the insufficiency is the prism, with edge turned horizontally outward, which is required to convert the oblique into a vertical diplopia. This test, which may be applied both at a long range and at shorter distances, reveals the state of the convergence as related to the degree of accommodation which is brought into play at the particular distance.

The "glass-rod" test of Maddox (see Vol. III., p. 492), especially in its later form as developed by its inventor, is even more convenient in use, and is of wider applicability than the vertical prism. By rotating the disc of fluted glass in front of one of the eyes, the resultant bright streak may be given any desired direction, from the vertical to the horizontal, thereby revealing a deviation of the visual axes from parallelism in any direction. The measure of the deviation is the prism, or sum of two prisms before the two eyes, which brings the streak through the flame.

Insufficiency of the recti externi, or preponderance of the recti interni, is tested, *mutatis mutandis*, in the same manner as insufficiency of the interni.

Binocular vision, conditioned on the simultaneous perception and comparison of the two retinal images of the

FIG. 3702.

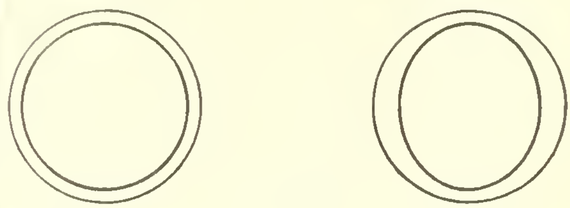

FIG. 3703.

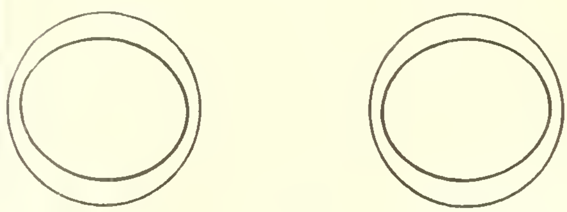

FIG. 3704.

FIG. 3705.

object upon which the two eyes are directed, is most easily tested by means of the stereoscope. Rejecting all representations of objects in which solid forms are suggested by perspective, as is almost always the case with photographs of objects in nature, we make use of diagrams of the simplest possible construction; a few examples of these are shown in Figs. 3702 to 3705.[36]

Digitized by Microsoft®

Viewed in the stereoscope Fig. 3702 is seen as two discs, the one vertically above the other, but lying in two different planes at different distances from the observer; the more distant of the two discs appearing also to be the larger. Inverting the slide in the stereoscope, the relative distances and sizes of the discs appear reversed. Fig. 3703 shows a circle and an ellipse, which may be considered as two different perspective views of another, larger ellipse; when the two images are combined in the stereoscope a horizontally elongated ellipse is seen rotated about its vertical diameter as an axis; inverting the slide, the ellipse is seen rotated in the opposite direction. In Fig. 3704 the ellipse is seen to tip backward or forward, according as the slide is placed in the stereoscope in the position shown in the plate, or inverted. Fig. 3705 shows a combination of a ring with a white centre and a black disc of the same diameter; the effect is that of a mirror or of a shining surface polished with plumbago. *John Green.*

ORANGE, SWEET AND BITTER.—(See also *Citrus.*)

I. *Citrus Aurantium* L., the sweet orange, is a familiar plant in all warm countries. It is a small, rather slow-growing tree, with hard wood, an upright, much-branched trunk, bearing a well-rounded, rather close head. Leaves numerous, thick, evergreen, smooth, and shining, oval; the blade articulated to the distinctly winged petiole. Flowers axillary, perfect, regular, large, fragrant, white; calyx short; petals five, long, fleshy, spreading; stamens numerous; ovary free, eight- or more celled, several ovules in each cell. The leaves and petals are fragrant, and show by transmitted light pellucid spots indicating the large oil reservoirs in their parenchyme.

II. *C. vulgaris* Risso, the source of the bitter or Seville orange, is a smaller tree, with a closer head, larger, more fragrant flowers, and a rougher, darker, sour, and bitter fruit. This plant is also rather more spiny than the other, and propagates more truly from seed.

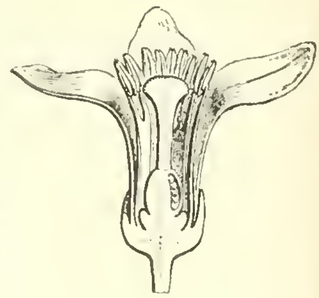

FIG. 3706. — Sweet Orange Flower. (Baillon.)

The official products and preparations are as follows:

Sweet Orange Peel. Aurantii Dulcis Cortex. "The rind of the fresh fruit of *Citrus Aurantium* L." The preparations of this are the five-per-cent. syrup, used wholly as a vehicle and for flavoring, and the twenty-per-cent. tincture, chiefly used like the last, but a stimulant in doses of 2–8 c.c. (fl. ʒ ss.–ij.).

Bitter Orange Peel. Aurantii Amari Cortex. "The rind of the fruit of Citrus vulgaris Risso."

Preparations, the fluid extract, dose 2–4 c.c. (fl. ʒ ss.–i.) and the twenty-per-cent. tincture, dose 2–8 c.c. (fl. ʒ ss.–ij.). It will be observed that this peel may be used dry, while that of the sweet orange must be used in the recent state. The bitter principle of this peel makes it an important aromatic bitter, as well as a flavoring agent.

Oil of Orange Peel. Oleum Aurantii Corticis. "A volatile oil obtained by expression from the fresh peel of either the sweet or the bitter orange." This is purely a diffusive stimulant, but is almost wholly used for flavoring. Its preparations are the five-per-cent. spirit and the twenty-per-cent. compound spirit, made with five per cent. of oil of lemon and two per cent. of oil of anise. This latter enters into the aromatic elixir.

Oil of Orange Flowers. Oil of Neroli. Oleum Aurantii Florum. A volatile oil distilled from the fresh flowers of the bitter orange. (The flowers themselves are no longer official.) This is used purely as a perfuming and flavoring agent. The following are the preparations: *Stronger Orange Flower Water* (*Aqua Aurantii Florum Fortior*) is obtained as a by-product in the distillation, being the water so used, saturated with the oil. From this is made the *Orange Flower Water* (*Aqua Aurantii Florum*) by mixing it with an equal volume of distilled water. From this, in turn, is made the syrup, by adding to 850 grams of sugar enough of the water to make 1,000 c.c.

Oil of Petit Grains, not official, is distilled from the unripe fruits of the bitter orange, and is very similar to oil of orange flowers, but much less agreeable.

The use of orange fruit is like that of other laxative fruits, with the special effect of citric acid. It is to be borne in mind that, while a moderate use of oranges is wholesome, the excessive use can bring on very stubborn and severe dyspepsia, especially in tropical countries. *Henry H. Rusby.*

ORBIT, DISEASES AND INJURIES OF THE.—These affections have great interest and importance, not only with reference to the preservation of sight, but also on account of the close topical and vascular connection of the contents of this cavity with other parts, particularly the brain, and the difficult and serious problems in diagnosis and prognosis which they frequently offer. They are, comparatively, not very common. The one most frequently met with is

ORBITAL CELLULITIS.—This is not generally difficult to recognize. It is usually an acute disease, and often of a violent inflammatory character. Pain, which is a prominent symptom, is in proportion to the degree of swelling and consequent pressure, and, when this is ex-

Digitized by Microsoft®

cessive, it is very intense. It is referred to the ball and orbit and to the parts of the face to which the ramifications of the ophthalmic branch of the fifth nerve are distributed, and is always increased by the slightest backward pressure of the globe. The conjunctiva is congested and soon becomes chemosed, and the lids are swollen and oedematous and have an erysipelatous appearance.

www.libtool.com.cn

The most striking symptom is the exophthalmus, which is decided, even in slight cases and in the early stages. The diplopia resulting from displacement of the eyeball is sometimes among the first symptoms, and may even occur before the exophthalmus attracts attention. In severe cases, particularly if an abscess is formed, the protrusion of the ball may be so great that the lids can no longer cover the cornea. The movements of the eye are, of course, restricted and painful, or it may be completely fixed in its unnatural position.

More or less constitutional disturbance is to be expected, and the formation of pus is usually announced by well-marked rigors. Suppuration is the rule, but a few cases end in resolution, a result said to be much more frequent in children than in adults. This form of the disease is sometimes called "oedematous cellulitis." When an abscess is evacuated spontaneously, the pus escapes through the skin of the lids, near the superior or inferior orbital margin, or sometimes behind the lids, through the palpebro-ocular fold of the conjunctiva. In the latter case the disease is sometimes mistaken for purulent conjunctivitis. In rare cases orbital cellulitis assumes a chronic form, and ends by the escape of pus only after the lapse of months or years. There may be little or no pain, and no decided symptom except the exophthalmus. There is likely to be periostitis or caries in such cases.

Etiology.—Idiopathic cellulitis is so rare that Pagenstecher is disposed to deny its occurrence, and to maintain that cases described as such have been due to the extension of inflammation from a focus which had escaped the attention of the observer (*Arch. of Oph.*, vol. xiii.). Primary cellulitis in healthy adults must be considered, to say the least, a very unusual affection, but its occasional occurrence in delicate children is generally admitted. Perhaps the most frequent causes are direct injuries of the orbital tissue and extension of local inflammation from neighboring parts. Operations upon the appendages of the eye, or even upon the ball itself, are sometimes followed by this complication. Bull (*Jour. Med. Sci.*, July, 1878) reports a case following excision of a prolapsed iris, and one after iridectomy for glaucoma. The most frequent cause of orbital abscess is empyema of the accessory cavities of the nose with caries of their walls. Phlegmonous erysipelas of the face has extended to the orbital tissue in a number of cases. Finally, orbital abscess may be the result of a metastatic process in puerperal fever, phlebitis, typhus, carbuncle, etc. While thrombosis of the orbital vein necessarily occurs in orbital phlegmon, and may extend to the cavernous sinus, orbital cellulitis may have its origin in suppurative phlebitis of the ophthalmic vein. It is well known that suppuration may be communicated to the ophthalmic vein and cavernous sinus from abscesses of the lids or lips, operations about the face, the extraction of teeth, and especially from facial erysipelas. In a fatal case of suppurative phlebitis of the ophthalmic vein and cavernous sinus, following malignant abscess of the tonsil, Professor Panas (*Arch. d'Ophthal.*, t. v.) thinks that the disease was communicated through numerous anastomoses which have been shown to exist between these vessels and the spheno-palatine vein. Cases of orbital cellulitis following diphtheria are reported by Knapp and Heyl (Nettleship, "St. Thomas' Hospital Reports," vol. xi.). Knapp (*Arch. of Oph.*, xiii.) has shown that orbital cellulitis is present in all cases in which blindness results from facial erysipelas.

Diagnosis.—The conditions with which orbital cellulitis is most likely to be confounded are periostitis of the orbital walls and new growths in the cavity. In periostitis the progress of the disease is usually less rapid, and the pain, though perhaps less severe, is an earlier symptom and may even be the first. Except in cases in which only the deeper parts of the orbit are affected, a tender spot can frequently be detected by passing the finger as far back as possible and pressing against the wall. While in cellulitis the eye is usually protruded directly forward, and its motions are limited equally in all directions, it is likely to be given a special direction by the more localized swelling of periostitis. These two lesions may, however, sometimes appear together, the inflammation extending from the periosteum to the orbital cushion. The acute course of cellulitis will usually distinguish it from orbital growths. The eye is rarely protruded directly forward by a tumor, and the latter may often be felt with the finger. The diagnosis is, however, sometimes extremely difficult, and may prove a stumbling-block to the most skilful and careful observer. This is well illustrated by a case which occurred some years ago in the experience of no less an authority than Professor Jaeger. He was sent by the Emperor to Milan to examine Marshal Radetzky, who had been suffering for three months with a high degree of exophthalmus and its accompanying symptoms. He reported that the patient, who declined any operative interference, was affected with scirrhus of the soft parts of the orbit, which would probably soon end his life. Not long afterward, under homoeopathic treatment, there was a copious discharge of pus, and the eye returned to its normal position (*Annales d'Oculist.*, xxiii., p. 14).

Prognosis.—Though a large proportion of cases of orbital cellulitis recover without serious injury to the eye, the disease is a dangerous one and places not only sight but sometimes life in peril. The most frequent causes of loss of sight are injury to the optic nerve from pressure and stretching, and interference with the circulation in the central vessels of the retina. The tense chemosis may cause the cornea to slough, or panophthalmitis may result from interference with the circulation of the choroid or from direct extension of the inflammation to that membrane. The movements of the ball are sometimes permanently impeded by cicatricial contractions or atrophy of the external muscles, or their paralysis from injury to the nerves. Life is threatened by direct extension of inflammation to the meninges, through the sphenoidal fissure or optic foramen, by flow of pus into the intracranial cavity, or by thrombosis of the ophthalmic vein. According to Berlin (Graefe-Saemisch, vol. vi.), fatal pyæmia may result without extension of thrombosis beyond the orbit, or the thrombosis may extend to the brain sinuses. He thinks that the latter condition may be diagnosticated positively if exophthalmus occurs suddenly in the other eye. Exophthalmus frequently results from venous obstruction only, with little or no inflammation of the orbital tissue, and is a constant and important symptom of phlebitis of the cavernous sinus.

Treatment will necessarily vary with the violence of the local inflammation and the general condition of the patient. In traumatic cases, and others occurring in persons in fair health, leeches may be applied to the temple in the early stages of the affection before suppuration has commenced. Even this kind of depletion, however, is to be condemned in the large proportion of cases in which the inflammation of the orbital tissue is a complication of some exhausting disease. Hot stupes will promote resolution while there is hope of that termination; but warm fomentations or poultices should be applied when it is desirable to encourage suppuration. Extract of belladonna applied to the temples and brow is useful in relieving pain, but most cases will require the liberal exhibition of anodynes. When suppuration is evident, there is no question about the propriety and urgency of free incision, and when it is doubtful it is often prudent to make an exploratory puncture. When great swelling inflicts intense pain and threatens the integrity of the eyeball and optic nerve, deep and free incisions should be made without waiting for indications of suppuration, and with a view to relieving the tension of the parts. A narrow, straight bistoury or a long Graefe cataract knife

Digitized by Microsoft®

is entered near the upper or lower margin of the orbit, and its point kept near the roof or floor, while it is passed toward the apex of the orbit. It is well to keep the wound open by a tent of carbolized or borated lint. Curetting of the inner wall of the orbit and drainage through the nose may be necessary when the accessory sinuses are involved (see Transactions of the American Ophthalmological Society, 1900).

www.libtool.com.cn

TENONITIS.—The capsule of Tenon is a fibrous envelope of the ball, derived from the dural sheath of the optic nerve, and lined by a serous membrane which, according to some authorities, is continuous with the arachnoid. The eyeball moves in this envelope like the head of a bone in its articular capsule. The recti muscles pass through this capsule at the equator of the ball, where it is intimately connected with their sheaths, and in the neighborhood of the corneal margin it is merged in the conjunctiva and subconjunctival tissue. While it forms a barrier to the extension, within the eye, of inflammatory processes when they commence in the orbital tissue, its direct connection, by means of the anterior ciliary vessels with the intra-ocular circulation makes this danger greater when the capsule itself is inflamed. On the other hand, it probably rarely entirely escapes participation in very acute and intense intra-ocular inflammation, and is the cause of the protrusion of the ball in panophthalmitis. In enucleation in such cases the extensive and firm adhesions of the capsule and the muscles and connective tissue about the ball often considerably complicate the operation. Tenonitis is said to occur occasionally after facial erysipelas or as a rheumatic affection, but is usually the result of extension of inflammation from the ball, or of direct injury. It has sometimes followed operations, especially those upon the external muscles. I have met with two cases: one after simple division of a muscle for strabismus, the patient recovering in the course of a few days, without injury to the eye; and one after the advancement of the internal rectus. In the latter case the disease ended in disorganization of the ball.

The *symptoms* are conjunctival and subconjunctival congestion, sometimes with chemosis, moderate exophthalmus, restriction of the movements of the ball, and pain, greatly increased by pressing the eye backward. The lids are less affected than in cellulitis, and if pus forms it escapes on the surface of the ball.

Treatment will, of course, depend upon the cause and the intensity of the inflammation. Rheumatic cases require hot stupes, cotton compresses, anodyne applications, and the appropriate internal medication. In the early stages of traumatic tenonitis leeching at the temple, the local application of ice, and calomel internally may be needed.

PERIOSTITIS of the orbital walls is sometimes difficult to distinguish from cellulitis, and indeed the two conditions may exist together, or phlegmonous inflammation of the orbital connective tissue may originate in periostitis. The usual seat of periostitis of the orbit is near the margin, where it can be detected by pressure with the finger. The exophthalmus is not directly forward as in uncomplicated cellulitis, and the movements of the ball are limited more in the direction of the seat of the disease than in other directions. When the disease is at the apex, paralysis of some of the muscles of the ball is likely to ensue from involvement of the nerves at their entrance into the orbit. Periostitis usually, though not invariably, ends in suppuration. Sometimes there are more or less permanent localized thickening of the periosteum and consolidation of the neighboring tissue, which closely simulate a tumor. I have met with several such cases. In one there was a distinctly localized hard swelling in the upper inner wall of the orbit, extending as far back as the finger could reach. An exploratory incision was made, and when the finger was introduced into the wound it was found that the swelling was much less clearly defined than it had appeared to be—in fact, that it was merely a localized engorgement of the periosteum and neighboring orbital tissue. The part was freely scarified and the wound was kept open with a tent. The case soon ended in complete recovery without suppuration. In another case there was such a decided resemblance to a tumor in the region of the lachrymal gland that extirpation had been advised by two experienced surgeons. As the patient was known to have been under treatment some months previously with an aggravated attack of syphilitic pharyngitis, periostitis was diagnosticated, and a rapid cure followed the administration of heroic doses of iodide of potassium.

Prognosis.—A large proportion of cases end favorably. The bone may become involved in the disease. In a few cases death has resulted from direct extension of inflammation from the periosteum to the meninges of the brain, or from the escape of pus into the intracranial cavity. The danger is, of course, much greater when the deeper parts of the orbit are affected. In the chronic form the progress of the disease is very slow, sometimes extending over months or even years.

The *cause* may be traumatic or rheumatic, or the disease may be due to an extension of inflammation from one of the neighboring cavities, but it is most frequently syphilitic. The local *treatment* is the same as in cellulitis, and when suppuration is suspected or when excessive swelling endangers the eye or brain, early and free incision should not be neglected. Iodides and tonics are generally needed.

CARIES AND NECROSIS of the orbital walls are usually the result of periostitis when not due to disease of the accessory sinuses. The seat of the disease is, fortunately, most frequently near the margin of the orbit, where the danger of injury to the eye or of extension to the brain is much less than when the deeper parts of the orbital cavity are involved. The adherent cicatrix of the skin, however, which invariably forms, is likely to cause serious deformity of the lids by its excessive contraction. This cannot be prevented, but must be remedied by operation, as best it may, after the affection of the bone has run its course. Abscesses should be promptly evacuated and a free opening maintained. When they discharge spontaneously the resulting sinuses will frequently need to be enlarged. The cavity should be frequently syringed with antiseptic solutions. The danger of reckless probing should be borne in mind, and no forcible attempts to remove sequestra should be made. Acute cases, which are often mistaken for erysipelas of the lids and face, may need local treatment. Iodide of potassium is always in order, and should be given in large doses if syphilis is suspected. Many patients require a long course of treatment by quinine and iron and cod-liver oil, and careful attention to diet and hygiene.

HEMORRHAGE IN THE ORBIT is extremely rare from other than traumatic causes. It has occasionally occurred in scorbutic subjects, in sudden suppression of the menses, and from violent coughing or muscular straining. Permanent hæmatomata have been formed by repeated hemorrhages.

When hemorrhage occurs in the orbit after serious injuries of the head, it is an almost certain symptom of fracture of the walls of the cavity; though intracranial hemorrhage may find its way into the orbit without fracture. In a few cases of injuries bleeding has resulted from rupture of vessels within the orbit. The symptoms are exophthalmus and ecchymosis of the lids and conjunctiva. The ophthalmoscopic appearances are those resulting from sudden pressure.

Treatment.—Iced-water or pounded ice should be applied while there is probability of further hemorrhage, and afterward absorption may be hastened by a compressive bandage.

EMPHYSEMA of the orbit is still more rare than hemorrhage. The symptoms are exophthalmus and the characteristic crepitation on pressure upon the puffy lids. The *causes* are rupture of the lachrymal sac, or communication between the orbit and the frontal sinuses, ethmoidal cells, or nasal cavity. This communication with neighboring air spaces is generally traumatic, but may be the result of ulceration. Rampoldi reports

Digitized by Microsoft®

a case in which the emphysema developed, without injury, from chronic coryza. Exophthalmus, with diplopia, appeared whenever the patient sneezed or coughed, until he learned to prevent it by supporting the eye with his hand. The story is told of a convict who produced exophthalmus by introducing a pin at the root of a molar tooth and forcing in air from the mouth; and malingerers are said to have produced the same result by making a puncture beneath the eyeball and blowing in air through a tube. French jockeys have been accused of resorting to the latter expedient to give a youthful appearance to old horses with sunken eyeballs. No *treatment* is likely to be of much use. The patient should be cautioned against blowing his nose and encouraged to wait for the rent to close.

EXOPHTHALMIC GOITRE, often called Graves' disease or Basedow's disease, is a complicated affection in which, in its typical form, protrusion of the eyeball is associated with enlargement of the thyroid gland, functional disturbance of the heart, and marked nervous and nutritive derangement. Though cases presenting this association of symptoms had previously been reported by Parry and others, the first systematic description of the disease now known as exophthalmic goitre was given by Graves in 1835, and his name is associated with it by English, American, and some French authors; while the Germans claim that Basedow was the first to describe it accurately (Casper's *Wochenschrift*) in 1840, and they always speak of it as Basedow's disease.

The exophthalmus is not usually so excessive as that met with in cases of abscess or tumor of the orbit, but in a few instances it has been so great as to prevent the lids from closing over the cornea. The effect of the protrusion of the ball is, in a large proportion of cases, heightened and the deformity much increased by an associated affection of the lids, a symptom to which attention was first called by von Graefe. The upper lid does not follow the movements of the ball as its axis is directed upward or downward, but remains fixed and more or less retracted, exposing the sclerotic and giving a staring and startled expression to the patient. This is due to contraction of the small, flat muscular fibres, extending from the lid back into the orbit, which were discovered by Müller and are known by his name. They are of the unstriated kind and are under the control of the sympathetic nerve. Sometimes, also, reflex contraction of the orbicularis from irritation of the eye is diminished, and winking is absent or incomplete. These lid symptoms are not constant, but are sometimes found when the disease is but slightly developed, and may be valuable indications in doubtful cases. The ball can be forced back nearly or quite to its normal position by pressure with the fingers, but it projects immediately when the pressure is removed. Vascular bruit has been detected with the stethoscope by Snellen. Diplopia from displacement of the visual axes may occur, even as an early symptom, and, in some advanced cases, continued stretching produces paresis of the external muscles of the ball. There has been much discussion about the condition of the pupil: some cases have been reported in which it was dilated, and a few in which it was contracted, but, without doubt, it is usually unaltered. Vision is not generally impaired. The ophthalmoscope has occasionally shown retinal hemorrhages, and Becker (*Klin. Monatsblatt für Augenheilk.*, 1880) has observed pulsation of the retinal arteries in some cases, but, as a rule, there is little or no change in the fundus beyond a dilatation of the retinal veins, and even this is not constant. Both eyes are almost invariably affected. Cases have been reported in which one only was involved, but this is so rare that Eulenberg thinks that some suspicion must remain in respect to the diagnosis. Slight keratitis, with conjunctivitis, is common in severe cases, but blindness from ulceration of the cornea is a rare occurrence. Some authorities attribute this ulceration to simple exposure of the cornea from excessive exophthalmus, while others believe it to be an instance of so-called neuroparalytic keratitis, due to a disturbance of nutrition resulting from the obscure neurosis that lies at the bottom of all the manifold symptoms of this disease. The latter is the view taken by von Graefe and others, who consider the corneal affection a result of paralysis of the "trophic" fibres of the ophthalmic branch of the fifth nerve; the corneal sensibility being lost or retained according as all the fibres of the nerve, or the trophic only, are involved. Some authors, among them Charcot, are disposed to think that the corneal inflammation is produced by irritation of the nerve (see "Neuroparalytic Keratitis," Harlan, *Am. Jour. of the Med. Sci.*, April, 1874).

In nine cases out of ten the subjects of the disease are females, usually adults under thirty years of age, but a few instances in children under ten have been recorded. Male patients are generally older and their attacks are likely to be more severe. Most cases of corneal ulceration have occurred in males.

The exophthalmus usually disappears entirely after death, and no constant lesion is discovered by post-mortem examination of the orbit. Fatty degeneration of the muscles, from disuse and stretching, has been noted; and hypertrophy of the orbital fat has been found in some cases, but it may be considered an accidental result of the vascular engorgement which seems to be the cause of the protrusion of the eyeball.

The *pathology, symptomatology, and treatment* of exophthalmic goitre will be discussed in a separate article in THE APPENDIX.

PULSATING EXOPHTHALMUS, a comprehensive term based on convenience rather than on scientific accuracy, is now quite generally used to include a large class of cases which are dependent upon different pathological conditions, and which in the present state of our knowledge it is always difficult and generally impossible to distinguish positively during life.

Symptoms.—There is protrusion of the eyeball, and pulsation is evident to the touch and sight. Above the eye, and beneath the upper and inner margin of the orbit, is a rather firm, elastic tumor, also pulsating. The patient complains of a puffing or whirring noise in the head, and an aneurismal bruit is heard, on auscultation, over the eye and temple, and sometimes over the whole side of the head. In some cases this sound has been audible at a distance of several feet from the patient. There are usually distention and pulsation of the supra-orbital vein, and sometimes of the infra-orbital also. When the carotid is compressed in the neck the pulse and bruit cease, the tumor becomes soft, and the eye can be pushed back into the orbit. The hollow between the ball and the orbital arch is obliterated. The conjunctiva is congested, and in many cases a tumor is formed by intense chemosis of its lower fold, which projects beyond the lid. There may be no decided ophthalmoscopic changes, but the retinal vessels are usually congested, and the disc is sometimes found swollen as a result of pressure upon the optic nerve in the orbit. Pain may be slight or severe.

Vision is not generally much affected in recent cases, but the eye has often been destroyed by long-continued and excessive pressure. The symptoms usually appear suddenly, after direct injury to the orbit or a severe blow upon the head in traumatic cases; or during violent effort, as in childbirth, in cases of spontaneous origin. They have not been noticed, however, in a number of traumatic cases until some weeks or months after the injury.

In several spontaneous cases the patients have been roused from sleep by a loud sound like the report of a pistol.

Progress and Termination.—The deformity and inconvenience are so great, and the danger to the eye and to life is so decided, that few cases have been allowed to pursue a natural course, uninterrupted by more or less active treatment. As a rule, the character of the affection is chronic, and some cases have undergone little or no change in the course of years. In others the eye has been destroyed by sloughing of the cornea and general ophthalmia. The causes of death include erysipelas, complications of brain and heart, and hemorrhage. Of

the last class, in the cases of Hussey and Critchett ("Ophthalmic Hospital Reports," vol. ii., p. 127; *Med. Times and Gaz.*, December, 1854), the patients died of hemorrhage directly from the orbit, and in one of Nélaton's cases (*Lancet*, 1873), profuse epistaxis, resulting from fracture of the body of the sphenoid bone and rupture of the carotid, was the cause of death. In 1876 (Trans. Internat. Med. Cong.) I reported a case of spontaneous

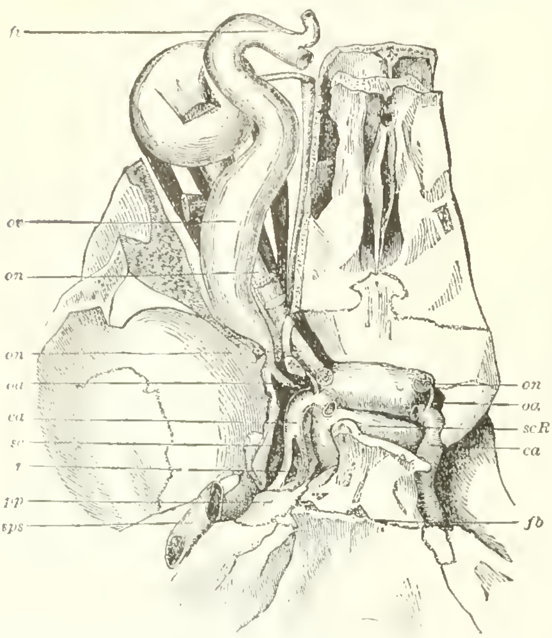

FIG. 3707.—*sc*, The dilated cavernous sinus, opened from above. Within this, the internal carotid (*ca*), which is cut open above to show the perforation in the under and outer side of its wall (*r*); *fb*, the fracture in the sphenoid bone; *pp*, detached spicula from the point of the petrous bone; *scR*, sinus circularis Ridlevi; *sps*, a part of the dilated superior petrosal sinus; *ov*, dilated ophthalmic vein; *fr*, vena frontalis; *oa*, ophthalmic artery; *on*, optic nerve. (After Delens.)

cure, and gave abstracts of six other cases recorded in literature up to that time, and I find three others which have been reported since:

1. Bitsch (*Klin. Monatsbl. f. Augenhk.*, xvii., 1879): Exophthalmus, murmur, pulsation. Probable spontaneous rupture of carotid in cavernous sinus. Cure by extra- and intra-ocular inflammation.

2. Gauran (*Gazette des Hôpitaux*, October, 1883): Aneurism of both orbits, caused by a fall upon the head, cured spontaneously.

3. Glascott (*Brit. Med. Jour.*, November 25th, 1882): "Arterio-venous aneurism of orbit," lasting two years. Spontaneous cure in the course of phlegmonous inflammation of the face and head.

This makes a total of ten cases, to which might be added several others in which the effect of remedial measures was doubtful.

Pathology.—The typical symptoms of "pulsating exophthalmus" are protrusion of the eyeball, pulsation, and aneurismal bruit, and all cases presenting these symptoms were formerly classed as "orbital aneurism." Following the view maintained by Travers, in his report of the first case in 1809 (Med.-Chirurg. Trans., vol. ii.), for thirty years writers generally held that these cases of so called aneurism of the orbit were all of the anastomotic variety. Then Busk's paper (*ibid.*, vol. xxii.) threw a doubt on this, and most authors thought that they were of the ordinary spontaneous or traumatic kinds, affecting the ophthalmic artery, until Nunneley, in 1864, maintained that in the great majority of such cases of protrusion of the eyeball there is no disease whatever in the orbit, but that the symptoms depend on obstruction to the return of blood through the ophthalmic vein. Though there is no positive proof that such a thing as an aneurism of the orbit has ever existed, it is, of course, not an impossible condition.

A review of the now very extensive literature of the subject makes it seem probable that pulsating exophthalmus may be produced by true arterio-venous or anastomotic aneurism of the orbit; by aneurism of the carotid artery, or of the ophthalmic at its origin; by aneurismal varix between the carotid and the cavernous sinus; by thrombosis of the ophthalmic vein or cavernous sinus; by dilatation of the sinus; or by obstruction of the return of venous blood by growths at the bottom of the orbit or behind it. The protrusion of the ball is the result of venous engorgement; while the pulsation and bruit are communicated from the carotid, or are produced by the rush of blood into dilated vessels confined in a bony cavity and with obstructed outlets, or are symptoms of an aneurismal varix of the orbit due to a communication between the carotid artery and the cavernous sinus. From a study of the comparatively few post-mortem records, and the histories of a large number of cases in which the patients have survived, I am convinced that marked pulsation and bruit have most frequently been produced by aneurismal varix of the orbital veins. In three traumatic cases direct communication between the carotid artery and the cavernous sinus was found after death; and in three spontaneous cases post-mortem examination showed that there had been rupture of diseased carotid arteries in the cavernous sinus. In a number of cases the diagnosis of arterio-venous communication in the cavernous sinus has been made, with more or less confidence, during life.

In a traumatic case, reported by Knapp, this diagnosis was subsequently confirmed as positively as it could have been by a post-mortem examination. Ligature of the carotid gave partial relief, but, nearly two years afterward, there was a recurrence of the orbital disease, with great increase of the pulsating tumor, enormous protrusion of the eye, and sloughing of the cornea. After extirpation of the eyeball, the orbit was found to be filled with an irregular pulsating mass, which was removed entire, and was found to consist chiefly of an aneurismal varix (*Arch. Ophthal.*, vol. xii.). The accompanying illustration (Fig. 3707) shows the condition found, post mortem in one of Nélaton's cases (Sattler, Graefe and Saemisch "Handbuch," vol. vi., p. 848). There was a fracture of the sphenoid bone and of the petrous portion of the temporal, and a small hole in the carotid communicating with the cavernous sinus. The sinus and the ophthalmic vein were dilated and tortuous.

It must be confessed that serious objections can be urged against the use of the terms "pulsating exophthalmus" and "vascular protrusion," and perhaps it may be well to discard them when accurate and definite diagnosis is possible. It is quite true that, as Mr. Curling said in opposing the introduction of these terms, "to class affections of very different character under one common head, taken from a prominent symptom, is not calculated to advance surgical pathology and practice"; but it is equally true that such advance is not promoted by feigning a positive knowledge when we have it not, and giving a definite name to indefinite conditions. Confession of ignorance is an essential preliminary to the acquisition of accurate information, and the lesions producing the prominent symptoms of protrusion of the ball and pulsation may be conveniently and profitably classified with reference to these symptoms, until the accumulation and study of post-mortem records throw more light upon the subject.

In 1875 (Trans. Am. Ophthal. Soc.) I published abstracts of fifteen cases, including the imperfectly reported one of Guthrie, in which post mortem examinations had been made. As in two of these cases (Lenoir's and Hamilton's) the symptoms had been produced by vascular malignant growths of the orbit, this number should be reduced to thirteen. In the papers since published, of

Rivington (Med.-Chirurg. Trans., vol. lviii., p. 282) and Sattler (Graefe-Saemisch. vol. vi.), are quoted the following two cases that escaped my search:

1. Hirschfeld (*Gazette des Hôpitaux*, 1859, p. 51; *Lancet*, 1873): Traumatic; post mortem, a blood-clot found in the cavernous sinus, and this clot covered a small circular hole in the carotid, which looked as if it had been punched out and was occupied by a string of decolorized clot about two inches long passing into the mass of coagulum.

www.libtool.com.cn

2. Oettinger (Sattler, *ibid.*): Spontaneous; post mortem, no change in the arteries, but traces of inflammatory processes in the retrobulbar tissues, and obliteration of the ophthalmic vein.

I can find only the three following reports of post-mortem examinations recorded since 1875:

1. Blissig, 1876 (Sattler, *ibid.*): Traumatic; post mortem, "decided dilatation of the internal carotid in the cavernous sinus." As the common carotid was tied eight weeks after the injury, and the patient lived five weeks after the operation, Sattler seems to think that the cause of the dilatation may have been a wound in the artery that had closed.

2. Schlaefke, 1879 (*Arch. für Ophthal.*): Traumatic; post mortem, dilatation of the cavernous sinus and aneurismal enlargement of the cavernous portion of the carotid artery; all the orbital veins enormously distended and the frontal and supra-orbital dilated.

3. Coggin, 1883 (*Arch. of Oph.*): Spontaneous; post mortem, marked aneurismal dilatation of the cavernous portion of the carotid artery, ophthalmic vein not much enlarged. In this case the pulsation and bruit seem to have been communicated from the carotid aneurism.

This makes a total of eighteen post-mortem records, an analysis of which gives the following result:

True aneurism of *both* ophthalmic arteries in the orbits (doubtful), 1; post-orbital aneurism of ophthalmic artery, 1; aneurism of carotid in cavernous sinus, 1; dilatation of carotid in cavernous sinus, 4; wound of carotid in cavernous sinus, 3; thrombosis of cavernous sinus and ophthalmic vein, 5; dilatation of cavernous sinus and ophthalmic vein, 2; pressure on cavernous sinus and ophthalmic vein by new growth, 1.

The case considered doubtful is that recorded by Guthrie ("Operative Surgery of the Eye," p. 158, 1823). The following is his report: "I have seen one case of true aneurism of the orbit which terminated fatally. The symptoms were similar to those above mentioned (cases of Travers and Dalrymple), but no tumor could be perceived; the hissing noise in the head could be distinctly heard. On the death of the patient an aneurism of the ophthalmic artery was discovered on each side, about the size of a large nut. The vena ophthalmica cerebralis was greatly enlarged and obstructed where it passes through the foramen lacerum, in consequence of a great increase in size which the four recti muscles had attained, accompanied by an almost cartilaginous hardness, which had been as much concerned in the protrusion of the eye as the enlargement of the vessels." The description is so meagre and loose, and the post-mortem appearances reported are so very peculiar, that this case is not generally regarded as affording positive proof of the existence of true orbital aneurism.

An aneurism of the ophthalmic, the size of a hazelnut, just at the entrance of the artery into the orbit, was accidentally discovered in a cadaver by Carron du Villards (Sattler, *ibid.*, p. 846). There was no history of the case, and it is not even known that it was one of pulsating exophthalmus.

Finally, in one of Nunneley's spontaneous cases (Med.-Chir. Trans., vol. xlviii., p. 28) a circumscribed aneurism of the ophthalmic artery, as large as a hazelnut at its origin from the carotid, was discovered. The post-mortem was made nearly five years after a successful ligation of the carotid. The arteries of the orbit are described as unusually small. These three cases comprise all the post-mortem evidence of any connection of the ophthalmic artery with the symptoms of pulsating exophthalmus.

While the above was passing through the press, I met at last with a report of what seems to have been a veritable case of "orbital aneurism," carefully examined and treated during life and verified by autopsy—the only one, so far as I know, on record. The report was read at the last meeting of the British Medical Association by Dr. Alexander Dempsey, of Belfast, and may be found in the *British Medical Journal* of September 18th, 1886. The symptoms, which first appeared a few hours after childbirth during violent vomiting, differed little from those observed in the reported cases of carotid aneurism which have occurred under somewhat similar conditions. The common carotid was tied, and death resulted from secondary hemorrhage from the wound in the neck and from bleeding from the aneurism through the cornea. There was an aneurism of the internal carotid artery, at the point of origin of the ophthalmic, which had no communication with the cavernous sinus. Its diameter at its widest part was from one-half to three-fourths of an inch. The orbital aneurism is described as follows: "The ophthalmic artery, from its origin, was also very considerably dilated, I should say to fully four times the size of the opposite one, and on tracing it into the orbit we found an immense sacculated aneurism developed on its superior aspect. The sac would contain easily a mandarin orange. In its centre there was a post-mortem clot, but around its circumference there was a firm, laminated fibrous ante-mortem clot which was a complete cast of the sac, except at its anterior part, where it was open and communicated with the eyeball by a large opening at the upper, back, and outer part of the globe. The contents of the globe had escaped, when hemorrhage had taken place, through the cornea. The superior petrosal sinus of the opposite side was distended, but the other sinuses of the brain appeared normal. The arteries of the circle of Willis were dilated, especially the anterior communicating. The veins of the orbit were all very much enlarged, especially those at the inner angle of the eye."

While it would seem that any obstruction to the return of blood by the ophthalmic vein may produce the symptoms of pulsating exophthalmus, even complete obstruction by thrombosis of the sinus does not, by any means, always do so. In a case reported by Lloyd (*Oph. Rev.*, vol. iii., No. 37) there was aneurism of both the basilar artery and the internal carotid, and the cavernous sinuses of both sides were blocked with firm fibrinous red thrombi; yet there had been but slight exophthalmus, which lasted only a few days, and never any pulse or bruit. Lloyd attributes the recession of the globe to the establishment of collateral circulation; and Sattler says that when an intracranial aneurism is formed gradually it may completely compress the ophthalmic vein and cavernous sinus without producing either pulse or exophthalmus.

Though *aneurism by anastomosis* was formerly the favorite diagnosis in cases of so-called "orbital aneurism," it has never been verified by post-mortem observation, and more recently its occurrence has been doubted. The following congenital case (Harlan, Trans. Am. Ophthal. Soc., 1875, and Internat. Med. Congress, 1876) seems scarcely to admit of any other probable view than that of aneurism by anastomosis, or cirsoid aneurism. The patient was a healthy man, twenty-five years of age. The left eye had always been prominent and the left side of the head larger than the right. From his earliest recollection there had been a rushing sound in his eye and head. The left eye was enormously protruded and forced downward and outward. No useful vision. Whole left side of face hypertrophied. Above the eyeball, and lying more to the nasal side, there was a distinct tumor of almost cartilaginous density. Pulsation was strong enough to communicate an evident motion to the head of the auscultator; and a loud aneurismal bruit was not only an annoyance to the patient, but could be heard by others some distance from his head. There was a doughy

Digitized by Microsoft®

swelling of the soft parts, extending about an inch above the orbit, in which strong pulsation could be felt. Pressure upon the left carotid stopped all pulsation, and the tumor became soft and could be pressed back into the

www.libtool.com.cn

FIG. 3508. Congenital Aneurism by Anastomosis of Orbit.

orbit. The supra orbital and frontal arteries were much distended and pulsated strongly, and this aneurismal condition extended down the angular branch of the facial on the right side. A vascular tumor, formed by engorgement and hypertrophy of the inferior conjunctival fold, almost concealed the cornea, and had several times bled quite freely; this was removed by constriction with silk ligatures. Some months later, the patient presented himself with violent acute inflammation of the contents of the orbit. The tumor was increased to twice its former size, the exophthalmus was enormous, the eye could no longer be covered by the lids, and the cornea sloughed. In a few weeks the tumor had completely consolidated and was rapidly diminishing in size. In this case the congenital origin, the hypertrophy of the whole side of the face, the involvement of the external vessels, and the evident extension of the disease beyond the orbit to the subcutaneous tissue of the brow point to aneurism by anastomosis, or cirsoid aneurism. The only other possible supposition is a rupture of an aneurism of the carotid in the cavernous sinus and consequent aneurismal varix of the orbit, but the history of the case makes this more than improbable.

Vascular malignant growths of the orbit may produce the symptoms of pulsating exophthalmus, and in at least two such cases the carotid artery has been tied for the cure of orbital aneurism. The bruit in these cases may be very decided, but is not likely to be so loud; the tumor shows more tendency to extend toward the temporal side of the orbit, and is less reducible after compression of the common carotid than in cases of pulsating exophthalmus dependent upon the causes that we have been considering. Of course, multiple tumors and other indications of malignant disease should be carefully looked for.

Treatment.—The long continuance of some cases without material change, and the recovery of a few without interference, or with only hygienic care and medical treatment, should discourage resort to serious surgical procedure when there is no immediate danger or decided suffering or deformity, though these conditions may, perhaps, be considered exceptional. Milder remedies should, at least, be given a trial first.

In a very decided traumatic case reported by Dr. Holmes, of Chicago (*Am. Jour. Med. Sci.*, July, 1864), complete cure followed the exhibition of veratrum viride and extract of ergot for two months; and Dr. Freeman, of Canada (*ibid.*, 1866), reports the cure of a spontaneous case, in a few weeks, by application of cold, direct pressure on the swelling, and the use of digitalis. In a few cases, digital compression of the carotid artery has effected a cure.

Compression of the common carotid has been frequently tried. In my own traumatic case (Trans. Am. Oph. Soc., 1875) the patient himself kept up intermittent compression for several hours daily. At the end of six months there was decided improvement, in two years all prominence of the eye had disappeared, and some months later he was entirely cured. Of course, this case is open to the suspicion of spontaneous cure, but the patient always experienced great immediate relief from the compression, and was confident that it was the cause of the final cure. It is almost impossible to apply instrumental compression effectually, and it has never been successful. According to Sattler, of twenty-nine cases treated by compression, continued or intermittent, permanent cure can be claimed in only four, though more or less improvement followed in five others.

Galvano-puncture has been tried in two cases unsuccessfully (Petréquin, *Gazette Médicale*, 1846, and Bourguet, *ibid.*, 1855). In Petréquin's case the patient died.

Acupressure, with hot needles, has failed in one case.

Injection of ergotin has been tried once without success.

Injection of coagulating fluids has effected a cure in three cases (Bourguet, *loc. cit.*; De Sormeaux, quoted by Rivington, Med.-Chir. Trans., vol. lviii.; and Brainerd, *Lancet*, 1853). Bourguet and De Sormeaux used tincture of the chloride of iron, and Brainerd used the lactate.

Ligature of the common carotid has proved by far the most efficient means of treatment, and a number of brilliant successes have been reported. It must be remembered, however, that it is not without its chances of failure and its dangers of a fatal issue. Sixty three ligations of the common carotid, performed on 61 patients, in the treatment of pulsating exophthalmus, have been compiled by Sattler. In 17 cases (26.98 per cent.) the operation had little or no permanent effect; in 8 (12.70 per cent.) it resulted fatally; and in 38 (60.30 per cent.) the result was favorable.

Extirpation of the orbital tumor is a bold procedure and has a brief but favorable record. In his report of a successful case of this operation Knapp (*Arch. of Oph.*, vol. xii., No. 2) makes the following reference to three others: "Among the different methods recommended and practised, I chose the one, extirpation, which I find mentioned in Sattler's compilation of one hundred and six cases only three times, namely: (1) Morton's case (Sattler, No. 70), excision of the whole contents of the orbit, excessive hemorrhage arrested by glowing iron and compression, recovery; (2) Frothingham's case (Sattler, No. 80), ligation of common carotid, retardation of increase for three years, then rapid growth, extirpation with very considerable hemorrhage; (3) Hanson's case (Sattler, No. 106), ligation of common carotid, return of symptoms as early as the second day, three weeks later extirpation of the tumor with preservation of the globe, profuse hemorrhage arrested by perchloride of iron."

VASCULAR PROTRUSION, WITHOUT PULSATION.—As has already been stated, in thrombus of the cavernous sinus, though more or less exophthalmus is almost invariable, pulsation and bruit may be absent; and this is, perhaps, the rule. *Cavernous tumors* of the orbit have been met with in a few cases. A typical one is described by von Graefe (*Arch. für Ophthal.*, t. vii.), in which the

Digitized by Microsoft®

whole mass was removed with the eyeball. Wecker ("Maladies des Yeux") extirpated a somewhat similar tumor without removing the ball. In each of these cases the tumor consisted of spongy tissue encysted in a dense capsule. There has never been pulsation in any well-established case of cavernous angioma of the orbit. The only remedy is extirpation. The exophthalmus in goitre may be considered of the nature of vascular protrusion without pulsation.

www.libtool.com.cn

Simple Angioma (Telangiectasis) sometimes extends into the orbit from the skin of the lids, forming a soft, slightly compressible tumor. The best treatment is extirpation or electrolysis. Simeon Snell has lately reported several successful cases of the latter, and considers it especially applicable when the disease extends deeply into the orbit (*Lancet*, July, 1886). Frequent repetition of the operation is usually necessary.

Encephalocele.—Though encephalocele, or meningocele, of the orbit is extremely rare, it is important to bear in mind the possibility of its occurrence. This is well illustrated by a case described by Guersant ("Maladies des Enfants," p. 246). The patient was examined by a number of the fellows of the Surgical Society of Paris, who all agreed in considering the case one of vascular tumor, and in advising treatment by setons. The patient died with cerebral symptoms, and a post-mortem examination showed that the tumor consisted of brain substance, covered by membranes, which had passed through the fronto-ethmoidal suture. It may be extremely difficult to distinguish such a tumor from a vascular swelling, particularly as, if of considerable size, it would be likely to pulsate; and, if situated behind the ball, it would cause exophthalmus. Its congenital character should excite strong suspicion; it would be increased in size by forced expiration and much diminished by pressure. If the contained fluid, obtained by acupuncture, is found to be not coagulable, it is probably cerebro-spinal. Other congenital defects would be likely to occur in connection with it. In a case in which Oettingen (*Klin. Monatsblatt*, February, 1874) diagnosticated a spheno-orbital meningocele associated with some angiomatous tumor, there was also a small occipital meningocele, which bulged out when the orbital tumor was pressed upon; and tapping the latter with the finger communicated an impulse to the former. Even here, however, the author could not feel quite sure of his diagnosis, and suggested the possibility of a vascular tumor communicating with the intracranial cavity by means of absorption of the orbital wall.

Tumors of the Orbit.—The remaining tumors of the orbit may be classed as cystic and solid. The most prominent *symptom*, and one that, in greater or less degree, is necessarily constant when the tumor is situated behind the ball, is exophthalmus, which will vary in extent and direction with the size, position, and character of the tumor. If the latter is situated outside the muscular pyramid, it will cause the ball to protrude in a direction opposite to its own position; if within the pyramid, it will press the eye more directly forward, and will participate more in its movements. Diplopia is a frequent and sometimes an early symptom. The motion of the ball is not necessarily affected by a small tumor, but is limited by a large one; and, if this is outside of the muscles, the limitation will be chiefly in the direction of its site. Complete immobility of the eye suggests malignant growths, as their well-known tendency is to involve and include the neighboring structures. Paralysis of the orbital muscles often causes squint, ptosis, etc., and compression or stretching of the optic nerve may produce blindness in an otherwise sound eye; or, the nerve may be involved in a morbid growth. Injury to the ciliary nerves may be shown by dilatation of the pupil, or may result in sloughing of the cornea from neuroparalytic keratitis. Finally, the eye may be destroyed by ophthalmitis resulting from interference with its nervous and vascular supply. Pain is a very variable symptom, being sometimes severe and sometimes absent. It is in some cases referred to the bottom of the orbit, in some it appears as frontal or ciliary neuralgia, and in others as general headache. The ophthalmoscopic appearances are sometimes negative, but often show some signs of pressure upon the optic nerve, such as venous congestion and arterial contraction, retinal hemorrhage, "choked disc," or optic atrophy.

Diagnosis between tumors of the orbit and periostitis or phlegmon, vascular protrusion and disease of the neighboring cavities often presents serious difficulties. The mode of onset of the disease, whether sudden or slow, and whether accompanied or not by acute inflammatory symptoms, is an important consideration, but will not always be a safe guide in case of chronic periostitis or chronic abscess (p. 399). Vascular protrusion may generally be distinguished by the fact that the ball can be pressed back, by the effect of compression of the common carotid, by the dilatation of vessels beyond the margin of the orbit, and by the existence, in some cases, of pulsation and bruit. It must be remembered that pulsation and bruit have led to mistakes in cases of highly vascular malignant growths. Careful inquiry should be made as to predisposition to syphilis or malignant disease. Valuable information is obtained by careful exploration with the finger pressed well back behind the ball. Osseous growths and solid tumors attached to the walls of the orbit, if not too deep in the cavity, can usually be distinguished in this way with a considerable degree of certainty, though periostitis will sometimes simulate the latter closely. An effort should be made to decide, by palpation, whether the tumor is hard, elastic, or fluctuating, whether fixed or movable, and whether situated outside of or within the muscular pyramid. Enlargements of the lachrymal gland, on account of their position, can generally be recognized with comparative ease. It may sometimes be necessary to determine the character of the contents of a supposed cyst by puncture. The nasal cavities and the vault of the pharynx should be explored with the mirror.

Cystic Tumors.—The most common true retention cysts found in this locality are the *sebaceous*. They probably arise from the skin, though their connection with this point of origin may not always be traceable.

Fig. 3709.—Congenital Cyst of the Lower Eyelid with Microphthalmos.

Cysts of the lachrymal gland ("dacryops") are rare. They are due to retention of the tears from obstruction of the ducts. The swelling enlarges with increased secretion of tears and its character is not usually difficult to recognize.

DROPSY OF TENON'S CAPSULE has been described as a form of exudation cyst, but its pathology is somewhat doubtful, and its occurrence is, to say the least, extremely rare. *Serous cysts* have been attributed to dis-

www.libtool.com.cn

FIG. 3710.—Orbital Sarcoma.

ease of the bursa in the trochlea of the superior oblique muscle, or of those sometimes found on the levator and superior rectus; and Wecker considers it probable that most serous orbital cysts arise in this way. This view is probable, but lacks proof in pathological anatomy. Congenital *dermoid cysts* are found more frequently in the orbit than elsewhere. It is generally stated that their usual seat is near the external angular process of the frontal bone, but of 51 cases collected by Berlin 27 were on the nasal side, 12 on the temporal, 8 below, and 4 above. Their walls are of a cutaneous structure, and contain sebaceous matter and sometimes hair. Teeth have also been found in them. Wecker (*loc. cit.*) says that serous cysts may form voluminous tumors, which enlarge the orbit by excessive pressure, and extend through foramina into the cranial cavity. He, however, gives but one instance, quoted from Delpech. The cyst was prolonged into the cranial cavity through the optic foramen, which was sufficiently enlarged to admit the index finger. Inflammation of the sac, induced by incision and exploration, extended to the brain and resulted in death. It was found that a diverticulum of the cyst, three inches long, had encroached upon the under surface of the cerebral lobe, and had contracted firm adhesions with the meninges. This case, which is also quoted by Mackenzie as one of hygroma, Berlin thinks must have been a meningocele. If serous tumors of very large size have ever existed in the orbit, it is not likely that they originated in diseased bursæ, which are never known to produce such tumors elsewhere, but it is more probable that they were *cysts of new formation*, similar to the so-called hydrocele of the neck, whose pathology is not well known. A rare form of cyst is usually described as "congenital orbital cyst with anophthalmos or microphthalmos." In a few cases there has been entire absence of the eye, but generally there has been a rudimentary ball. In the latter case the tumor appears beneath the lower lid and is described as "lower lid cyst." The lower lid is bulged forward by an incompressible but tensely fluctuating cyst, the bluish color of which is evident through the thin and distended skin. Fig. 3709 shows a typical example. Behind the cyst was a rudimentary ball, hardly larger than a pea (Harlan, Trans. Am. Oph. Society, 1893 and 1902). The pathology of these cysts is obscure, but it is generally believed that they are formed of embryonic elements intended for the development of an eye. *Hæmatoma* of the orbit has already been referred to in discussing hemorrhage. *Echinococci* and *cysticerci* have been found in the orbit. Though some of the text-books refer to them as if not very infrequent, they are, in fact, extremely rare. Berlin says that, with an experience of forty thousand eye patients, he has not met with a single case of either, but that thirty-nine more or less reliably reported cases of the former are to be found in literature, while he has been able to find reports of only three rather doubtful cases of cysticerci in the orbit, though they are comparatively frequent in the eyeball and its appendages. Furnaget has collected eight cases. (*Archives of Ophthalmology*, xvi., p. 6.)

SOLID TUMORS.—As almost every form of tissue is represented in the orbital cavity, almost all kinds of tumors are possible there. In addition to the vascular and cystic tumors referred to above, the following forms of more solid growths have been described by authors: Lipoma, fibroma, enchondroma, carcinoma, osteoma, neuroma, and sarcoma. A discussion of the histology and pathology of these various diseases is, of course, beyond the scope of the present article. Epithelioma may extend into the orbit from the skin of the lids. Enchondroma and carcinoma are very rare, and fibroma and neuroma not much less so. Lipoma is frequently referred to in a general way, but only a few cases have been recorded. Osteoma is, comparatively speaking, not very uncommon. The larger proportion of solid tumors met with in the orbit belong to some of the numerous forms of sarcoma. Berlin (*loc. cit.*) says: "When we perceive in any part of the orbit a solid tumor with a nodulated surface, which does not fluctuate or pulsate, is not compressible or stone-hard, is not in probable connection with the brain, and does not arise from the lids, the ball, the lachrymal gland, the optic nerve, or the neighboring cavities, we may decide on the diagnosis that we have to do with a sarcoma of the orbit."

Some of the most extensive growths that attack the orbital tissue originate in the eyeball. By far the most common intra-ocular tumors are retinal glioma and choroidal sarcoma, and these, when they have once passed the fibrous envelope of the ball, extend rapidly in the orbit. The former generally ends fatally by direct extension to the brain, or by metastasis to that or some other organ. Orbital sarcomata sometimes grow to an enormous size and make terrible ravages upon neighboring parts. Fig. 3710 is from the photograph of a patient nine years of age at the Wills Eye Hospital. (Harlan, Trans. Am. Oph. Society, 1894.)

Enlargements of the lachrymal gland may be due to acute or chronic inflammation. In the case of the former there are redness and swelling of the upper lid, congestion of the conjunctiva, and considerable pain. It frequently ends in suppuration, which is sometimes followed by fistula. In the chronic form the inflammation is usually indolent, and the swelling may be mistaken for a neoplasm.

Simple hypertrophy of the lachrymal gland is rare. It is said to result from repeated attacks of inflammation, and to occur sometimes spontaneously or even congenitally. Exact observations in regard to it are wanting.

Various forms of degeneration of the gland have been met with, the most frequent of which, according to some authorities, is the adenoid. There are a few well-established cases of sarcoma and carcinoma. I exhibited a sarcomatous lachrymal gland as large as a hen's egg, at the meeting of the American Ophthalmological Society, in 1882, and Dr. Knapp referred to one nearly as large, which he had recently removed. There were no adhesions in either case and the tumors were easily enucleated. The prognosis as to the probability of a return of the disease is favorable.

Digitized by Microsoft®

The position of such tumors makes their diagnosis comparatively easy. The ball is usually forced downward, forward, and inward; but in the case referred to above its direction was decidedly outward. This exceptional symptom, which is probably unique, may be accounted for by the unusual size of the tumor and its development toward the inner side of the orbit (Fig. 3711). The ball resumed its normal position in a few weeks after the operation.

www.libtool.com.cn

Tumors of the optic nerve have been reported in thirty odd cases, and have consisted of glioma, myxoma, sarcoma, endothelioma, and carcinoma. (Knapp, Trans. Internat. Med. Congress, 1876, Berlin, Graefe-Saemisch.) Graefe reported several cases and gave the following symptoms as diagnostic: Progressive protrusion of the eyeball, parallel to the axis of the orbit, or a little outward; preservation of the mobility of the eye; preservation of a layer of connective tissue between the eye and the tumor, and the integrity of the centre of rotation; soft consistence of the tumor; absence of pain; absence of subjective luminous sensations, and rapid abolition of vision. In some cases more recently reported there was more loss of mobility of the ball than von Graefe seems to have met with, and in several there was severe pain in the eye and orbit, and the tumors have not always been of soft consistence. Valuable assistance in diagnosis can be obtained by palpation—pressing the finger deep into the orbit behind the ball.

Osteomata may grow immediately from the diploë of the bone, or originate in inflammatory exudations from the periosteum. In the former case they are likely to extend at the same time into the orbit and into one of the neighboring cavities. They vary in size from a mere nodule to a mass filling the whole orbit, and may be of cancellous structure or of ivory-like density. The latter is much the more common form. They have, in a few cases, occurred in both orbits at the same time. The etiology of orbital osteoma is very obscure. Syphilis, which might naturally be thought a frequent cause, is an extremely rare and even doubtful one. Bony tumors of the orbit are of slow growth, and are injurious only by their mechanical effects, which, however, are sometimes serious enough. A few cases are reported in which a cure resulted from necrosis and spontaneous separation. (Lediard, Trans. Oph. Soc. United Kingdom, iii., p. 23.)

In the *removal of orbital tumors* antiseptic precautions should be carefully carried out. If there is useful vision, or even a sound eye, the eyeball should be preserved whenever possible, unless its retention renders impracticable the thorough removal of tissues involved in malignant disease. It will usually be possible to retain the ball when the growth is outside the intramuscular space, and sometimes even when it is within it. This has been done, with satisfactory results, in the case of tumors of the optic nerve, by Knapp and by Grüning. (*Arch. of Ophthal.*, iv., p. 323, and v., p. 508.) To avoid the deformity of the resulting cicatrix, it is usually better, when practicable, to operate through the conjunctiva, and this will, of course, be necessary in the case of tumors within the muscular space. To gain room, the external canthus may be freely incised, the upper lid may be dissected back, or the external wall of the orbit may be temporarily resected, and replaced after the removal of the tumor, by the method devised by Krönlein. (Knapp in Norris and Oliver's "System of Diseases of the Eye," viii., p. 918.) In removing tumors situated well forward or attached to the orbital walls, or of large size, it may be necessary to make the incision through the skin of the lid. The handle of the knife will often be found of more use than its edge in freeing the growth from its attachments, and much of the operation can most conveniently be performed with a strong pair of blunt-pointed scissors, curved on the flat. Extensive malignant disease sometimes necessitates the removal of all the contents of the orbit, and the application of the chloride of zinc paste to its bared walls. Though such cases are extremely discouraging, in a few that were apparently desperate the operation has succeeded at least in securing some years of comfort to the patient. According to Bull, surgical interference in malignant orbital tumors is almost invariably followed by recurrence, the growth of the secondary tumor is more rapid, and repeated operations shorten the life of the patient. (Trans. Am. Oph. Society, 1896.) It may be necessary to resort to the actual cautery to check hemorrhage, though this can usually be accomplished by hot water and compression. When extension of the disease to neighboring cavities renders its complete removal impracticable, the operation should never be undertaken. Exostoses may be removed with comparative safety when situated on the floor or on the inner wall of the orbit, but the attempt is rarely justifiable when the deeper parts of the roof are involved. Of sixteen cases collected by Berlin, in which exostoses of the orbital roof were operated on, in six the patients died of meningitis. Knapp reports several cases in which osteomata of the roof, situated peripherally, were successfully removed. (Trans. Fifth Internat. Oph. Congress.) It has occasionally been found possible to cut these bony tumors with the pliers or to wrench them from their bases with the forceps, but usually the chisel and mallet will be found more efficient. The use of the dental engine has been suggested and may be applicable to some cases. The attachment of the base to the orbital wall is less firm than the structure of the tumor, and in operating this should be made the point of attack. The difficulties of the operation are greatly increased when the growth originates in the diploë and extends on both sides of the bone. Knapp (*Arch. of Oph.*, ix., p. 464) describes a method of shelling out such tumors within their periosteal envelope, by cutting, with the chisel, the orbital wall encasing them and removing them entire. He thinks the operation may be performed with success even though the exostosis project into the cranial cavity.

Injuries of the Orbit derive their greatest interest and importance from the fact that only a thin plate of bone separates this cavity from the brain. Punctured wounds of the roof of the orbit may very easily penetrate the intracranial cavity. Such injuries were formerly sometimes inflicted by the sword, while in more modern times the umbrella-stick has figured most prominently as the offending instrument. These, of course, are very fatal wounds. Out of fifty-two cases of perforation collected by Berlin (Graefe-Saemisch, vol. vi.) the patients survived in only eleven, and of these five suffered from subsequent effects. Great caution should be used

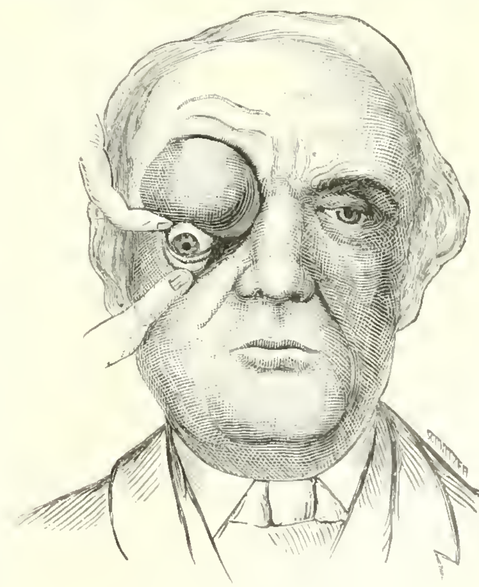

FIG. 3711.—Sarcoma of the Lachrymal Gland.

Digitized by Microsoft®

in the treatment and prognosis of such cases, as the surgeon is liable to be misled by the innocent appearance of the external wound and the absence of immediate symptoms of an alarming character. Mackenzie relates several cases in which the patients walked considerable distances after receiving the injury and then fell dead.

The result of a *gunshot wound* of the orbit will depend upon the direction that the ball takes. In a large proportion of cases the brain is injured and death ensues; but a ball passing obliquely through the temporal region may destroy one eye only, and cases are reported in which sight was entirely destroyed, without other injury, by balls crashing through both orbits behind the eyes. I met with one such case, during the civil war, in which very little deformity resulted, and the external appearance of the eyes was not affected.

www.libtool.com.cn

Fractures of the base of the cranium frequently extend into the walls of the orbit, generally the roof. In the post-mortem examination of eighty-six cases of fracture of the base, von Hölden found fracture of the orbit in seventy-nine. (Berlin, *loc. cit.*) Blindness may result immediately from rupture of the optic nerve, or from hemorrhage in its sheath, or it may be subsequently induced by neuritis. Intracranial hemorrhage and hemorrhage and emphysema of the orbit, as results of fracture of the orbital walls, have already been referred to.

It is important to remember that *foreign bodies*, even of considerable size, may easily escape detection in the orbit. A number of striking instances of this have been recorded. Mr. Carter has reported a case in which a piece of iron hat peg, nearly three inches and a half long, remained concealed in the orbit for several weeks, without the knowledge of the patient. It was removed, and the eye remained uninjured. Hennen found a flattened musket ball which had lodged in the orbit, without injury to the eye. Shot from fowling-pieces and chips of iron driven with force by the hammer or lathe sometimes pass through the ball and lodge in the orbit. Shot may become encysted and cause no irritation, and even larger and rough substances may give little indication of their presence. A man presented himself at the Wills Hospital, in Philadelphia, with a wound near the corneosclerotic junction, but he was very positive that the foreign body that inflicted it had rebounded. The eye was but slightly inflamed, and the patient continued to improve and would have been discharged if a little sympathetic irritation of the other eye had not been noticed. In enucleating the ball great difficulty was experienced in cutting the optic nerve, and a splinter of iron, one inch long, was found lying by its side.

x-Ray examination may be made useful in detecting the presence of a foreign body and even in determining its location.

Cases were formerly reported in which impaired vision was attributed to injury of the supra-orbital or infraorbital nerve by blows upon the edge of the orbit, but it is probable that the ophthalmoscope would have revealed some intra-ocular lesion produced by concussion, or that a fracture involving the apex of the orbit may have injured the optic nerve. Contusion of these nerves is not now recognized as a cause of amblyopia.

Dislocation of the eyeball may be caused by a foreign body thrust into the orbit behind it. It has frequently been produced by the "gouging" thumbs of brutal fighters. The ball lies, upon the malar bone and the orbicularis muscle contracts behind it, retaining it beyond the lids. The optic nerve is, of course, violently stretched, but is not usually permanently injured if the dislocation is soon reduced.

In the *treatment* of injuries of the orbit it is important to bear in mind the dangerous character of its anatomical relations, and the serious mischief that may easily be inflicted by probing. It is better to treat many trivial cases with unnecessary caution than to underestimate the danger of one that may have a serious or even fatal termination. Complete rest, cold applications, and sometimes leeching will be required in the early stages, and if pus forms subsequently it should be allowed prompt and free escape. If incisions are necessary for the removal of foreign bodies, they should be made through the conjunctiva rather than through the lids, to avoid the danger of ectropium or other deformity that might follow the contraction of cicatrices. In reducing dislocation of the eyeball, the upper lid should be stretched and drawn forward, while the ball is gently pressed back. It may be necessary to divide the external commissure. A compress bandage will be required to retain the eye in position for a few days.

Diseases of the Neighboring Sinuses may seriously affect the orbit by pressure upon its walls or by extension into its cavity.

The *frontal sinus* is sometimes greatly distended by the accumulation of retained muco-purulent secretion in chronic inflammation of its lining membrane. The upper and inner wall of the orbit is bulged by pressure, and the eyeball is forced downward and outward. These accumulations are sometimes very extensive, and involve the ethmoid sinus or the frontal sinus of the other side by destruction of the intervening walls. Dr. Bull (Trans. Am. Oph. Soc., 1885) reports a case of chronic abscess involving both frontal sinuses and the ethmoid sinus of one side, the result of an injury received fourteen years before. The disease may also result from direct extension of inflammation from the mucous membrane of the nose. The pus may finally escape into the nose, into the orbit, or externally, but the opening that gives it exit is not likely to be free enough to lead to a cure. The most common locality for spontaneous discharge is at the inner canthus, above the tendo oculi, and a permanent fistula is likely to result. When the bone over the swelling is very much thinned by distention and absorption it yields to pressure by the finger with a kind of crackling sensation, which has been well compared to that produced by pressure upon the lid of a tin box, and which will distinguish the case from one of solid growth. The sinus should be freely opened with a strong knife, or, if necessary, with a drill, near the inner canthus or beneath the superciliary arch, and a silver tube inserted, through which the cavity can be washed out frequently with disinfectant and stimulating solutions. It may be necessary to open the cells through the inner wall of the orbit, remove all carious bone, and establish drainage through the nose.

Similar distention of the *maxillary antrum* by fluid accumulation forces the floor of the orbit upward. It may result from any cause that produces chronic inflammation of the lining membrane of the cavity, but the most frequent cause is a diseased tooth. Pus may escape into the nostril, through the alveolus at the canine fossa, or into the orbit. When it enters the orbit it causes an infiltration and swelling of the lower eyelid, and finally a fistula. When there is a diseased tooth, the best plan of treatment is to extract it and puncture the antrum through its socket; or, if the abscess points in the alveolar process, an opening may be made behind the upper lip. In either case a tube should be inserted and injections used.

A few cases of retention tumor of the *ethmoid cells* have been met with. Dr. Knapp (Trans. Fifth Internat. Oph. Cong.) reports one in which the wall felt so dense that he took it for an exostosis and proceeded to remove it, when the chisel pierced a bony shell, and a quantity of muco-purulent discharge escaped. And a similar experience occurred in my own practice (Trans. Am. Oph. Soc., 1900).

Cysts, polypi, or solid tumors of any of these cavities, or of the nares, may press upon the walls of the orbit or destroy them and extend into its cavity. A discussion of all of these diseases would lead into too wide a field for the limits of this article, and the reader must be referred to works on general surgery and to the elaborate chapter on this subject in Mackenzie's treatise on "Diseases of the Eye." Intracranial growths sometimes involve the roof of the orbit, and in chronic hydrocephalus its cavity is narrowed by pressure, and the eyeball is pushed forward.

George C. Harlan.

OREXIN.—(Phenyl-di-hydro-quinazoline hydrochlorate.) This is the trade name applied to a complex derivative of quinoline. It forms in bright, colorless, lanceolate crystals, without odor, containing two molecules of water, which effloresce on exposure. It has a bitter, pungent, and almost caustic taste. It is freely soluble in hot water. It is almost free from toxic effects, as two grains per pound weight were required to cause death in a rabbit.

www.libtool.com.cn

Orexin was introduced by Professor Penzoldt, of Erlangen (*Therap. Monat.*, February, 1890), as a stomachic, as it was found to exert a tonic influence over the digestive organs, and a stimulant action on the appetite. It possesses neither antipyretic nor antiseptic properties. Penzoldt used it in a great number of cases of anorexia in healthy individuals, as well as in others suffering from various diseases accompanied by loss of appetite. Its use is contraindicated when there are gastralgia, acute catarrh, ulcers, or any condition in which there is hypersensibility of the mucous lining of the stomach, on account of its local irritant action. The class of cases in which it proved most serviceable were those in which the stomach was not diseased, but in which the loss of appetite was due to some general condition, such as anæmia, phthisis, or debility. It was said to be of special value in commencing pulmonary tuberculosis, its employment being followed by a considerable increase in body weight. The dose is from three to seven grains, once or twice a day. Within the last few years the *tannate* of this agent has been brought forward as being superior to the hydrochlorate. It is a yellowish-white, odorless, and almost tasteless powder, soluble in water.

Although favorable reports of its use appear from time to time, it has failed to gain the confidence of the profession and is rarely employed. *Beaumont Small.*

ORGANOTHERAPY.—(Synonyms: Histotherapy—from ἱστός, tissue; cytotherapy—from κύτος, cell).

History.—The oldest medical manuscript in existence, the "Papyrus Ebers," mentions the use of animal extracts in medicine. Among the writers of antiquity Homer, Democritus (450 B.C.), Aretæus, Dioscorides, Galen (600 A.D.), among writers of the Middle Ages, Guido de Chauliac (1300 A.D.), John Hunter, Burton (in his "Anatomy of Melancholy") all speak of the treatment of disease with various animal products. It is interesting to note some of the bizarre preparations that were recommended, *e.g.* (Dr. William Salomon, "New London Dispensatory," 1677), human heart, *cor hominis*, in powder for epilepsy, human skull and human brain, *tinctura cranii*, *essentia cranii hominis*, *spiritus cerebri humani*, for a variety of disorders, chiefly "debility."

Brown-Séquard, in 1869, advanced the hypothesis of the "internal secretion" of the glands and tissues; he held that all the cells of the body manufacture specific soluble products which, entering the blood, exercise "an important if not necessary" influence on other cells. Insufficiency of this function in certain organs, he argued, produces certain definite disorders that can best be remedied by supplying the deficient secretion. The extravagant and sensational claims advanced by over-enthusiastic disciples of this "method" have done much to discredit organotherapy. Of recent years, however, many clinical and experimental data have accumulated to show that certain organs actually do manufacture internal secretions, and that these products profoundly influence metabolism. The postulates of Brown-Séquard were in part, therefore, correct and his method was not altogether irrational.

It is manifestly a precarious and an unscientific procedure to introduce substances of unknown properties into a sick organism without first determining their effect on the healthy body. Before organotherapy could be raised above the level of crude empiricism and could attain the dignity of a rational system of treatment, the power of organ extracts to influence physiological processes had to be studied. This problem was approached in two ways, viz.: on the one hand, different animal preparations were administered to normal animals or human subjects and the effects determined; on the other hand, different organs (chiefly ductless glands) were removed and the perversions of function that followed established. The knowledge, moreover, obtained from operative ablation of organs was in many instances supplemented by clinical observations on human subjects in whom spontaneous degeneration or atrophy of these organs had occurred. In this way a fund of knowledge was acquired that based organotherapy on a rational foundation, and furnished concise indications for the administration of definite organ preparations in definite diseased states. Organotherapy was finally rendered still more exact by the discovery and isolation of "active principles" that possessed all the specific properties of the organs from which they were derived; these, it was shown, could be advantageously administered in the place of the crude extracts, of indefinite and uncertain composition, that were formerly employed.

I. The Ductless Glands.

1. Thyroid Gland.—The *administration of thyroid gland* in large doses accelerates proteid and fat metabolism, causes increased elimination of nitrogen, phosphorus, and chlorine, and leads to an increased absorption of oxygen. Clinically, polyuria, polyphagia, polydypsia, sweating, tachycardia, palpitation, tremor, emaciation, fever, and occasionally glycosuria are observed. This syndrome is called *thyroidism*, and has so many cardinal features in common with exophthalmic goitre (Basedow's, Graves' disease) that this affection is held by many to be due to excessive activity of the thyroid gland, *scil.*, *hyperthyroidism*.

Removal of the thyroid gland is followed in a few days or often after a longer time (as late as nine months) by anæmia and oligæmia (*cachexia thyreopriva*, if the normal gland is removed, *cachexia strumipriva* or *operative myxœdema* if the diseased gland is removed); there is often an initial rise of temperature usually followed by a descent to subnormal; the growth of the bones is retarded in young animals, and various trophic disturbances develop; the rate of respiration increases; a variety of nervous phenomena are observed that may be either irritative or depressive in character, viz.: at first fibrillary twitchings of the muscles followed later by tetany and contractures, or again paresis and diminished sensibility. Other symptoms are palpitation, tachycardia, vomiting, loss of mental vigor, irritability followed by languor and lassitude, apathy, and finally idiocy.

A similar syndrome is presented in myxœdema and cretinism (synonyms: infantile or fœtal myxœdema, myxœdematous idiotism); myxœdema is undoubtedly due to arrest or insufficiency of thyroid function, *scil.*, *athyroidism*. We witness the same arrest of development of bones and external soft parts, the impairment of psychic and of nearly all somatic functions. The infantile type is maintained throughout, the physiognomy is typical, there are characteristic disturbances of the organs of sense and of the intellect, the skin is bloated, the sweat glands are depressed, the heat regulation is disturbed. There are general muscular quiescence, apathy, and idiotism. Exact metabolic studies have so far not been made. In one case the oxygen absorption was found subnormal and the nitrogen excretion reduced. It is probable that metabolism becomes retarded after ablation or atrophy of the thyroid gland.

The function of the thyroid is either nutritive or antitoxic, *i.e.*, it either supplies something to the blood that is necessary to normal life or it removes something that is harmful. The most plausible theory advanced to explain hyperthyroidism and athyroidism is the following. The blood normally contains certain bodies that can inhibit metabolism; the origin of these bodies is obscure; the thyroid secretion possesses the power of neutralizing these substances and rendering them inert. Normally metabolism is regulated in this way. Hyperthyroidism causes complete neutralization of these inhibitory sub-

Digitized by Microsoft®

stances followed by acceleration of metabolism; athyroidism, on the other hand, by permitting the accumulation of excessive quantities of the inhibitory bodies, favors retardation of metabolism.

The active principle of the thyroid gland is thyroidin (iodothyrin), a proteid body containing over nine per cent. of iodine. Removal of the iodine renders this substance inert. Iodothyrin administered to healthy animals produces the same effects as fresh thyroid gland or thyroid extracts. When administered immediately after ablation of the thyroid it is capable of arresting the convulsions that frequently follow this operation. The action of iodothyrin is cumulative, but only of short duration. In order to do good it must be administered continuously. When iodothyrin is given to dethyroidized animals all the iodine appears in the urine in a short time and is wasted. In animals with a thyroid the bulk of the iodine is retained. The thyroid, therefore, seems to be concerned in arresting and preserving the valuable iodine that is ingested with the food and that is intended to play some physiological rôle.

www.libtool.com.cn

It appears, from experimental investigation, that the iodine body of the thyroid is an indispensable regulator of oxidation, and is also needed to preserve the normal function of the brain and nervous system and possibly of other organs. The "colloid substance" of the thyroid that was long believed to be the active ingredient of the gland has been shown to contain an organic iodine compound, probably iodothyrin.

Various *preparations of thyroid gland* are in use in medicine. Bircher in 1889 implanted a piece of thyroid gland under the skin. Later different extracts were prepared with glycerin alone, or with glycerin and carbolic acid or thymol. These extracts were administered hypodermically. The French favor fluid extracts made with carbolized physiological salt solution sterilized under pressure with carbonic acid gas and pressed through clay candle filters; this extract, too, is used for hypodermic injections. Vermehren precipitates the glycerin extract of thyroid with alcohol, gathers the sediment, desiccates it, and administers it in pill form (Vermehren's thyreoidinum). Many clinicians give the fresh gland raw by mouth; some boil the gland to make it more palatable, and claim equally good results as from the raw organ.

Still others give clysmata of thyroid gland. The most popular preparations nowadays are compressed thyroid tablets made from the desiccated gland. These are less disagreeable to the patient, and if prepared by a reliable house enable the physician accurately to determine the dose. True, very little is known of the amount of active principle which they contain, but the same objection applies to all the other preparations. As it is essential to individualize in thyroid medication, it is at all events of advantage to know that the qualitative and quantitative composition of the tablets is approximately uniform. For the many methods in use for preparing dry thyroid extracts and tablets we refer to text-books of pharmacology.

The *dose* to be administered naturally depends on the preparation employed. Many subjects manifest an idiosyncrasy for thyroid products, so that it is always well to begin with very small doses and carefully to watch for symptoms of thyroidism (see above). Dried thyroid powders frequently contain ptomains and peptonized proteids that are toxic; they may consequently give rise to additional untoward symptoms. The best guide is the pulse. Quickening of the heart beat and palpitation should lead us to stop the administration of the drug until the heart action becomes normal. Gastric disturbances or rapid loss of flesh should also put us on our guard. Occasionally a change of preparation or a different mode of administration will enable the patient to tolerate the drug, but it is usually best either to stop its exhibition, or at least materially to diminish the dose.

The fresh gland furnishes about twenty seven per cent. of dry powder, so that each unit of powder corresponds to about four times its equivalent in fresh gland. Manufacturers of thyroid tablets always indicate the amount of thyroid powder contained in each tablet. Beginning with a fraction of a tablet a day the dose may be gradually increased to seven or eight tablets in the twenty-four hours. Of the raw gland one-eighth to two may be given in the course of a day. The common dose of the desiccated powder is from one to five grains three times a day.

Therapeutics.—Thyroid preparations are employed most successfully in all those diseases which are due to insufficiency of thyroid function, viz., infantile myxœdema (*cretinism*), operative myxœdema (*cachexia strumipriva*), and adult (*sporadic*) *myxœdema*. Thyroid treatment in these states is a true substitution therapy.

In all forms of myxœdema thyroid medication as a rule produces amelioration of all the symptoms; in a minority of the cases only the main symptoms are relieved, while the minor and probably secondary manifestations persist. In adult myxœdema, for example, the swelling may recede while the anæmia persists. In cretinism the results are particularly brilliant. The skin becomes soft and moist, the bloating disappears, the physiognomy changes, healthy growth of the bony structures and of the soft tissues is stimulated, normal development of the teeth sets in, and the mental condition improves.

The younger the subject the better apparently the result, although all ages seem to react favorably. A case is on record, for instance, of a woman of seventy-two years who had been a sufferer from myxœdema for twenty-six years, and who was completely cured in three months. Some authors maintain that the older the disease the more rapidly does it yield to thyroid therapy. The sex of the patient is without influence. Each individual seems to react differently.

In a very small proportion of cases thyroid treatment is without result, and one or two cases are on record in which the disease was aggravated. The unsuccessful cases constitute not quite two per cent. of all the cases reported in the literature. As it is not excluded that in some of these instances the thyroid preparation employed was worthless, this is a remarkably good showing, and one that warrants the use of thyroid, with the precautions outlined above, in all cases of myxœdematous disease.

Thyroid preparations have also been employed in a large number of other diseases; the indications for the exhibition of thyroid being based either on our knowledge of its physiological effect or, in many instances, on pure speculation. In some diseased states the results obtained have been sufficiently favorable to warrant recording.

As trophic disturbances of the skin are common in sporadic and operative myxœdema, thyroid preparations have been used in the treatment of many *skin diseases*. The best results have been obtained in psoriasis. The sphere of usefulness in this disease is, however, limited, and thyroid should be employed as a last resort, only after all other standard remedies and measures have failed. In lupus, cutaneous tuberculosis, leprosy, keloid, alopecia, eczema vulgaris, acne rosacea, ichthyosis, thyroid has also been tried with varying effect. The results are often negative and uncertain throughout. Scleroderma does not yield to thyroid therapy. It is probable that thyroid gland acts favorably in some cutaneous affections by stimulating the circulation of the skin. Improved vascular supply leads to improved nutrition, increased activity of the cutaneous glands, and increased vitality of the epidermal layer, all tendencies that must act beneficially in correcting the trophic perversions that form the basis of many skin lesions. Thyroid preparations, either in the form of the dry powder or as an ointment, have also been applied locally to *serpiginous ulcers, suppurating buboes*, syphilitic and soft *chancres*. Good results are claimed for this method.

Loss of weight is a common result of thyroid medication. This observation has led to the employment of thyroid gland for the reduction of *obesity*. A loss of fat undoubtedly can be brought about in the majority of

Digitized by Microsoft®

Organotherapy.

cases. Patients with anæmic obesity are more suitable for thyroid therapy than patients with plethoric obesity. In the latter the results are as a rule indifferent; in the former oxidation is increased, as shown by the increased amount of oxygen that is absorbed and the greater amount of carbon dioxide that is eliminated. Together with the fat some proteid is, however, always lost in these cases, so that from this point of view alone thyroid medication is to be condemned in the treatment of obesity. As obesity, moreover, is frequently complicated by various cardiac disorders, gout, diabetes, and kidney lesions (all conditions in which thyroid preparations may do harm), this therapy is dangerous also on these grounds. It must further be remembered that as soon as the administration of thyroid gland is discontinued the fat returns; consequently the drug must be taken continuously. This leads to the indiscriminate use of thyroid preparations by the laity, a procedure that is manifestly dangerous. Finally, the exhibition of thyroid is totally unnecessary in obesity, for correct dietetic treatment produces results that are equally favorable, more constant, more permanent, and not at all dangerous. In carefully selected cases which are rigorously supervised by the physician small doses of thyroid, together with rational dietary regulations, produce satisfactory results and may be permitted.

In *insanity* the results of thyroid therapy are not constant; some cases are strikingly benefited, others are not affected at all. It is probable that in many sufferers from melancholia, recurrent mania, delusional insanity, and the insanities of adolescence, the climacterium, and the puerperium there is at the same time some derangement of thyroid function, and that these cases precisely, and possibly these cases alone, derive benefit from the use of thyroid preparations. The insanities of myxœdema, needless to say, often improve under thyroid medication. The largest statistics on the subject show that of 1,032 such cases 16.8 per cent. recovered, 24 per cent. were improved, and 59.2 per cent. remained unimproved. The results, therefore, in this particular form of mental derangement are fairly good.

Because infantile myxœdema and *rachitis* are both characterized by disturbances of the bony development thyroid medication has been employed in the latter disease. The relation between the two diseases is, however, purely superficial and their pathogenesis radically different, so that we need not be surprised to learn that thyroid therapy has led to absolutely negative results in rickets.

There is a superficial resemblance between *acromegaly* and myxœdema, and in some cases of acromegaly the thyroid has been found degenerated or atrophied. Some experiments are also on record that seem to show that the pituitary body hypertrophies after removal of the thyroid. These observations have led to the employment of thyroid in acromegaly. The results of this treatment are not satisfactory. A few isolated cases are on record, however, in which thyroid medication seemed to do good after all other measures, including the exhibition of pituitary extract, had failed. The method deserves further trial.

Simple goitre often yields to thyroid treatment. Some statisticians report improvement in two-thirds of the cases. Young persons, it is claimed, are more benefited than older subjects. It is necessary to continue the administration of the remedy for a long time, as otherwise the goitre is liable to return. The swelling rarely if ever disappears completely. The treatment must be considered symptomatic and in no case curative. The treatment is useless in goitre that has undergone secondary degeneration (colloid, cystic). The simple parenchymatous form is the most suitable for treatment with thyroid gland. Of 60 cases of the latter kind 14 were cured, 29 improved, and 19 not benefited. One author reports improvement in all of a series of 79 cases, another one improvement in 92 per cent. of a large series of cases.

The treatment of *Basedow's Disease* (exophthalmic goitre) with thyroid preparations seems altogether paradoxical, for, as we have seen, the cardinal symptoms of this disease are actually produced by the administration of thyroid. To expect a cure would be to avow faith in the homœopathic "law" of similars. Nevertheless the remedy has been extensively employed in this disease either empirically or from ignorance of the physiologic action of the thyroid extract, and finally on the basis of various hypotheses that are not worth recording. The consensus of opinions, as was to be expected, is that thyroid has a tendency to do harm in this disease. In many instances no effect was noticed when small doses were given. A few cases of improvement are also reported, chiefly by American and French authors, but the case reports (which have been carefully studied by the author) do not show that the amelioration of symptoms could in any way be attributed to the action of the thyroid preparations given. In exophthalmic goitre, therefore, the use of thyroid should be discouraged as useless.

A more rational method of treating Basedow's disease has recently been tried, apparently with good results. It consists in injecting the serum of dogs whose thyroid has been removed. This method is at least based on sound physiologic reasoning. It warrants further trial, for of the nine cases treated all improved.

Thyroid preparations have at one time or another been tried in nearly every known disease. Benefits have been claimed in tetany, the various disorders of lactation (galactagogue action), certain middle-ear disorders, muscular and osseous dystrophies, hemorrhages in uterine diseases, cancer of the breast, and syphilis. Very little value, however, attaches to isolated case reports, for in the majority of them grave sources of error are not excluded, and no conservative judgment in regard to the therapeutic value of the thyroid preparations administered can be rendered.

2. The Suprarenal Glands.—Injection of suprarenal extract produces a very marked rise of blood pressure. This is primarily due to vaso-constrictor action, for suprarenal extract exercises its chief effect on the peripheral circulatory apparatus. This is made manifest after section of the medulla or the cord (even complete removal of the cord), section of the vagi, of peripheral nerves, or paralysis of the nervous end apparatus with atropine, for all these operations do not hinder the rise in blood pressure after injection of suprarenal extract. Direct application, moreover, to mucous surfaces causes rapid contraction of the blood-vessels of the part. It is not established whether suprarenal extract acts directly on the muscle cells of the arterial muscularis or on the ganglion apparatus of the vessel walls. Suprarenal extract also acts directly on the heart, causing retardation and strengthening of the heart beat, and in this way, too, a rise in blood pressure. It seems that the extract directly stimulates the heart muscle and at the same time irritates the vagus centre. The former action strengthens the heart beat, the latter retards it. If the medulla is destroyed or the vagus severed, the heart beat is greatly accelerated after the exhibition of suprarenal extract, more so than after simple section of the vagi. Applied to the excised heart of a frog suprarenal extract also causes quicker and more forcible contractions. The *direct* effect of the extract on the heart muscle is accelerating, in other words, excitory, as in the case of the arterial muscularis.

Other effects that follow the injection of suprarenal extract are: (1) The excretion of dextrose (suprarenal glycosuria); (2) local pigmentation around the point of injection; (3) destruction of red blood corpuscles and deposit of hæmosiderin in the spleen and lymph glands; (4) excretion of pigments related to bile pigments.

Removal of the suprarenal glands, a very difficult operation, is invariably followed by the death of the animal. If one gland alone is removed or if accessory adrenals are left behind, compensatory hypertrophy of the remaining organ occurs and the animal may survive for months or even years.

The statements made by different authors in regard to the effect of removal of the adrenals on general nutrition are contradictory. The same applies to the effect on the

Digitized by Microsoft®

temperature; some report a rise, some no change, some subnormal temperatures. The effect on the nervous system is marked. All authors agree that degenerative changes in the brain, cord, and sympathetic plexuses follow removal of the adrenals. The statements in regard to the clinical nervous phenomena observed are not uniform. There is always great muscular asthenia. The digestion is always impaired, with vomiting, hæmatemesis and diarrhœa. The blood pressure always falls. No uniform changes in the pulse rate or the respiration have been noted. Occasionally, when the animals survived for a period of several months, abnormal pigmentation of mucous and cutaneous surfaces has been noted. The most marked changes occur in the chemical composition of the blood. (The statements in regard to changes in the hæmoglobin content and the number of red blood corpuscles are absolutely contradictory.) The blood of an animal whose adrenals have been removed becomes very poisonous and acts like curare on healthy animals. It accelerates the death of other animals whose adrenals have been removed, whereas the injection of normal blood into such animals improves their condition. It appears that after removal of the adrenals certain substances accumulate in the blood that paralyze the motor endings of the nerves and may be the muscles themselves. We are justified in assuming, therefore, that one of the functions of the suprarenals is to disintoxicate the blood. There is much experimental evidence to show that the toxic principle which the adrenals normally arrest or neutralize is a fatigue product of muscle and nerve activity.

Our knowledge of the *function* of the suprarenal glands is supplemented by clinical studies in Addison's disease. Here we find in the majority of cases spontaneous degeneration of the adrenals (usually tuberculous) and a symptom complex which corresponds in many features with some of the symptoms that follow *removal* of the adrenals, viz., asthenia, cardiac weakness. In other features Addison's disease resembles the syndrome following *injection* of adrenal extract (pigmentation, glycosuria).

This observation makes it probable that the function of the suprarenals is twofold, viz., that on the one hand they supply a substance that stimulates the sympathetic ganglia and striped and unstriped muscle fibre; on the other hand, that they arrest or disintoxicate certain poisonous principles which are the product of nervous and muscular activity. The latter fatigue products, we must imagine, when present in excess produce asthenia, blood impoverishment, and occasionally pigmentation and glycosuria. Only on this duplex basis can we explain how insufficiency of suprarenal function or absence of the glands can produce the whole syndrome of Addison's disease.

The "*active principle*" of the suprarenal glands has recently been isolated; it is called adrenalin. Older impure preparations are sphygmogenin (a syrupous liquid), suprarenin, and epinephrin (both albuminoid bodies). Other substances (lecithin, jecorin, pyrocatechin, neurin, etc.) that have been isolated from adrenal extracts, do not possess the specific properties of the fresh glands. With the discovery of adrenalin and its manufacture on a large scale all the other preparations have been superseded with the exception possibly of the desiccated and powdered gland itself.

Dose and Administration.—In one case of Addison's disease a piece of fresh gland was implanted under the skin of the patient. No effects were observed and death occurred in three days. The dry powdered extract is given by mouth in capsules or in compressed tablets, in doses varying from twenty to forty grains a day. The gastric juice does not destroy the action of suprarenal preparations. It must be remembered, however, that the drug when given by mouth exercises no effect on the blood pressure.

For hypodermic use, for administration by mouth, and for local application adrenalin is the most convenient, the most accurate, and the safest preparation at our disposal. It is usually dispensed in the form of the hydrochlorate (adrenalin chloride) as a white crystalline powder. It is a most powerful remedy. One part to ten thousand blanches the conjunctiva in from thirty to sixty seconds; 0.000008 of a grain, injected intravenously, causes a rise of blood pressure that is equal to the effect of 0.005 gm. of the dry powdered extract; 0.0000014 gm. per kilogram of body weight exercises a distinct physiological effect. It is the most powerful hæmostatic and astringent known, and the strongest stimulant of the heart. The preparation is non-irritating and non-cumulative. It is generally employed in the strength of 1 to 1,000 for hypodermic and local as well as for internal use. Hypodermically a few drops (two to ten) usually suffice to bring about the desired immediate effect (see below). By the mouth, from five to ten drops should be given every fifteen to thirty minutes for two or three times, and then every three hours, as needed.

Therapeutics.—In *Addison's disease* suprarenal preparations have been extensively employed. The results are not altogether unfavorable. In many instances improvement seemed to be maintained as long as the drug was exhibited. In one case the patient improved for two years under adrenal treatment. As soon as the remedy is stopped in these cases relapses are liable to occur; they are often sudden and severe, and may even terminate fatally. In the majority of cases the remedy is altogether without effect. In a few cases the patient's condition seemed to grow worse. No case of a complete cure is on record.

A number of statistics on the treatment of Addison's disease with suprarenal preparations have been published, but they are essentially without value because the stage of the disease, the time during which the cases were under observation, the quality of the suprarenal preparation are not included in the tabulation. In many instances the diagnosis is not even positive. One series, the most accurate one, includes 48 cases. Of these 6 were greatly improved, 22 slightly improved, 16 were not affected, and 2 grew worse. The results obtained so far are withal sufficiently encouraging to stimulate further trial.

Suprarenal preparations are the most rapid *cardiac tonic* which we possess. In sudden heart failure due to shock or hemorrhage, narcotics, anæsthetics, etc., hypodermic injections of adrenalin are very effective. The action of adrenalin is very transitory, however, so that in chronic heart lesions it cannot take the place of nitroglycerin, digitalis, or strychnine, but should merely be employed as an adjuvant to these remedies.

As rapid and powerful *vaso-constrictors* suprarenal preparations have a large sphere of usefulness. They can be given by mouth for the arrest of *internal hemorrhages* of all kinds (hæmoptysis, hæmophilia, etc.), and can be applied locally as *hæmostatics* to all bleeding surfaces. In the treatment of epistaxis adrenalin is particularly useful. In *inflammation of the conjunctiva* depletion of the engorged vessels with relief of pain and redness is rapidly brought about by the instillation of a few drops of adrenalin solution into the eye. In *glaucoma*, *episcleritis*, *vascular keratitis*, and *kerato-conjunctivitis* suprarenal gland is a valuable adjuvant to other treatment. In *operations on the nose* or other mucous surfaces the application of a spray of adrenal extract or of adrenalin will produce rapid ischæmia of the parts and consequently render surgical interference practically bloodless. Whenever it is desired to apply cocaine to intensely inflamed surfaces suprarenal extract may be first applied with profit, as it relieves the congestion of the tissues and in this way renders the action of cocaine more powerful. For the details of the employment of suprarenal preparations in ophthalmology, in intratympanic surgery, and in nose and throat work we refer to special articles on these subjects.

Suprarenal gland has been used in the treatment of *diabetes* (this use being based on the view that certain forms of disturbed carbohydrate metabolism are due to "lack of vaso-motor tension"), but the results of this treatment have been quite unsatisfactory. In view of the fact that fluctuations always occur in the condition of diabetic subjects, the reports in regard to temporary amelioration.

Digitized by Microsoft®

following the use of suprarenal extract, must be judged with caution. The discovery of suprarenal glycosuria has also led to the employment of adrenalin in diabetes, but the results obtained are altogether negative so far. In a few cases the dextrose excretion was even increased for a short time.

www.libtool.com.cn

In *asthma* with vaso-motor ataxia occurring in neurotic subjects the drug apparently has a certain application, and beneficial results from its administration are reported.

In the *asthenia* of certain nervous diseases, both functional and organic, the drug may do good as a muscle tonic. It is said to cause the feeling of profound fatigue so frequently complained of by neurasthenics to disappear. It also acts on the uterine muscles, and has been successfully employed to stimulate uterine contractions and to arrest uterine bleeding.

Other conditions in which suprarenal preparations are reported to have exercised favorable effects are acute maniacal excitement with low blood pressure, cyclic albuminuria, and the pain of cancer of the breast and the œsophagus.

3. Thymus Gland.—*Removal of the thymus* in animals in which it persists during life is not followed by any characteristic perversions of function. In man the gland spontaneously decreases in size from the second year, and is almost totally obliterated in adult life. The organ is therefore not essential to life, nor apparently of physiological importance in adult man. Of its function we know nothing.

Injection of thymus extract produces a fall of blood pressure, acceleration of the pulse rate, restlessness, dyspnœa, and in large doses collapse and death.

No *active principle* has been isolated. The gland contains iodine in smaller quantity than the thyroid. Dogs who are fed on thymus excrete a peculiar purin body, and the theory has consequently been advanced that the thymus is concerned in the metabolism of nuclein and the genesis from nuclein of uric acid and its chemical congeners.

The *dose* of thymus is much larger than the safe dose of thyroid. From ten grains to several ounces of the fresh gland have been given per day. Of the dry extract the common dose is from twenty-five to sixty grains a day. No thymus preparation is used hypodermically.

Therapeutics.—Thymus is particularly useful in *simple goitre*. In this disease it acts very much like thyroid, only not so energetically. The statistics in regard to the efficacy of thymus treatment of simple goitre vary greatly. In many of the successful cases reported other treatment was given at the same time; and some of the cases were not kept under observation for a sufficiently long time to justify final conclusions in regard to a cure. The consensus of opinions is, however, very favorable. A critical review of the whole literature of the subject seems to show that about one-half the cases of simple goitre are much benefited by thymus. In several instances thymus brought improvement after thyroid had failed.

In *exophthalmic goitre* the reports are very much at variance. A few authors report aggravation of all the symptoms; others report altogether negative and indifferent results; a few report improvement. One author studied twenty cases of Basedow's disease treated with thymus, and contrasted with them twenty cases treated by various other means. The balance in regard to the retardation of the pulse rate, the decrease of the thyroid swelling and of the exophthalmus inclined toward treatment without thymus. The statistics as a whole are better than for thyroid treatment, but not as good as for other standard methods of treating exophthalmic goitre.

4. Pituitary Gland.—*Removal of the pituitary body* constitutes an operative inroad of such magnitude that only very few statements in regard to the effects of ablation of this organ are recorded in the literature. All the symptoms described, moreover, are ambiguous, and may be ascribed to shock or to injury of neighboring vital parts. From this source, then, we gain no reliable information. Spontaneous degeneration consisting in hypertrophy of the connective-tissue portions, cystic degeneration, sclerosis, atrophy, and tumor formation on the other hand is almost invariably followed by the syndrome of acromegaly. One case of hypertrophy of the pituitary body is on record in which acromegaly was absent, and a few cases of acromegaly are reported in which the gland was not found diseased. The connection between disease of the organ and acromegaly is nevertheless sufficiently apparent to warrant the employment of pituitary preparations in the treatment of this disease. In two cases of adiposis dolorosa the pituitary is also reported enlarged.

Injection of the infundibular portion of the organ produces a rise of blood pressure. Injection of the hypophyseal portion does not produce such a rise, but merely retardation of the pulse beat that persists to a certain extent, even after division of the vagi. A substance has also been isolated from the gland that causes contraction of arterioles and augmentation of the heart beat.

The *function* of the gland is not understood. Some authorities claim that it regulates the intracranial blood pressure, and is also concerned in the regulation of general metabolism. It is finally believed to exercise some effect on the growth and development of the bony structures and the cutaneous tissues of the body.

No *active principle* has been isolated.

The gland is usually administered in the form of a trituration or desiccated as a powder ("hypophysin"). The *dose* varies from one and a half to ten grains a day.

Therapeutics.—Pituitary gland is used exclusively in *acromegaly*. It seems to exercise no effect on the course of the disease, but does seem to be efficient in relieving some of the most distressing symptoms, as, for example, the headache, the neuralgic pains in the limbs, the general lethargy, and the loss of memory. In a series of thirteen cases seven showed relief of symptoms, five showed no improvement, and one case grew worse. Some authors claim to have seen marked benefits accrue from the combined use of pituitary gland and thyroid, particularly in regard to the relief of headache; but it is difficult to determine how much of this good effect must be attributed to the thyroid (see above) and how much to the pituitary gland. It is best in the present state of our knowledge to give sufferers from acromegaly the benefit of the combined use of thyroid and pituitary, in connection, of course, with other established measures for the relief of symptoms.

II. The Blood-Forming Organs.

The rôle which the spleen, the lymph glands, and the bone marrow play in blood formation has suggested their employment in various diseases of the blood. Extracts made from the three organs are used rather indiscriminately, either singly or in combination. Very few clinicians in administering these preparations apparently have clear conceptions in regard to the physiologic function in blood formation which these different organs perform. A summary of our present knowledge in regard to the hæmatopoietic function of the spleen, the lymph glands, and the bone marrow reads as follows:*

The *spleen* plays only an insignificant part in blood formation. It is not at all concerned in the formation of red blood corpuscles (in man!) nor in the formation of granular mononuclear and polynuclear leucocytes, nor of eosinophile leucocytes. It appears to manufacture a small proportion of the lymphocytes. Its chief rôle is to arrest the fragments of red and white corpuscles that are carried to it in the blood of the splenic artery (spodogenic tumor of the spleen in infections).

The *lymph glands* manufacture only lymphocytes and have no other function in hæmatopoiesis. The lymph glands are closely related to the spleen; both contain lymphoid tissue.

The *bone marrow* forms the granular mononuclear and polynuclear leucocytes, and in all probability the red

* The views held by different authors are greatly at variance in some respects. I have in the main followed Ehrlich, who is *facile princeps* in this field.

Digitized by Microsoft ®

www.libtool.com.cn

blood cells. It is not related to the spleen and lymph glands and consists largely of myeloid tissue.

There are then two types of leucocyte-forming tissue—the lymphoid (spleen, lymph glands) and the myeloid (bone marrow). Metaplastic transformation of lymphoid to myeloid tissue may, however, occur. In myelogenous leukæmia, for example, large quantities of myeloid tissue are found in the lymph glands and the spleen. Under these conditions, therefore, the spleen may be said to play an important part in blood formation.

1. THE SPLEEN.—*Extirpation of the spleen* is invariably followed by vicarious hypertrophy of numerous lymph glands, and in many instances by enlargement of the thyroid. A colossal lymphocytosis develops very soon, but no increase is witnessed in the number of mononuclear and polynuclear granular leucocytes. If the animal survives for a year or longer, marked eosinophile leucocytosis develops.

The injection of splenic extracts produces a fall of blood pressure followed by a continuous rise and often by elevation of temperature. Splenic juice is irritating and may produce abscesses when injected hypodermically, and inflammation of the upper digestive tract when given by the mouth. "Erythrol" is a salt-water extract of spleen that is given in the dose of one or two teaspoonfuls a day, and is said to be non-irritating and not disagreeable to the taste.

Therapeutics.—On physiological grounds splenic extract should be administered only to increase the lymphocytes. The spleen, however, contains much nuclein, and it is well known that this substance produces a marked general leucocytosis. From this point of view spleen may be used to produce general leucocytosis, but it seems much more simple and expedient to employ pure nuclein for this purpose.

It is very difficult to render conservative judgment in regard to the efficacy of splenic extracts in diseases of the blood. Innumerable reports have been published, but very few of them are free from ambiguity.

The most careful and exact observers report very little benefit. In the majority of cases other preparations were used together with the organ extract, so that no positive conclusions in regard to the latter can be reached. How splenic extract should produce an increase of red blood corpuscles, as some writers claim, or how, *e.g.*, red bone marrow should cause a marked lymphocytosis, as others relate, it is difficult to understand on the basis of the physiological considerations we have outlined above.

In *leukæmia*, in which disease we have a relative decrease of lymphocytes, and also often a decrease of polynuclear neutrophiles, splenic extract might be expected to act beneficially. Physiologically, the supplying of spleen would raise the number of lymphocytes; chemically, the presence of nuclein would raise the number of granular leucocytes. What effect, however, splenic extract would have on the development of the myelocytes that are so colossally increased in this disease, what effect finally on the primary process, it is hard to foresee. Some good results have been claimed from this therapy, notably in regard to the increase of polynuclears (nuclein?) and the improvement in the subjective sensations of the patient. It does not appear from the case reports that the course of the disease is appreciably modified.

In *other blood diseases* no valid reports of good results are on record. In *typhoid fever* and in *tuberculosis* splenic extract has been given, apparently with some benefit. We are inclined to attribute this to the nuclein leucocytosis.

As the spleen is occasionally found enlarged in operative and sporadic *myxœdema*, splenic extract has been employed in this condition. It seems to improve the general condition of the patient and to ameliorate the distressing mental symptoms. Combined with thyroid it seems also to enhance the efficacy of the latter. In this disease spleen has been given in the form of the dry desiccated organ (four hundred to six hundred grains a week) and as fresh gland (twenty grains per dose three times daily in capsules).

A few cases of *exophthalmic goitre* and of *paludism* (*cachexie paludienne*) are on record in which great benefits were claimed from splenic medication.

2. LYMPH GLANDS.—*Total extirpation of all the lymph glands* is manifestly impossible. In many clinical cases, however, the lymph glands are found extensively degenerated or involved in tumor formation. In all such cases the number of lymphocytes is greatly reduced.

What has been said in regard to the physiological function of the spleen applies with equal force to lymph glands; they, too, may possibly increase the lymphocytes, and they, too, contain much nuclein and consequently can produce leucocytosis. Theoretically, therefore, lymph gland extract is indicated wherever splenic extract is indicated in blood diseases. As a matter of fact, lymph-gland preparations have not been extensively used. All the case reports describe the administration of lymph-gland extract in combination either with spleen or with bone marrow.

3. BONE MARROW.—*Removal of all the bone marrow* is of course impossible. Comparative counts of corpuscles in the afferent and efferent blood-vessels of the marrow have yielded essentially negative results. In clinical cases in which the bone marrow was largely displaced by other tissues (malignant tumor formation), the number of polynuclear leucocytes was found greatly decreased. In the bone marrow are found preliminary forms of red blood corpuscles, and after great loss of blood the yellow marrow of certain bones is converted into red marrow, showing that a process of regeneration is stimulated here. It seems, therefore, that bone marrow should be employed to stimulate the formation of red blood corpuscles and of leucocytes other than lymphocytes. In addition it contains iron in organic combination, and many clinicians recommend its use on these grounds. They argue that the iron in the form found in bone marrow is more readily assimilable than iron in other combinations or metallic iron.

These claims are probably exaggerated, and are not based on experimental or clinical evidence of value. In fact, the majority of clinicians obtain equally good and equally bad results with the standard inorganic preparations of iron.

Bone marrow is either given raw in doses of several ounces a day or in the form of glycerin extracts. As the marrow of young animals is more active in blood formation than the marrow of adult animals, it seems advantageous to employ the former alone. The anterior extremities of the ribs are crushed so as to expose the cancellous tissue. The fragments of bone are then extracted with glycerin for a number of days, the extract is filtered off and given in teaspoonful doses from three to six times a day.

What good effects have been claimed from bone marrow can hardly be attributed to any ingredient that might be utilized to build up corpuscles, or, as we have seen, to the iron which it contains. We must hypothetically assume the presence of some body in bone marrow that is capable of stimulating blood formation.

In *leucocythæmia* (leukæmia) the employment of bone marrow is altogether irrational, because in this disease we have already hypertrophy and overactivity of the bone marrow.

In *progressive pernicious anæmia* some good results are claimed. No case is on record, however, in which bone marrow was given alone. The best that can be said, therefore, is that as an adjuvant to other remedies it may be tried. It certainly cannot replace arsenic.

In *chlorosis* and in secondary *anæmias* the results have been more favorable than in the primary anæmias. Here again it may be used in combination with iron, but cannot replace the latter.

In *pseudoleukæmia* (Hodgkin's disease) the best results have been recorded. The exhibition of bone marrow is a more rational procedure in this disease than in all the other diseases of the blood, for here the spleen and the lymph glands are extensively diseased and the bone marrow, we must suppose, vicariously assumes the greater portion of

Digitized by Microsoft®

the hæmatopoietic function. Anything that can stimulate the bone marrow to increased blood formation is indicated. It is not impossible that bone marrow does this (see above). The best results are reported from the combined use of bone marrow, thyroid, and arsenic.

www.libtool.com.cn

III. The Generative Organs.

The use of orchitic and of ovarian extracts is of historical interest. Brown-Séquard, when an old man, performed his first experiments with "*suc testiculaire*" on himself, and claimed to experience "a return of vital energy and rejuvenescence with renewed and efficient peristalsis and control over the bladder and sphincter." His conclusion was that the testicles secrete into the blood a substance that profoundly influences nervous and possibly muscular metabolism and increases mental vigor. There can be no doubt that the ridiculous claims of charlatanistic advocates of this particular application of the "Brown-Séquard method" have done much to bring organotherapy into disrepute. Nevertheless, the use of testicular and ovarian extracts, if we carefully weigh all the clinical evidence, cannot be absolutely condemned as useless. Favorable symptomatic results at least, that are not due to suggestion, are obtained without question in certain conditions.

1. The Testicles.—*Removal of the testicles* in children exercises a very marked effect on growth and development. The voice remains treble, the subjects usually grow obese, show lack of mental vigor, and manifest psychic perversions of various kinds (eunuchs). The *injection of testicular extract* into normal subjects produces indifferent results.

Several so-called active principles have been manufactured from testicles. The best known is spermin. There are two different kinds of spermin. The one can be converted into its polymer piperazin (dispermin), the other cannot. Poehl discovered the latter, and claims the most startling effects from its exhibition. His statements are borne out by many Russian and some French authors, but the reports are not convincing. The majority of conservative French and German authorities failed to witness any physiological effects from Poehl's spermin and report negative results from its administration in all the morbid conditions for which it is recommended. Brown-Séquard states that spermin is not the active principle of testicular extract. Charcot's crystals which are found in testicle juice are phosphate of spermin.

Testicular extract is best made from the testicles of young animals by maceration of the glands, extraction with normal physiological salt solution, to which may be added a little carbolic acid, thymol, or glycerin. The extract is sterilized according to d'Arsonval, under pressure with CO_2 and filtered through a clay candle filter. No uniform data in regard to the concentration of this extract nor the exact dosage are given by the different authors who have written on the subject. The best results are claimed from hypodermic injection, and Brown-Séquard states that testicular extract is inactive when given by mouth.

The most interesting results are claimed in the treatment of *locomotor ataxia*. The destructive sclerotic lesions of the spinal cord that form the anatomic basis of tabes cannot of course in any way be influenced by the injection of testicular fluid. A cure is, therefore, *a priori* out of the question. It appears, however, that many of the symptomatic manifestations of the disease can be ameliorated by orchitic medication, so that the remedy may be tried. The statistics published are altogether contradictory. Brown-Séquard and d'Arsonval have published the most comprehensive tabulation of results. Three hundred and forty-two cases were treated. All improved, and some, they claim, were "cured" (!). Other French authors report eighty-five and ninety per cent. of successful cases. German clinicians, on the other hand, claim essentially negative results throughout.

In neurasthenia, hysteria, hypochondriasis, melancholia, and kindred *psychoses* transitory improvement is reported by many writers, but the element of suggestion can hardly be excluded in cases of this character.

In general *debility* from wasting disease and in *senility* a certain tonic effect is conceded by nearly all authorities. It appears, therefore, that the chief therapeutic sphere, and probably the only sphere of testicular extract is to act as a tonic to the cerebrospinal centres. This power, it seems, is also inherent in many other organs, though possibly not to such a marked degree as in the testicles. Whether the latter produce a specific internal secretion that is distributed to other organs, or whether all organs secrete such a tonic principle, cannot be determined.

For the arrest of *surface hemorrhage* minced testicle, locally applied, has been found to be of value.

2. The Ovaries.—*Removal of the ovaries* before the age of puberty prevents the appearance of the characteristic phenomena of puberty. The pelvis does not enlarge, menstruation fails to appear, the mammæ and the genital organs atrophy, and occasionally certain male attributes develop. In adults, aside from the cessation of menstruation (a few cases are recorded in which periodic uterine bleeding persisted even after removal of the ovaries) and atrophy of the genital organs, a variety of distressing nervous phenomena and in many patients obesity are apt to develop. In cows removal of the ovaries causes the milk to become richer in fat.

The *administration of ovarian extract* to healthy animals has been known to cause death from hemorrhage into the spinal cord. Males are claimed to be more susceptible to this influence than females.

No *active principle* has been isolated.

Ovary is administered as dry powdered gland in *doses* of from one to five grains. The powder is conveniently dispensed in compressed tablets. Glycerin extracts have also been recommended for hypodermic use.

Therapeutics.—Ovarian extract is a useful remedy for all the symptoms following double *oöphorectomy*. The nervous and vaso-motor disturbances (insomnia, headache, psychoses, flatulence, lumbar pains, etc.), of the climacterium and of certain uterine disorders also often yield to ovarian medication. The drug is not, however, reliable in all cases, and it is impossible to predict in any given case whether or not ovary will do good.

Senile debility in old women seems to be counteracted by the use of ovary. Of sixty-four old women treated in one of the Paris hospitals all, we are told, were greatly benefited and rejuvenated.

In *hysteria* good results are also related. In a young child hysterical contractures disappeared after a few doses; "*mais que n'obtient-on pas dans l'hystérie!*"

In *chlorosis* ovary is of greater benefit than spleen, lymph glands, or bone marrow. It is believed by leading authorities that the ovaries secrete a substance that stimulates blood formation, and that in chlorosis this function is insufficient. On these grounds they supply ovary and claim very favorable results.

Ovarian extract has finally been given with success as an *aphrodisiac*.

IV. The Nervous System.

Brain cortex, cord, and nerve tissue have been employed either singly or in combination in many nervous or mental disorders. The most common preparation used is a sterile glycerin extract that is injected hypodermically.

All nervous tissues contain cholin and neurin, two bodies that are highly toxic. They are probably catabolic products of brain and nerve activity, for in nervous diseases in which nerve metabolism is increased the cerebrospinal fluid contains abnormally large quantities of cholin. It is probably due to the action of the latter substance that the injection of nervous extracts often produces a rise of temperature, leucocytosis, increased absorption of oxygen, and increased excretion of nitrogen. In addition to this toxic action nervous tissue, and particularly brain cortex, seems to exercise a distinct tonic effect, *i.e.*, in healthy subjects a feeling of exaltation and of in-

Digitized by Microsoft®

creased energy. There is no record of any influence having been exerted on the pulse and respiration.

Therapeutics.—The best results, it is claimed, are obtained in *neurasthenia*, but suggestion cannot be excluded. In *epilepsy* and in a case of *bulbar palsy* one authority reports www.libtool.com.cn *mental diseases* the psychopathic disorders seem to remain unaffected, whereas the physical condition of the patients improved greatly under this treatment. Of eleven cases of *tabes* treated with nervous extracts seven are reported benefited.

As against many favorable reports we find an equal or even greater number of absolutely negative results. Nerve-tissue extracts probably possess tonic properties for the nervous system and merit employment in this sense. Many other remedies that we possess are, however equally efficacious, so that nerve extracts are by no means an indispensable adjuvant to our therapeutic armamentarium. Charlatans in and out of the profession have utilized these preparations extensively to impose on a credulous laity, so that their employment has fallen into considerable disrepute among conservative physicians.

V. The Secreting Glands.

Aside from their external secretion some of the glands of the body seem to furnish an "internal secretion" that plays an important part in intracellular digestion. In the case of the pancreas and the kidneys this may be practically considered established; in the case of the liver the intestinal glands, the mammæ, and the salivary glands it is highly probable.

1. The Pancreas.—Complete extirpation of the pancreas is invariably followed by the complete syndrome of diabetes mellitus. If a small portion of the gland is left behind, or if a piece of the extirpated pancreas is subsequently grafted under the skin, diabetes does not develop. Ligation of the pancreatic duct does not cause diabetes. There are numerous theories in regard to the rôle of the pancreas in carbohydrate metabolism; they cannot all be discussed in this place. The preponderance of experimental evidence points to the secretion by the pancreas of a glycolytic, *i.e.*, dextrose-destroying ferment. If this secretion becomes insufficient or is arrested, the blood sugar is not destroyed, consequently it accumulates. This leads to hyperglycæmia and glycosuria. Diabetes may also be due to other causes. Degeneration of the pancreas in man may and may not produce diabetes. From very recent investigations it appears that in nearly all cases of diabetes certain cell groups in the pancreas (the "islands of Langerhans") are found degenerated. These cells are not connected with the efferent ducts of the gland, but pour their secretion into the lymph spaces. It is probable that they furnish the specific internal secretion. Ligation of the pancreatic duct causes atrophy of the cells furnishing the external secretion, whereas the islands of Langerhans remain intact for a long time. The writer is at present engaged in studying the effects of pancreas prepared in this way, *i.e.*, of "isolated" islands of Langerhans in carbohydrate metabolism, both *in vitro* and *in vivo*. It is expected that these researches will throw light on the nature of the internal pancreatic secretion, and will advance the organotherapy of diabetes. For the present this method of treatment, although so clearly indicated on theoretical grounds, has furnished essentially negative results. This may be due to the fact that all pancreatic extracts contain digestive ferments and certain nucleoproteids that are toxic and produce local necrosis when injected hypodermically; thromboses, pyrexia, tachycardia, increased diuresis, and increased N excretion when administered intravenously. The administration by mouth is negative in diabetes. It is probable that the trypsin contained in pancreas extracts destroys the "internal secretion" as it destroys the fat splitting enzyme that we *know* to be present. An extract of pancreas containing no digestive ferments, prepared as suggested above, may act more favorably.

The administration of pancreas by mouth is practised for the relief of *steatorrhœa* and other *intestinal disorders* that are due to perversion or absence of the external secretion of the gland. This treatment is not, however, organotherapy proper, and will therefore be discussed under other headings.

2. The Kidneys.—Complete anuria may persist for many days without causing the development of uræmic symptoms (*e.g.*, hysterical anuria). If a double nephrectomy is performed in a dog and kidney extract is injected intravenously, the life of the animal will be prolonged beyond that of a nephrectomized control animal that is not treated with renal extract. The onset of uræmic symptoms can be delayed in this way. From these observations the conclusion has been drawn that the kidneys furnish an internal secretion that is disintoxicating for certain urinary bodies, and that prevents the occurrence of uræmia. It has also been shown that the toxicity of the blood of uræmic animals is greatly reduced by its passage through healthy kidneys. Uræmia is not, therefore, considered to be due to the retention of urinary bodies alone, but also to insufficiency of the internal disintoxicating secretion of the kidneys. In harmony with this theory kidney extract has been employed in the treatment of a considerable number of uræmic cases, apparently with good results. Kidney therapy is too modern, and case reports are too scanty to warrant extended analysis. The subject, however, seems capable of fruitful development.

3. The Liver.—Liver extract contains many substances with active physiologic and toxic properties, and no less than ten well characterized ferments besides. It is difficult therefore to understand how those who employ liver extract for the sake of an hypothetical internal secretion of the hepatic cells can exclude the action of all these bodies. It has been claimed that the virtues of cod-liver oil are due to the presence in this product of an internal secretion. A few good results are reported from the use of hepatic extract (prepared according to d'Arsonval's method) in *diabetes*. The preparation is said to stimulate the liver cells to increased activity in the sense that it enables them to store more glycogen. A great reduction in the sugar excretion has been reported by reliable clinicians. Some authors have also used liver extract symptomatically for "*hepatic insufficiency*" following alcoholic cirrhosis, and report improvement of many of the subjective symptoms.

4. Mammary Gland.—Mammary gland extracts are believed to exercise an influence on the female generative organs. Desiccated sheep's mamma has been given by mouth in twenty-grain doses for *uterine hemorrhages*. It is said to cause contraction of the uterine muscles and to arrest bleeding. Good results are also claimed from this therapy in the leucorrhœa and irregular bleeding of subinvolution, and in benign tumors of the uterus it is said to relieve many of the reflex symptoms, to control the leucorrhœa and bleeding, and to improve the general health of the patient.

5. Intestine.—There is some experimental evidence to show that the intestinal wall neutralizes many of the toxic products that are generated in the bowel lumen. Insufficiency of this function would lead to autochtonous intestinal intoxication. It has also been shown that the injection of sterile fæces does not produce death so rapidly in animals which have been treated with intestinal extract as in animals which have not. The disintoxicating action of the cells of the intestinal wall is believed to be carried out with the aid of a soluble internal secretion which they produce. It does not seem improbable that the violent systemic disturbances of intestinal strangulation, volvulus, and invagination are in part due to insufficiency of this function and the resulting self-intoxication. The same applies to certain anæmias, psychoses, etc., which may be attributed to auto-intoxication from the bowel.

Extract of intestine has, in fact, been employed with some success in *chlorosis*, and in several cases of stercoræmic poisoning following *strangulation* of intestinal hernias. We are told that in a few of the latter cases the general condition of the patients improved so much un-

Digitized by Microsoft®

der this treatment that operative interference was rendered more safe. This field of organotherapy also merits further cultivation.

6. PAROTID GLAND.—The parotid gland and the ovaries appear to stand in some sympathetic relation to one another. Parotid extract has been used with success by eminent clinicians in Germany and Scotland for the relief of certain symptoms due to ovarian disorders, notably the pain and reflex manifestations of ovaritis in cases in which the glands were enlarged and prolapsed.

www.libtool.com.cn

VI. MISCELLANEOUS TISSUES.

Nearly every tissue of the body has at some time been made to yield an extract. No exhaustive experimental or clinical data relating to their employment are, however, recorded excepting in the case of muscle tissue, lung tissue, and heart. We will therefore discuss these three alone.

1. MUSCLE TISSUE.—Muscle extracts contain abundant quantities of potassium salts and consequently are toxic when given hypodermically. In addition, muscle juice has a distinct thermogenic action and can produce salivation. Reliable investigators claim that small quantities of muscle extract prepared in the cold and sterilized under CO_2 pressure act as distinct muscle tonics.

Muscle extract has been employed apparently with some success in all primary myopathies in which there was no injury to the anterior horns or the peripheral nerves. A leading French neurologist recommends its use in all "*dystrophies musculaires progressives*" with lesions of the fibrillæ of the muscle and connective tissue.

2. LUNG TISSUE.—Pulmonary extract has been successfully employed in the treatment of pulmonary arthropathies. It is believed that destructive lesions of the lungs, in addition to interfering with the respiratory interchange of gases, inhibit the formation of an internal secretion of the pulmonary cells, and that the lack of this secretion in the blood leads to the development of the osteo-arthritic lesions of lung disease. Very good results are reported from pulmonary therapy in a case of Marié's disease (*ostéo-arthropathie hypertrophiante pneumonique*). The arthritic process was arrested, the dynamometric pressure rose from 9 kgm. to 19.5 kym., and the general health of the patient was markedly improved after the twenty-ninth injection. In pleuro-pulmonary suppuration with osteo-arthritis pulmonary extract is also said to act beneficially, and recently "pulmozyme," a pulmonary preparation, has been advised for the treatment of lesions of the lungs themselves. Case reports are scanty and results not uniform, so that judgment cannot as yet be rendered on this therapy.

3. HEART.—Heart extract was extensively used a few years ago in the treatment of a large variety of disorders. The effects claimed from the injection of this preparation were, among others, an increase in the pulse rate, a rise of arterial pressure, increased diuresis, and a general tonic effect. The extract used by the chief advocate of cardiotherapy unfortunately contained appreciable quantities of alcohol, so that we need not be surprised to learn that it exercised the above effects. The literature on cardiotherapy is large and many cures are reported. A careful analysis of the case reports, however, reveals the method to be utterly devoid of value and the claims of its advocates to be unfounded. Cardiotherapy is mentioned only to be condemned. *Alfred C. Croftan.*

ORPHOL. See *Naphtol-bismuth.*

ORRIS ROOT.—(*Rhizoma Iridis*, Ph. G.; *Iris de Florence*, Codex Med.) The peeled rhizomes of three or more species of *Iris* are cultivated for this object in the south of Europe, especially in the vicinity of Florence. They, and a few other species also, are familiar garden flowers both there and in this country. The three following are recognized as the sources of "Orris": *I. florentina* L., with very sweet-scented, white, or pale slaty-blue flowers; *I. Germanica* L., with dark, violet flowers; and *I. pallida* Lam., with flowers light blue, very large, and fragrant. They all resemble each other in respect to the more important particulars. The former is a native of the southern and eastern Black Sea regions, the others of Europe; all have been cultivated for a long time.

The rhizomes are gathered in the latter part of summer, trimmed and peeled, and then dried in the sun, and afterward separated into grades, according to size, symmetry, and appearance. The pieces are more or less long and flattened, with rounded surfaces and ends, often curved or twisted in drying, of a nearly white color, a hard but brittle texture, and a yellowish fracture. Pieces with the branches attached are called "hands"; the detached branches, "fingers." The scars where the roots have been cut away may be seen on the lower surface. Taste bitterish, aromatic, and sharp. Odor, for which it is valued, mild and pleasant, recalling that of violets. Orris which has been kept for one or two years is more fragrant than that just dried. This product has been for centuries used as a perfume, and less generally as a medicine, and is mentioned by most of the classical writers upon medicine. It yields, upon distillation, about 0.1 per cent. of a so-called volatile oil, "*orris camphor*," a buttery-looking substance. This consists chiefly of *myristic acid*, with a trace of *irone*, a liquid with a violet-like odor. *Iridin* is a glucoside, occurring in acicular crystals, in very small amount. There is a specific amaroid, giving the bitter taste. Orris contains also a little resin and fixed oil, and a very little tannin. Starch is abundant.

ACTION AND USE.—Internally given, orris, like our Blue Flag (*Iris versicolor* L.), is a cathartic and occasional emetic, but it is almost never employed in this way. It is a common ingredient of tooth powders, as well as of sachet powders (violet), and is otherwise used as a perfume. The oil is also used in tooth washes. Large, fine pieces are now and then given to teething children to chew upon. *Henry H. Rusby.*

ORTHIN.—This is one of the numerous compounds introduced for its antipyretic properties. It is a combination of hydrazin and para-oxybenzoic acid; the base is an unstable body, but the hydrochlorate is a stable preparation, and is the salt supplied under the name of orthin. It is very soluble in water. The solution should always be freshly prepared and preserved from the light. It is recommended as an antipyretic in typhoid fever, pneumonia, rheumatism, and all febrile disorders. Kobert, who introduced it into therapeutics (*Deutsche med. Wochen.*, 1890), claimed that it was non-toxic and free from all ill effects. Its use, however, has been accompanied by sweating, prostration, and other symptoms of poisoning. The dose advised by Kobert is from five to eight grains. *Beaumont Small.*

ORTHOFORM—meta-amido-para-oxybenzoic methyl ester ($C_6H_3.OH.NH_2.COOCH_3$)—is a white powder without odor or taste, and permanent in the air. It is soluble in alcohol, ether, chloroform, and some of the oils, but very slightly soluble in glycerin or water. It is precipitated, but not rendered inert, by formaldehyde and mercuric bichloride (Luxenburger), produces a brown color with bismuth subnitrate, and decomposes silver nitrate and potassium permanganate. It is not affected by zinc oxide, iodoform, salicylic acid, carbolic acid, lysol, aluminum acetate, or iodine, and may be safely combined in prescription with most of the ordinary antiseptics and dusting powders. It is said to remove most of the odor of an equal amount of iodoform.

Acting on the sensory end-organs, orthoform produces a local anæsthesia, which, owing to the insolubility of the drug, is mild and long continued. This slow action, together with a distinctly antiseptic power, makes it a valuable dusting powder for raw surfaces. It is therefore applied to burns, fissures, painful ulcers, ulcerating hemorrhoids, etc. The anæsthetic effect from a ten-per-cent. powder or ointment lasts for from two to forty-eight hours (Kindler). As the drug has no penetrating power,

Digitized by Microsoft®

www.libtool.com.cn

it is of little use on unbroken skin or mucous membrane. Blondel used a few drops of a saturated solution in forty-per-cent. alcohol for fissured nipples. In zoster or herpes with ruptured vesicles much relief is obtained.

In throat and nose work its use is chiefly limited to ulcerative conditions, though Cheatham reports good results in rose fever. Garnaud's formula for laryngeal tuberculosis is: Menthol 3.0 (gr. xlv.), cocaine alkaloid 0.5 (gr. viij.), orthoform 2.7 (gr. xl.), expressed oil of almonds, 100 (℥ iij. ʒ ij.). It is also used as a spray in five-per-cent. solution in albolene. In painful cancer and ulcer of the stomach it has been administered in dose of 0.5 (gr. viiss.) several times a day with relief from the pain and without any systemic effect. Suspended in water it has been thrown into the bladder for painful cystitis. In dentistry, its slow anæsthesia fits it for allaying the ache of an exposed nerve.

Orthoform is used in five to twenty per cent. powder, ointment, collodion, or solution in oil. Injected hypodermically in alcoholic solution it acts like cocaine, but the latter drug is generally preferred.

Ruhemann, H. H. Wilson, Vogt, Decker, and others who have extensively employed the drug, report the occasional occurrence, from its use, of a peculiar vesicular dermatitis resembling that from poison ivy and very resistant to treatment. Brocq observed hyperæmia and pruritus. Miodowsky had a moist gangrene following the application of a five-per-cent. ointment, and Friedländer collected fifty cases of local or general poisoning and eczema.

W. A. Bastedo.

ORTHOFORM, POISONING BY. See *Synthetic Poisons, Organic.*

OSMIC ACID.—In medical parlance the title *osmic acid* is given to the body *osmic tetroxide*, OsO_4. True osmic acid (H_2OsO_4) is not known in the free state. Osmic tetroxide is a volatile crystalline substance, softening at a moderate heat like wax, and melting at a lower temperature than does that body. It dissolves slowly but completely in water, forming a colorless solution, which, however, on exposure to light, rapidly darkens, even to blackness, by decomposition of the tetroxide with formation of the tetrahydroxide, $Os(OH)_4$. Osmic tetroxide is a powerful oxidizer, and, to living tissues, is excessively irritant. Its odor is powerful and disagreeable, and its vapor intolerably pungent and poisonous, with a peculiar faculty for exciting irritation of the conjunctiva. In the event of the inhalation of fumes of osmic tetroxide, hydrogen sulphide ("sulphureted hydrogen") has been recommended as a chemical antidote, to be taken by inhalation; but since in this case the remedy is itself a powerful poison, the greatest care would be required in its employment.

Osmic tetroxide is of peculiar service to the histologist, by reason of a faculty it possesses of staining nerve tissue. As a medicine it has been used, by hypodermatic injection, for the relief of peripheral neuralgias. The results have been quite variable, but a certain amount of efficacy for the remedy seems to have been demonstrated. A one-per-cent. aqueous solution of the tetroxide is used, and the same should be made only in small quantities when wanted, and kept in the dark. Of such a solution, quantities from 0.20 to 1 gm. (from ♏iij. to ♏xv.) have been injected at a dose. The injections are made as near as possible to the painful spot. The operation is often severely painful, is occasionally followed by temporary swelling and thickening of the tissues at the site of the puncture, and, practised over an efferent nerve, has in one instance been followed also by paralysis. No constitutional effects have followed these injections.

Edward Curtis.

OSPEDALETTI, ITALY, a town of one thousand inhabitants, with nearly a mile of frontage toward the sea, is situated midway between Bordighera and San Remo. It is a quiet Riviera resort, lying under the spurs of the Ligurian Alps, well sheltered from the winds and with a southern exposure. "There is no doubt," says Dr. Wendt, in an article upon this resort in the previous edition of the HANDBOOK, "that little Ospedaletti is more effectually protected from winds than almost any other resort on this coast. Moreover, it gets the sun early and keeps it late. There is less blinding calcareous dust there than, for example, at Hyères, Cannes, or Nice."

"Ospedaletti spreads out for something like a mile along the head of a small crescentic bay. The eastern headland of this bay is formed by Cape Nero, and the western extremity, much farther from the village than the former, by Cape Sant Ampeglio. Thickly planted olive hills surround the place, relieved in the plain by orange and lemon trees, and the usual array of graceful palms. Successive girdles of mountains protect it from the icy north blasts, but less in a northeasterly than in a northwesterly direction. It is fully exposed only to the warm westerly marine breezes." "Immediately behind this village there rises a hill of gentle slope, and a number of mountain torrents of mild proportions trace their undulating course seaward." "The place is so hedged in as to constitute a veritable sun trap." "For undergoing a course of absolute quiet and repose," continues Wendt, "in a sunny, well protected situation, no more suitable place has yet come to my notice on the Riviera."

The hygienic conditions of Ospedaletti appear to be good; the town is spoken of by Linn as having a particularly clean and neat appearance. The drinking-water comes from the same mountain source as that which supplies San Remo, and is "soft, sparkling, and pure." The mean temperature of five winters is given by Linn ("The Health Resorts of Europe," by Thomas Linn, M.D., 1901) as follows: January, 49.82° F.; February, 51.62° F.; March, 53.42° F. The mean relative humidity is 62 per cent., and the number of rainy days, 32.

There are several hotels and pensions of moderate price, well kept, and very comfortable. There is also a fine casino. Medical service can be had there. A short distance from the village are some hot sulphur springs. "Gouty and rheumatic elderly people," says Wendt, "should do particularly well at Ospedaletti." Linn states that this place is rapidly coming into favor as a resort, and it seems to combine very many favorable conditions for a winter health station, viz., its fine natural situation, its pleasant surroundings, its excellent protection from cold winds, the large amount of sunshine, its near proximity to San Remo and Bordighera, and the quiet and repose obtainable there. Moroever, it is said to be two degrees warmer than its neighbors, Bordighera and San Remo.

Edward O. Otis.

OSTEITIS, OSTEOMYELITIS, PERIOSTITIS.—I. OSTEITIS.—Inflammation of bone may be induced by simple traumatism—as a fracture or stripping away the periosteum, by thrombosis or embolism of a nutrient artery, by extension from a periostitis, by extension from arthritis, by exposure to cold or to the action of certain poisons—as phosphorus and mercury, by syphilis, by pressure—as the rarefying osteitis of aneurism, by the eruptive fevers, and especially by typhoid fever. While these fevers may possibly act as primary causes, it is quite certain that they predispose to the development of an osteitis. Lastly, certain germs play an important part in the causation of an osteitis. They are either introduced through compound injuries, or else they are carried to the bones by way of the circulation. The emphasis which should be laid upon this last factor in the causation of osteitis cannot be exaggerated.

It is of little clinical value to classify the inflammations of bone, from an anatomical standpoint, into osteitis, osteomyelitis, and periostitis, since primary periostitis, with the exception of the traumatic and the syphilitic varieties, is very rarely observed; and, on the other hand, every case of myelitis leads, sooner or later, either rapidly or slowly, to involvement of the periosteum in the inflammatory process.

Regarding the firm bony substance itself, when compared with the marrow and the periosteum, it may be

Digitized by Microsoft®

truly said not to take any active part in inflammation; and therefore osteitis, in a narrower sense of the word, as compared with myelitis and periostitis, is unimportant. The firm bone, however, is passively affected, as we shall subsequently notice; and clinically the death of the bone, or of a part of it, may prove to be an affair of the greatest gravity. So much is this true that it has been customary to study acute osteitis under the title of one of its most frequent results—necrosis—and a certain form of chronic osteitis under the heading of caries.

II. PERIOSTITIS.—Periostitis, like osteomyelitis, may originate from traumatism, either simple or compound, and in character may be simple (that is, aseptic) or septic (from the presence of micro-organisms). The syphilitic variety of the disease should probably be classed under this latter heading, although we cannot to-day speak with certainty as to its germ origin. The periosteum is first affected during the secondary stage of syphilis, that is, the stage of invasion following the incubation of the syphilitic virus in the system. Those bones which are subcutaneous seem especially liable to periostitis—for example, the tibia, sternum, and ulna; but the others are not exempt. In severe cases there sometimes appears to be a simultaneous involvement of most of the bony sheaths of the body, with consequent almost unbearable osteocopic pains. These pains are distinctly worse at night, and seem to be increased by warmth; but I am inclined to think that sufferers from osteitis and periostitis of other than syphilitic origin also complain most at night.

The syphilitic periosteum is quite tender, and I have many times noticed pitting on pressure. In this disease it is rare for the periosteum to become separated from the bone by exudations; and consequently necrosis, from failure of the superficial blood supply, is very infrequent in this form of periostitis.

In the later or "tertiary" stages of syphilis, nodes, usually flat, and of sharply defined extent, sometimes make their appearance. They are caused by infiltration of the periosteum with small round cells, and, like all gummata, tend to soften and break down. Their course, and the probability of bone involvement, seem influenced for the worse if the medical attendant, finding fluctuation, use the knife instead of rapidly pushing the iodides or other appropriate medicines.

In acute periostitis, when accompanied by free exudation of fibrin, serum, and pus, the cortical lamellæ of the Haversian systems may be separated from their vascular supply; and unless the surgeon promptly realizes the state of affairs, and makes free incisions down through the dense, unyielding periosteum to the bone, a necrosis of more or less superficial character may, and often does, result.

The clinical picture of acute periostitis is best studied, as it will be later, together with osteomyelitis; for these two diseases are commonly associated together.

A rather rare concomitant of an acute osteomyelitis, usually of a mild type, is a periostitis with exudation of a simple serous character between the periosteal sheath and the bone. Because of the abundance of albumin in this fluid, Ollier here adopted the title of "osteitis albuminosa."

Chronic, non-infective periostitis may be either fibrous or ossifying in character. In the former there is much increase in the amount of connective tissue, and the thickened membrane adheres unusually closely to the bone. In the latter we have as a result an ossific deposit, which may go on increasing for months or even years, ultimately producing exostoses or osteophytes. The new bone of inflammatory origin is not deposited in a regular system of lamellæ, probably owing to faulty nutrition; and it is sometimes absorbed, and disappears, the abnormal activity of the osteoblasts ceasing. This variety—ossifying periostitis—may be associated with either rarefying or condensing osteitis.

With regard to tuberculous periostitis I may state that it is especially apt to appear in the subjects of the so-called scrofulous diathesis, and in the poorly nourished, and to be accompanied by tuberculous osteitis. The discussion of its symptoms, course, and treatment need not be dissociated from that of the latter disease.

III. OSTEOMYELITIS.—The terms osteitis and osteomyelitis will here be considered as one. Where the vascular changes greatly predominate, where pus, fibrin, and serum are abundantly produced, where the brunt of the inflammation is felt by the marrow and contents of the Haversian spaces, the latter term may be applied with especial propriety. And, on the other hand, those cases in which changes in the firm bony structure itself form the prominent feature, may properly be designated as cases of osteitis. However, the two go hand-in-hand. Changes in the relative density of the bony structure can occur only through cellular activity in the marrow spaces and vascular canals. These changes are of two kinds: osteoporosis, or rarefying osteitis, and osteosclerosis, or condensing osteitis. In the former the character of the bone changes from compact to cancellous, and if the process continue the bone may even entirely disappear, its place being taken by a mass of granulation tissue. This variety of osteitis is very common. It is one of the essential phenomena in tuberculous osteitis; it is the process by which the rough, ossified callus following fractures is rounded off; and when a bone is subjected to pressure—as by a growing aneurism—it is a rarefying osteitis by which it is eroded.

In osteosclerosis, on the other hand, the bone grows more compact, and may even—as may be observed in some exostoses—become as dense as ivory.

It often happens that both osteoporosis and osteosclerosis are going on at one and the same time in different parts of the same bone: an osteoporosis within, for example, and an ossifying, even condensing, periostitis externally; and as a result the bone may become widely expanded, although it is a mere shell filled with granulations or with inflammatory deposits.

Or, again, following an osteoporosis, the opposite process may be inaugurated, and the cavities caused by the former morbid process may become filled with new bony deposit, perhaps of even abnormal density. We do not yet know why inflammation of bone terminates sometimes in one and sometimes in the other of these conditions. It is supposable that in condensing osteitis the osteoblasts have an undue activity. In rarefying osteitis the absorption of bone is thought by some pathologists to be caused by the presence of certain large, multinucleated cells—the myeloplaxes of Robin; cells which are also by reason of the power which they are supposed to possess called osteoclasts. In subacute osteomyelitis ragged holes, opening from the marrow spaces and Haversian canals, are formed in the solid bone. These cavities are known as the caverns or lacunæ of Howship. They contain many of the so-called osteoclasts, which, if not the cause, are certainly the witnesses of the osteoporosis.

Other pathologists repudiate the idea that these large cells possess any such power, and attribute the absorption to the influence of the new granulation tissue which is present in these cases, and which lies in contact with the bone. In agreement with Billroth they hold that just as a granulating synovial fringe erodes the articular cartilage against which it rests, "like ivy climbing over a ruin," so here in bone the granulations possess a similar disintegrating power.

In acute osteomyelitis the vascular changes are of the deepest import, since obstruction of the nutrient arteries means death of the bone *en masse*. Let us study the common cases of apparently spontaneous origin. Here the marrow tissue is at first of a deeper red, from intense congestion. Sometimes it is mottled with hemorrhagic spots. Later, a grayish hue appears, due to the presence of great numbers of pus cells; and occasionally little medullary abscesses develop. In bad cases not only does thrombosis of the nutrient vessels occur, but gangrene of the marrow and of the contents of the Haversian canals also takes place, with rapid liquefaction. The bone cells being no longer nourished die. The infection may spread rapidly, involving the whole length of the bone.

Digitized by Microsoft®

or, in the milder cases, it may remain limited to a comparatively small area.

Usually the process begins in the bone, and extends thence along the course of the nutrient vessels to the periosteum, which then becomes involved. Some surgeons think that the infection spreads also through the canaliculi, from bone cell to bone cell, and from centre to surface.

Sometimes the reverse is the case, the periosteum being first attacked. Inflammatory products—pus, fibrin, and serum—rapidly strip the swollen and œdematous periosteum from the bone, inducing the most frequent form of necrosis, that of the superficial lamellæ.

The pressure caused by the exudations is very great; so much so that fat contained in the medullary tissues may be forced out, and can sometimes be seen in globules upon the surface of the pus (Roser).

The pus finally breaks through the periosteum at some point of softening and disintegration; it enters the intermuscular connective tissue, and may finally reach the surface. In that case the pus can sometimes be seen to pulsate from its contact with the richly vascular medullary substance.

When the osteomyelitis is near a joint, the articular lamella may become involved by extension, perforation through the cartilage may occur at some point, and the most dreadful arthritis ensue. In the very young, separation of the epiphysis from the shaft may, after a week or two, occur. The cartilaginous epiphysis, from its comparative lack of vascularity, is not so subject to attack as is the adjacent bone; yet even this may die.

Those parts of the bone which are cut off from their blood supply die in consequence; and this necrosed bone, upon its subsequent separation, is called a *sequestrum*. Next in frequency to the cortical sequestrum is the central sequestrum—that composed of the bone surrounding the main medullary canal. In extreme cases the whole thickness of the bone, or even the whole bone, may die. This separation of living from dead bone occurs, however, only at a much later period. On an average from three to five months is required for the complete separation in the case of a young adult. The length of this period of time also varies according to the extent of the involvement and the degree of vascularity. In the elderly, the same separation may need, perhaps, as long a period as one year for its accomplishment.

Along the line of demarcation between living and dead bone, granulations spring up; they start from the blood-vessels. The granulation tissue seems to possess the power to erode and absorb the dead bone with which it is in contact, until at last the sequestrum lies loose upon a bed of granulations springing from the sound bone. In the process of solution of the dead osseous substance, whereby separation is effected, certain salts—such as calcium phosphate—which are not soluble in an alkaline medium, are dissolved and disappear. Hence it is thought that the granulations evolve an acid. Formerly it was believed that lactic acid was the solvent. Tillmanns' later researches seem to show that it is the active, nascent carbonic acid contained in the blood which dissolves the dead bone tissue; and that, in the accomplishment of this, aid is derived from the activities of the osteoclasts.

Unfortunately, this process of absorption is extremely slow, so that we can hardly hope for the complete disappearance of even a moderate-sized sequestrum. Evidences that a certain amount of absorption has already taken place are found, however, upon almost all loose pieces of dead bone.

When a sequestrum lies near the surface of the body, nature is sometimes able to extrude it, and new bone, the *involucrum*, is formed from the granulation tissue, and pushes the sequestrum out. More commonly, however, it cannot escape. The greatest growth of involucrum springs from the periosteum, save in those cases in which the bone-forming layer of the periosteum has been destroyed by the suppurative process; and this new bone of periosteal origin, while it strengthens the shaft as a whole, prevents the escape of the sequestrum. The reason for the failure of a central sequestrum to be ejected is obvious.

For mechanical reasons, therefore, nature cannot, as a rule, complete a cure after separation of the sequestrum. Consequently, if the surgeon do not interfere, there will continue to be, for an indefinite length of time, a discharge of pus through more or less tortuous openings, called *cloacæ*. As regards the kind of interference which is needed, I will simply state briefly that the surgeon must chisel, saw or drill through the ensheathing involucrum (involving the transverse diameters as little as may be) and release the imprisoned dead bone. It is very unwise to delay interference after the cast-off bone is found to be loose in its cavity, since the patient is thereby subjected to serious danger from exhausting suppuration, from amyloid degeneration of the viscera, from involvement of the neighboring joints in the inflammation, and from hemorrhage, through mechanical erosion of some large nutrient vessel by the jagged sequestrum.

Causation.—Although we have discussed to some extent the pathology of acute suppurative osteomyelitis, we have not as yet dealt with its true cause. The question arises, Have we not here to deal with microbes? Numerous accurate investigations of the pus obtained either directly from the medullary canal or from the depth of the tissues immediately in contact with the bone, and subsequent pure cultivations, have settled this question definitely. "It is not due to a specific poison, however, as was believed to be the case for a long time, but it may be caused by any kind of micro-organism which excites acute inflammation and suppuration" (Tillmanns). Among these the variety most frequently found in cases of this nature is the staphylococcus pyogenes aureus; less often the staphylococcus albus and staphylococcus citreus; and rarely the pneumococcus, the bacillus communis coli, Eberth's bacillus, the typhoid bacillus, the bacillus pyogenes fœtidus and pyocyaneus, and the micrococcus pyogenes tenuis and tetragenus. Although I mention the pyogenic streptococci last, they are far from being the least in importance. They are found chiefly in the osteomyelitis of young children, and this type of the infection is very apt to prove promptly fatal from sepsis.

How are we to explain the entrance of germs into the bone without an apparent traumatism as a doorway? The only plausible assumption seems to be that they pass into the blood through slight abrasions of the mucous or other tegumentary surfaces of the body and eventually find lodgment in the bone. Clinical facts support the theory that, preceding osteomyelitis, patients will be found to have suffered from bronchitis, enteritis, etc. (Kocher).

The majority of cases of this disease, with the exception of suppurative myelitis in connection with compound fracture, occur during the time of the development of the skeleton—*i.e.*, during childhood and adolescence. One is inclined to think that the physiological growth of the bone predisposes to inflammatory processes. This theory finds support in the fact that in most cases of acute and chronic myelitis the disease is found to be near the epiphyseal cartilage, and therefore in the most newly formed bone. It furthermore seems to appear with greatest frequency in that end of a long bone which furnishes the greatest amount of growth, and in which the current of blood is least active. It is commonest in the upper end of the tibia and the lower end of the femur; and in the upper end of the humerus and the lower end of the radius and ulna. It will be remembered that the nutrient arteries of the long bones of the lower extremity run *away* from the knee; and in the upper extremity they run *toward* the elbow.

The selection of the youngest bone tissue as the favorite nidus of the microbes seems dependent upon the peculiar form of the developing blood-vessels. It will be found upon investigation that the sprouting blood-vessels of the growing long bone correspond to wide, hollow spaces close to the epiphyseal cartilage. It will be easily

Digitized by Microsoft®

seen that the blood current grows less rapid in these lacunæ, where the capillaries enlarge, thus giving the cocci contained in the blood a better opportunity to adhere and remain. It is further stated (Hoyer, Rindfleisch) that the blood of the medullary canals flows unenclosed by any tunic in these spaces, and thereby the cocci are brought into direct contact with the bone.

www.libtool.com.cn

Schiller has demonstrated by a series of experiments that coloring matter introduced into the circulation is retarded in its course and deposited in the blood-vessels of the youngest bone tissue; thus showing, as Hueter says, that there is a tendency for the cocci contained in the blood to be left at this point as a sediment. This being so, we can readily understand how the infection of the young medullary substance occurs.

Clinical Picture.—Sometimes exposure to cold, a wrench or a blow, exhaustion from eruptive fevers, etc., may act as predisposing causes, determining either the time or the seat of the attack, or both. Or, again, no cause whatever may be discoverable. In any case of acute, suppurative osteomyelitis the actual and exciting cause is probably always bacterial.

The disease usually begins with one or more chills, followed by fever, which is often very high. In a child delirium is common, and the little sufferer may not be able to point out the seat of pain, which, however, rapidly becomes severe.

With the intensity and mode of infection, and the degree of vital resistance possessed by the patient, the symptoms vary. He may even die within a day or two, overwhelmed by the poison. To rather less severe cases, from a resemblance in the violence of their onset and symptoms, Chassaignac has given the title "typhus des membres." Later, and in more insidious cases, typhoid fever may be simulated. There may be some slight resemblance to a cellular erysipelas. In not a few instances, owing to the fact that the constitutional manifestations alone were taken into account, a dozen other diagnoses—some of them quite absurd—have been made.

Repeated rigors and pyæmic temperatures may point to the involvement of more than one bone, or to suppurating foci elsewhere, and pyæmia, septicæmia, ulcerative endocarditis, etc., may develop in the worst cases, especially in the absence of prompt surgical intervention.

Diagnosis.—The disease with which that under consideration is most often confounded is acute articular rheumatism, and this mistake is especially likely to occur when more than one long bone is attacked. The local symptoms, however, will soon clear up the diagnosis, unless, owing to delirium of the patient, or to the fact that he is too young for speech, attention is not called to the real seat of suffering. Rather near the articular end of the bone, as a rule, a distinct swelling is soon observed. This is caused first by the great congestion and œdema of the periosteum and adjacent tissues, and later by the separation of the periosteum from the bone by inflammatory products. While the tenderness over this swelling is very marked, it does not extend beyond the limits of the tumor. Furthermore, unlike what is observed in acute rheumatism, motion of the neighboring joint is not specially painful. The skin over the swelling is not reddened at this time; it may even be paler than normal. Later, when the pus is about to escape through some disintegrating point of its dense sheath, the skin becomes reddened, softened, and gives way.

Acute Epiphysitis.—Acute epiphysitis presents problems of the gravest importance. In addition to the risk of a suppurative joint trouble, by extension, the focus of infection—whether it begins in the shaft or in the epiphysis—is commonly close to the narrow line of cartilage which connects the two. The importance of this lies in the fact that if the cartilage become severely involved in the inflammation there may result a diastasis—*i.e.*, a separation of the epiphysis from the shaft, with dislocation, a condition which demands the utmost care and the most skilful splinting to prevent a final deformity from union in a bad position. Even when the involvement of the cartilage is somewhat less grave, if the normal cellular activity in the vicinity of this narrow line of cartilage be permanently impaired or destroyed, growth of the bone, so far as this end is concerned, will cease. And the seriousness of this circumstance is still further enhanced by the fact that the greater portion of the growth of the long bones takes place normally from that end which is most subject to attacks of acute osteitis. For example, in the case of the long bones of the extremities the ends which are nearest the knee, and farthest from the elbow, supply most of the growth, and are also more subject to acute osteitis than are the opposite ends. And—to mention a single instance only—von Bruns has collected evidence which shows that diastasis of the femur from all causes occurs in the proportion of twenty-eight cases of separation of the lower epiphysis to one of the upper. And according to Ollier, the development in length of the thigh bone is about two-thirds from the epiphyseal cartilage of the lower end and one-third from that of the upper end. When it occurs in a little child, a diastasis of the lower end of the femur, even though the separated parts are properly replaced and adequately splinted until bony union shall have taken place, may result in a shortening of as much as nine inches; whereas if the diastasis occurs at the upper end, the records show that only about half this amount of final deformity results. These are facts, therefore, which it behooves the physician in charge to know in order that he may, for his own protection, and especially in view of the possibility of a suit for malpractice, give timely warning to the parents.

Treatment.—As regards the treatment of acute epiphysitis, prompt surgical intervention and careful splinting to prevent diastasis are the only means worth mentioning. On the other hand, the proper management of the sequelæ will depend upon the precise character of the pathological conditions left by the acute disease. A problem very difficult to solve is that which is presented when the epiphyseal cartilage of only one of the two bones (of either the forearm or the leg) is involved by the disease. In such a case growth will be entirely arrested in one bone while it will continue to take place in the other. Under such conditions the ultimate result—if the parts are left to themselves—can scarcely fail to be a dwarfed and grotesquely twisted limb. Surgical intervention may be resorted to at a relatively early period, with the idea of preventing the evil to which attention has just been called, or surgical measures may be adopted for the correction of the deformity after it has been fully established.

In the former case the surgeon, having to do with a case of diastasis, should—after all suppuration has ceased—chisel through the thin plane of cartilage of the neighboring or sound bone of the same extremity. This stops the growth of that bone, and results in a straight though shortened limb. On the other hand, if interference is postponed until the deformity shall have reached its full measure of development, the surgeon will have to tax his ingenuity by the employment of various means (chiselling, aseptic fracturing, resection, etc.), to overcome in a measure the extreme deformity so commonly found at that time.

Something further needs to be said about the treatment of acute osteomyelitis in its incipient stages. In the first place, it must be borne in mind that the inflammation, in a case of this nature, has already produced, or is soon to produce, pus, and that this pus is confined beneath dense, unyielding tissues. The indication is therefore plain: the knife must be used, and that too with as little delay as possible. A free cut should be made through the periosteum, clear down to the bone; and with a dressing forceps entered closed and withdrawn opened, the wound should be enlarged for free drainage. Then it should be irrigated with some antiseptic solution—bichloride of mercury 1 to 2,000, for example—and, if the incision has been made through deep tissues, a drainage tube is to be inserted down to the bone. Otherwise the wound may be packed loosely with wet antiseptic absorbent gauze.

When, in 1854, Chassaignac and other French surgeons

Digitized by Microsoft®

advocated a similar free incision, their advice was followed by disastrous results; generally by pyæmia and death. That was before the days of antisepsis. To-day, any surgeon who knows what surgical cleanliness means can make such an incision without threatening the life of his patient; and it is, in fact, his duty to employ the knife. Whether this incision alone will be of much value will depend upon whether the infective nidus was situated in the periosteum, or whether that membrane was only secondarily involved by extension of inflammation from the marrow. The latter supposition is in most cases the correct one, and may be considered almost a certainty if drops of free oil be observed between the periosteum and the bone—it evidently having been forced out by the tremendous pressure within the bone.

www.libtool.com.cn

It is well to wait a very few hours after cutting down to the bone, rather than to penetrate at once to the marrow; unless indeed the violence of the onset seems to the operator disproportionate to the amount of trouble thus far discovered, in which case delay would add to the peril. If, at the end of this period of delay, the local and general symptoms seem aggravated, or at least not diminished in intensity, showing that the trouble is within the bone, and not mainly periosteal, then the trephine should be used, or the burr or chisel, and the marrow should be exposed, curetted just as far as it appears to be diseased, irrigated, and freely drained. This should be done at several places if the disease seems to be extensive; and it should be followed by continuous irrigation with solutions of bichloride of mercury, or of acetate of aluminum, of appropriate strength—this irrigation to be kept up until the more severe symptoms shall have subsided.

Such treatment seems radical, but is really conservative of the patient's limb, and very possibly of his life.

The constitutional treatment consists simply of measures intended to support the patient's strength. It is, perhaps, of little avail to give antiseptics; still, the safer ones—as benzoate or salicylate of soda—may be employed. It may also be well to use free inunctions of the Credé liquid silver ointment. The writer's experience has not been favorable to the injection of antitoxin serums in such cases.

As regards those cases which are seen at a later stage and in which the disease is complicated by the presence of a certain extent of necrosis of the bone tissue, the practical questions which present themselves are these: How is the existence of such a bone necrosis to be ascertained? and, What steps are to be taken for the relief of the condition after we have discovered its existence? By the intelligent use of the flexible silver probe—or, in certain cases, of two probes—the surgeon should have no difficulty in ascertaining that a necrosis exists, and also occasionally in determining how great is its extent, and whether the necrosed portion is or is not loose. In other instances, however, he will be forced to resort to an explorative operation in order to determine to how great an extent the bone is necrosed, and whether the sequestrum has become sufficiently detached to warrant the adoption of radical surgical measures for the removal of the dead bone. Furthermore, in reaching the latter decision he will have to weigh very carefully the question how far the patient's health is being undermined by the constant discharge of pus which invariably accompanies the separation of the dead from the living bone.

The late Prof. Thomas M. Markoe, in his article on "Necrosis" in the first edition of the HANDBOOK, expressed himself as follows in regard to the steps which should be taken in the presence of a necrosed condition of the bone:

"Having now settled the question as to the propriety of operation, the time of its performance may be considered. As a general rule, it is better to remove the sequestrum just as soon as it can be ascertained to be loose. But if the patient be much reduced in health, if the season be unfavorable, and if the discharges and the sufferings from the local disease be not excessive or exhausting, then it is quite proper, and generally quite safe, to wait until, by careful attention to nutrition, by fresh air and exercise, perhaps by change of air and surroundings, we secure a better reparative condition of the system, in view of the often serious operation which is contemplated. If there be no considerations of this nature, the operation should be undertaken without unnecessary delay.

"The operation itself consists in releasing the sequestrum from its mechanical confinement within the tissues, and removing it. The operative procedure will vary, therefore, with the extent and solidity of the tissues enclosing the sequestrum, and with the accessibility of the sequestrum from the surface. In most cases of superficial necrosis, or exfoliation, it is only necessary to divide the soft parts covering the dead piece in order to remove it with great ease. This, however, is not always the case in exfoliation, for it sometimes happens that the dead plate extends on the sides of the bone far from the surface, and it occasionally occurs that a thin plate of superficial necrosis surrounds completely certain portions of the shaft of the bone, thus producing a condition of things which renders operation extremely tedious and severe, and, not infrequently, even then the entire removal of the deepest portions of the sequestrum is not accomplished.

"To take a typical case of necrosis of the shaft of the tibia, where the diagnosis is clear, the involucrum sufficient, and the sequestrum entirely separated, the steps of the operation may be described as follows: A free incision is made on the anterior surface of the limb, where the bone is most superficial, and this incision should extend as far as the supposed limits of the necrotic action, and may be crossed by another at about its middle, so as to give easy access to the surface of the involucrum. The flap then being dissected up clean from the exposed bony surface, we select the most favorable point for attacking the bone case enclosing the sequestrum. This is generally to be found at one of the larger cloacæ, which, being further enlarged by the chisel or gouge, soon gives us access to the cavity in which the dead bone lies. By means of this first exposure of the cavity we learn the size, the degree of freedom, and the extent of the sequestrum, and we take our measures accordingly. If the sequestrum prove to be very long, then the incision through the involucrum must be extended so as, if possible, to release it without breaking off any of the irregular and slender processes in which it terminates. About this the operator should be extremely careful, as, if any of these fragments are left in the bottom of the wound, they are apt to give trouble, and if we cannot reach and remove them with slender forceps they are frequently a long time in making their way to the surface, during which time, of course, the wound will not heal. In exposing one of these large sequestra, it should be borne in mind that restoration of the involucral bone which we are cutting away takes place to only a very limited extent, particularly in those who have passed the earlier periods of life. It must be remembered that nature has already, in forming the involucrum, accomplished a very elaborate and extensive restoration of bone, and if we destroy this new formation she will hesitate about repeating the process. In point of fact, we find that the cavity left after these operations does not, except in very young subjects, fill up with bone, but rather with a firm, fibrous, cicatricial tissue, which, while it fills up the gap left in the bone, contributes very little to its strength. We must be careful, therefore, not to weaken the bone by any unnecessary cutting in its transverse diameter, though in the longitudinal direction we may proceed with more freedom. The cutting is done most satisfactorily, I think, with a gouge, though if a cloaca is not in a favorable position for enlargement a small trephine answers a good purpose in making the first opening through the involucrum. The gouge and the rongeur, however, will be all that in most instances will be required. After the removal of the sequestrum a careful examination should be made with the finger and the probe, to make sure that no fragments remain, and that no cavities are left without sufficient openings to secure drainage."

By way of supplementing the remarks quoted above I

Digitized by Microsoft®

will state that it is important, after laying bare the bone, to curette away the entire granulating surface, and to sterilize the living bone, thus laid bare, by peroxide of hydrogen or other effective means. Often such curetting lays bare the entrance to more than one chamber containing sequestra. There may even be a chain of such running along the marrow. And unless the operator makes sure by probe and curette that this is not the case, his work, in removing the first sequestrum exposed, may prove by no means a success; and a continuing discharge of pus will show that he has not removed the whole cause. Following these steps, it is possible by at least nine different ways to treat the bony cavity in an endeavor to hasten its healing. (1) The old-fashioned way of simply packing with gauze to compel healing from the bottom. (2) Neuber's plan of "deep canalization." (3) Schede's healing by the moist blood clot. (4) Thiersch's skin-grafting directly upon bone. (5) Lücke and Bier's "osteoplastic necrotomy." (6) Healing by aid of decalcified bone chips. (7) Autogenetic fresh bone chips (human). (8) Heterogenetic fresh bone chips (rabbit or calf or lamb, for example, have been used). (9) Heteroplastic fillings. These are still largely in the experimental stage; but we may mention sterilized plaster-of-Paris, bone charcoal, iodoform starch, dental gutta percha, and Richter's cement. Upon the skull the writer has successfully used a specially prepared celluloid plate, deprived of all excess of nitric acid, and substituting in its composition a little synthetical urea for the more irritating camphor, to give resiliency. The lack of space permits us to discuss briefly only two or three of these nine methods.

According to Neuber's plan, which has for its object a material shortening of the tedious healing by granulation, the integument and subjacent connective tissue, for a short distance on either side of the wound, should be stripped up in the form of flaps, and then these should be stretched in such a manner as to cover, either entirely or at least to a large extent, the excavation left in the bone by the removal of the sequestrum. They may be retained in place by nailing them to the bone. The deep trough-like depression in the skin which remains after healing takes place soon grows shallower through the development of connective tissue between the bone and the skin; and eventually this connective tissue is supplanted to a greater or less extent by newly formed bone.

A still more recent method is that for which Schede deserves the credit. It consists in allowing the wound, after removal of the sequestrum, to fill entirely with blood clot. This, under perfect asepsis, does not break down or putrefy, but undergoes rapid organization, blood-vessels springing into and permeating it from all sides. This idea, in properly selected cases, proves an excellent one. It is, of course, unsafe unless accompanied by absolute sterilization of the cavity and by protection from atmospheric germs.

Thiersch's method of skin-grafting directly upon the bone is frequently successful in hastening a cure. As with Neuber's plan, nature, in the course of time, deposits new bone beneath the skin, and to a large extent fills up the deep depression left by the removal of the sequestrum.

Still another recent plan which deserves to be mentioned here is that of Lücke and Bier. It is spoken of as "osteoplastic necrotomy." In the execution of this plan the long bone is sawn transversely with the wire saw, half-way through at two points, viz., just above and just below the seat of the necrosis. These transverse lines are connected, on one side, by a longitudinal one, and along this latter line the chisel is used, until the cavity of the bone is opened; then, by depressing the handle of the chisel, the rectangular flap of bone and superjacent parts is broken loose along a line opposite to that made by the chiselling, and is temporarily turned back like the lid of a box; and, finally, as a last step, the sequestrum is to be extracted. The cavity in which it lay must next be well curetted and irrigated, and then, after provision has been made at the most dependent point for free drainage, the lid-like flap mentioned above is to be restored to its natural position.

There are certain subacute and chronic cases of osteomyelitis, limited in extent and indicating a mild degree of bone infection, which deserve mention. They are accompanied by more or less pain and tenderness of the bone over a small area, and this may continue for months and years with slight or no constitutional symptoms. In some of these cases, called "Brodie's abscess," the pus may finally reach the surface, or may remain permanently surrounded by compact bone; an osteoporosis has occurred, sufficiently great to hollow out a pus cavity, usually lined with granulations; but commonly no necrosis—no death *en masse*—takes place. It may be that a few of these abscesses represent the site of softened and broken-down gummata of late syphilis.

The treatment is self-evident. By means of the trephine the cavity is to be reached and drained. Even supposing the diagnosis to be erroneous; supposing the case to be in reality that uncommon disease, a neuralgic osteitis—one in which a chronically congested vascular state in the bone seems to induce nerve dystrophia and consequent neuralgia,—experience proves that penetration of the bone gives the surest relief, and is a safe operation.

Rheumatic Osteitis does occur, but is very infrequent, and is apt to be secondary to rheumatic periostitis. The coexistence of rheumatism elsewhere in the fibrous framework aids the diagnosis. Heat, counter-irritation, and, as a last resource, opening the bone, give the greatest relief, and should be conjoined with the usual purely medicinal and hygienic means of treatment.

Syphilitic Osteitis presents itself chiefly as a result of gummatous involvement in the later stages of the disease. It is also, however, to be noted as one of the manifestations of inherited syphilis. The osteochondritis of infants, first described by Wegner, is a frequent manifestation, as is also dactylitis syphilitica. Regarding the former, Taylor states that it is often the only sign of this inheritance; and that at other times its presence decides the syphilitic nature of coexisting lesions. It involves chiefly the shafts and epiphyseal junctions of the long bones; and is usually found at birth or within the following month. The swellings are rather distinctly limited, as a rule, and the baby suffers when they are handled. In bad cases separation of the epiphyses, suppurative osteomyelitis, and necrosis may develop.

The dactylitis when present affects mainly the first phalanges. It differs from the tuberculous variety in this regard, as also in the fact that when luetic it is apt to be multiple, and to appear upon both hands.

"Parrot's nodes," involving the two halves of the frontal bone and the two parietal bones, are found in infancy, and are due to the same cause. These swellings, upon all sides of the anterior fontanel, are very characteristic, and are caused by both a periostitis and an osteitis of these bones.

In later childhood and in adolescence are found the bony irregularities, hypertrophies, and asymmetries which often are so characteristic of syphilis. In the face, the nasal bones are those which suffer most. As a result of necrosis of the bony support the nose undergoes shortening, the lower part retreating toward the upper part; or else the bridge is sunken. Of the remaining parts of the skeleton the tibia presents the most striking of these late bony inflammatory changes due to syphilis. It may be greatly thickened, its crest being no longer a mere ridge, but broadened and swelling forward, so that when seen from one side the tibia presents the characteristic shape of a sabre.

For a fuller study of the bony stigmata of this disease, including the pathology and clinical course of gumma of bone, the reader is referred to the article upon *Syphilis*.

Necrosis of the Jaws Dependent upon the Action of Phosphorus.—This is a condition which the surgeons of the present generation rarely have the opportunity of observing. I may therefore be permitted

Digitized by Microsoft®

again to quote from Professor Markoe's article on "Necrosis" in the first edition of this work.

"These cases occur almost exclusively among the operatives in match factories, who are living in an atmosphere containing the fumes of phosphorus and phosphorous acid. The workmen most liable to be affected are those employed in the dipping-room, and in the packing-rooms. In the first there is a constant prevalence of the fumes of the volatilized phosphorus, and the air in the second is still further vitiated by phosphorous acid from the frequent burning of the matches while being counted and packed. It is believed that these phosphorous emanations, which are quite soluble in water, are dissolved in the saliva, and thus come in contact with the teeth and gums, upon which latter the poison seems to exert its primary influence. Why these particular parts are selected by the poison in preference to the rest of the buccal and to the Schneiderian membrane, which are equally, if not more, exposed to its action, is a pathological fact which we are not able to explain. That the poisonous action is a local, not a general, one seems further proved by the fact that constitutional cachexia does not often appear as a condition preceding the local outbreak; and still more strongly by the fact that if the teeth be sound, and the gums unbroken, the disease is rarely developed. On the other hand, it ought to be stated that there are sometimes evidences of slow systemic poisoning by phosphorus, terminating in necrosis; and also that it is rarely those who have been for only a short period subjected to the poison who develop necrosis, but rather those who have been some years in the occupation. Again, it has been recorded that the prolonged internal use of phosphorus may lead to typical necrosis of the jaw, as in a case recently reported by Mr. Hutchinson. It may, therefore, in the light of our present knowledge, be assumed that the action of the poison, at least in most cases, is purely a local one, though the system is probably predisposed to the local outbreak by a constitutional infection from the poison slowly introduced into the blood, either by inhalation of the vapor or by the ingestion of the drug as a medicine. It acts by inflaming first the gums and the linings of the tooth sockets, from these spreading to the alveolar processes of the bone, and finally, by extension by continuity, involving a large part, and not infrequently the whole, of the bone. This destruction of the entire bone is sometimes found in the lower jaw. In all the cases I have seen affecting the upper jaw, the ravages of the disease were mainly confined to the alveolar arch."

(For further information in regard to this subject consult the articles on *Occupation, Hygiene of*, and on *Phosphorus, Poisoning by*.)

Osteitis Deformans.—This essentially chronic condition is, though recognized and studied since 1876, still illy understood as to its etiology. It occurs most often in middle age, and involves perhaps more frequently the long bones, but also at times the skull, pelvis, and vertebræ. Hypertrophy may go hand-in-hand with softening, resulting in malformations which give the disease its name. Nevertheless, it does not advance to the extent of causing fractures. Some authors—Tillmanns for instance—differentiate two clinical varieties, the painful and the painless. The former is the more frequent, usually involving the bones of the lower limbs. The painless is believed to occur more often in the upper limbs, and in females rather than in males. Generally several bones are involved, thus indicating a systemic rather than a local cause. Treatment has thus far proved of little avail; and since we cannot definitely ascertain the real cause and direct our treatment to that, the only course which remains to us is to alleviate pain or other symptoms.

Tuberculous Osteitis.—Under this title we shall discuss that inflammation of bone which, until within a few years, writers have studied under the name of caries; paying more attention, as in necrosis, to the result of the process than to the causative agent.

This is a chronic malady, affecting mainly the red-marrowed, cancellous bones, such as the bodies of the vertebræ and the carpal and tarsal bones. It is essentially an osteoporosis, with tuberculous deposit as its cause and accompaniment, and it results in molecular death of the bone. Sometimes, by extension, the compact tissues are involved, but here the bone first changes its character, becoming cancellous through osteoporosis; and later even the remaining bone trabeculæ may disintegrate, and a suppurating cavity be left. The lime salts are dissolved, and the remaining membranous or gelatinous bone breaks down under the devitalizing influence of the tubercles.

It may be objected to the term *tuberculous* that caries is not always of this nature. It is undoubtedly true, however, that chronic, granulating, rarefying osteitis is commonly so, and at the present day the cases of caries in which careful investigation fails to find the bacillus tuberculosis are very few, and are becoming fewer.

The bone frequently expands in one or both of its diameters while becoming a mere shell filled with pus, bony detritus, and granulations. Apparently the growing mass of granulation tissue forces out the walls of bone when they become thin enough to permit it. A rather common example of this condition is found in "spina ventosa." Here the bone—a metacarpal, for instance—may gradually assume the shape of a spindle. Syphilitic dactylitis may produce the same distention; this latter inflammation, which is usually a result of inherited syphilis, most often involves one of the first phalanges.

The deposit of tuberculous material in bone may or may not present all the ordinary appearances of a focus of tuberculous disease. It may undergo caseation, or it may, as it usually does, soften and liquefy. Some suppuration is probably always present, but this varies greatly in degree. In the caries of children it is almost always a feature. Pott's disease, for example, is accompanied by the formation of so-called "cold abscesses" of varying size, and the pus starting from the disintegrating bone follows a downward course, governed by gravity and the path of least resistance, and may finally find an exit for itself upon the surface. Or, in cases with less discharge, the pus may become cheesy, its ensheathing connective-tissue covering may undergo a change into calcareous material, and the abscess may never descend far from the diseased vertebral bodies which gave it origin. Such an abscess may be discovered only at the autopsy.

In elderly individuals the formation of granulation tissue and a slow advance of the disease, with but slight discharge—a "caries sicca"—are generally to be expected.

Tuberculous osteitis may occur at any age, but it develops more commonly in early childhood than at any other time. Its onset is usually insidious. The patient may, after a time, complain of a little tenderness or aching after exertion. Later, some swelling of the bone may perhaps be noted. The skin is not involved at first; after several weeks—possibly months—it becomes distended, looks inflamed, breaks down at one or several points, and gives exit to pus. This pus varies in consistency, and is sometimes gritty to the feel, containing minute spicula of bone. A probe introduced may—if the sinus be moderately straight—touch bare bone, and may by moderate pressure be made to fix itself firmly in the cancellous tissue; this could not be done in the case of the compact sequestrum of necrosis. The lips of the sinuses and their walls soon become lined with flabby, inactive granulations, in which the bacilli are sometimes to be discovered. Meanwhile the patient may be subject to more or less fever, night sweats, and similar signs of vital depression.

By extension a caries may involve an adjacent joint, with resulting "white swelling" and all the manifestations of tuberculous osteo-arthritis. Or, conversely, a primary joint tuberculosis may lead to erosion of the articular lamella of the bone, and then to tuberculosis of the cancellous tissue.

Caries commonly, though not invariably, makes its ap-

Digitized by Microsoft®

pearance in individuals of the so called scrofulous diathesis—*i.e.*, those who are especially subject to affections of the glands, skin, and mucous surfaces. Often a family history of tuberculosis may be obtained, or it may be learned that the parents died from some unnamed lung trouble. The patient is apt to be pale and anæmic in appearance, although this is not always the case. In adults the bone disease is sometimes a reappearance of inflammation which existed there for a time during childhood, and then remained for years quiescent.

At any stage in its progress the disease may come to an end, and reparative processes of varying degree begin. Caries does not necessarily go on to the complete destruction of all the cancellous bone involved. If the patient's general condition can be improved, so that the vitality of the bone is enabled to resist the encroachment of the tuberculous disease, suppuration may cease, fistulous sinuses close, and new bone form to some extent. This is the rule in Pott's disease. The bodies of one, two, or sometimes more vertebræ melt away, the comparatively sound bodies above and below come in contact, and if the patient continues to live, as he commonly does, the disease is brought to an end, and the vertebral bodies near the focus of the disease, but which have escaped, unite by firm bony union. In some bones—the calcaneum for example—there is very little tendency to bony repair. The space once occupied by bone becomes partly filled by simple connective tissue.

It is important to bear in mind that a mere local bone tuberculosis may at any time give rise to a general tuberculosis. Although such a catastrophe is quite exceptional, it does sometimes occur. Therefore, when it is possible to remove by surgical means the diseased bone, it should be done. It has even been suggested, of late, that in spinal caries an attempt be made to scoop away the diseased tissue and thus hasten recovery; if need be, resecting one or more ribs to allow thorough work. But whether this become a recognized practice or not, in all readily accessible regions the proper treatment consists in the free use of Volkmann's sharp spoon; the most thorough work under these circumstances being always the best. As with suppurating tuberculous lymph nodes, so here this treatment may save months of effort on the part of nature to remove the tuberculous deposit.

It goes without saying that surgical cleanliness must be strictly observed during and after the operation.

It is to be expected that, in many instances, one such scraping will not suffice entirely to put a stop to the disease. Perhaps the step may have to be repeated a number of times before all the affected tissue is reached and eliminated. During the dressing of bones or of sinuses which have been operated upon for caries, iodine should be our main reliance. In irrigation we may wisely employ a one- or a two-per-cent. solution of the compound tincture, which does not precipitate as does the simple tincture upon dilution with water. This strength will stain the tissues a yellowish hue.

The gauze used for packing and drainage should be first moistened, and then well rubbed with some one of the numerous powders which depend for their value chiefly upon the iodine which they contain—such as (in order of strength) iodoform, iodol, nosophen, aristol, and europhen. The author rather inclines to aristol, and considers it practically as effective as iodoform without the objectionable odor of the latter.

In obstinate cases of caries, after the vigorous use of the sharp curette or gouge, it is well to cauterize also, before beginning the iodine treatment. Perhaps the application first of pure carbolic acid and then of strong alcohol is as effective a measure as any that can be adopted. The severity of this procedure may be easily regulated by shortening or protracting the time during which the pure acid is allowed to remain in contact with the parts before the neutralizing action of the alcohol is brought to bear upon them.

The prognosis in children, after such thorough treatment, is fairly good. In adults it is distinctly more difficult to eradicate the disease completely. In the tarsal bones, for example, it is questionable whether in adults it is not wiser to excise entirely the affected bone or bones in order to prevent a relapse.

When despite thorough local treatment the disease extends and perhaps involves an entire extremity, amputation at some distance above may be our only remaining resource.

Regarding medicinal treatment, cod-liver oil, iron, and good nourishment are to be administered in the hope of improving the general condition. In the phlegmatic temperament cold bathing daily is of more value than the oil. These means, however, will not remove the bacilli from the bone marrow. They are merely useful adjuvants to the proper local treatment.

OSTEOCHONDROMA. See *Chondroma.*

OSTEOMA.—An osteoma is a tumor consisting of bone tissue.

Not every bony new formation is an osteoma. The bones occasionally found in the deltoid muscles of infantrymen, caused by the pressure of the rifles, and the "riders' bones" forming at the attachment of the adductor longus in cavalrymen are not true tumors, nor is the new formation of bone at the site of a fracture an osteoma, even though the callus formation be exuberant. A true osteoma may, however, arise from a callus. Furthermore, inflammatory new growths are not true tumors. Thus the newly formed bone around a sequestrum in osteomyelitis, and the osteophytes, periostoses, and hyperostoses resulting from ossifying periostitis are inflammatory new growths and not osteomata. It seems probable that the so-called "osteomata" of the choroid and vitreous should be looked upon as inflammatory new growths. The absence of sufficient, evident etiological factors and the purposeless character of the new growth are to be emphasized as two important criteria of osteomata.

Osteomata are most usually found in connection with bones. Either long bones or flat bones may be affected. In the long bones the tumors are especially apt to arise near the epiphyseal lines. As a rule the bony tumor is formed from a connective-tissue periosteum, after the manner of the cranial bones; less often the osteoma is formed by the transformation of cartilage, while osseous tumors in other tissues are less common, being found occasionally in the membranes of the brain and cord, in tendon, ligament, muscle, in the mammary, parotid, adrenal, thyroid, or prostate gland, in the tracheal mucosa, pleura, or lung, and rarely in the skin. Osteoma in the corpora cavernosa is rare.

In addition to simple osteomata, bony tissue is also found in the mixed tumors of the parotid and testicle, in osteosarcomata, osteochondromata, etc.

Osteomata may be single or multiple. "Cortical osteomata" or "exostoses" are bony tumors on the surface of bone; a "central osteoma" or "enostosis" is a bony tumor in the interior of bone. A "continuous osteoma" is directly continuous with bone; a "discontinuous osteoma" is separate from adjacent bone. "Dental osteomata" spring from the cement substance of the teeth. "Subungual exostosis" is employed to designate the osteoma occurring beneath the nail of the great toe.

There is much confusion in the use of the terms "exostosis," "enostosis," or "endostosis," "hyperostosis," "periostosis," and "osteophyte." Although it is customary to give the termination "oma" to all tumors, the use of "exostosis" and "endostosis" to designate certain osteomata is so common that it seems necessary to continue to employ these terms. The terms "osteophyte," "periostosis," and "hyperostosis," however, should be applied only to the inflammatory new formations of bone, such as occur in ossifying periostitis. Since certain true tumors are called "exostoses" and "enostoses,"

www.libtool.com.cn

Digitized by Microsoft®

it would be well if these terms were not applied to other bony growths, but, in addition to their more limited significance, the terms are generally applied to almost any irregularity on or in bone. In this article, "exostosis" signifies an osteoma situated on the surface of a bone; "enostosis," an osteoma situated in the interior of a bone.

www.libtool.com.cn

Osteomata have in the main the structure of normal bone, though they have not the regular architecture of the trabeculæ, nor the typical arrangement of the vascular and medullary canals and bone corpuscles.

Virchow classified osteomata according to their structure as osteoma eburneum, osteoma spongiosum, and osteoma medullosum.

"Osteoma eburneum," or "eburnate osteoma," or "ivory exostosis" is a tumor consisting altogether or for the most part of dense osseous tissue. In this form the tumor is made up of nearly parallel or concentric branching layers of compact bone, containing possibly a few small vessels, and covered by a connective-tissue periosteum. The number of bone corpuscles is usually not great.

"Osteoma spongiosum," or "spongy osteoma," consists of looser, cancellous bone. In the spaces between the trabeculæ there may be marrow.

"Osteoma medullosum," or "medullary osteoma," has an outer shell of compact bone covering cancellous bone and a central marrow cavity, the tumor having the structure of a long bone. At times the marrow cavity composes the greater part of the tumor. The marrow in the osteomata may be either normal red or white marrow, or a myxomatous change may occur, such as is seen in osteomalacia, etc.

The eburnate osteomata are more frequently found on the bones of the head than elsewhere; they are usually multiple, rarely attain a greater diameter than 1 or 2 cm.; and occur as small, flat, rounded outgrowths from the bones. The eburnate osteomata of the orbit and frontal bone, and the osteomata occurring near the epiphyses of the long bones may grow to the size of a man's fist or larger. These tumors have a very rough, irregular surface; they may be very firmly or loosely attached to the bone. The multiple osteomata of the dura and arachnoid are small and very rough and spiculated. The multiple osteomata of the skin are the smallest medullated osteomata. They occur as platelets the size of a grain of sand in the cutis or subcutaneous tissue. Skin osteomata are more common in old people.

It is at times impossible to tell where normal bone ends and osteoma begins; in other cases a slight attachment gets severed, the osteoma becomes necrotic, and is discharged as a foreign body. This has happened in the case of some of the tumors arising in the diploë of the frontal bone.

The tumor formed from cartilage, "osteoma cartilaginea," is covered by a more or less incomplete layer of cartilage. These tumors are found on the long bones, especially on the humerus, tibia, and femur. They may be progressive and form tumors as large as a man's head. In the early stages they are usually made up of compact bone; later they may be spongy. It is often impossible to distinguish between osteomata of cartilaginous origin and ossifying enchondromata.

The following are the chief etiological factors:

1. Misplacement of embryonal bone elements. Although formerly it was considered the most important factor in the etiology of tumors, the tendency of the present day is to attribute importance to this factor only in those rare cases of multiple osteomata which are present from birth.

2. Post-natal disturbances of development are supposed to be of much more importance. Under this heading rachitis is of special interest. It is supposed that, as a result of the irregular growth which takes place in rachitis, small bits of cartilage are nipped off and come to lie behind the growing line of the bone. These islands for some unknown reason develop into enchondromata or osteomata. Usually osteomata arising in this manner are multiple. According to Otto Müller, this post natal misplacement of cells is most apt to occur in cases of recurring rachitis. Müller traces the different possibilities which may result from misplacement of these cartilaginous elements. The focus may disappear, or persist unaltered, or it may persist as a tumor-like centre without sufficient vitality to cause it to grow; the focus may develop into a chondroma, or an osteoma; into a rapidly growing myxo-enchondroma, or into a malignant tumor (chondrosarcoma, etc.).

3. Trauma is a factor in the production of some osteomata.

4. Heredity has been observed to be of etiological importance quite often. Reinecke collected from the literature thirty-six cases of multiple osteomata which occurred in families. In one instance the condition was transmitted through five generations; in two instances to the fourth generation; in fifteen instances to the third generation; and in twelve instances to the second generation. It has been observed that the inheritance is more common among the male members of a family. Inheritance is of importance chiefly in connection with multiple osteomata.

5. An osteoma may arise secondarily. In the case of some of the osteomata of the membranes of the brain and cord it appears that a soft, fibrous tumor of the arachnoid may impinge upon the periosteal dura mater, and a new growth of bone from the dura may then replace the fibrous tumor.

6. The opinion which prevails at the present time is that the osteomata arising in gland, muscle, lung, tracheal mucosa, etc., are best accounted for on the hypothesis that they arise from a metaplasia of cells.

7. It must not be forgotten that heredity, trauma, disturbances of development, etc., are of themselves not sufficient to account for the presence of osteomata, and in every case there is some unknown influence at work, which gives the decisive impulse to tumor formation.

Diagnosis.—An osteoma is a painless, benign, slow-growing tumor, usually small, in most cases arising from bone, appearing, as a rule, during childhood or early youth, that is, during the developmental period of bone. The tumors are seldom seen in very young children, and are rare after the third decade. Tumors found in older people have their origin earlier in life. The growth of osteomata is slow and ceases after middle life. The exostoses at the epiphyses do not enlarge after the growth of the skeleton is complete. Osteomata occur more frequently in males than in females. The tumors are sometimes symmetrical, as in the nasal osteomata. The position, the consistence, and the features that have been mentioned will usually give the basis for a diagnosis. It is often difficult to distinguish between "dental osteoma," which arises from the cement substance and is found at the root of the tooth, and "odontoma," which arises from the dentin and may be found also on the shaft or crown of the tooth.

Prognosis.—All osteomata, even the progressive osteomata, are benign. This of course does not apply to the mixed tumors containing bone. No osteoma is dangerous except as a result of its pressure upon neighboring parts. The frontal or orbital osteomata may press upon the brain or eye; an osteoma of the pelvis may obstruct labor; an osteoma may press upon vessels or nerves, or the skin over the tumor may be injured and a chronic ulcer result.

Unless treatment is indicated to relieve pressure, the tumor should not be attacked.

Treatment is altogether operative. Owing to the firm attachment and dense structure of some osteomata, it is often difficult to remove them without injury to the adjacent soft parts. *Harry T. Marshall.*

OSTEOMALACIA.—(Synonyms: Mollities ossium; malacosteon; halisteresis ossium.)

Pathology.—Under this name is recognized a disease in which an unusual softening of fully formed, hard bone develops; this softening being followed by great deformity of those bones upon which strain is placed, either by the action of muscles or by the mere weight of the body. The softening is caused by an insufficient amount of in-

Digitized by Microsoft®

organic salts. Whether this insufficiency of salts is due to absorption (decalcification) or to failure of calcification during the regeneration of the bone, has not been fully determined. Recent investigations seem to indicate that both processes go hand-in-hand. By the absorption of the calcareous matter in the bones the medullary substance encroaches upon the bone. Two forms of the disease have been distinguished—viz., osteomalacia cerea, or waxy osteomalacia, in which the whole shaft is softened and consequently bends like wax; and osteomalacia fragilis, or brittle osteomalacia, in which the inner portion of the bone is affected, and there remains a thin bony shell which is very liable to fracture.

www.libtool.com.cn

In the spongy parts the process starts in the medullary spaces, and in compact bone from the periphery of the Haversian canals: in the latter case the affected area constitutes a margin of bone in which the calcareous salts are absent, although it still retains its connections with the calcified portions. The limits between the decalcified and the normal bone may be quite regular, or they may present an irregular or even a zigzag outline. The affected margin of bone stains red in Van Gieson's mixture. At first, when the salts of lime begin to disappear, the basement substance still presents a finely fibrillated or a homogeneous appearance, with the original lamellation still preserved; but after a time the decalcified tissue may disintegrate and be absorbed, its place being occupied by new-formed marrow or granulation tissue. The canals either disappear or persist as small, oval vacuoles. The canaliculi along the softening margin become irregularly widened and enlarged, and appear like "latticework" spaces, star-shaped and feathery. Large and small smooth-walled cysts may be found in decalcified areas; they are filled with mucoid material, resulting from the enlargement of the Haversian canals and spaces, and they may extend into the marrow itself. Canals perforating the bone trabeculæ also appear in considerable numbers, but osteoclasts and Howship's lacunæ are not present any more numerously than in normal growing bone.

The marrow is variously changed. In some places it is yellowish and fatty, in others it contains reddish lymphoid tissue with giant cells, while in still other places there are gelatinous areas. It may also contain cysts. Constant and characteristic changes do not occur; in fact the marrow may even become quite fibrous. Some areas are very anæmic while others are distinctly hyperæmic. Pigment and hemorrhages are frequently found in the marrow, and there may be a great accumulation of small spheroidal cells.

The periosteum is thickened in many places and has a fibroid structure with few nuclei. When it is stripped off, the underlying bone is found to be rough, and often is perforated by openings from which marrow escapes.

Simultaneously, or subsequently, there takes place a more or less extensive formation of new osteoid tissue, which in many instances is excessive, and which for the time being may remain uncalcified. This new tissue is produced by the osteoblasts, and may be quite dense and contain only fine spaces; it may present a lamellated appearance, or more frequently an interwoven, fibrillated structure, with large corpuscles. This new tissue is formed most extensively at points of flexion and of fracture of the softened bone; the callus formation may be prolific, but it is not followed by perfect calcification. It also forms to an excessive degree at the points where the bone is exposed to mechanical strain, *i.e.*, where strong muscles, tendons, and ligaments are attached. This new-formed osteoid tissue is easily distinguished from decalcified old bone, as it contains larger, better formed cells.

Owing to the softness and pliability of the bones which are acted upon by the superimposed weight, by the resistance of ligaments, and by the traction of muscles, there is sure to be produced a series of deformities. These consist of curvatures of the spine, sternum, ribs, and long bones, of partial and complete fractures of various bones, and of contractions and alterations of shape of the pelvis. Fractures refuse to unite properly and false joints result; or if they do unite, angular deformities occur.

The chest is flattened laterally, its antero-posterior diameter increased, and the ribs and sternum are much distorted. Softening of the clavicle allows the weight of the limb to rest on the thorax, and a corresponding depression in the wall of the chest results. The bones of the arm are usually fairly free from marked deformity, owing to the absence of pressure. The lower ribs may come into contact with the crests of the ilia. The spine is variously altered. The normal curves may be accentuated, or new ones produced. In some cases there is a simple curve of the column backward, a condition of kyphosis; or this may be accompanied by a compensating curve inward in the upper part of the column, or the curves may be exclusively lateral. For this reason the stature of the patient is much decreased.

The abdomen bulges and is very prominent. The deformities in the pelvis are characteristic. The iliac bones may yield when pressed together, and spring back when released. The pelvis is usually very flat, the promontory being on the same plane as the pubis and pressed forward and downward. The sacrum is strongly curved longitudinally, the apex being turned forward. The acetabula are pressed inward and approximated, the ascending branch of the pubis being bent inward. The pillars forming the pubic arch are also pressed inward and approximated, so that the symphysis pubis protrudes forward in a beaked form. The tuberosities of the ilia are brought nearer to each other, and may even come in contact. The brim of the pelvis has the shape of the letter Y. In some cases, in consequence of these deformities, the cavity of the pelvis may be reduced so as scarcely to allow the passage of the natural evacuations through it.

The early deformity of the bones of the lower extremity consists in an exaggeration of the normal curves of the bones, but in the later stages there will be bends and twists which are due to the traction exerted by certain muscles. Fractures at the angles are frequent. Imperfectly healed masses of callus are found about these points of fracture, and these contribute greatly to the deformity of the bone. In the femur, as a rule, the greatest deformity is found in the angle of the bone just beneath the great trochanter. The pressure of the body above causes the bone to give way at this point, so that the trochanters may be higher than the head of the bone. It is characteristic of the puerperal form that the bony changes almost always begin in the pelvis, and from here advance upward upon the spinal column; while in the other form of the disease, which occurs in both men and women—after the puerperal period in the latter,—the disease usually begins in the lower extremities. In order of frequency the various bones are affected as follows: most frequent of all is the pelvis, next the sternum, then the upper extremities, and lastly the lower extremities. While the proportion of inorganic to organic matter in normal bone is about two to one, this is reversed in osteomalacic bone until the proportion is as one to two. The nervous system is found post mortem to be free from gross lesions, but histo-pathological examination has revealed in the cord organic changes which appear to begin in the cells of the anterior cornua. These are not inflammatory in character, and clinical evidence shows that they are capable of repair.

The weakened muscles show, post mortem, fatty degeneration, multiplication of nuclei, and other changes similar to those observed in progressive muscular atrophy. The chest and abdominal organs usually are not altered.

The urine presents no characteristic changes and is of little importance for diagnostic purposes. The presence of lactic acid in the urine cannot be regarded as proven. The same holds true of albumose. In some cases the excretion of lime salts has been very great, leading to the formation of gravel and small calculi. Albumin has been found in some cases.

The microscopical examination of the blood is of no

Digitized by Microsoft®

importance in the matter of diagnosis. Under various conditions there may be a slight increase in the eosinophile cells in the blood, but variations in the number of these are not an uncommon occurrence in normal individuals.

The ovaries have been thought to have an influence on the disease. In some cases of osteomalacia they were found in a hyaline condition, in others in a fibrous or other pathological condition, but in many they were perfectly normal. Perhaps the ovarian internal secretion plays a part of some importance in the chemistry of the organism. Removal of the ovaries has seemed in a number of cases to have been followed by a surprisingly beneficial result.

Etiology.—The real cause of this remarkable affection is unknown. It is a singular fact that the disease is much more frequent in certain regions than in others. It is very common along the Rhine and in Westphalia, in Eastern Flanders, in Schütt Island in the Danube, and in Northern Italy. This suggests that there is some specific cause for the disease, endemic in certain localities. It is in addition found occasionally in almost every country in Europe, but in North America Dock was able to collect records of only ten cases. It is mainly a disease of adults, occurring between the thirtieth and the fortieth years, but it may exceptionally be found later or earlier in life. The disease attacks females almost exclusively during the child-bearing period. Isolated cases have been found in men, but are extremely rare. Among exciting causes, child-bearing is certainly the most important, for both the first signs of osteomalacia and also fresh exacerbations of the disease usually date from a pregnancy. It has, however, been found in women who have never had children, and it may begin after the menopause. The relations of osteomalacia to the sexual processes are so close that there is some justification for the supposition that osteomalacia is directly dependent for its development upon disturbances of metabolism in the ovaries.

Individuals in all classes of society may be affected, but the disease appears to be favored by damp and unsanitary surroundings. Various theories have been put forward to account for the disease, but none of them is satisfactory. Lactic acid has been found in the bones, and the solution of the lime salts in the bones has been attributed to this substance. It has, however, been conclusively shown that the acid may be in excess without producing the disease, and efforts to cause the malady in the lower animals by feeding them with lactic acid have signally failed. Micro-organisms again have been carefully searched for, but with no constant result, and there is no ground for believing that bacteria are instrumental in producing this condition. Fehling's theory is that there is a trophoneurosis, due to reflex irritation from the ovaries, and the remarkable results of castration in osteomalacia seem to confirm this theory; but while the facts cannot be doubted, there is a growing tendency to question the theory. In some cases in which recovery followed the operation of castration, no abnormality could be discovered in the uterus, ovaries, or vessels. The disease has also been attributed to affections of the nerve centres, but anatomical observations on the nerve centres are very scanty and inconclusive. Virchow asserted that the disease was of an inflammatory or hyperæmic nature, but study of the bones gives rise to strong doubts about the validity of this theory.

There are on record a number of cases in which, while the symptoms were somewhat similar to those of osteomalacia, multiple myeloid tumors were found in the bones. In osteomalacia the bones are softened, owing to the removal of the earthy salts by absorption. In multiple myeloma the osseous tissue undergoes atrophy without at the same time being changed in its chemical composition. The atrophy, in this case, is due to the development of a new growth in the marrow spaces and to its spread outward, causing absorption of the hard parts of the bone, and ultimately leading to fractures and deformities. There can be no doubt that cases of multiple myeloma have been confounded with osteomalacia, but they are distinct conditions, and not dependent in the slightest degree on each other. According to Bradshaw, the cases of multiple myeloma may be divided into those with and those without albumosuria. Of these latter there are seven cases in the literature. The first case of this albumosuria was reported by Bence Jones in 1847. Most of these cases were considered to be osteomalacia, and were supposed in some way to depend on the albumosuria; hence the origin of the theory that osteomalacia was due to an albumosuria. This view, it is needless to say, is incorrect, for it has been shown that they were not cases of true osteomalacia at all, but the albumosuria occurred in persons affected with multiple myeloid tumors of bone. The Bence Jones albumose has never yet been found in a case of pure osteomalacia. This condition, known as multiple myeloma, has been variously designated in the literature, some calling it sarcoma, others (*e.g.*, Marchand) calling it "general marrow hyperplasia with disappearance of the bone substance." Schönenberger reports a case of osteomalacia in which there were found, as complications, multiple giant-celled sarcomata and multiple fractures.

Hirschberg reports a similar case, as does also von Recklinghausen. The publication of all these cases seems to render improbable the theory of the neoplastic origin of osteomalacia.

Symptoms.—In the beginning the disease is obscure; it starts very gradually, in most cases, with an ill-defined, deep-seated pain, most often felt in the sacral region of the back, in the pelvis, and down the thighs, and at times even in the legs. Pressure seems to increase the pain. This pain is more or less constant and persistent, is increased by movements, and is usually diagnosed as rheumatic. An important feature of the pain is that it usually starts in the latter part of pregnancy, ceases after delivery, and recurs with subsequent pregnancies. While the pain continues, motion becomes gradually impaired, and there is more and more difficulty in walking, partly because of the pain and partly because of the muscular weakness. This weakness in the muscles of the thigh and pelvis may be present before any bony deformity is discoverable.

Attacks of painful spasm are often present, particularly in the adductors of the thigh. Owing to weakness of the ilio-psoas muscle as well as to deformity of the pelvis, the trunk is thrown from side to side to enable the foot to clear the ground in walking, and thus a peculiar waddling gait results. In other cases the steps are short, slow, uncertain, and almost hobbling, the lower limb and pelvis being jerked forward as if they were one piece. There is tremor of the muscles, the knee jerks are increased, and ankle clonus often is present. After a longer or shorter time walking becomes absolutely impossible, and the patient is permanently bedridden. Even then severe pain persists in most cases, often spontaneous in character and much increased by pressure of bed clothes, etc.

While these symptoms are going on, various distortions of the body occur, sufficient to cause a decided alteration in the appearance of the skeleton. Deformity of the spinal column is usually the first to be noticed. As a rule, there is kyphosis, less often some other deformity, and the head generally becomes more and more bent on the sternum, resulting in the patient growing decidedly shorter. This may help in diagnosis because the patient is apt to remark that she has to keep shortening her gown in front. If the patient becomes bedridden early in the disease then the extremities become less distorted and are less often fractured. The softened bones are usually painful when pressed upon, and they may bend under pressure. The bones of the face and skull are almost never involved. The thorax becomes barrel-shaped and pressed together laterally, so that the sternum has an almost horizontal position. The abdomen becomes very prominent. The teeth become carious or are lost. The pelvis is deformed as described above. In the muscles several observers have noticed trembling and

Digitized by Microsoft®

fibrillary contractions, also paresis and sometimes complete paralysis. In a few reported cases the softness of the bones of the extremities was so extreme that one could bend the limbs at will, like wax, and give them the most extraordinary positions.

The internal organs perform their functions well for a long time, and the appetite remains good. Fever is observed only when the disease is undergoing some marked temporary exacerbation. With regard to changes in the urine, it is a fact that a great many statements have been made, but their significance is extremely doubtful. It is said, for example, that the amount of phosphoric acid excreted is diminished. With regard to the amount of lime, no definite statement can be made. Lactic acid has been repeatedly detected in the urine, as has also albumin. Concretions of lime have been found in the bladder and the kidneys. Microscopical examination of the blood gives no aid in diagnosis. Neusser has found myelocytes and an increase of eosinophile cells in the blood in some cases; but these results in general do not seem to have been confirmed by other observers. Women affected by the disease are said to be more fruitful than others. Eisenhart found the average number of children born in Germany to be 3.9, whereas it was 6.4 in the sufferers from this disease; abortion is also more frequent.

Prognosis.—The course of the disease is a chronic one, most cases lasting for years and undergoing remissions and exacerbations. Pregnancy has a very deleterious effect, always lighting up a fresh attack. The prognosis now is much better than it was twenty-five years ago. We know that the disease is curable in some cases, and we have gained considerable control over it by medical and surgical means. The most important part of the treatment depends upon the possibility of preventing conception. The more frequent termination of the disease, however, is in death, after a duration of time seldom less than two or three years, although in some cases this event may be postponed for five, ten, or even a greater number of years. Death results either from general debility, or, more often still, from the dyspnœa caused by the compression of the lungs, or by some such disease as lobular pneumonia. Death sometimes occurs in labor and is then due to the rupture of the uterus, or it follows one of the more or less dangerous operations for the extraction of the child.

Diagnosis.—This is somewhat difficult to make in the sporadic cases in the early stages. It is almost always called rheumatism, on account of the pains which are located in the pelvis and lower extremities, and which are made worse by bad weather. More careful examination and a rigid inquiry into the history will elicit points—such as sensitiveness of the pelvic bones to pressure, increased knee jerks, and muscular weakness, etc.—from which a diagnosis may be made. At the outset the symptoms may suggest incipient disease of the cord or of the vertebræ. Strümpell mentions the fact that he has repeatedly seen cases in which women, as a sequel to pregnancy or even apparently spontaneously, have developed paresis in the lower extremities, particularly in the psoas and iliacus muscles, associated with pain and exaggerated tendon reflex, and in which diagnosis at first was very difficult. At any rate, it is important to know that even before there are demonstrable changes in the bones there may be paralysis, probably due to an early involvement of the muscles in the morbid process. As soon as bone tenderness and deformity arise, the diagnosis is rendered easier.

From peripheral nervous diseases osteomalacia is distinguished by a careful examination of the bones. In the latter disease the tendon knee reflexes are increased, while in almost all peripheral nervous lesions the tendon reflex is diminished or entirely abolished.

Not very infrequently the complaint of the patient at the start is regarded as hysterical.

As the disease is almost entirely confined to adults we are seldom in danger of confounding it with rachitis. In addition, osteomalacia does not produce swellings of the epiphyses or changes in the bones of the skull. Examinations of the urine and blood do not help us in diagnosis.

There may be difficulty in differentiating the disease from malignant tumors of the bone—for example, from primary sarcomata and especially from diffuse carcinomatous infiltration of the bones, and there is little doubt that the older writers confounded these conditions with osteomalacia. According to Köhler, who carefully investigated cases of the latter type, they are to be distinguished from cases of osteomalacia, first, by the fact that the growths occur only in the bones of the trunk, and second, by the absence of muscular weakness and of any unnatural elasticity of the bones. In multiple myeloma the disease mostly occurs in men in the latter half of life, the bones of the thorax are those chiefly affected, the patient is able to leave his bed until near the end, deformities are not extreme, and fractures are common.

Treatment.—If the case be seen early in pregnancy, in view of the gravity of the labor and the bad influence of pregnancy upon the disease, abortion should be produced if the fœtus can easily be removed by the natural way.

The patient should then occupy a dry, sunny house, and should be put on a very substantial diet, of which milk should form a large part. The chief remedial agent is phosphorus, one-twentieth to one-fifteenth of a grain three times a day. Extract of red bone marrow, a tablespoonful three times a day, is also highly recommended. Others advise the administration of cod-liver oil, quinine, arsenic, etc. Above all things subsequent pregnancies must be avoided. Phosphorus seems to be the most efficient drug and produces at times strikingly good results.

If a woman becomes affected with osteomalacia during the nursing of a child, this must be at once stopped, as it is found to exert an injurious effect upon the disease.

If in spite of all treatment, diet, etc., the disease progresses, recourse should be had to surgical means—*i.e.*, the ovaries should be removed, or, what is probably better, a Porro operation—supravaginal amputation of the uterus—may be performed. Either of these operations fulfils two conditions, viz., it prevents further pregnancies and apparently often arrests the disease. Improvement sets in sometimes surprisingly early, the pains being relieved within forty-eight hours. Many from being bedridden recover so far as to walk and perform their ordinary duties. Of 44 cases collected by Baumann in which Porro's operation was performed, 18 died and 26 recovered. Of the latter, 3 died from other diseases, and 2 were lost sight of. Of the remaining 21 cases, 17 were cured or markedly improved. Finley collected the histories of 40 cases, and the after-histories of 16 of these were traced; 12 of these were cured and 4 improved.

If a case be seen late in pregnancy, the procedure to be adopted will then depend on the degree of the deformity. If this be slight, then premature labor may be induced. If, however, it be very great, Cæsarean section should be done. If the patient be found in labor, the procedure will likewise depend on the condition which is found on examination. If it is found that the child will be able to pass with some help, we may use forceps; or if it may pass after some reduction in size we may perforate, crush the head, and extract the child. Even this latter may not be possible, and we are then forced to perform Cæsarean section. In case this is done the ovaries should be removed, or hysterectomy performed, so as to prevent future pregnancies, and also in order favorably to influence the disease. What the relation between the ovaries and the disease may be is at present inexplicable. We know that there is a close connection between the various processes of nutrition and certain organs of the body. This has been shown in the case of the pancreas, the thyroid, and other glands, but what the influence is, or how much is exercised by the ovaries, is entirely conjectural.

OSTEOMYXOMA. See *Myxoma.*

OSTEOPOROSIS. See *Atrophy.*

OSTEOPSATHYROSIS.—This term is used in a general sense to designate the condition of excessive brittleness of the bones, and is practically synonymous with *fragilitas ossium.* It may occur as the result of senile or cachectic atrophy, prolonged activity, pressure atrophy, neuropathic atrophy in such diseases as paralytic dementia, locomotor ataxia and syringomyelia, and in syphilis, leprosy, osteomalacia, and rachitis. In rare cases the condition appears in an idiopathic form, apparently of congenital origin, and may be inherited. The etiology and pathology of this form are unknown. Senile osteopsathyrosis is the result of the old-age osteoporosis. The skeleton as a whole, or only certain portions, may be involved. The bones usually become fragile and are easily broken; but in other cases the bones lose their lime salts to such an extent that they may be easily bent or may be cut with a knife. A similar condition may occur in the cachexia of various chronic diseases. In syphilitic infection of long standing and associated with marked cachexia, there often occurs a marked osteopsathyrosis of the long bones and also the bones of the cranium. In the great majority of syphilitics there is an increased fragility of the skeleton. In leprosy there is found in a certain class of cases a very characteristic osteopsathyrosis (leprous osteomalacia) affecting chiefly the bones of the hands and toes. The phalanges, one after another, may be affected until all the fingers and toes are destroyed, or they may be irregularly involved. OSTEOSARCOMA. See *Sarcoma.*

OTTAWA, CANADA.—Ottawa, the capital of the Dominion of Canada, is situated upon the river of that name, in the eastern part of the Province of Ontario, about one hundred and ten miles west of Montreal. It has a population of about fifty thousand, and is the centre of a large lumber traffic. The extensive government buildings are noteworthy for their architecture and material; and in the vicinity are various points of scenic interest—the Chaudière and Rideau Falls, and the Rideau Canal with its series of locks. A journey down the Ottawa River to Montreal (ten hours) is one of great interest, and affords constant views of imposing scenery. The climate is a cold one, comparable with that of northern New York and New England; the winters are long and there is much snow.

The accompanying chart will indicate the various climatic features.

Edward O. Otis.

OUABAIN.—This name has been applied to at least three distinct glucosides, by different chemists, under the impression that they were identical, all derived from African arrow poisons, or from the substances used in their manufacture. The name was derived from "Ouabaio," "Wabei," or "Wabajo," in relation to the Indians who used the arrow poison referred to. Fraser, in order to eliminate this indefiniteness, proposed for one of these substances, that generally employed, the name *Acocantherin* ($C_{30}H_{46}O_{12}H_{26}O$). It is derived from a species of *Acocanthera,* almost certainly *A. Schimperi* (A. DC.) B. et H. (*Carissa S.,* A. DC., fam. *Apocynaceæ*), though the present article of commerce is believed to be derived chiefly from a species of *Strophanthus* ("*S. glaber*"), of the same family. This glucoside occurs in colorless, transparent plates, if crystallized from water, or in fine tufted acicular crystals, if from alcohol. Nearly one per cent. dissolves in water and nearly two and a half per cent. in alcohol, but it is insoluble in ether and chloroform. The aqueous solution is tasteless. Sulphuric acid turns it red, afterward becoming green. Its primary effect is to slow and strengthen the heart. If the dose is very small, there is little effect upon blood pressure; if large, the latter is greatly increased, apparently through the vaso-motor effects. It powerfully stimulates unstriped muscle. In toxic doses it is an extremely active poison, 5-10 mgm. producing death in animals in a very short time. It is estimated that gr. $\frac{1}{65}$ introduced into the blood of man, would prove fatal. There is an early rise of blood pressure accompanied by increased cardiac action, which is followed by weakened contractions of the heart, rapid pulse, and paralysis of the vaso-motors. For further reference to the physiological action of ouabain see *Pharm. Jour.,* 1888, 162; London *Lancet,* xi., 1888, 392; *Ther. Gaz.,* November, 1891; *Br. Med. Jour.,* i., 1892, 27; *Virchow's Arch.,* Bd. cxxxiv., 1893; *Pharm. Jour. and Trans.,* July, 1895; *Berlin. klin. Woch.,* Mar. 31, 1902.

The local application of ouabain produces a condition of anæsthesia, and it has been found that a few drops of a 1 to 1,000 solution, instilled into the eye, cause an insensibility of the conjunctiva and cornea. This lasts for one or two hours, the pupil at the same time being powerfully contracted and the tension of the eye increased.

The medicinal uses of ouabain have not been developed, though they would undoubtedly be almost identical with those of strophanthin, with which ouabain was for some time believed to be identical. The dose of ouabain is

commonly given at from gr. $\frac{1}{2000}$ to gr. $\frac{1}{500}$. It is really probably much larger, though its little known character requires that it be used with great caution.

Ouabain has been employed as an antispasmodic in whooping-cough, by Dr. William Gemmell, of Glasgow (*British Medical Journal*, April 26th, 1890). He reports the treatment of forty-nine cases, of which twenty-five had been dismissed cured, four had died, and the remainder were under treatment. The fatal terminations were due to diphtheria, meningitis, and progressive emaciation. From his observations, he arrives at the following general conclusions: 1. Ouabain is of marked benefit during all stages of whooping-cough, and if carefully used produces gratifying results. In the first stage it cuts short the attack; in the second, it reduces the violence and frequency of the cough, and diminishes the number of whoops; and in the third, it hastens convalescence in a remarkable manner. 2. Ouabain is a drug which does not appear to be cumulative; its administration can be stopped suddenly without any ill effect beyond an exacerbation of the whooping-cough; it can be as suddenly resumed. 3. It should be given, at first at any rate, in a dose of gr. $\frac{1}{1000}$ every three hours (gr. $\frac{1}{125}$ daily). 4. For children under one year of age the dose should not exceed gr. $\frac{1}{2000}$ every three hours. 5. In children of from six to twelve years of age, if the cough be very violent and the whoops are numerous, gr. $\frac{1}{500}$ may be given in each dose, but the action of the drug must be carefully watched. 6. Ouabain may be given alone, dissolved in water, or in combination with potassium bromide, or with chloral hydrate. The simplest way is to dissolve one grain in distilled water, so that each minim of the solution shall be equal to gr. $\frac{1}{1000}$ ouabain, as: ℞ Sol. ouabain, ♏ xlviij.; syr. aurantii, ʒ iv.; aq. ad ℥ vi. M. Sig.: A teaspoonful every three hours. 7. Under the administration of ouabain, it is found that the temperature, pulse, and respiration are, in uncomplicated cases, slightly below normal. When the drug is pushed, the respirations become very slow indeed; in one patient, aged four, they were often as low as sixteen per minute. It is from this that danger is to be expected. During the administration the action of the skin is promoted, the amount of urine is increased, and the movements of the bowels become more regular. Ouabain has also been used with equally satisfactory results by Dr. J. Lindsay Porteous, of Yonkers, N. Y. (*New York Medical Journal*, vol. liv., 345). He gave it in three cases, one adult and two children, and in all marked improvement was immediately noticed. To a child of fifteen months gr. $\frac{1}{4000}$ was given every three hours; to a child of four years, gr. $\frac{1}{2000}$ every four hours, and to the adult, gr. $\frac{1}{500}$ every three hours. In all these cases the patient was entirely well at the end of a week.

Beaumont Small.

OURAY SPRINGS.—Ouray County, Colorado. Post-Office.—Ouray. Hotel and cottages.

Access.—Via Denver and Rio Grande Railroad (narrow gauge) from Denver, Colorado Springs, and Pueblo.

The town of Ouray is situated in a picturesque amphitheatre of the Rocky Mountains, 389 miles from the city of Denver. The altitude of the town site is 7,500 feet above the sea level, but the neighboring mountain peaks tower several thousand feet higher. Mount Sneffils, five miles west, reaches an elevation of 14,225 feet, while Uncompahgre Peak, ten miles east of the town, attains the superb altitude of 14,440 feet above tide water. The famous and beautiful Bear Creek Falls are two miles south of the town, and near them is the wonderful piece of toll-road, cut in walls of perpendicular quartzite. All about the neighborhood are rich mines of gold and silver. There are also many other natural features of interest, including caves, waterfalls, cañons, peaks, lakes, and gorges, reached by good roads or mountain trails. The climatic conditions about Ouray are quite unexceptionable, sunshine being the rule, with warm and pleasant days during the summer, followed by cool, refreshing nights. The highest summer temperature is about 90° F., and the lowest winter minimum 5° F.; but owing to the rarity and dryness of the atmosphere, these extremes represent much less variation than in most localities of the East. The number of springs in the town limits is estimated at more than one hundred, the temperature of their waters ranging from 130° to 140° F. No analysis has been made, but we are informed by the proprietor of a number of the springs that the waters contain lime, soda, manganese, and iron, and some of them sulphur. Two bath-houses have been fitted up, and are much resorted to in the treatment of rheumatic affections. It is said that the internal use of the waters has been found beneficial in cases of dyspepsia, indigestion, constipation, and blood and skin disorders. The town of Ouray has about twenty-five hundred permanent inhabitants, and is well supplied with pure and wholesome water from mountain springs by water works constructed on the gravity plan. The city possesses a complete system of sewerage, and is always in a clean and healthful condition. The climate is said to be very beneficial to persons suffering from bronchial and pulmonary troubles.

James K. Crook.

OVARIES, DISEASES OF.—The ovaries are two small ovoid or rounded bodies, one of which is attached to the posterior surface of the broad ligament just internal to and below the fimbriated extremity of each Fallopian tube. They are of a pinkish color and vary in size and shape, even in health, without being actually malformed. The average measurements are: Length, 30-50 mm.; breadth, 15-30 mm.; and thickness, about 12 mm. Ovaries greatly exceeding the above in size are rarely met with, but Altoukhov reported before the members of the Moscow Obstetrical and Gynæcological Society the case of a patient whose right ovary measured 35 × 13 × 7 mm., and the left one 80 × 14 × 6 mm., and at the same time mentioned a patient of Nega's in whom the left ovary was 54 and the right 108 mm. in length. In the latter case the uterus was infantile and the patient a pronounced nymphomaniac; but whether or not the enlarged ovary caused the nymphomania it is very hard to say. Probably excessive irritation of the vulva caused the hypertrophy of the ovary.

The function of the ovaries of producing and discharging ova has long been known, but of late they have been credited with producing an internal secretion which alleviates or prevents the troubles of the menopause.

Absence of Ovaries.—One or both ovaries may be congenitally absent. When both are wanting there is usually a lack of development of the mammæ and other sexual organs, and when only one is missing the corresponding side of the uterus is poorly developed. When a woman has absolute amenorrhœa, without any molimina, and sterility, you may suspect that she has no ovaries; but as long as one ovary and tube are present maternity and menstruation will likely go on undisturbed. The only way to make sure about the presence or absence of both sets of appendages is to open the abdomen and explore the pelvic cavity.

Transplantation of Ovaries.—On account of the serious results, matrimonially and otherwise, of the absence of both ovaries, either congenitally or as a result of operation, the procedure of transplanting ovaries is of considerable interest. J. Lankashevitsch interchanged ovaries between rabbits, dogs, etc. The operations were carried out with the strictest aseptic precautions. Each ovary was removed along with its mesentery, the cut edge of which was attached to the broad ligament of the new host near the spot from which the corresponding ovary had been taken, but sufficiently far from the cornu of the uterus to avoid compression. In a few instances, however, the ovary was fastened to either the mesentery or the peritoneum of the abdominal wall; the sutures used were fine silk and were placed very close together.

The only dog used was killed nine months after operation, and the transplanted ovary was found firmly adherent in its new situation, and to be but slightly diminished in size. Capillaries and muscular tissue ran from

Digitized by Microsoft®

Ovaries.

the ovary to the subjacent tissue. Germinal epithelium was seen in places and a few normal follicles lay in the cortex side by side with others which had undergone atrophic change. Yellow areas of degenerated tissue were scattered here and there throughout the organ. In the case of animals which were killed two or three years after operation, the large ovaries remained, whereas the smaller ones had almost entirely disappeared: and in the latter case the genitals also had become atrophied if the animal's own ovaries had been removed. Conversely, it may be stated that the transplantation of large (*i.e.*, from large animals) ovaries exerts an inhibitory action upon the atrophy of the genitalia, and also upon the deposit of fat in the pelvis which usually accompanies the menopause.

www.libtool.com.cn

B. A. Katsch has also investigated this subject, and practically obtained similar results to the above.

The ages of the animals from which the ovaries are taken have an important bearing upon the result as regards rapidity of regeneration of the follicles, etc., this rapidity of regeneration being inversely proportional to their age. When the ovaries are first implanted their tissues tend to degenerate to some extent in the following order, viz., connective tissue, germinative tissue and its derivatives, and lastly, the medullary layers, the Graafian follicles undergoing a change similar to that which occurs at the menopause. Their death takes place centripetally, but they may become regenerated from the germinal epithelium. When this rejuvenescence of the ovaries, as one might call it, does not take place, the genitals atrophy.

In none of the animals operated upon did pregnancy follow, although ample opportunity for this to take place was given.

The conclusions to be drawn from the consideration of the above facts are: (*a*) Ovaries can be transplanted from one animal to another, (*b*) ovaries from the carnivora will take the place of those of herbivora and *vice versa*; and (*c*) the transplanted organs flourish and partially functionate. These reported results open up visions of the practicability of performing the same operations upon women, but the field of feasibility would necessarily be very limited by the difficulty of obtaining absolutely healthy ovaries to transplant, as well as for other reasons which it is unnecessary to mention.

R. T. Morris adds as further proof of the possibilities of this operation that the occurrence of pregnancy after oöphorectomy is due in many cases to the transplantation of portions of the ovary. As early as 1895 Morris began ovarian grafting in the human being, having had twelve cases up to 1901. He places the ovary in normal saline solution at a temperature of 100° F. In his early cases he made a slit in the fundus of the uterus and placed the ovary in it, but in his more recent ones the ovary was attached to the broad ligament as near the seat of attachment of the patient's own ovary as possible. The result thus gained is the avoidance of a premature menopause, thus showing that the ovarian graft has retained its vitality. In one case pregnancy resulted, but an early abortion occurred.

Accessory or Third Ovaries.—These have been described, but were probably merely pieces of an ordinary ovary, which had become separated from the rest of the organ by fissures. It is significant that during the thousands of cœliotomies which have been performed of late years, no competent observer has definitely reported a case in which more than two ovaries have been found in any one patient.

Displacements of the Ovary.—While the ovaries are developed in the abdomen they usually descend into the pelvis, but now and then one or both fail to do so and remain at the level of the pelvic brim. This malposition, however, gives rise to no symptoms, but will prevent the physician from feeling the organ during an ordinary bimanual examination. It may be diagnosed by not discovering the ovary in its usual place, or in thin subjects by feeling it at the pelvic brim during deep abdominal palpation.

Hernia.—A more important form of displacement, on account of the discomfort to which it may give rise, is hernia of the ovary. Here it descends along the round ligament and lies in the sac of an ordinary inguinal hernia, or it may lie in one of the labia majora, or even form part of a femoral or obturator hernia. In addition to the usual symptoms of a hernia, one gets an exacerbation of pain at the menstrual period and also an increase in size and tenderness at the same time. Pressure gives rise to a peculiar nauseating pain, which is almost pathognomonic of pressure on either an ovary or a testicle.

Treatment.—If in a position in which it is subjected to much irritation or pressure, the ovary may be protected by a cap or pad; but if these fail, it may be removed by an ordinary herniotomy operation.

Prolapses of the Ovary.—In health the ovary lies to one side of the uterus, at the level of or slightly below the fundus. In certain conditions, however, it falls considerably below that level, at which time the position may be considered to be pathological. It is due to a retroposition of the fundus dragging it out of place, or to adhesions due to an old pelvic peritonitis, acting in a similar manner. A general want of tone of the parts or prolonged ovarian congestion will also cause the ovary to become prolapsed. Other causes of this condition are sudden strains or any enlargement of the organ.

The *symptoms* are caused by the congestion consequent upon the displacement of the organ and by the disturbance of and pressure upon it by the distended bladder or rectum, and the various movements of the pelvic muscles. These all cause a dragging, aching pain in the pelvis, which is exaggerated at the onset of the menstrual congestion. More or less severe paroxysms of pain are caused by coitus and the passage of hard fæcal matter along the rectum.

When the organ is not embedded in adhesions, the *diagnosis* of a prolapsed ovary is comparatively easy. On making a vaginal examination a tender ovoid, mobile body is to be felt, either low down behind the uterus or in one or other lateral region of the pelvis.

The *treatment* consists in finding and removing the cause wherever possible. If the uterus is prolapsed or retroverted, restore it to its normal position, and keep it there by tampons or a pessary. If there is a general want of tonicity in the parts, try to improve the condition by hot douching, local counter-irritation per vaginam, and the insertion of a boroglyceride or glyceride of tannic-acid tampon, as well as by the local use of electricity, especially faradic. The bowels should be kept regular, and gentle exercise (walking) be encouraged. Some writers advocate pelvic massage for this condition, and claim to have obtained striking results from this line of treatment. It is questionable, however, if the doubtful good obtained is not entirely eclipsed by the ill effects which the necessarily prolonged handling of the genitals produces.

When the ovary is adherent, and the above treatment fails to relieve the pain, etc., an operation will be required. The indication will then be to separate the adhesions and possibly stitch the ovary in a more favorable position on the broad ligament. In order to prevent the formation of fresh adhesions the raw surfaces may be covered with Cargile's animal membrane or with a small portion of omentum, which may be cut off and carefully sutured over them. The abdominal route is the one recommended for this operation, as you are able to expose the parts thoroughly, and treat any small pockets of pus which are so apt to be present in old cases of pelvic peritonitis. You can also stitch the ovary in place better by the abdominal than by the vaginal route.

Atrophic Disturbances.—*Atrophy of the ovary* may be physiological (as when it follows the menopause) or pathological. Pathological atrophy is apt to accompany excessive obesity, while prolonged pressure by adhesions or tumor, interference with the vascular supply and removal of the uterus, are also causes of this condition. It is also said to follow alcoholism, acute exanthemata, rheumatism, etc., but the condition then is not one of true atrophy but of cirrhosis.

Digitized by Microsoft®

In *cirrhosis of the ovary* there is an increase in the fibrous tissue of the organ at the expense of the glandular and muscular elements. In the early stages the ovary is of normal size, but is firmer than usual; while later it is small and very hard, its surface is glistening white and thrown into brain-like convolutions by contraction of the fibrous tissues.

www.libtool.com.cn

The *symptoms* are pain, sterility, and various reflex neuroses, the patient often complaining of gastric disturbance, visual defects, and headache. The pain is usually related to menstruation, or is of a peculiar dull sickening nature, coming on from ten days to two weeks before the onset of the flow. Local examination of the pelvis is not apt to reveal very much, as the ovaries are too small to be felt except in particularly favorable cases, when they are felt to be very hard, painful, and small.

In the way of *treatment*, not much can be done, although in the earlier stages electricity may possibly check the condition. When fully established, however, oöphorectomy is indicated.

The *etiology* of the condition is unknown.

HYPERTROPHY.—This is caused by anything which produces chronic congestion, or by any inflammatory process which stops short of the formation of pus. As examples of those causing congestion may be cited chronic constipation, prolapsus ovarii, too frequent coitus, etc. Pure hypertrophy, however, is where there is an increase of all of the constituent parts of the ovary, and is extremely rare, the above conditions being much more likely to be followed by cystic or fibrous enlargement than by true hypertrophy.

The *symptoms* of hypertrophy of the ovary *per se* are practically *nil*, but will be those of the condition giving rise to it; consequently no *treatment* is necessary.

INFLAMMATION OF THE OVARY.—In the ovary, as elsewhere, *congestion* is an early stage of inflammation. Just as in other regions, it has its own symptoms and may be checked without going further.

The causes of congestion are exposure to cold, especially during menstruation; chronic constipation, in which case the left ovary is the one chiefly affected, owing to its proximity to the rectum; excessive sexual excitement, prolapse of the ovary, inflammation of neighboring structures, bacterial toxins or germs (invasion by the latter rarely stops short of producing pus), and twisting of the pedicle of the ovary. Sometimes the removal of one ovary produces an hypertrophy of the other, which, as a rule, is transitory. It may, however, go on to chronic inflammation and cystic formation; but if promptly, properly, and patiently treated by rest, hot douches, and boroglyceride tampons, the congestion should subside in a few months' time. One can readily understand how disappointed a patient is when the removal of one ovary has simply resulted in the transference of her pain to the opposite side. She will often blame the operator for not having removed both ovaries, and want him to perform a second oöphorectomy; but if he is firm in his refusal to do so until a more or less prolonged course of local treatment has been tried, both he and his patient will time and again be rewarded by the return of the diseased ovary to health and usefulness.

Besides the above pathological forms of congestion a physiological variety occurs during menstruation, pregnancy, and sexual excitement, but this does not require consideration in this article.

Oöphoritis, or inflammation of the ovary, may be either acute or chronic, the former usually passing on to the chronic variety if untreated, and if the infection is not sufficiently acute to carry off the patient before the affection reaches the chronic stage.

Acute oöphoritis is practically always caused by the presence of germs. These may be carried to the organ by the blood or lymph vessels from some more or less remote source of infection, or else may attack it by a more direct route, as where there is an acute infectious inflammation of the Fallopian tube, or where the ovary is adherent to the rectum, appendix, or other portion of the bowel, and the germs reach it from thence.

The two most common forms of infection are gonorrhœa and puerperal septicæmia, both of which may cause a most severe disease. In addition to these, however, acute inflammation may be set up by injury, by poisons, such as arsenic and phosphorus, by the acute exanthemata, mumps, acute rheumatism, etc. The writer, some years ago, saw a woman who was suffering from an ordinary attack of typhoid fever; she was quite suddenly seized by a sharp pain in the region of the right ovary, the pulse became more rapid and the temperature rose. Appendicitis and perforation of the bowel having been excluded, the abdomen was opened and the right ovary was found to be enlarged and acutely inflamed. The removal of the organ was followed by relief of all pain, with ultimate recovery of the patient.

Symptoms.—The patient suffers from an acute agonizing pain in one or other ovarian region, the pain radiating up toward the umbilicus into the loin, down the leg, etc. More or less nausea is present. Defecation and micturition are frequently painful. Examination of the lower abdomen reveals great tenderness over the affected region, and the same will be found per vaginam, by which passage also one can feel the ovary to be somewhat enlarged if the parts are not too tender.

Treatment.—Absolute rest in bed is distinctly indicated, as is also the application of ice, or, if that fails, heat, over the lower abdomen. The parts may be too tender to allow of hot douches being used, but they usually give great relief. The water ought to be as hot as the patient can possibly stand it, and at least one gallon should be used. The force of the water may be regulated by the height of the douche pail above the patient's bed, and ought not to be too strong. Lavage of the rectum is often of service, especially when the left ovary is the one affected. Blistering the abdomen over the diseased area will often be of service.

The tincture of aconite, given in doses of one or two drops every hour, often benefits the condition by quieting the circulation, but there is no drug which has any specific action upon the malady. The bowels should be well emptied early in the attack and then kept at rest. The best way to influence them is by sulphate of magnesia in drachm doses every hour for five or six hours; the drug being dissolved in hot water. After this has taken effect keep the bowels closed by tinctura opii, or by a pill plumbi cum opio. As regards diet, it should be fluid, light, and non-stimulating, consisting principally of milk and its preparations.

Prognosis.—If the patient is seen in time and if the infection is not too virulent, the above treatment suffices to cure the vast majority of cases. But the disease may pass into the chronic variety, or else an abscess may be formed. This abscess if not interfered with may either resolve, remain quiescent, or rupture. If the organ has become adherent to either the bladder or the bowel, it may rupture into them and its contents be discharged externally. Otherwise it will rupture into the general peritoneal cavity, causing acute inflammation of its lining membrane and the death of the patient. After the escape of the contents through either the bladder or the rectum the sac may refill, and should then be removed by the surgeon; in fact, when an abscess of the ovary exists which will not yield to milder measures, the surgeon must interfere. It is better if he can wait until the virulence of the germs is lessened, as this greatly reduces the risk of the operation and occurs within a few weeks, probably not more than five or six.

Diagnosis.—This is sometimes a matter of great difficulty and importance. The conditions with which it is most likely to be confused are: (*a*) appendicitis (when the right ovary is attacked); (*b*) intussusception; and (*c*) pelvic tumor with a twisted pedicle.

In appendicitis the pulse and temperature are more liable to be interfered with, there is more vomiting, the tenderness is higher in the abdomen, and it is more than probable that a vaginal examination will give a negative result, whereas in acute oöphoritis the examining finger will probably feel the diseased ovary.

Intussusception rarely occurs in adults. It gives rise

Digitized by Microsoft®

to a sausage-shaped tumor, and either to complete constipation or to bloody and mucoid stools.

A tumor with a twisted pedicle makes itself evident either to sight or touch, if not to both. An ovary enlarged by an abscess would give a more chronic history, *i.e.*, it would not give rise to the sudden acute pain which torsion of a pedicle causes.

www.libtool.com.cn

Chronic Oöphoritis is much more common than the acute form which it may follow. It frequently, however, comes on quite independently of the acute variety, and is much more insidious in its onset. Women are most liable to it during the period of greatest sexual activity, from which statement it may be correctly inferred that it is much more common among married than among single women. Excessive sexual excitement, especially without gratification of the desires, is one of the commonest causes of this condition. In addition to this, mumps, masturbation, operations upon the cervix (?), and prolonged congestion of the ovary are prolific causes.

Pathology.—When an ovary which is the seat of chronic inflammation is examined, it is found to be somewhat enlarged, and to contain more or less numerous small cysts. The organ is firm, and its peritoneal covering is tough and thickened. There is also an increase in the fibrous tissue.

Symptoms.—Chronic inflammation of the ovary produces pain in one or both sides of the pelvis, according as to whether or not one or both ovaries are affected. When the disease is unilateral, the left is the one usually the seat of the trouble on account of the proximity of the rectum. This pain may radiate down the thighs, across the abdomen, or up toward the umbilicus, and is aggravated by defecation, by any sudden movement, as on taking a jump or misstep, by jolting, coitus, etc. It also becomes more marked a week or ten days before the menstrual flow appears, being relieved by the local depletion which is thus caused, in proportion to the amount of blood lost. A sharp pain in either one or both breasts, and especially in the left, is often experienced. Pressure through the abdomen over the diseased organ causes pain, as does also coitus. On making a local vaginal, or, better, rectal examination of the pelvis, the ovary is felt to be enlarged, tender, and often more or less prolapsed.

The *diagnosis* is not difficult as a rule. The location, in the ovarian region, of a pain which becomes more severe several days before menstruation; the reflex mammary pain; painful defecation and the presence of an ovoid tender mass in the region usually occupied by the ovary, will point strongly to chronic inflammation of the ovary. Of course the inflamed organ may be plastered against the pelvic wall by adhesions, in which case you will have to be guided by symptoms alone.

Treatment.—This consists in finding and removing the cause wherever this is possible. Regulate the bowels and diet and limit the patient's exercise. This may require to be entirely prohibited in obstinate cases, the patient being confined to bed. Stop excesses of all kinds, whether bacchanalian, gastronomic, or sexual. The domestic duty most likely to aggravate or at all events keep up the trouble, is working the treadle of the sewing-machine, which should be strictly forbidden. Depletion of the pelvis may be effected by accelerating the action of the bowels by means of sulphate of magnesia or one of the many aperient waters, by hot douching, by hip baths, by medicated tampons, or by vaginal cones or bougies. For the douchings plain boiled water cannot be improved upon, but it must be used in quantities of not less than a gallon, and must be as hot as the patient can possibly bear it. The vagina, not being a very sensitive organ, can tolerate a much higher temperature than the skin of the perineum and vulva, but these parts may be protected by a towel wrung out of warm water. The tampons are better if they are made small, about the size of a large walnut, using two or more if necessary. They will thus fit more snugly and cause the patient less discomfort than if a single large one is used. While tampons saturated with boroglyceride or pure glycerin are useful, the employment of a ten-per-cent. solution of ichthyol in glycerin, or a combination of ichthyol, tincture of iodine, glycerite of hydrastis, and boroglyceride is to be preferred. Counter-irritation through the skin of the abdomen, or per vaginam, is a valuable adjunct to the above course of treatment. The first may be carried out by painting the skin of the abdomen with the tincture of iodine, or blisters may be employed. When these are used a small blister should be placed over the centre of the painful area. When this one heals a second is to be placed at its side, and so on until the first one has been completely surrounded; each one being allowed to heal before applying the next. The counter-irritation per vaginam is best effected by painting the lateral fornices with a mixture of equal parts of the liniment and tincture of iodine.

Little can be done in the way of internal medication for this condition. The bromides, especially a combination of those of ammonium and sodium, have been highly commended and may be of some use in quieting the circulation and pain. The chlorides of gold and sodium have also been employed with benefit. Temporary exacerbations of pain must be combated by the local application of heat and the administration, by the medical attendant himself, of morphine. Alcohol should be absolutely forbidden as it only aggravates the condition eventually, although it may relieve the pain for the time being.

The above line of treatment ought to be conscientiously persisted in for many months before abandoning it as useless—that is to say, when the woman can give up the time for it. When she cannot do this, and it is necessary to cure her quickly so that she may return to her ordinary sphere of usefulness in a comparatively short time, as also in those cases in which all non-operative means have failed, removal of the offending organ is the only resource left. This may be done per viam abdominalem or per vaginam, but this operation will be fully described in another article. (*Cf. Ovariotomy.*)

Hæmatoma of the Ovary.—During the course of acute fevers, as a result of injury or pressure upon or torsion of the broad ligament containing the ovarian vessels, one of the capillaries within the stroma of the ovary or wall of a Graafian follicle may rupture and give rise to a collection of blood, which is called an hæmatoma ovarii. It may also be caused by the impregnation and rupture of an ovum in the ovary, the possibility of the occurrence of which has been but recently demonstrated. Hæmatoma of the ovary is not at all uncommon, but is rarely of any clinical significance. On inspection the ovary is seen to have a larger or smaller bluish-red mass projecting from its surface, which mass is semifluctuating. Microscopic examination reveals a mass of blood clot lying within a more or less well-formed capsule.

Ovarian hæmatoma rarely gives rise to any symptoms or calls for any treatment. If symptoms are present they are usually those of chronic ovaritis and call for the same treatment, except that where operation is indicated nothing should be removed but the diseased portion of the ovary.

Ovarian Pregnancy.—In Clifford Allbutt's "System of Medicine," published as recently as in 1896, the writer on "Diseases of the Ovaries" says: "It is extraordinary that belief in the occurrence of ovarian pregnancy should have obtained currency," and that "until some specimen is forthcoming in which an early embryo in its membranes can be demonstrated in a sac inside the ovary, we need not trouble ourselves to discuss ovarian pregnancy." Only three years later Croft and van Tussenbroch each reported an undoubted case, and since then at least three other cases have come to light, viz., those of Anning and Littlewood in 1901, Mayo Robson in 1902, and Thompson in 1902. It is a curious fact that of the five cases no less than three occurred in Leeds, England.

Symptoms.—Ovarian pregnancy gives rise to very much the same symptoms as those of ordinary tubal gestation, except that, as a rule, rupture is not preceded by the dull aching pain in the side, to which the latter gives rise. The absence of this pain may be ascribed to earlier rup-

Digitized by Microsoft®

ture and to there being no firm muscular fibrous tube wall to distend.

The patient passes her time by a week or ten days, or else her last period has been replaced by a dribbling of blood which has persisted. This is followed by a sudden sharp pain in one ovarian region, accompanied by faintness, with possibly actual loss of consciousness, by sighing respirations, pallor, a cold clammy sweat, and rapid thready pulse. Although the temperature is usually subnormal, some elevation of it is quite compatible with the condition, as was recently seen in a case which the writer had under his care in the Montreal General Hospital.

On examining the patient the surgeon will find some tenderness over the affected organ, slight dulness in the flanks, and the seat of the effused blood will be warmer than the rest of the abdomen. Attention was first drawn to this sign by Grandin, and while it cannot be always distinguished, the writer has seen it in at least one case since the publication of Grandin's paper. Vaginal examination will reveal an oozing of blood from the vagina, a softened velvety cervix, normal uterus, and a rather vague mass in one fornix.

The *etiology* is still *sub judice*. As shown by the fact of only five undoubted cases having been reported, pregnancy occurring in the ovary is extremely rare; but it is quite possible that many of the cases of hæmatoma of the ovary which have been reported have really been cases of ovarian pregnancy, it being probable that villi and other signs of gestation would have been observed if they had been carefully searched for. On the other hand, it is almost certain that many of the older cases of reported ovarian gestation have really been nothing more than hæmatomata, as proved by microscopic examination. In order to be certain that the gestation is ovarian, it must be shown that the original attachment is inside the ovisac, and that the ovum derives its nourishment from thence. This can be done with certainty only in the very earliest weeks of pregnancy, as the ovarian tissue is liable to become so displaced in cases of tubo-ovarian pregnancy as to appear to have been the original seat of implantation of the ovum. In a true ovarian gestation the ovum immediately upon impregnation attaches itself to the wall of the ovisac; villi are thrust into this wall, and by this means the ovum is nourished. In the majority of cases the ovum continues to grow until between the fifth and sixth week, at which time it ruptures into the peritoneal cavity. This is followed by severe intraperitoneal hemorrhage, although, judging from the small numbers and size of the vessels, one would not expect such a result. In at least two of the fully reported cases the abdomen was found to be filled with blood at the time of operation.

Treatment.—This will vary according as to whether or not hemorrhage has ceased and the patient can be kept under observation and constant readiness for operation, and also whether or not the clot is undergoing absorption. If seen some time after rupture has taken place and if the patient can be kept under close observation, temporizing measures may be adopted. In such a case one of the most important points to be remembered is that all cardiac stimulants are absolutely contraindicated, as their exhibition is very liable so to increase the force of the heart's action that the clots, which are plugging the mouths of the ruptured vessels, will be forced out and a fresh hemorrhage take place. The very best way to improve the patient's condition is to use decinormal saline solution, either per rectum, or subcutaneously, or intravenously, according to the acuteness of the symptoms. It is only in the most urgent cases that the latter method is required, as the solution is very quickly absorbed from either the bowel or the submammary region. Absolute quiet and rest in bed are strongly indicated, and the circulation and pain may be calmed by the subcutaneous injection of morphine. Ice should be applied to the abdomen over the point of rupture, and hot vaginal douches may be begun some days after cessation of the bleeding. The diet should be nutritious but non-stimulating. Where under this treatment the clot does not become absorbed within a reasonable time, it may be cleared out by means of an incision through the posterior vaginal wall.

When the patient is seen soon after rupture, or when she cannot be kept under observation, the quicker the abdomen is entered, the bleeding controlled, and the gestation removed, the better it will be for the patient, shock or no shock. This condition of shock is to a very great extent due to loss of blood, and will not be lessened by allowing this to proceed. While some few of these patients will recover without operation, a much larger percentage of recoveries will take place if the knife is used early, energetically, and judiciously.

Tuberculosis of the Ovary.—Tuberculosis of the ovary is extremely rare, the ovary being only the third in order of frequency of the female genitals to be affected. In fact so rare is the disease that the older writers did not deem it worthy of consideration in their works. The rarity and almost impossibility of occurrence of primary ovarian tuberculosis can be readily understood when one realizes that in order to have such a condition the bacilli would require to enter the body from the exterior and then traverse a more or less complicated system of blood-vessels or lymphatics before entering the ovary. No case of primary tuberculosis of the ovary in the human subject has yet been reported. Although Acconi experimentally produced it in animals, Spaeth, Blebs, Oppenheimer, Sippel, and others have recorded cases in which the ovary was the only genital organ to show the disease in patients who were otherwise tuberculous. In the majority of cases it was the superficial part of the organ which was the seat of the disease, the presence of which in the deeper layers was frequently unsuspected until the ovary was examined under the microscope.

The form of tuberculosis present is the miliary form, and it may affect either the superficial or the deep layers. When the latter part is affected, the disease is apt to proceed until an abscess is formed, and this may rupture into the peritoneal cavity. The germs may reach the ovary either through the blood or the lymph current by direct continuity, as in the case of tuberculosis of the peritoneum or tubes, or by bacilli working their way through a weak spot in the bowel wall and falling upon and infecting the ovary.

No age is exempt from this disease, but those under fifty are the most liable to be attacked. Out of 17 cases reported by Griffith 5 were under fourteen, 8 were between fourteen and twenty-five, 3 between twenty-five and forty-five, and 1 was fifty-five years of age.

The *clinical history* is very vague and there is no symptom or series of symptoms which can be considered to be at all pathognomonic of this condition. There may be absolutely no symptoms or else those described as occurring in chronic oöphoritis may be present. Where such is the case and you have a semifluctuating, rounded, non-sensitive mass occupying the region of the ovary, together with an evening rise of temperature, in a young woman who is otherwise fairly healthy, and who has not been exposed to the two common causes of pelvic abscess, viz., gonorrhœa and sepsis, you may suspect the presence of a tuberculous abscess of the ovary. Anything short of abscess formation cannot be definitely diagnosed previous to operation, as both physical signs and symptoms are too indefinite. Menstruation may or may not be affected, but when it is interfered with amenorrhœa is the form usually taken, and is more the result of the general than it is of the local condition.

Once diagnosed the only *treatment* to be adopted is removal, but this can be advocated only in the absence of extensive disease of other organs.

Tumors of the Ovary.—The ovary itself may be divided into the oöphoron which contains the ova, and the paraoöphoron or part nearest the ovary. Although this latter is anatomically quite distinct, it might be considered clinically to be part of the ovary. Of these three parts, the oöphoron is the most active as far as the formation of tumors is concerned. From it are derived 1.

Digitized by Microsoft®

Fibromata; 2. Myomata; 3. Sarcomata; 4. Carcinomata; 5. Cysts; 6. Adenomata; 7. Dermoids.

The paraoöphoron gives rise to papillomatous cysts, and from the parovarium are developed unilocular, thin-walled cysts. Of the above tumors cystomata form about ninety-five per cent., the multilocular cysts being the commonest.

www.libtool.com.cn

1. *Fibromata.*—These are the rarest of all ovarian tumors, muscular tissue being found along with fibrous in most benign solid ovarian tumors. When pure, these tumors consist of many bands of white fibrous tissue which interlace and include in spaces round cells, and here and there among the fibres a few small spindle cells are seen. No blood-vessels or nerves are found in the substance of the growth. Fairbairn divides them into three groups: (1) Where the whole ovarian stroma is replaced; (2) where part of the stroma only is affected; and (3) where a pedunculated fibroid springs from the surface of the ovary.

Fibroids of the ovary are more likely to develop in women who have passed the menopause than are fibroids of the uterus, and they occur twice as often in married as in single women.

Herbert Spencer found the tumor to originate in the fibrous capsule of the Graafian follicle in three cases. Peter Horrocks asserted that when carcinomatous and sarcomatous tumors are bisected the cut surface remains flat, whereas in fibroids it becomes concave, owing to the elasticity of the fibres. But this diagnostic sign is untrustworthy. The disease is usually unilateral, but Cleeman recently reported before the Philadelphia Obstetrical Society a case in which a pure fibroma of each ovary was found in a patient. Ascites was also present.

Symptoms are often absent until the tumor has been present for a long time. The patient may, however, complain of dysuria, dragging pain in the pelvis, dysmenorrhœa, and enlargement of one side of the lower abdomen. Ascites is frequently present, but it does not form a constant sign. Local examination reveals an extremely hard, firm tumor of ovoid shape, situated to one side of the uterus; it is non-sensitive and usually mobile.

The only *treatment* is removal, and this ought to be effected as soon as the tumor is discovered, on account of the difficulty of diagnosis between it and sarcoma.

The *prognosis* is unfavorable if the fibroids are not removed, as, unlike uterine fibroids, they are liable to take on active growth at any period of the patient's life.

2. *Myomata.*—Tumors of the ovary composed wholly of muscular tissue are almost as rare as pure fibromata. They usually develop from near where the ovarian ligament joins the ovary, as this ligament contains an abundance of muscular tissue. In 1896 Gessner found a small fibroid tumor on the ovarian ligament, situated at an equal distance from both the ovary and the uterus, and he inferred from this "that a myoma of the ovarian ligament might invade a healthy ovary and convert it into a myoma of the ovary." Baldy, in "American Gynæcology," reports a case which occurred in a married woman, thirty-six years of age. Operation revealed multiple uterine fibroids, and that the right ovary was replaced by a fibroid mass of the shape and size of a lemon. This mass was attached to the posterior layer of the broad ligament and had the Fallopian tube running over its upper surface. The fimbriated extremity of the tube ended on the external surface of the capsule of the tumor. This latter itself was composed of smooth muscular fibres and a little connective tissue. A band composed of connective tissue and large blood spaces separated it from the true ovarian tissue which was apparently normal.

3. *Sarcomata.*—The ovary is not infrequently affected by tumors of a sarcomatous nature. Apart from regular sarcomata, masses of tissue indistinguishable from sarcoma sometimes occur in dermoids, the removal of which in these cases may be followed by malignant disease of the pelvis. When the ovaries are affected by these growths the disease is frequently bilateral, here differing from what takes place in other parts of the body where the affection is usually unilateral.

The ovary may be invaded by either the round- or the spindle-celled variety. The former is usually found when both sides are affected and in young patients. At the Würzburg Frauenklinik, out of 295 cases of ovarian tumors 20 were sarcomatous; the ages of the patients ranged from twelve to sixty-three, 7 being over fifty years old. Out of 4 which occurred in females under twenty, 3 were of the round-celled variety. Seven died after operation, 3 within the first four days and 4 before six months had elapsed.

Cohn states that their occurrence in relation to ovarian cystomata is as 1 to 100, and that they form ten per cent. of all malignant tumors of the ovary. In 400 cases of ovarian tumors of all kinds, including endothelioma, he found 5.38 per cent. to be sarcomata.

The tumors may grow either rapidly or slowly, and often attain a weight of from twenty to thirty pounds. Their consistence varies, some being hard (the spindle-celled variety), and others (the round-celled) soft and brain-like. They are surrounded by an outer wall, which sometimes is very soft and friable. The pedicle is usually short, and it is but seldom that adhesions to neighboring organs are formed, but ascites is usually present.

On section the surface may be yellowish-white or pinkish-gray, this depending upon the number of blood-vessels present as well as on the structure. Small cysts are often seen, and are due either to hemorrhage into the tissue with subsequent softening or else to fatty degeneration of the tumor cells.

Of the two varieties, the small round-celled is the most malignant; the greater the amount of fibrous tissue present, the less danger is there of any secondary trouble. This secondary infection attacks structures in the following order: viz., peritoneum, omentum, stomach, pleura, lungs, uterus, liver, diaphragm, and kidneys. The tumor may undergo degeneration, the commonest being fatty and myxomatous.

The *symptoms* are few at first, but ascites may develop early, and this forms one means of differentiating sarcomata from fibromata or myomata of the ovary. Pain and disturbance of menstruation are also more frequent than in benign solid ovarian tumors. Physical examination yields similar results in both fibroma and sarcoma ovarii. Metastases are indicated by ascites, œdema, enlarged abdomen, and rapid decline in the patient's health.

The only *treatment* is prompt and thorough removal of the affected organ, and it is also wise to remove the ovary of the opposite side, as it may be affected without showing it macroscopically.

Post-operative *prognosis* as regards recurrence is not good, but is better than when the ovary is the seat of cancer. When both ovaries are diseased or when the round-celled variety is found, the prognosis is decidedly more grave than when one side only is affected or when the growth is composed of spindle cells.

Endotheliomata.—These are malignant tumors which begin by a proliferation of the endothelial lining of the blood or lymph vessels of the ovary. They may be said to occupy a place midway between carcinoma and sarcoma, differing from them in structure but possessing similar clinical features. Billroth regarded them as being as malignant as carcinomata.

Endotheliomata were thus named on account of their origin, by Marchand, who first described them in 1879. They are usually solid, but may contain spaces. The surface is smooth, but may present tuberosities, composed of tissue which is of a brain-like or spongy consistence. They occur mostly at middle age, although Leopold has seen one in a girl of eight, and Olshausen one in a girl aged seventeen. In size they vary from that of a closed fist to that of a fœtal head. Usually they are unilateral and rounded, but may be bilateral and lobulated. The pedicle is short and the tumor prone to form adhesions.

On section, the cut surface may be either gray, or yellow, or white, the tissue being soft and friable and easily torn by the fingers.

Pick differentiates endotheliomata into three types, of

Digitized by Microsoft®

which the first is of a rosary like form, consisting of chains of cells in rows lying in narrow clefts of fibrous tissue. The borders of the rows are parallel and frequently anastomose. In the second form the structure resembles glands and it is difficult to distinguish it microscopically from adeno-carcinoma, the spaces being encroached upon by several layers of polymorphous cells. In the third variety the cells are grouped as in alveolar sarcoma. All three forms may occur in the same tumor.

www.libtool.com.cn

Endotheliomata may occur in connection with other tumors, Pfannenstiel reporting a case in which an endothelioma and epithelial cyst-adenoma were present in the same patient. These tumors may degenerate, the usual form of degeneration being either hyaline or myxomatous, but colloid and fatty have been seen to take place.

Carcinoma.—Cancer of the ovary may be either primary or secondary. The latter usually accompanies malignant disease of the uterus, but it may complicate an affection of the stomach or mammary glands. It may originate in either the Graafian follicle or the germinal epithelium. It is convenient to divide cancer of the ovary into medullary carcinoma and adeno-carcinoma.

I. Medullary Carcinomata. These are solid tumors which are usually oval or rounded, but are also often nodular. They vary in size, but are rarely larger than the head of a full-term fœtus. There is usually a pedicle which is short and thick, but at times they are intraligamentous. Both ovaries are but seldom affected.

Medullary cancers have a dense, well-defined, fibrous capsule, and on section the cut surface is seen to be more or less homogeneous, of a yellowish or grayish-white color. At times extravasations of blood into the substance of the tumor produce a mottled appearance. Degenerations, especially caseous or fatty, are common, resulting in the formation of cyst-like cavities with irregular walls and turbid or yellowish contents.

Histologically the growth consists of carcinomatous cells infiltrating a fibrous stroma, which may predominate and form alveoli filled with cancer cells, but usually the cellular elements predominate.

II. Adeno-carcinomata. Adeno-carcinomata are tumors which closely resemble ordinary serous cysts of the ovary. They are oval or rounded, and rarely exceed an adult head in size. They usually have a short pedicle, but may develop between the layers of the broad ligament and often form adhesions to neighboring structures. Although they may appear to be unilocular, they are usually multilocular. The disease is generally bilateral.

In about half of the cases examined, Pfannenstiel has seen papillæ on the surface. The cyst wall is composed of connective tissue which is quite friable. This wall may be thickened in spots, owing to the development of carcinomatous nodules. Papillary and cauliflower growths may spring from the internal surface of the cyst wall and may nearly fill the cavity. The cyst contents may be clear, turbid from cellular elements, or blood-stained from hemorrhages into the cyst.

Cystic carcinoma of the ovary is usually papillary, the papillæ usually resembling ordinary papillomata, but on section the microscope reveals the presence of cancer cells, and the carcinomatous structure may at times even be observed by the naked eye. Any individual tumor may contain masses which vary greatly in structure from one another. One form consists of a diffuse infiltration of a medullary character. More often the masses are composed of papillæ and glandular structures with their lumen still apparent. An atypical proliferation of epithelial cells is everywhere seen and the papillary growths are covered with several layers of cells asymmetrically arranged. A similar arrangement of the epithelium is seen in the glandular forms of the disease, this giving rise to their alveolar appearance. Lime salts become deposited in the tumors, especially those of a papillary nature, and give rise to psammomata.

It is almost impossible to tell when an adenomatous tumor of the ovary is benign and when malignant, as the gradation from an ordinary cyst-adenoma to primary carcinoma is so gradual. Ziegler holds that no clear line of demarcation between the two can be drawn, and Pfannenstiel estimates that one-half of ovarian papillomata are carcinomatous. He, however, is rather an extremist, claiming that tumors which become carcinomatous should be classified as primary carcinomata, whereas most writers would consider these to be merely cases of carcinomatous degeneration of benign growths. Metastases frequently occur, affecting, in the following order, the peritoneum, omentum, liver, stomach, intestine, the ovary of the opposite side, and, but rarely, the pleura.

Differential Diagnosis of Solid Ovarian Tumors.—During the following brief consideration of this subject, it must be remembered that it will often be quite impossible to differentiate between a solid ovarian tumor and a solid subserous tumor of the uterus with a long pedicle, as, even where this is felt on palpation, the pedicle may be mistaken for the Fallopian tube, unless it be thicker than is commonly seen in the case of a long pedicle. A kidney may be prolapsed into the pelvis and give rise to some difficulty in the diagnosis, but it can usually be replaced.

First, these solid ovarian growths have to be distinguished from tumors of other organs; and secondly, from one another. The tumor is one of the ovary because (1st) it is situated in one side of the pelvis or lower abdomen; (2d) it is unconnected with any other abdominal organ, as ascertained by palpation and percussion; and (3d) uterine movements are not influenced by those of the tumor.

A *fibroid* is the hardest, slowest-growing, and least liable to produce other than pressure symptoms of any tumor of the ovary. It is more liable to appear after the menopause than a fibroid of the uterus.

Sarcomata are firm, and may be quite hard, but they grow rapidly, occur at an early age, and produce ascites, emaciation, secondary deposits, etc. They usually also have longer pedicles than the next variety.

The *malignant solid ovarian tumors* are more apt to be nodular than the above and produce the other signs of malignancy (ascites, emaciation, etc.) more quickly.

OVARIAN CYSTS.—Cystomata of the ovaries may arise from infolding and downward prolongations of the germinal epithelium, or else by enlargement of follicles which have failed to rupture, this failure frequently being due to inflammatory thickening of the outer coat of the ovary. Herman says that this latter "is such a simple and natural way of explaining the development of ovarian tumors that one would think that any other must only apply to exceptional cases," and there is much wisdom in this statement. Why these follicles develop into large cysts in some cases and not in others is not really known, although various theories have been advanced. They may occur at all ages and in every condition, but are more often seen in women who have borne few children than in those who have large families.

Hydrops folliculi is a condition in which one or more follicles become distended by fluid to the size perhaps of a cherry, retaining their globular form. One variety of this affection has been called Rokitansky's tumor, which consists of many distended follicles which have become pedunculated in some cases or compressed laterally in others. They contain a thin serous fluid and sometimes ova. This variety of tumor is both bilateral and rare.

Neoplastic Cysts.—Most ovarian cysts are of the proliferating variety, which Waldeyer divided into the proliferating glandular and the proliferating papillary cysts; but this is merely a clinical division. A more scientific classification is that of Pfannenstiel. He found that the contents of the two varieties differed from each other. In one there is a clear, thin, serous fluid, while in the other class the fluid is dark and turbid and contains a substance called pseudo-mucin. Using this fact as a basis, he named the two groups pseudo-mucinous and serous.

The *pseudo-mucinous* are the most numerous of all ovarian cysts. They are usually unilateral and the size may vary from that of a hen's egg to a tumor weighing two hundred and forty pounds; but one rarely now sees an

Digitized by Microsoft®

ovarian cyst weighing over thirty or forty pounds, as they are usually removed as soon as discovered. No age beyond puberty is exempt from these growths, but they are more liable to attack women between the ages of thirty and forty-five, especially if they are sterile or unmarried. The shape is usually www.libtool.com.cn may be either even or lobulated, the latter being most often seen in the case of the smaller tumors due to the presence of daughter cysts. The color is usually bluish or purplish-white and glistening, with here and there blood-vessels running over the surface. At times bands of unstriped muscle are also seen upon the surface, on which portions of ovarian tissue may become flattened out.

When opened up, the tumor may consist of one large sac with its contents, but if the interior is carefully examined bands of tissue, the remains of the walls of previously existing loculi, will usually be seen. More frequently many smaller cysts with their walls agglutinated together are discovered making up the large tumor. The contents of these numerous loculi may vary from a thin serous fluid to that of a jelly-like consistency. The inner surface of the cyst wall is usually smooth, especially if the tumor is of large size, this pressure causing atrophy of the epithelium; but in the small cysts, small papillæ and other excrescences are often seen. This lining is composed of a single layer of cylindrical mucous-like cells, which stain very readily with eosin and hæmatoxylin. These cells are implanted upon a layer of connective tissue and at times ovarian or unstriped muscular tissues. Outside this again is a layer composed of germinal epithelium.

The *serous cysts* are much less common than the above, nor are they so large, rarely exceeding the size of a pregnant uterus at term and usually being much smaller. Externally they resemble the pseudo-mucinous, but have a greater tendency to adhere to the surrounding organs by means of bands. They are usually multilocular, but contain fewer divisions than do the pseudo-mucinous cysts. They contain a clear, thin, yellowish or greenish fluid, in which albumin is present to a large extent. This fluid is produced partly from the blood-vessels and partly by secretion by the glands in the lining membrane. The composition of the cyst wall is the same as that of the pseudo-mucinous; the cells of the epithelium are columnar and ciliated.

Symptoms of Ovarian Cysts.—The patient may merely have a vague sense of fulness of the abdomen or of weight in the pelvis, or else she may experience no sensations whatever until she accidentally discovers a lump in the lower abdomen. There may be no interference with menstruation, so that when it ceases suddenly one should always be on guard lest pregnancy has occurred. At times the flow is increased, in which case an endometritis may be found to exist.

The physical signs will vary according to the size of the tumor. Where this is small and confined to the pelvis, a bimanual examination will reveal an ovoid, tense cystic swelling to one side of the uterus. Rarely it may occupy the middle line, as occurred in a case of the writer's, the tumor lying in front of the uterus, where it was held by an adhesion on one side and the Fallopian tube on the other. A tumor of this size would cause a downward bulging of the vaginal fornix and could be easily felt by the finger in the vagina, as would also be the case when the contents of a large tumor were very fluid or the cyst was unilocular. When, however, the tumor has risen out of the pelvis it rests upon the brim, and the only sign of its presence to be made out by the examining finger is the depression of the uterus. On inspecting the abdomen, an enlargement is to be seen of the lower part and usually to one side, this enlargement being either regular or uneven. Upon palpation the mass will usually be felt to be tense, but fluctuating, though when the contents are gelatinous the sensation may be similar to that caused by a soft myoma. When the tumor is unilocular, or one loculus is especially large with very fluid contents, a thrill may be obtained by flicking the mass with the finger on one side, while the other hand is placed on the opposite side. This may be intensified by requiring an assistant to exert pressure on the mass by means of the outer edge of his hand placed mesially on the abdomen. Percussion will show that the intestines are pushed into the upper part of the abdomen and to the sides, and turning the patient on one side produces no change in the areas of dulness, an ovarian cyst differing in these two points from free abdominal ascites in which the percussion note is clear in whatever part of the abdomen happens to be uppermost at the time.

Diagnosis of small ovarian tumors (*i.e.*, while they lie wholly in the pelvis) is not as a rule difficult. The peculiar tense, semifluctuating sensation imparted to the examining finger by an ovarian cyst is felt in practically no other conditions than hydro- and hæmato-salpinx and encysted peritonitis. In the two former conditions the mass is elongated or sausage-shaped instead of ovoid as in the case of a cyst. Encysted peritonitis is fixed and has not the clearly defined margin of the ovarian tumor. When the cyst is adherent the diagnosis is more difficult, but space forbids further consideration of the subject. Of course, a parovarian cyst may be mistaken for an ovarian growth, but the treatment is the same and a definite diagnosis can be made only by opening the abdomen.

When the tumor has risen out of the pelvis it may be mistaken for ascites, a distended bladder, a tumor of the uterus (fibroma, myoma, or fibro-cyst), cyst of the mesentery, ovarian dermoid, renal cysts, hydronephrosis, phantom tumors, cyst of the parovarium, and pregnancy with hydramnios.

In *ascites*, unless encysted, the flanks bulge and the enlargement does not stand up prominently, as in the case of an ovarian cyst. Percussion will give a clear note over the highest point in the abdomen. That is to say, with the patient on her back a tympanitic note will be heard in the region of the umbilicus, while the note in the flanks will be dull; whereas if she is turned on her side, the flank which is uppermost will yield a clear note. Exceptions to this rule, however, occur now and then, as was well illustrated in a case which came under the writer's observation some years ago. An immigrant woman was brought into hospital and found to have a swelling of the abdomen which progressed rapidly. The fluid impact wave was readily obtained and percussion gave a dull note all over the abdomen, except just below the sternum. Posture made no change in this note. The uterus and vaginal fornices were depressed. The heart, liver, and kidneys were healthy, and a diagnosis of a rapidly growing parovarian cyst was made. On opening the abdomen for its removal a large quantity of fluid was removed from the general peritoneal cavity and the pelvic organs were found to be healthy. Shortness of the mesentery preventing the intestines from floating to the surface and the excessive quantity of fluid present accounted for the absence of the clear percussion note from its usual situation.

A *distended bladder* occupies the median line of the lower abdomen and appears as a tense pyramidal mass above the pubes. There is generally dribbling of urine, and careful catheterization of the bladder will clear up the diagnosis. For this little operation a male metallic instrument is the best, as something may be pressed against the bladder diagonally, thus cutting off the part into which the ureter of one side opens. A rubber catheter will coil up in the free part of the bladder, and this also will be the only part of the organ which can be emptied by the ordinary short glass catheter, while the long metallic instrument can be cautiously guided past the obstruction into the dilated portion.

Myomata and *fibromata* of the uterus are hard, and palpation fails to elicit any fluctuation. They move with the uterus, the cavity of which is enlarged. If they are interstitial or submucous, menstruation is increased.

A *fibro-cyst* of the uterus gives fluctuation, but moves with and is evidently attached to the uterus. It is a very rare form of neoplasm, and if it is punctured and if the fluid is allowed to stand spontaneous coagulation quickly supervenes.

Digitized by Microsoft®

Cysts of the mesentery have a clear percussion note all around them, if they are not large enough to fill the whole abdomen, in which case a history of the growth having proceeded from above downward and not vice versa, as is the case of ovarian affections, can usually be obtained.

www.libtool.com.cn

A *dermoid of the ovary* is of slow growth and may occur in a very young girl.

Renal cystic tumors and hydronephrosis give a history of progressive enlargement from above downward and can usually be separated from the pelvic organs. In the case of a hydronephrosis ureteral catheterization will usually clear up the diagnosis.

Phantom tumors disappear when the patient is anæsthetized.

Pregnancy with hydramnios may be diagnosed by observing the rhythmical uterine contractions, by auscultation, and by the softening of the cervix and the changes in the breast coexistent with pregnancy. There will also be the history of amenorrhœa, and when all else fails time will clear up the diagnosis.

A *cyst of the parovarium* grows quickly, is never nodular, and, owing to its being unilocular and containing very limpid fluid, gives the wave impact very distinctly.

Complications of Ovarian Cysts.—Any organ or structure in the body may become diseased contemporaneously with tumor formation in the ovary, but the most common complications are albuminuria, ascites, adhesions, pregnancy, rupture of the tumor, and torsion of the pedicle.

The coexistence of *pregnancy* and ovarian cyst is grave and requires care before, during, and after labor. If the cyst is large an abortion is very apt to result. The tumor is very liable to rotate, causing torsion of its pedicle after labor, owing to the change in the intra-abdominal pressure. Infection and consequent suppuration of the cyst are also apt to occur. When pregnancy goes to full term the fœtal and maternal mortality is high. In 271 cases of ovarian tumor complicating labor, there was a maternal mortality of 25 per cent. and a fœtal of 75 per cent., while Zitter and Litzmann place the maternal death rate at 30 and 43 per cent. respectively.

Torsion of the pedicle is a not infrequent complication of ovarian cysts; dermoids, probably on account of the difference in consistence and weight of various sections of the growth, being the variety most often affected. Its onset may be either acute or gradual, the former being naturally the more grave.

The *symptoms* of a twisted pedicle are a sudden, acute pain, followed by rapid enlargement of the tumor. The abdomen becomes tender and the patient may show evidences of most profound shock, the respirations becoming rapid, the pulse small, thready, and rapid, with later on a rise of temperature.

When the onset is more gradual there may be few or no special symptoms. There may be an increase of the previous pain and some enlargement of the tumor. The rapid increase in size of the tumor is due to congestion, which may be so great as to cause hemorrhgae into the tumor substance or even into the peritoneal cavity.

The only *treatment* is to operate without delay.

Ascites may accompany an ovarian tumor, especially if it be malignant. Its chief importance lies in the probability of there being disease of the heart, kidneys, or liver, and in its rendering the diagnosis difficult.

Albuminuria should be looked for and cured if possible before any operative interference is carried out. It *may* be caused by pressure of the tumor on the ureters, in which case it will disappear after removal of the growth and no casts will be found in the urine.

Adhesion of the tumor to neighboring organs forms a serious complication when an operation is called for. These adhesions may be so intimate as to offer sufficient nourishment to the tumor even after it has been freed from its usual attachment, as sometimes occurs in torsion of the pedicle. They also complicate the diagnosis, as, for instance, when the tumor becomes adherent to and moves with the uterus.

Rupture of the cyst may occur and may be followed by permanent disappearance of the growth, or this may refill. When the contents are either irritating, as in the case of a dermoid, or malignant, a general peritonitis or secondary infection of the peritoneal cavity will follow. In some cases a blood vessel will be torn through and a more or less severe hemorrhage into the peritoneal cavity may take place.

Prognosis.—If left alone ovarian cysts are apt to increase in size until they prove fatal through interference with the alimentary, cardiac, digestive, and respiratory systems.

Treatment.—Removal of the cyst by either the abdominal or the vaginal route is the only treatment indicated. Formerly frequent tapping of the tumor and withdrawal of the contents were practised, but ovariotomy is now so safe a measure as to have no rival in the treatment of this condition. Tapping is not only useless, but is distinctly dangerous, as it sets up adhesions and may allow leakage into the peritoneal cavity, is liable to cause sepsis, and puncture of bowel or blood-vessels may occur, and the fluid tends to accumulate more rapidly afterward. Even when the tumor has ruptured spontaneously operation may be indicated by peritonitis or by hemorrhage. In a case of the writer's, rupture took place half an hour before the time appointed for operation, and on opening the abdomen the cavity was found to contain a large quantity of fluid blood which had escaped from a vessel that had been torn across.

Ovarian Dermoids.—In women dermoid tumors have never been found growing from any other organ in the abdominal cavity than the ovaries. They are comparatively rare, only between three and four per cent. of all ovarian tumors being of this nature. They may occur at any age, but are more liable to occur before puberty than any other form of ovarian tumor. Usually only one ovary is affected, but now and then the disease attacks both.

Until recently it was maintained that they were due to inclusion, in the developing ovary, of cells from the other layers, but Wilms has lately suggested the probability of their being caused by some eccentric development of ova, and he supports this theory by the facts of their being found occasionally in the fœtus, and of the tumor containing traces sometimes of nearly every organ in the body, which is not the case with dermoids situated elsewhere.

Ovarian dermoids are not large tumors, rarely being seen larger than a man's head. They contain a cheesy material, in which may be found almost any organ of the body, sometimes in a very rudimentary state. One of the commonest structures found is hair, which may measure five feet in length but which is usually short. In addition to these substances, teeth are often found embedded in the cyst wall, where also rudimentary mammæ may be seen. A heart with a mitral valve and chordæ tendineæ has once been described as having been found in a dermoid of the ovary. The more fluid contents are extremely irritating to the peritoneum, and if they escape into the peritoneal cavity they are almost sure to set up a most intense inflammation of its lining.

An ovarian dermoid gives rise to the symptoms of an ordinary ovarian cyst, from which it may be diagnosed by its slow growth and the peculiar want of elasticity which it imparts to the examining hand. An ovarian tumor seen in a girl before puberty is much more likely to be a dermoid than one of any other variety.

The proper *treatment* is to remove the tumor.

Papillomatous Tumors of the Ovary.—This variety of ovarian cyst is of sufficient importance to warrant some special consideration, and is divided into two groups, according as to whether the papillomata occur inside the cyst or on the outside of its wall.

1. *Papillomatous cystoma of the ovary* may be shortly described as a cystic tumor of the ovary containing masses of papillæ; from the tendency to form secondary growths, it may be looked upon as malignant.

Olshausen, in 1877, noted the difference between sim-

Digitized by Microsoft®

ple cysts and those containing papillary projections. Inspection of the tumor with the naked eye reveals numerous papillæ on the inner surface of the cyst wall. These may be few in number or else so numerous as completely to fill the cavity of the cyst and even at times cause its rupture. The papillæ are pedunculated and vary from a simple www.libtool.com.cn complicated branching structure. Not only does this shape vary, but the color may range from almost white to a pinkish hue, this depending on the supply of blood going to the papillæ and also on their consistence. They are usually soft, but may contain sand-like bodies which cause the growths to feel gritty. After perforation of the cyst wall the peritoneum and other organs may become infected.

These cysts usually contain a clear, thin, watery fluid of a yellow color and alkaline reaction. It has a specific gravity of from 1.005 to 1.040, and does not coagulate on standing. It responds to the tests for albumin. On examining the fluid with the microscope, it may be seen to contain epithelial elements, compound granular bodies, and sometimes cholesterin and hæmatoidin crystals. Instead of the fluid being clear, however, it may be dark and turbid or even grumous the character varying at times even in different parts of the same tumor.

Microscopical Appearances.—In a pedunculated cyst the wall has an outer layer which is thin and dense. It is composed of laminated tissue, a few cells, and occasionally non-striped muscular tissue may be seen. The next layer is thicker and more cellular. Both contain blood-vessels. Internal to this second is a third layer, composed of epithelium which sometimes rests upon a thin homogeneous basement membrane. The epithelial cells may be cuboidal, cylindrical, or, in fact, almost any shape. Cilia may or may not be present, and even in the same tumor some cells may bear cilia while their neighbors do not, their absence or presence being purely accidental and having no bearing upon the case (J. W. Williams). These cells may be in one layer or in several, and in small cysts they are not usually so high as where they simply cover papillæ, the low merging gradually into the high. In the smaller cysts also, part of the outer wall may be replaced by true ovarian tissue. The stroma of the cyst wall, which may be dense and well formed, or else somewhat myxomatous, continues up through the pedicle into the papillæ, and is usually well supplied with blood-vessels, which are thus enabled to pour out a portion of their serum and so contribute their quota toward the fluid contents of the cyst.

The sand-like bodies, above referred to, are called psammomata, and consist of particles of carbonate and phosphate of calcium arranged in concentric rings.

Papillomata may extend from their primary site by three methods. They may do so by direct extension to contiguous structures, by the attachment of small broken-off fragments of the growth to the peritoneum, and lastly by true metastatic formation.

In the early stage no diagnosis of the exact nature of the pathological process is possible. This is clear only when the ascites can be made out, when the psammomata can be felt per vaginam, or when papillomatous masses burst into the bladder or rectum. Freund considers that the simultaneous appearance of ascites and hydrothorax favors the diagnosis of papilloma ovarii.

These cysts are apt to burrow between the layers of the broad ligament, both toward its base and laterally toward the uterus. They occur most frequently between the ages of twenty-five and fifty.

2. *Superficial papillomata of the ovary* are more rare than intracystic growths, and like them are nearly always bilateral. They are formed of branched, usually pedunculated masses, springing from the surface of the ovary. Their histological structure resembles that of the intracystic form of the disease, the epithelium being continuous with the germinal epithelium, as is also the case in some intracystic growths, although the etiology of the latter is uncertain.

The *treatment* of papillomatous disease of the ovary is prompt and thorough removal of the diseased structures, and this is usually followed by permanent relief.

F. A. L. Lockhart.

OVARIOTOMY.—Ovariotomy (from the Latin ovarium, ovary, and Greek *τομή*, cutting) is to be classed among the unsatisfactory terms which unfortunately are too common in medical nomenclature. Leaving out of consideration its hybrid formation, the word by no means expresses the removal of the ovary. In this sense oöphorectomy (*ὠόφορον*, ovary, *ἐκτομή*, excision) is far more appropriate; and if the Fallopian tube be also removed, *salpingo-oöphorectomy* should be employed.

Under the heading "ovariotomy" most text-books consider the operation for tumor formations alone of the ovary, ignoring the inflammatory and other conditions for which identically the same procedure is more frequently undertaken. In accordance with custom, however, the first class of cases will be dealt with here.

History.—The history of this procedure is of considerable interest. The kings of ancient Lydia are said to have had it performed upon women either for the purpose of preserving their youthful characteristics, or in order that they might be employed in the place of eunuchs. The actual nature of the operation, however, is somewhat doubtful, as in some instances in all probability only the clitoris was removed, although from the scanty details procurable it may be inferred that at least some genuine ovariotomies were performed. During the seventeenth century a Hungarian sow-gelder is said to have removed the ovaries from his daughter as a punishment for her frequent lapses from virtue. In the eighteenth century, although suggested much earlier by continental surgeons, the possibility of the operation was seriously discussed, more particularly by John Hunter in England and John Bell of Edinburgh, although, owing to the high mortality of all intra-abdominal operations, these men lacked the courage of their convictions and were unwilling themselves to undertake a hitherto untried procedure. Their teachings, however, bore fruit, and the first prearranged and successful ovariotomy was accomplished in 1809 by Ephraim McDowell, of Kentucky, who had been one of Bell's students in Edinburgh. It must of course be conceded that the ovaries had been removed by operation previous to this time, but in the majority of such cases, if not in all, the real nature of the procedure had not been recognized until later. Moreover, in several other instances ovarian cysts had been tapped through an abdominal incision, and portions of the sac walls had been resected. Nevertheless, it is important to recognize the fact that all such operations had lacked the careful pre-arrangement or the successful issue of McDowell's case.

In the United States the operation was repeated by the originator twice before 1817. Nathan Smith, of Connecticut, unaware of McDowell's cases, performed it in 1821; Rogers, of New York, in 1829; Billinger in 1835; and in 1843 Dunlap, of Ohio, and the Atlee brothers, of Pennsylvania, obtained favorable results. From this time on, the operation gained in favor in America, and the excellent work of W. L. Atlee and of Peaslee did much to popularize it.

In Great Britain Lizars, of Edinburgh, performed the operation four times in 1825, but no other attempts were made in Scotland until 1845. In 1833 Jeaffreson, of Framlingham, obtained the first successful result in England, although Granville had had two failures in 1826 and 1827. Interest in the procedure was revived in 1842 by Clay, of Manchester, who soon became noted for his work. Spencer Wells from 1858 to 1871 performed the operation 410 times, and his total number of ovariotomies reached nearly 2,000. His successors, Keith and Tait, also obtained splendid results. The first successful operation in Europe was performed by the German surgeon Chrysmar in 1820, a similar case in the previous year having terminated fatally. In Germany, until 1850, only 23 ovariotomies with 7 successes had been done, and until

Digitized by Microsoft®

1870 there had been only 180 with a mortality of 105, or over 58 per cent.

It was not until 1844 that Woyerkowsky scored the first success in France, but here as in Germany the profession were so opposed to the operation that it made but little headway, and was not recognized until long after it had been established in America and England.

Following the introduction of the principles of antisepsis and asepsis the mortality was reduced to a remarkable degree until, instead of being regarded, as it was by many leading surgeons of fifty years ago, as almost the equivalent of murder, the procedure is now looked upon in uncomplicated cases and in the hands of a skilful operator, employing a rigid aseptic technique, as one of the simplest of abdominal operations. The gradual development of ovariotomy is very fully presented by Peaslee ("Ovarian Tumors," 1872).

Indications.—Internal medication and local treatment are futile in cases of ovarian tumor, and the days of simply tapping cysts are now past. So soon as the diagnosis is made, operative measures should be instituted. Some operators prefer the vaginal route, wherever possible, and in suitable cases this answers the purpose admirably. The relative merits of the two methods cannot be discussed here, but to-day, as a rule, the abdominal incision is chosen; since by its employment the tumors can be rendered plainly visible and accessible to close examination, and the question of complete or partial removal of one or both ovaries is consequently more easily decided.

It is true that in many instances an ovarian tumor may exist throughout a patient's lifetime, without detriment to her health, or without producing any symptoms whatever, so that its discovery is often more or less accidental. But despite this well-recognized fact we must always take into consideration the comparative frequency of malignancy in these tumors, and the liability to the occurrence of secondary implantations and metastases, even at a period when the main growth is causing no unpleasant manifestations. Moreover, the possibility of certain accidents, as torsion of the pedicle, or rupture of a cyst with perhaps a resulting hemorrhage or peritonitis, is worthy of consideration. Infection of the cyst contents from an adherent bowel may also occur and greatly increase the danger. Adhesions are likely to form, rendering operation at a later date more difficult, and secondary changes in other organs may begin insidiously and make considerable and rapid progress.

Age as a rule seems to make but little difference. Generally speaking, elderly women bear the operation very well. In children we must always bear in mind the relative frequency of sarcomatous tumors.

The coexistence of pregnancy does not modify to any extent the indications for operation, inasmuch as statistics show that fatalities to the mother and fœtus are much more likely to occur when the ovarian tumor is allowed to remain undisturbed than when it is removed even during the pregnancy. In the case of a malignant tumor the dangers incident to expectant treatment are even greater than in the non-pregnant state, since the physiological congestion tends to promote rapid growth. The liability to torsion of the pedicle is naturally increased as the enlarging uterus crowds the tumor, often rotating it, in its attempts to occupy the narrowing space to the best advantage. Thus in one series of one hundred and nine cases of ovarian tumor with pregnancy torsion occurred ten times. Large tumors in the presence of the additional bulk of the uterus may lead to pressure symptoms, sufficiently severe to endanger the life of the mother, and growths of relatively small size have been known to cause the death of the fœtus. Smaller tumors, especially if solid, may become impacted in the pelvis below the growing uterus, the accident either leading to abortion or giving rise to an impassable obstacle to delivery at term, thus necessitating a Cæsarean section or other radical measures. The pregnant uterus may also be crowded backward under the promontory of the sacrum, so that its development is hindered, and abortion is very likely to occur. Adhesions of the ovarian tumor to the uterus may prevent the symmetrical enlargement of the latter, leading to abortion or sometimes to a malposition of the fœtus. The adhesions may be torn apart by the traction exerted by the uterus, sometimes in conjunction with a sudden trauma. In such cases alarming or even fatal hemorrhage has been known to take place. Rupture of an ovarian cyst is also liable to occur from pressure or trauma, in the latter case because there is less room for the movement of the tumor, so that even a slight blow might suffice to cause such an accident.

The question of the advisability of operation during pregnancy is very apt to present itself, since a tumor that has existed unknown to the patient may attract her attention as soon as it is displaced upward, into the abdomen, by the growing uterus. The physician may also discover it during an examination in a case of apparently normal pregnancy.

If the tumor be discovered only in the later months, especially if it be small and cause no trouble, and if after it has been carefully watched for some time it shows no signs of enlarging, operation may be deferred until after delivery has taken place. All the various factors, however, in the individual case must receive careful consideration. If a cyst causes disturbances only during the last four weeks of pregnancy, or after the onset of labor, tapping may become necessary, and the short respite thus obtained may tide the patient over until a more favorable time for a radical operation. There is also the possibility that the cyst may not refill. In the earlier months, inasmuch as pregnancy is less liable to be interrupted by operation, interference is clearly indicated. The operation should be done as rapidly as is consistent with proper precautions, and during all the various manipulations the pregnant uterus should be protected from trauma, and the pedicle carefully ligated. In view of the stretching that may be exercised by the enlarging uterus, the tissues should not be too tightly bunched; it is far preferable to employ several ligatures, each including a small portion of the pedicle. The case should be treated afterward as if abortion were imminent, and opiates should be administered if necessary.

The only absolute contraindication to the operation may be the enfeebled physical condition of the patient. Thus in torsion of a pedicle with resulting collapse it will sometimes be very difficult to decide whether a postponement is not justifiable in the hope that the patient can be tided over the acute attack, and not submitted to operation until some days later when her condition is improved. Many unfavorable symptoms apparently contraindicating operation may be due entirely to the tumor, and disappear after its removal. Among the most important of these are ascites, circulatory and even respiratory changes induced by pressure, albuminuria, and in some cases glycosuria. In several instances sugar, which had been present in the urine of patients suffering from ovarian cysts, disappeared entirely after removal of the tumor.

Even in apparently hopeless cases unexpected results are sometimes obtained, and records are found of cases of widespread papillary adenocystomata and endotheliomata with peritoneal metastases, in which these latter caused no further trouble after the main tumor had been removed. Moreover, in densely adherent cases which at first seem to defy even an expert operator, by patience and careful work the tumor may probably be freed and then removed. At times in almost moribund patients radical measures may be indicated, and unless the condition be due to cachexia brought about by a malignant tumor, after prompt and active stimulation and infusion or intravenous transfusion of decinormal salt solution, operation will sometimes save. More particularly is this true in cases of torsion or rupture of a cyst or when the symptoms are due to pressure.

In brief, then, the indications for treatment in cases of ovarian tumors may be summed up as follows: Operate as soon as you are satisfied of the presence of such a tu-

Digitized by Microsoft®

mor, unless there is good reason for believing that the physical resistance of the patient may be materially improved by waiting a few days.

Technique.—Too much stress cannot be laid upon a rigid technique. In view of our present knowledge it is absolutely criminal knowingly to transgress its well-recognized principles. The whole subject is dealt with in detail elsewhere. Suffice it to say here that we must bear in mind that asepsis not only regards our actions in the operating-room and our surroundings there, but also includes the careful preparation of the patient as concerns the field of operation, the evacuation of the bowels and all other details the proper conduct of which will put her in the best condition possible for the operation. In the room itself everything should be as clean as possible, and all materials coming in contact with the field of operation should be sterile. Especially does this apply to the hands which, although they cannot be rendered absolutely aseptic, can at least be made innocuous by means of diligent scrubbing, by the employment of antiseptic solutions, and by the additional precaution of using rubber gloves. Instruments should be boiled in soda solution, all dressings, towels, etc., should be sterilized with steam, preferably in the autoclave. Sea sponges, owing to the difficulty of satisfactorily disinfecting them, had better be discarded. Frequent rinsing of the hands in a basin of sterile water during the course of the operation is to be recommended, for by so doing we are less liable to transfer infection from one part of the field of operation to another, as for instance if the hand has become contaminated by the contents of a cyst during evacuation.

Instruments.—For an ovariotomy the instruments used in an ordinary abdominal section are required, and in addition several others devised more especially for this operation. The choice of instruments is largely an individual matter, and in simple cases one can manage with but very few. Nevertheless it is always best to be prepared for every contingency and the routine sterilization of a few extra instruments, even if they are only occasionally required, will sometimes save no little vexation. The following list of instruments will suffice:

Scalpels	2
Dissecting forceps, toothed	2
Dissecting forceps, toothed, long	1
Artery forceps, small	12
Artery forceps, long	6
Retractors	2
Transfixion needles	1
Needleholder	1
Needles (assorted sizes)	6
Scissors, straight	1
Scissors, curved on the flat	1
Museux forceps	2
Sponge holders	4
Ligatures and sutures, trocar with rubber tubing.	
Cyst forceps	2
Catheter.	
Syringes, dressings, drainage gauze, cautery, portable electric light and other accessories of an operating-room.	

The above instruments are all well known and need not be described here; the pattern is immaterial so long as each is satisfactory to the individual surgeon. The long dressing forceps will be found useful in repairing injuries deep down in the pelvis. The needles, ligatures, and suture material will vary with the predilections of the operator. The writer prefers full-curved sharp needles of three sizes for suturing everything, except the bowel, for which full-curved round needles are used. I generally employ Chinese silk twist for the pedicles and close the abdomen in layers, using a continuous catgut suture for the peritoneum, mattress sutures of silver wire for the fascia, and a subcuticular catgut suture for the skin. The Museux forceps proves of value when traction has to be made on a solid tumor, and the cyst forceps serves a similar purpose if the growth is cystic. The trocar and rubber tubing should be of rather large calibre, since the cyst fluid is often thick and tenacious and is liable to clog a narrow lumen. Sponges are preferably made of gauze, and must be carefully counted before and after the operation, to guard against the possibility of leaving one in the abdominal cavity. The cautery is used in searing the pedicle, to lessen the chance of the formation of adhesions; moreover, its employment will often control oozing from denuded surfaces where it may be impossible to pass sutures.

Anæsthetic.—The relative merits of ether and chloroform as an anæsthetic, and the cases most suitable for each, cannot be discussed here. The main point is that the patient remain deeply narcotized throughout the operation, and that there be a condition of complete muscular relaxation. It is very disturbing to have the patient vomiting or straining during an abdominal operation, and the anæsthetizer should have served a thorough apprenticeship in giving anæsthetics for minor procedures before being entrusted with this duty in abdominal sections. The administration of nitrous oxide gas with oxygen until the patient is completely unconscious and then continuing with ether is a very satisfactory plan. With the former the muscular relaxation is not so complete as with ether or chloroform, and as yet we have not sufficient data to warrant its use alone for ovariotomy, although in certain cases anæsthesia has been prolonged for several hours. Local anæsthesia with cocaine has also been used for abdominal sections, but is applicable only to exceptional cases, and general anæsthesia is almost always preferable.

Incision.—Everything being ready for the surgeon, so that he may proceed with the operation, the patient should be put in the Trendelenburg position, which facilitates the exposure of the pelvic organs. The abdominal incision should be in the median line and should be short at first; if it be necessary to enlarge it later, this can be very easily done, while in many cases of large ovarian cysts it may be possible to remove the sac, after evacuation of the contents, through a very small opening. Before the incision is made the bladder should be catheterized, and it is a good rule to pass a sound in all cases of pelvic tumor in order to determine whether the viscus has been carried upward. Not infrequently the bladder has been opened in making the abdominal incision through neglect of this simple precaution. The skin and subcutaneous fat are divided and the bleeding, which is usually slight, is controlled by hæmostatic forceps. The fascia is then divided in the median line. In doing this very frequently the sheath of one rectus will be opened, but this is a matter of no great moment. The adipose and areolar tissue having been separated down to the peritoneum, the latter is carefully picked up between two pairs of dissecting forceps and a small nick made in it. Through this the air enters, allowing the intestines to fall away, after which the opening can be enlarged as much as necessary. When the parietal peritoneum is adherent to the tumor, the intestines, or the omentum, great care must be exercised in opening it in order not to injure the structures lying beneath. It is important to see that the peritoneum is actually opened before attempting to separate the adhesions, as a mistake may lead to a widespread separation of the peritoneum from its attachment to the abdominal wall. Occasionally it will be found possible to get in above the adherent area through an opening made a little higher up. During the progress of the operation the incision may be enlarged as much as is found necessary, it being borne in mind that when we meet with a cyst, a small opening may suffice, while even solid tumors with a little judicious manipulation may often be delivered through a relatively small incision. The operator must not, however, handicap his efforts by trying to work through too small an aperture. Two fingers are now introduced, or if need be the whole hand, and the nature of the tumor, its location, the presence or absence of adhesions and their extent, are then determined. If it be a cystic growth the question of evacuating the fluid will have to be considered.

Emptying a Cyst.—If the cyst be small enough to allow readily of removal through the incision, puncture is not necessary. If, however, it be large and free from ad-

www.libtool.com.cn
Digitized by Microsoft®

hesions, it had better be emptied. On the other hand, if it be adherent it may be easier first to separate the adhesions, as the contour and relations of the tumor are then more easily recognized than when it is collapsed. Usually it is best to empty it at once, otherwise it is liable to rupture during manipulation. In the case of a large cyst there will also be more room for working, and the site of the adhesions can be more readily exposed if it is first emptied. It is important to avoid contaminating the abdominal cavity with the cyst fluid, inasmuch as we can never be sure that the contents are innocuous. Thus in the case of a papillary adenocarcinoma, the escape of the cyst contents into the abdomen would be very likely to cause secondary implantations. Or, again, the contents may be the greasy product of a dermoid cyst which may possibly be infectious in character, and at any rate will be extremely difficult to remove if once they become distributed in the abdominal cavity. To guard against such accidents gauze sponges are carefully packed around the presenting tumor to wall off the peritoneal cavity and to protect the edges of the incision. The patient is turned slightly on one side so that the escaping fluid may be more readily prevented from soiling the field of operation, and a cyst trocar with rubber tubing attached is then plunged into the tumor. If the tumor wall be too resistant, a small nick with a scalpel may greatly facilitate matters. In making the puncture the large vessels, which can be plainly seen coursing over the cyst wall, should always be avoided. As the sac wall collapses it is gradually drawn out with the hand or with a pair of cyst forceps, and the remaining part squeezed; or pressure is made upon the abdominal walls in such a manner as to get rid of as much of the fluid as possible. A lateral position of the patient is also of advantage in this connection. Any compartments in a multilocular cyst are usually broken down with ease. As soon as the sac has been emptied as far as is possible, the trocar is removed and the opening closed by grasping the edges in a pair of hæmostatic forceps, or by tying a ligature securely around it. The surrounding part of the wall should be carefully cleansed and the whole enveloped in a piece of gauze which has been saturated with sterile hot salt solution.

Adhesions.—Ovarian tumors that are not adherent or that have not grown downward between the layers of the broad ligament can usually be removed without much difficulty. The tendency of the growth at first is to drop down into the cul-de-sac, or later, if there be much enlargement, to ascend out of the pelvis into the upper abdominal cavity, where there is more space for it. Either of these displacements tends to produce an elongation of the broad ligament, to the posterior fold of which the ovary is attached, and also of the infundibulo-pelvic and ovarian ligaments, at the outer and inner poles of the ovary respectively. In this way a pedicle is formed which allows the tumor to be delivered through the abdominal incision, and which can be ligated and then severed.

True ovarian tumors rarely extend between the folds of the broad ligament, such growths being usually of parovarian origin. If there be no inflammatory action tumors of the latter class, as a rule, can be shelled out from between the folds by splitting the peritoneal covering and stripping back the two layers of the ligament. After the growth has been removed the two edges may be sutured with catgut. Hemorrhage is rarely severe, but any excessive bleeding can be controlled by clamping or ligating the ovarian vessels in the infundibulo-pelvic ligament, and the communicating branches from the uterine vessels at the cornu of the uterus. On the other hand, if chronic inflammatory changes exist, the removal of the uterus together with the tumor may be necessary. In these cases it is well to begin with a supravaginal hysterectomy on the side opposite the growth. The uterine vessels on the affected side are ligated and divided and the tumor is attacked from below. Removal, even in this manner, may at times appear too risky, in which case an incomplete operation must be done. Fortunately, however, in such instances drainage per vaginam is usually a feasible procedure.

Adhesions to the surrounding viscera form the most frequent complication of ovarian tumors. These vary from a few spider-web-like strands to masses of dense, organized connective tissue, requiring division with the scalpel or scissors. The method of dealing with these adhesions varies. If they are of recent origin they may be separated with the fingers, or pushed apart with a gauze sponge. If they are more resistant, the handle or blade of the scalpel may be required to divide them. Whenever possible, the separation should be done under the eye of the operator. By dragging the collapsed cyst well out of the incision with a pair of cyst forceps, or with the fingers covered with a gauze sponge to prevent slipping, or by making traction on a solid growth with a Museux forceps, the adherent structures can usually be drawn up also and separated in plain view. On the other hand, when the adherent viscera are fixed, it is sometimes impossible to expose the site of the adhesions satisfactorily, even with the aid of retractors and by packing aside the intestines with gauze. This complication is likely to occur when a large solid tumor is adherent posteriorly. In such cases it is necessary to deal with the adhesions by the aid of the sense of touch, and the knowledge of the anatomical relations. The site from which the tumor has been separated should be examined at the earliest possible moment to ascertain if there has been any damage done, in order that instant repair may be instituted. Adhesions to the parietal wall, which have been mentioned already, occur only in connection with tumors of considerable size.

Omental adhesions are rarely troublesome since, if need be, this tissue can always be sacrificed. It can usually be peeled off from the surface of the growth, but when more resistant it can be ligated and cut away. Even small omental vessels, if left unligated, are apt to continue to bleed; hence the omentum should be examined carefully for any hemorrhage before closing the abdomen.

Bowel adhesions represent the most serious complications, and great care must be exercised in dealing with them. In cases of inflammation of recent origin no trouble is apt to be found, as the adherent bowel may be gently peeled back with the finger or a sponge. If the adhesions be older and firmer, an occasional touch with the scalpel may be required, and if no line of cleavage be apparent, part of the tumor tissue may be left adhering to the bowel. In carrying out this manipulation a cyst, which has not been previously emptied, is liable to rupture at the weakened spot, and the operator must be prepared for this accident. If the intestinal wall be injured it must be immediately repaired, a round-pointed needle being employed for this purpose, and care being taken that no undue narrowing of the lumen of the bowel be produced. Free oozing from the outer surface of the bowel may continue for a short time, but unless the muscularis itself or the mesentery be injured it will soon stop. If the bleeding persists, however, measures must be taken to control it. When the injury has been severe and there is doubt as to the success of the repair, the question of drainage comes up. This will be discussed later.

The bladder is seldom apt to be injured, as it is less likely to be drawn up out of the pelvis than is the case in uterine tumors. The necessity of obtaining a positive assurance on this point has already been mentioned. The same rules, as to the separation of adhesions and repair of injuries, apply to this as to other important organs.

The ureters are rarely involved unless the growth be intraligamentary. If they be liable to injury, their relations must be established either by following their course down from the pelvic brim over the pelvic floor, or by means of catheterization through the bladder.

Adhesions in the cul-de-sac, and posterior to the broad ligament, are often very troublesome. They are separated most easily by getting the fingers below the tumor and working upward. By following the posterior surface of the uterus downward from the fundus and then

Digitized by Microsoft®

separating the adherent surfaces laterally, this can often be quite readily accomplished. Hemorrhage may be profuse and may require the placing of clamps or ligatures on the ovarian vessels and at the cornu. If progress be not satisfactory at any one place another point of attack should be selected.

www.libtool.com.cn

Ligating the Pedicle.—As soon as all adhesions have been divided, the operation has been much simplified. If the pedicle be long enough the mass is now delivered through the abdominal incision; otherwise the ligatures are passed through the pedicle within the abdomen. If there be oozing from the raw surfaces of the viscera or pelvic walls, sponges wrung out of hot salt solution may be packed against them while the tumor is being removed. Silk is generally considered to be the most suitable ligature material. If properly boiled it is sterile, does not slip or swell like catgut, and very rarely causes any trouble. The broad ligament is transfixed in the thin area below the vessels, and a double ligature is carried through. Without being interlocked, one is tied externally over the infundibulo-pelvic ligament, while the other comes close to the uterine cornu. When the pedicle is large and thick more ligatures may be required and the tissues tied in three or four divisions. The ligatures having been secured, the pedicle is severed at least 1 cm. outside them, as the stump is apt to retract through the grasp of the ligatures, an accident which has often been followed by serious or even fatal hemorrhage. The stump may be seared with the Paquelin cautery to lessen the liability of adhesions forming to it, or the peritoneal edges may be approximated with catgut. Silk ligatures for the pedicle have proven so satisfactory that the use of the angiotribe or electric cauterization does not seem necessary.

Incomplete Ovariotomy.—After opening the abdomen and carefully examining the conditions present we may find it utterly impossible or inadvisable to remove the tumors completely. The difficulty may be due either to the character and the extent of the disease or to the dense adhesions binding the growth to important viscera. Papillary malignant disease may be so far advanced that the removal even of the main mass is evidently impossible, or an attempt to do this may be attended by profuse hemorrhage, even after the preliminary ligation of the main vessels, so that it only remains to pack tightly with gauze and not proceed further. In these malignant cases the marked cachexia, which is often present, may contraindicate a radical operation. Even if removal of the main tumor be accomplished, it is impossible to deal with the metastases upon the peritoneum, which, although occasionally disappearing, as a rule cause death. Where there have been inflammatory complications, and especially when chronic suppuration has occurred, the adhesions may be so firm that the time wasted in separating them and the attendant hemorrhage may injure the patient far more than the adoption of one of the alternatives at our disposal. Attempts to release a growth densely adherent to intestines, bladder, ureters, or vessels is liable to cause damage that may be irreparable or that may necessitate a prolongation of the operation which may prove fatal in the case of a patient whose vital energies are already exhausted.

When complete ovariotomy is impossible, various expedients come under consideration. In the case of a cyst we can resect as much of the walls as possible, and suture them to those of the abdominal incision. The interior of the cyst is then packed with gauze which acts as a drain and tends to destroy the epithelial lining of the walls and thus favors the formation of granulation tissue. In course of time this process leads to a union of the surfaces which thus effects a cure. A similar procedure may be carried out from the vagina. If the cyst walls cannot be brought up to the abdominal incision or down to the vaginal vault, the fluid should be evacuated, and an attempt made to destroy the lining epithelium by the application of carbolic acid, searing with the cautery, or even curetting lightly. A gauze drain is then inserted, the end being brought out through the abdominal incision or into the vagina. The principal indication in these incomplete operations is to see that all hemorrhage is controlled, and for this purpose gauze packing is often required. In the case of solid tumors that have to be left or can only partially be removed, if there be no oozing, the abdomen can usually be closed.

Not infrequently the question of conservatism arises, especially in the case of young women. In malignant conditions, it is best to remove both ovaries as the disease is often bilateral, although but one ovary may present gross pathological appearances. In retention cysts, follicular hypertrophy, corpus luteum cysts, as well as in some dermoid tumors, it is often possible to save a portion of the affected ovary. If the other one be normal, there is no absolute necessity for this; but in bilateral disease a small portion of ovarian tissue should be saved if possible, for the reason that even if pregnancy does not occur, a young woman may avoid a stormy menopause, not to mention the mental suffering that may be engendered by the knowledge of her condition. The Fallopian tube, if not seriously diseased, should also be saved. At times by resecting the diseased portion, enough of the healthy tube may be left to permit of a future conception.

Drainage.—In this respect the progress in surgical technique has been somewhat revolutionary. Whereas formerly drainage was regarded as indispensable in almost all cœliotomies, at the present day it is employed very much less, and very seldom in cases of ovarian tumor. By drainage we leave an avenue for infection which may cause the contamination of a sterile abdomen, and moreover drains partially or wholly fail to accomplish our object. That this is often the case is proved by the rush of fluid that not infrequently follows the removal of the drain. Besides the fact that such devices may be more dangerous than useful, their removal causes shock and pain to the patient, and their employment sometimes not only produces an elevation of temperature, nausea, and other unpleasant symptoms, but also tends to retard convalescence. Moreover, if a drain be employed, it is impossible to make use of the "peritoneal bath," by which is meant the leaving of 500 c.c. of sterile salt solution in the abdominal cavity before closing the incision.

Nevertheless, drainage is occasionally required in certain cases complicated by the presence of pus, which cannot be entirely removed, in persistent and dangerous oozing to meet which we are obliged to keep up compression for a certain length of time, after severe injuries to the bowel and in incomplete ovariotomy.

Fortunately, pus is encountered only in rare cases of ovarian tumor, and when present, as a rule, it is of slight virulence. Drainage may be considered necessary if it has been impossible to protect the general peritonal cavity from contamination by packing gauze around the pus focus before evacuating it. If, however, the pus as it escapes be caught on sponges, and if the pelvis or the site of the abscess be flushed out with salt solution and then sponged dry, by omitting drainage we have the additional safeguard of filling the abdomen with decinormal salt solution, to dilute any contaminated material that may remain, and to assist in its absorption. If the pus be considered virulent, as for instance when cover slips examined at the time of operation show streptococci, or when there is a communication with the bowel, drainage is usually indicated. A diffuse general peritonitis will often require similar measures. In the writer's experience the presence of gonococci in the pus has not proven an indication for employing the drain.

Persistent oozing from raw surfaces left after separating adhesions rarely requires drainage, but when it cannot be controlled by ligating the individual bleeding points, or by approximating the edges of torn areas, by the employment of mattress sutures and by tightly packing in sponges wrung out of very hot water, by touching the bleeding area with the actual cautery or by using some astringent iron solution, then a gauze drain applied to the bleeding area may give excellent results.

Injuries to the bowel wall sustained during the sepa-

Digitized by Microsoft®

ration of dense adhesions should be repaired as soon as recognized. In these cases the tissues are apt to be so infiltrated and friable that sutures will not hold unless so much tissue is included as dangerously to narrow the lumen of the bowel. In such cases, when subsequent rupture of the coats of the intestine is to be feared, a drain should be inserted. In injuries to the sigmoid flexure and to the lower rectum, which are frequently implicated, vaginal drainage is most suitable.

www.libtool.com.cn

When incomplete ovariotomy has been performed, drainage may be required to permit the escape of the fluids or the breaking-down tissues. The gauze thus applied facilitates the obliteration of the cavities of the cysts, which cannot be removed. For the same reason, if suppuration has occurred, and the abscess wall cannot be removed completely, a drain may be required.

In instituting drainage we have the choice of two routes, the abdominal and the vaginal. The latter is usually to be preferred, since it provides an exit at the most dependent point of the pelvis. The abdominal sinus which is left after removing the gauze, even with the greatest care and the best technique, is very liable to become infected, and as a result a track is left which must close slowly from the bottom. The drain inserted through the abdominal incision requires to be removed much earlier than one used through the vagina. The mental effect upon the patient is not unimportant, and the old saying, "Out of sight, out of mind" is not without weight here.

As regards the form of drain used, experience goes to show that glass tubes should be discarded. Gauze either in the form of strips or a "Mikulicz drain" answers very well. If strips be used, they may be tied end to end, forming one long continuous wick; but if left separate, the end of each should reach the external opening and the first to be removed should be identified in some way, as by tying a piece of silk around the end or by knotting the gauze itself.

Toilet of the Peritoneum.—Having removed the tumor, the surgeon's next duty is to inspect the field of operation very carefully, to see that everything is in order. After first satisfying himself that no hemorrhage is in progress, he should examine the pedicle, and then inspect the broad ligaments, the pelvic walls, and any other situation where he has had occasion to separate adhesions. If there be any oozing, measures to control it must at once be instituted. The bowel must also be examined, more especially the rectum and the sigmoid flexure, as these are the parts most likely to be injured. The omentum is drawn out of the incision and laid upon a gauze sponge, when any bleeding points will be indicated by the staining of the material, and can readily be secured. Any holes in the omentum should be sutured and any ragged ends should be ligated and removed. Owing to the occasional implication of the vermiform appendix in pelvic disease, it should be examined as a matter of routine and, if necessary, removed. All bleeding having ceased, the abdomen is to be thoroughly flushed out with decinormal salt solution, and then sponged dry. This can be done by holding the uterus forward and the intestine back, while an assistant pours the sterile salt solution down into the cul-de-sac. Occasionally the employment of a funnel and rubber tube will prove more convenient. All clots or fluid having been removed by this procedure, the sponges and instruments should be counted to prevent the possibility of any being left in the abdomen. If drainage be indicated, the gauze is now inserted; otherwise the abdomen is filled with decinormal salt solution and the incision closed by the method in favor with the operator.

Dressing.—The incision having been closed, the surrounding skin is sponged with a bichloride solution (1 to 1,000) and afterward with alcohol. A small amount of sterile iodoform or boric-acid powder may be dusted along the line of the suture. Several layers of fine gauze are then placed over the wound, and above this a liberal amount of absorbent cotton. To retain the dressing in place wide strips of adhesive plaster are used, reaching well around on the sides of the abdomen, and extending from the pubes for some distance above the umbilicus. Over this is placed a scultetus bandage reaching from just below the trochanters up to the costal angle, and held down snugly in place by means of two strips passing around the inside of the thighs. The scultetus bandage may be changed daily, or as frequently as it is soiled. Unless the skin show considerable irritation from the adhesive plaster, the latter may be left undisturbed for ten days. By this time the skin incision will be well united and the subcuticular catgut suture absorbed. If, however, there be a rise of temperature, and pain along the incision be complained of, the whole dressing should be removed, in order to ascertain if there be suppuration in the wound.

With an abdominal dressing firmly applied in the above manner, there is less danger of the sutures tearing out during the vomiting. Distention also seems to be lessened by it, and there is no danger in turning the patient on her side, as soon as the nausea has diminished. The change of posture is one of the most welcome privileges allowed to a patient after a cœliotomy. Care must be taken that the dressing does not become drawn away from the pubes, as the lower end of the incision is not far above this point and exposure of it may lead to suppuration and the breaking down of the wound. After the first ten days a small strip of gauze held in place by two strips of adhesive plaster is a sufficient protection.

After-Treatment.—The after-treatment is that usually carried out after any abdominal section, and the details will vary with different operators. It is a very good plan to have a definite scheme of procedure written down, to be given to the nurse in charge of the patient. This may be suited to a moderately severe case, but can be modified as desired. Even if the operation has been a simple one and the shock slight, the patient will not suffer from the extra precautions taken.

Before the patient leaves the operating-room the stomach may be washed out, and it is a good plan to administer a stimulating enema composed of an ounce of brandy, five grains of ammonium carbonate, and one-twentieth of a grain of strychnine sulphate in a pint of decinormal salt solution. This is rapidly absorbed, and while greatly diminishing the thirst, also promotes diuresis, diluting the urine which otherwise is apt to irritate the bladder from its concentration. On reaching her room the patient is put into a warm bed, and hot-water bottles are placed around her to counteract any shock. These must be carefully protected so as not to burn her. The foot of the bed is elevated fourteen inches to facilitate the absorption of the salt solution which has been left in the abdomen. With the head low, as in this position, the nausea probably will be less. An attendant must remain at the bedside until the patient is perfectly conscious, as she is very apt to try to get out of bed when coming out from the anæsthetic. Shock must be combated by the use of stimulants, and of these strychnine is the most satisfactory; one-thirtieth of a grain may be given hypodermically as soon as the patient reaches her room. If the pulse remain over 120 to the minute, this had better be repeated every hour for four or five times; otherwise every two hours for three or four doses is sufficient, and after this every four to six hours, according to the character and rate of the pulse. It is probable that the work now being done on the determination of the blood pressure will ultimately give us more definite data for the employment of stimulating drugs under these circumstances. For the nausea nothing much can be done; drugs as a rule are useless, and sips of hot or cold water only aggravate it. A hot turpentine stupe or a small hot-water bag applied to the epigastrium above the level of the dressing, often affords some relief. Gastric lavage at the time of operation acts as a preventive, and may also be employed after the first twenty-four hours in persistent cases. As soon as consciousness returns the first complaint will be probably of thirst, but beyond moistening the lips and wiping out the mouth with a moist piece of gauze nothing much can

Digitized by Microsoft®

be done for some hours. When, however, the nausea has subsided, water in small quantities may be given every few minutes. Hot water is preferable to cold, and the quantity may gradually be increased if no ill effects are seen. As has been said before, the administration of the enema and leaving 500 c.c. of salt solution in the abdomen will lessen the thirst very considerably. For the pain, if severe, a small dose of morphine or codeine may be given hypodermically. It is much better to avoid opiates whenever possible, and their routine use is to be condemned. Besides augmenting the nausea, in many patients they are apt to retard the opening of the bowels. Rubbing with chloroform liniment will often relieve the severe backache, and a change of position is always grateful. With the abdominal dressing described above there is no risk in moving the patient from one side to the other.

It is advisable to have the patient urinate naturally, and unless there is some contraindication, such as trauma to the bladder wall during the operation, from eight to ten hours may be allowed to pass without an evacuation of urine. After this time, if her efforts to void naturally have failed, she should be catheterized with the usual aseptic precautions. This should not be repeated unless it is absolutely necessary. If she have much distress referable to the bladder, it may be emptied earlier.

Most of the discomfort incident to abdominal operations is due to the tympanites, which is usually worse in those cases in which the structures have been adherent, and in which there has been much handling of the bowels. It is also frequently due to neglect in properly emptying them before the operation. This complication can be relieved very often by passing the long rectal tube and applying heat to the epigastrium. Tincture of capsicum in three-minim doses may be administered after the cessation of the nausea. In neurotic women a good deal of discomfort is usually the rule.

The patient generally feels much easier as soon as the bowels have been well moved. Eighteen or twenty hours after the operation two grains of calomel may be given. Eight or ten hours later a turpentine enema will often produce a satisfactory evacuation; if ineffectual it may be repeated in four hours, or a glycerin enema may be given instead. If there be still no results small doses of magnesium sulphate may be given.

The temperature, pulse rate, and number of respirations should be taken every three hours at first, and later every four or six hours, according to the progress made by the patient. A careful chart should be kept so that her condition from time to time may be readily ascertained.

In the matter of diet nothing but water had better be given by mouth until the bowels have been moved, but nutrient enemata consisting of peptonized milk, with the whites of two eggs and twenty grains of table salt, may be administered every three hours. As soon as the bowels have moved satisfactorily milk with lime water or carbonated water, albumin water or broth may be retained if given in small quantities at first. After the first three or four days, if satisfactory progress is being made, the patient may take soft food, and after about two weeks an ordinary light diet may be ordered.

Where there is no suspicion that suppuration is occurring in the abdominal wound, the dressing need not be disturbed for ten days; but if through-and-through sutures have been used for the abdominal incision, as in cases in which speed in closing the wound has been necessary, or if unabsorbable sutures have been employed for the skin alone, an earlier examination is advisable, and if any redness be found around the suture the offender had better be removed. All of them can be taken out as a rule on the seventh day. If the incision be firmly united, a small pad of gauze over it will be sufficient; transverse strips of plaster may be used to hold this in place, and at the same time prevent any stretching of the newly formed scar tissue. The scultetus bandage is worn until the patient is out of bed, after which a special elastic abdominal supporter should be provided. If no complications occur, the patient may sit up in bed on the sixteenth or eighteenth day after the operation, and get out of bed on the nineteenth or twenty-first day. Undoubtedly in many cases a shorter time than this is sufficient, but it is far better to be on the safe side.

Mortality.—The mortality depends upon a number of factors, such as the skill and experience of the operator, his facilities for carrying out an aseptic technique, and also the care of the patient after the operation. Granted that these have been all that could be desired and that the cases are uncomplicated, the percentage of deaths from the operation should be almost nothing. It is very difficult to determine the real mortality since statistics are notoriously misleading.

The results are steadily improving. A few references to the mortality in the early days of the operation have already been made, and half a century ago it was over fifty per cent. Owing to an aseptic technique, and to our knowledge gained by experience, the average mortality in cases subjected to operation for ovarian tumors at the present day is below ten per cent. Individual operators will have far better results than this. Lawson Tait a number of years ago reported a series of 139 ovariotomies without a death, and the results to-day are better than at that time. Even in cœliotomies for all sorts of pelvic diseases, including pelvic abscess, ectopic gestation, etc., records of series of over 100 consecutive cases without a death have been reported. The author has recently had two such series, one of 108, the other of 114 consecutive successful operations in a hospital practice, in which all conditions, including pus cases in a large proportion, were encountered.

The average skilful operator, taking cases as they come, and having every facility for good work, should have a mortality of not over three to four per cent. in ovariotomy.

OVUM.—(Greek ᾠόν, Latin *ovum*, an egg.)

The *ovum*, or egg proper, is a cell capable under certain conditions of giving rise by subsequent cell divisions to a complete multicellular organism. This definition applies to the female germ cells of plants as well as to those of animals. Frequently the terms ovum and egg are used loosely, however, not only to include the envelopes surrounding the egg proper, but even to designate the embryo and its fœtal membranes.

ever thought of domesticating wild animals, it remained for the anatomists of the nineteenth century to discover its true nature; and although investigators of this subject were never before so active as during the last decade, and have carried on their work with a refinement of technique not dreamed of in earlier years, there is still a great deal to be learned.

Modern embryological observations may be said to have begun with William Harvey, who published his results in 1651. The best microscope that he could obtain was a simple lens, and with this he was able to make out the general outline of a chick embryo during the second day of incubation. His view of the ovum was that it consisted of a fluid matrix in which the embryo appeared by a process of spontaneous generation. The female sexual product was supposed at that time to be a fluid secreted by the "testes muliebres," the term "ovarium" not having been invented by Stenson until some years later.

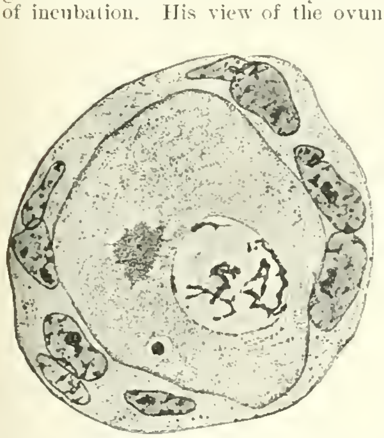

FIG. 3714.—Graafian Follicle and Ovum from the Ovary of a Rabbit Four Weeks Old. On the left of the egg nucleus is the attraction sphere containing two centrosomes and below is a small yolk nucleus. Highly magnified. (After Winiwarter.)

Regnier de Graaf published in 1677 a description of the follicles, which have since borne his name. He found that they contained a fluid which was capable of being coagulated by heat into a firm, white substance. He discovered also that in the Fallopian tubes of a rabbit killed seventy-two hours after coitus there were to be found a number of eggs which were vesicles and contained a fluid that could be coagulated by heat, like the white of egg, and, moreover, these corresponded in number to the empty follicles found in the ovaries of the same subject. He concluded, therefore, that the Graafian follicles were ova. But the chain of evidence was not complete because all trace of the eggs was lost between the time of coitus and the end of the third day, and, more-

over, the blastoderms in the Fallopian tubes were not so large as the empty follicles. During the same year, 1677, Leeuwenhoek announced the discovery of spermatozoa, and there followed a long dispute as to whether the spermatozoon is the true germ and the egg a matrix

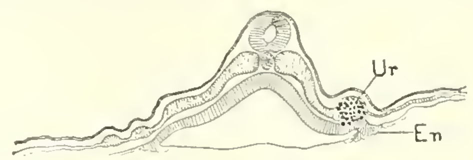

FIG. 3716.—Cross Section of an Embryo Dogfish, 3.5 mm. Long. *En*, Endoderm; *Ur*, germ cells. × 38. (After Woods.)

for its nutrition, or whether the germ dwells originally in the egg itself (see article *Evolution*).

It was not until 1827 that Carl Ernst von Baer was able to show that the Graafian follicle is not the ovum; but that the ovum is a minute body embedded in the follicular epithelium. And it was not until 1838 that Schwann was able to declare the egg to be a cell with the same fundamental structure as the other cells of the body.

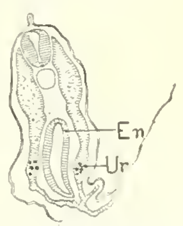

FIG. 3717.—Cross Section of an Embryo Dogfish, 5 mm. long. *En*, Endoderm; *Ur*, germ cells. × 38. (After Woods.)

Morphology.—The ovum is usually a more or less spherical body, but may be flattened or elongated, as is the case with most insect eggs.

The protoplasmic contents of the egg consist of a nucleus and a mass of cytoplasm, as in all cells, and, in addition, the cytoplasm usually contains a greater or less amount of yolk, or *deutoplasm*.

The cytoplasm of the eggs of echinoderms and other invertebrates has been shown to have a distinctly vesicular, or foam-like, structure, and it is probable that all eggs will show a similar structure. It is within the vesicles of the foam that the deutoplasm is deposited, sometimes in the form of clear oil globules, as in some worms and fishes, more often as more or less opaque yolk granules. In the hen's egg there are two principal kinds of yolk granules, the yellow and the white. The white granules are gathered together in the form of a small flask-shaped body, extending from the centre of the ovum to the upper pole, and the yellow yolk forms concentric layers surrounding this and alternating with thinner layers of white yolk (Fig. 3712). These may be seen in a carefully made section of a hard-boiled egg. Where the white yolk approaches the surface there is in the unfertilized egg a portion of the cytoplasm comparatively free from yolk and containing the nucleus.

Digitized by Microsoft®

The size of the egg, the position of the nucleus, and the subsequent course of development, especially in the early stages, depend to a large extent upon the presence or absence of a burden of food yolk within the cytoplasm of the ovum. For example, the eggs of reptiles and birds are heavily charged with yolk and are very large, while all mammals, except the Monotremes, have eggs almost free from yolk, and they are very minute, measuring about 0.2 mm. in diameter.

www.libtool.com.cn

Eggs are classified according to the absence, presence, and position of the yolk, into three groups: (1) *Alecithal* eggs, having very little or no yolk; (2) *telolecithal* eggs, in which there is a large accumulation of yolk at one pole; and (3) *centrolecithal* eggs, in which the accumulation of yolk is at the centre and is surrounded on all sides by a purely protoplasmic layer. Eggs of this type are especially characteristic of the arthropods. In telolecithal eggs the pole that is the richer in yolk is called the *vegetative* pole. The nucleus lies nearer the opposite, or *animal* pole, and the purely protoplasmic portion surrounding the nucleus may be confined to a very small area, the *germinal disc*, near the surface, as in the hen's egg.

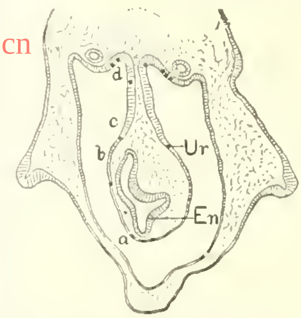

FIG. 3718.—Section of the Ventral Portion of an Embryo Dogfish, 15 mm. Long. *En*, Endoderm; *Ur*, germ cells. × 38. (After Woods.)

The nucleus is usually a spherical body surrounded by a delicate nuclear membrane, and is still frequently called by the old name, *germinal vesicle*, although it presents all the ordinary features of a cell nucleus (Fig. 3714), including linin network, chromatin granules, and nucleolus, the latter is called in the older books the *germinal spot* (see article *Cell*). The condition usually described is but one stage of a pretty definite series of changes which the chromatin and nucleolus undergo during the course of development of the ovum, and which will be referred to later.

In many eggs there may be seen near the nucleus an "attraction sphere" of finely granular protoplasm surrounding a very minute, darkly staining spot, the *centrosome*. The eggs of many animals of various groups contain also another body, often somewhat resembling a nucleus and hence called the *yolk nucleus* (Fig. 3714).

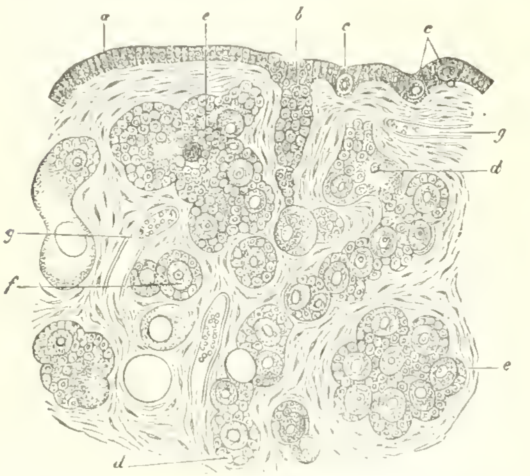

FIG. 3719.—Part of a Sagittal Section of an Ovary of a New-born Child. *a*, Ovarian epithelium; *b*, commencement of one of Pflüger's cords; *c*, *c*, "primitive ova" in the epithelium; *d*, *d*, and *e*, *e*, germinal involutions with developing ova and young follicles; *f*, young follicle; *g*, *g*, blood-vessels. Magnified. (From Waldeyer.)

It is also called, after the author who first described one of these bodies, the corpuscle of Balbiani. It is probable that the bodies classed together under this name are far from all having the same morphological or the same physiological significance.

The Envelopes.—The most primitive type of egg to be met with anywhere in the animal kingdom is that characteristic of the sponges and hydroids. In these groups we meet with eggs that are not only wholly naked, but also show the power, at least within the maternal body, of active amœboid movement. Naked eggs are found in representatives of other groups of cœlenterates; and the eggs of some echinoderms, at least, are without envelopes when discharged from the oviduct, although an envelope is formed immediately after the entrance of the spermatozoon.

In all the higher groups of animals the egg is provided with one or more coverings. These are divided into three principal classes. First we have the primary envelope or *vitelline membrane*, which is essentially a cell wall formed by the cytoplasm of the egg. This is found in representatives of all groups of the animal kingdom. It is generally thin and structureless, but it may consist of several layers or be pierced by radial pores forming a *zona radiata* (*b*, Fig. 3713). Sometimes the vitelline membrane is incomplete at the point where the egg is attached to the wall of the ovary, leaving an opening, the *micropyle*, which serves as a passageway for nutrient material during the ovarian life of the egg and later for the entrance of the spermatozoon.

The secondary envelope is found only in eggs that are surrounded in the ovary by a follicular epithelium, which gives rise to this envelope; and it is especially characteristic of the eggs of insects and mollusks. In these forms it is called a *chorion*, a term used also to designate a very different fœtal membrane of mammalia.

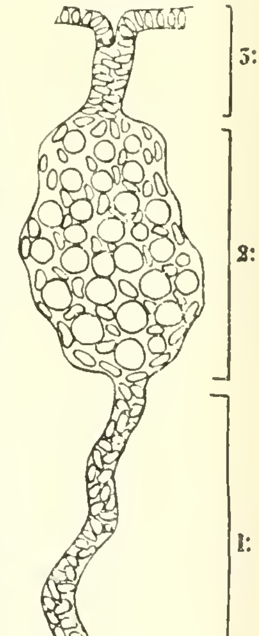

FIG. 3720.—Diagram of the Derivatives of the Germinal Epithelium in Mammalia. 1, Medullary cord; 2, germinal involution containing ova and follicle cells; 3, invaginated epithelium (Pflüger's cord) and covering epithelium. (After Winiwarter.)

After leaving the ovary the egg may receive one or more *tertiary* envelopes, which are secreted by the walls of the oviduct or by glands connected with it. These envelopes may be protective or nutritive in function or both. For example, in the hen's egg (Fig. 3712), the ovum, commonly known as the "yolk," covered by a thin vitelline membrane, lies embedded in a mass of albumen that serves as food for the embryo chick. But at opposite poles of the ovum there are attached much denser strands of albumen, the *chalazæ*, that undoubtedly serve also as a sort of packing to prevent the ovum from coming into too close contact with the ends of the shell. Outside of the albumen are two shell membranes and then the hard calcareous shell. The egg when it emerges from the ovary is provided with only a vitelline membrane. The albumen, shell membranes, and shell are tertiary envelopes and are secreted in succession by the wall of the oviduct as the egg passes outward.

Digitized by Microsoft®

The outer coverings of the eggs of the different groups of animals show much diversity of form and structure, and many of them present wonderful adaptive modifications. But to treat of this fascinating branch of the subject would carry one far beyond the possible limits of the present article.

Early Development.—In the sponges, some cœlenterates, and some of the lower worms the development of eggs is apparently not localized, but may occur in various parts of the body. In the higher forms, on the contrary, the germ cells always undergo their development in certain well-defined regions or organs known in the female as the *ovaries;* and in all animals possessing a distinct body cavity, or cœlom, the cells of the ovary are originally continuous with the peritoneal epithelium. In vertebrates the portion of peritoneum containing the primitive germ cells, the *germinal epithelium,* is in the dorsal part of the body cavity, usually on the inner side of the Wolffian body near the mesentery. In the development of the ovary the germinal epithelium thickens, and the connective tissue beneath it also grows outward into the body cavity, so that the two together form an elevation upon the Wolffian body known as the *genital ridge.* From this the definitive ovary is formed.

We have called attention elsewhere to the very early appearance of distinctly germ cells in the worm Ascaris (see article *Heredity*). It has been shown recently that in vertebrates the germ cells may appear at a considerably earlier stage than had been thought possible.

FIG. 3721.—Part of a Section of the Ovary of a Rabbit Half a Day after Birth. *a*, Covering epithelium; *b*, protobrochal nuclei of oögonia and follicle cells; *c*, deutobrochal nuclei; *d*, leptotænian nuclei; *e*, synapsis stage; *m*, oögonia in mitosis; *k*, nuclei undergoing degeneration; *c.m.*, medullary cord; *c.m.p.*, medullary connective tissue. × 450. (After Winiwarter.)

Minot in 1894 and Rabl in 1896 had shown that what appeared to be germ cells, or primitive ova, may be seen in early stages of the embryo lying in positions far distant from the genital ridge. More recently (in 1902) Woods has published the results of his studies upon the embryos of the common marine dogfish, *Squalus acanthias,* in which he has been able to trace the history of the germ cells back to a mass of seemingly indifferent cells forming the rim of the blastoderm (see article *Area Embryonalis*). At first these cells are all alike, but in an embryo of 2.75 mm. length they have become differentiated into somatic cells and so-called primitive ova, that is, primitive germ cells which may become finally either ova or spermatozoa (Fig. 3715). The germ cells retain their primitive embryonic character, while the somatic cells begin to change into forms characteristic of epithelium, mesenchyma, and the like. At a little later stage when the embryo is beginning to fold off from the blastoderm, the germ cells are found in a compact mass in the mesoderm near where it joins the endoderm (*Cf.* Figs. 3716 and 3717).

From this point the germ cells begin to migrate, apparently by their own amœboid movements, toward the region of the future genital ridge. When the embryo is between 6 and 8 mm. long the unsegmented mesoderm divides into two sheets with the body cavity between. After this the germ cells are practically all found in the inner sheet, or splanchnopleure, which forms the mesodermal portion of the wall of the gut and the mesentery. In an embryo of 15 mm. (Fig. 3718) germ cells are still to be found in the splanchnic peritoneum, but by the time the embryo has reached a length of 19 mm. these cells have very nearly all congregated in the genital region. While at present this is the only case on record of such a migration in a vertebrate, it is probable that more extended research will reveal many similar cases among this group.

Development of the Ovary.—As has been indicated, the ovary is formed by the enlargement and further differentiation of the genital ridge. In it we may distinguish two principal parts—the cortical layer and the medullary portion. The cortex is derived from the primitive germinal epithelium, and from it are formed the peritoneal, or epithelial, covering of the ovary, the Graafian follicles, and the definitive ova. The medullary portion is derived from the underlying mesenchyme cells, which form the connective-tissue stroma and the blood-vessels of the ovary, and within it are embedded the nerve fibres that supply these vessels. In the mammalia the medullary portion contains also during the early stages a large number of strands of cells of a more or less epithelial character, forming what are called the *medullary cords,* and these have given rise to a considerable amount of discussion. For it has been seen that in the embryo these medullary cords may sometimes be found in contact with the glomerulæ of the Wolffian body, and it has been supposed that they were formed by outgrowths from the renal tissue into the ovary. Moreover, there are indications that ova may be developed in the medullary cords, and, if this were generally true and the cords have the origin supposed, the ova of mammals would have an entirely different origin from those of other ver-

Digitized by Microsoft®

tebrates—from the renal epithelium instead of from the lining of the body cavity. This difficulty seems to have been cleared up very satisfactorily by the recent work of

FIG. 3722.—Nuclei from the Ovary of a Human Fœtus of about Seven Months. *B*, Two oögonia with protobrochal nuclei; *C*, nucleus of an oöcyte of the first order in the deutobrochal stage; *n*, nucleolus. × 1700. (After Winiwarter.)

von Winiwarter (1900). In his study of embryo rabbits he finds that the medullary cords are not formed as outgrowths of the glomerulæ, but are the first ingrowths of the germinal epithelium. They penetrate first the stroma of the ovary and then push through the hilum into the Wolffian body, where they may come into contact secondarily with the glomerulæ.

In the ovary of an embryo rabbit taken from the uterus twenty-three days after coitus, von Winiwarter distinguishes two principal parts in the primitive cortex. The outer one is the germinal envelope, which is continuous over the whole surface of the ovary and may be subdivided into a superficial distinctly epithelial layer and a deeper germinal layer. The inner part of the cortex is made up of the germinal involutions (*boyaux germinatifs*), which are simply thickenings of the germinal layer separated from one another by strands of the connective-tissue stroma of the medullary portion of the ovary. In their deepest parts the involutions are not yet sharply

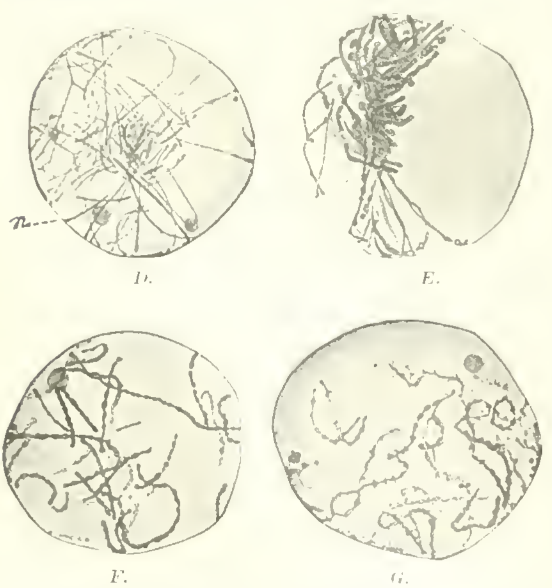

FIG. 3723.—Nuclei from the Ovary of a Human Fœtus of about Seven Months. Consecutive stages in the development of the oöcyte: *D*, leptotænian; *E*, synapsis; *F*, pachytænian; *G*, diplotænian; *n*, nucleolus. × 1700. (After Winiwarter.)

separated from the medullary cords, with which they were originally continuous. In the subsequent stages, by the combined ingrowth of the germinal layer and outgrowth of the connective tissue, the involutions become more separated from one another and from the outer epithelium, until in a new born child or a rabbit five weeks after birth the involutions are connected with the epithelium only by narrow cords of cells, the so-called egg tubes of Pflüger (Fig. 3719) (*Pflugerschen Schläuche*). Von Winiwarter's conception of the relations of these structures of the ovarian cortex is shown diagrammatically in Fig. 3720.

Development of the Definitive Ova.—The development of the ova in the later embryonic and early post-natal stages of mammalia (rabbit and man) has been described with great detail by von Winiwarter, and we will follow his account, except so far as it may be necessary to supplement it by reference to other forms in order to complete our general description of the later stages.

During its development the ovary is covered by a layer of epithelial cells with nuclei elongated at right angles to the surface. These nuclei (*a*, Fig. 3721) have a finely reticular structure with a few irregularly placed masses of chromatin. In an embryo rabbit of twenty-three days practically the whole cortex is composed of similar cells. Those beneath the epithelium differ only in having nuclei a little more rounded and more coarsely reticular (*b*, Fig. 3721 and *B*, Fig. 3722). This is the *protobrochal* (πρῶτος, first, and βρόχος, mesh) stage in the development of the nuclei and the cells are *oögonia.*

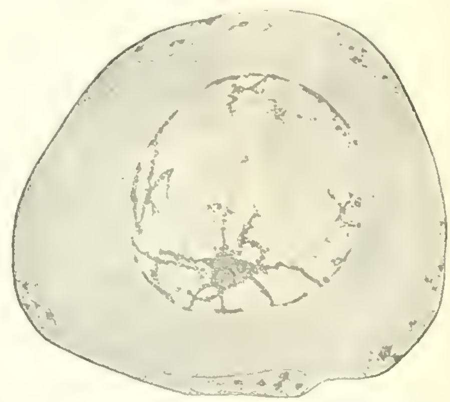

FIG. 3724.—Oöcyte of the First Order at the Beginning of the Second Period, from a Young Rabbit. The follicle cells are few and much flattened. × 1700. (After Winiwarter.)

That they are in process of rapid multiplication is shown by the presence of numerous mitotic figures among them (*m*, Fig. 3721). A large number of the protobrochal nuclei remain unchanged and the cells finally form the Graafian follicles (Fig. 3714). Others which are at first apparently exactly like them belong to the true oögonia, which finally cease dividing and begin to enlarge. They then become the *oöcytes of the first order.*

The ovarian history of the oöcytes may be divided into two stages: first, before the formation of the Graafian follicles; and, second, after that event. During the first stage the nucleus of the oöcyte undergoes a curious series of transformations.

The nuclei gradually enlarge and become globular in shape. At the same time the chromatin becomes more coarsely reticular, forming the *deutobrochal* stage (δεύτερος, second), and one or two nucleoli appear within the nucleus (*c*, Fig. 3721 and *C*, Fig. 3722). In the next stage (*d*, Fig. 3721 and *D*, Fig. 3723), the chromatin ceases to have a reticular appearance and is in the form of slender threads distributed evenly throughout the nucleus in more or less parallel pairs. From this the nucleus passes gradually into the synapsis stage (συνάπτω, to reunite, to condense), in which the chromatin threads are withdrawn from the greater part of the nucleus and are condensed into a tangled mass, generally near one side of the nucleus (*e*, Fig. 3721 and *E*, Fig.

Digitized by Microsoft®

3723). When the tangle is unravelled, the chromatin emerges as a thick, beaded cord without any appearance of doubling (*F*, Fig. 3723). Whether this is really a single filament or is composed of several, is difficult to determine. In the next stage, however, the chromatin is distinctly divided into segments which are double, often forming rings or figure eights (*G*, Fig. 3723). Finally, when the oöcyte becomes surrounded by the follicle cells, the nucleus resumes a coarsely reticular structure (Fig. 3724). It will be noticed that during these stages the nucleus has increased very much in size (compare Figs. 3722 and 3724).

www.libtool.com.cn

In the embryo rabbit of twenty-three days there are already a considerable number of oöcytes in the deutobrochal stage lying in the deep parts of the genital involutions. In the newly born rabbit the oöcytes are much more numerous, and those in the deepest parts of the ovarian cortex have reached the synapsis stage (*e*, Fig. 3721). The earlier stages (*c*, *d*, Fig. 3721) may be seen lying nearer to the periphery. The Graafian follicles begin to be formed in a rabbit when about ten days old; but they are already present in a human fœtus of seven months.

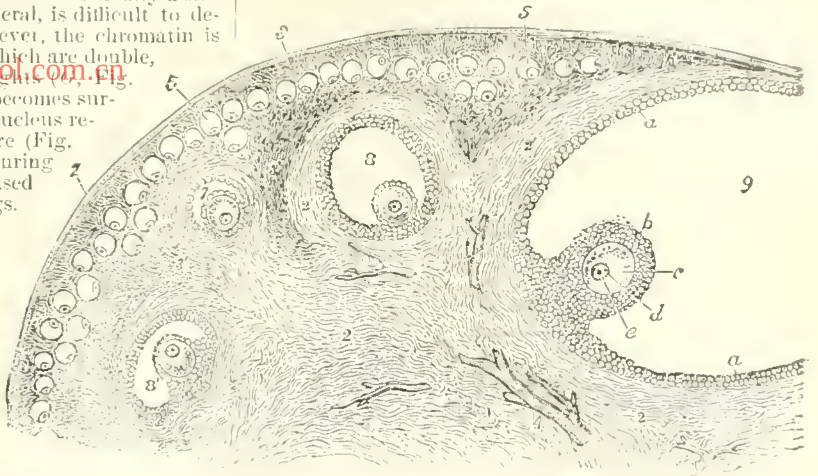

FIG. 3726.—Portion of the Section of the Cat's Ovary, represented in the preceding figure, more highly magnified. 1, Epithelium and outer covering of the ovary; 2, 2', fibrous stroma; 3, 3', less fibrous, more superficial stroma; 4, blood-vessels; 5, small Graafian follicles near the surface; 6, one or two more deeply placed; 7, one further developed, enclosed by a prolongation of the fibrous stroma; 8, a follicle further advanced; 8', another, which is irregularly compressed; 9, part of the largest follicle; *a*, tunica granulosa; *b*, discus proligerus; *c*, ovum; *d*, germinal vesicle; *e*, germinal spot. (From Schrön, in Quain's Anatomy.)

The egg follicle has a different structure in each group of vertebrates. In mammalia it is at first a single layer of flattened cells (Fig. 3724). But these cells soon increase in number until they form several layers surrounding the oöcyte. Then a fissure appears filled with fluid which incompletely separates the follicular cells into an outer and an inner sphere. The outer one is the so-called *tunica granulosa*, and the inner one, which surrounds the egg, is the *discus proligerus* and is continuous with the granulosa on one side, usually the side toward the centre of the ovary (Fig. 3726). This is now a typical Graafian follicle. In the mean time the connective-tissue stroma has so invaded the germinal involutions as to isolate the follicles and form a connective-tissue capsule, the *theca folliculi*, around each one.

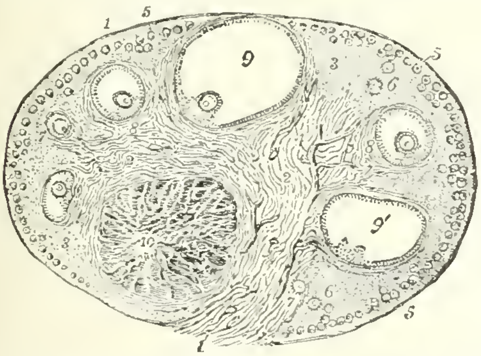

FIG. 3725.—Section of the Ovary of a Cat. 1, Outer covering and free border of the ovary; 1', attached border, or hilum; 2, the central ovarian stroma, presenting a fibrous and vascular structure; 3, peripheral stroma; 4, blood-vessels; 5, small Graafian follicles lying near the surface; 6, 7, 8, more advanced follicles, which are embedded more deeply in the stroma; 9, an almost mature follicle, containing the ovum in its deepest part; 9', a follicle from which the ovum has accidently escaped; 10, corpus luteum. × 6. (After Quain, from Schrön.)

At the time of the first appearance of the follicle cells the outline of the oöcyte appears to be clearly defined, probably by a thin cell wall. When the discus proligerus is established the oöcyte is seen to be surrounded by a clear membrane, apparently containing extremely fine radial canals through which there is supposed to be protoplasmic connection between the oöcyte and the surrounding follicular cells. This membrane is the *zona radiata*, or *membrana pellucida*. Whether it is a true vitelline membrane formed by the oöcyte or a secondary envelope formed by the follicular cells is still a matter of dispute.

After the follicle is developed the egg not only continues to increase in size, but also begins to acquire yolk material or deutoplasm. This is small in amount in man and other mammals, but in most other vertebrates a comparatively large amount of yolk is formed.

The final discharge of the egg from the ovary in mammals is brought about by the bursting of the Graafian follicle. This allows the egg with the surrounding fluid to escape into the body cavity whence it enters the Fallopian tube. For the details of this process see article *Menstruation*.

Before the egg can be fertilized, however, it must pass through two cell divisions of a peculiar character, which constitute the process of *maturation*. During the period of growth the egg is an "oöcyte of the first order." At about the time the egg is discharged it undergoes a very unequal cell division, forming the *first polar body* and the "oöcyte of the second order." The latter soon undergoes another division into the *second polar body*, and the definitive, or *ripe ovum*. The details of the process of maturation will be considered in connection with a similar process in spermatogenesis under the title *Reduction Division*.

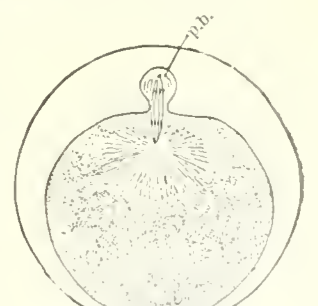

FIG. 3727. Egg of a Leech (Nephelis), three-quarters of an hour after being laid. Formation of the first polar body. Magnified. (After Hertwig.)

OWENS LAKE.—Inyo County, California. This second dead sea in California is located at the southern end of Owens Valley in Inyo County. It is eighteen miles long and ten miles wide. Its surface embraces one hundred square miles. The waters are remarkably rich in saline and alkaline ingredients. The following analysis was made by Professor Phillips, of London, in 1883: One United States gallon contains: Sodium chloride, gr. 2,450.81; sodium carbonate, gr. 797.01; sodium sulphate, gr. 2,427.69; potassium sulphate, gr. 29.77; potassium silicate, gr. 116.23; organic matter, gr. 14.11. Total, 5,835.62 grains.

We are informed by Dr. I. J. Woodin, of Independence, Cal., that numerous fresh-water springs are found along the shores of the lake, some of which are cold and others boiling hot. At the southwest end of the lake there is a valuable white sulphur spring which has not so far been improved. At a short distance from this spring is a mountain formed in great part of sulphur, of which Dr. Woodin sends us a handsome specimen, composed probably almost entirely of the pure element. The aspect of the country is mountainous, the elevation of the lake being three thousand feet above the Pacific. The region offers many attractions as a health resort, and it will no doubt soon be developed.

James K. Crook.

OWOSSO SPRING.—Shiawassee County, Michigan.
Post-Office.—Owosso.

Access.—Owosso is a station on the Detroit and Milwaukee Railroad, seventy-nine miles northwest from Detroit.

The following analysis was made by a chemist whose name has been lost: One United States gallon contains: Calcium bicarbonate, gr. 25.67; magnesium bicarbonate, gr. 19.09; iron bicarbonate, gr. 15.92; sodium chloride and potassium chloride, gr. 2.10; alumina and silica, gr. 0.62. Total, 63.40 grains.

This water, as shown by the analysis, is very heavily impregnated with iron. As the name of the analyst is not known, the analysis is not reliable.

James K. Crook.

OXALIC ACID.—Oxalic acid, having no medicinal virtues, is not official in the United States Pharmacopœia. Its importance depends entirely upon its toxicological relations. *E. C.*

OXALIC ACID, POISONING BY.—The salt obtained by evaporation of the juice of *Oxalis acetosella*, and now known as *binoxalate of potash*, *salt of sorrel*, or *salt of lemon*, was known at least as early as the middle of the seventeenth century, as Duclos makes mention of it in the "Memoirs of the Academy for 1668." A century later (in 1773) oxalic acid was obtained from this salt by Savary. Subsequently Scheele showed the oxalic acid obtained from sorrel to be identical with the *acid of sugar* obtained by Bergman, in 1776, by the action of nitric acid upon sugar.

The first case of poisoning by oxalic acid, of which we find record, occurred in England in 1814 (*Lond. Med. Repository*, i., 382). In this case the acid was taken in mistake for Epsom salt, a mistake which has subsequently become the most frequent cause of oxalic acid poisoning.

Attempts at homicide by oxalic acid are of rare occurrence, owing to the difficulty of disguising the taste. Christison mentions one as having occurred in England in 1827, and others have been subsequently reported from the same country, the acid having been mixed with gin, coffee, sugar, tea, or buttermilk.

Notwithstanding the very extensive use of oxalic acid and the oxalates in the arts of dyeing, calico-printing, etc., they are as yet innocent of industrial poisoning.

As many articles of vegetable diet—beet, spinach, rhubarb, sorrel, etc.—contain oxalates, their use in excessive quantity has been supposed by some to be attended with some danger of poisoning. As, however, the amount of hydropotassic oxalate present is only 0.75 per cent. (= 3 grains per ounce) in fresh sorrel (Mitscherlich), and much less in the other vegetables, their use in any reasonable quantity may be regarded as unattended with danger.

A more probable cause of poisoning is to be found in the adulteration of citric acid with oxalic acid, and the use of the adulterated product in the manufacture of medicinal effervescent drinks or of cheap "lemonade."

Poisoning by oxalic acid and the oxalates is of very rare occurrence in France, while in England, Germany, and the United States several cases occur annually. The reason for the greater frequency of oxalic poisoning in the last-named countries is to be found in the very extensive use in them of oxalic acid and salt of lemon for household purposes, to clean metallic vessels and to remove ink and fruit stains from fabrics, as well as in the popular habit of "taking a dose of salts" at certain times of the year. Oxalic acid and magnesium sulfate resemble each other very closely in appearance, and hence the former is frequently taken by mistake for the latter.

Symptoms.—Oxalic acid is both a corrosive and a true poison, one or the other action predominating according to the size of the dose and the degree of concentration of the solution. If it be taken in the solid form or in concentrated solution, as is usually the case, the symptoms of corrosion are the first to appear and may be the only ones observed. But if the poison be taken in dilute solution the symptoms of corrosion may be entirely absent.

In a typical case of oxalic-acid poisoning, the dose being in the neighborhood of 15 gm. (℥ ss.), taken in concentrated solution, the patient experiences the first effects of the poison either immediately, during the act of swallowing, or within a few moments. In exceptional cases the first appearance of symptoms has been delayed ten or twenty minutes, although larger doses were taken.

The strongly acid taste is observed and is followed by a sense of heat in the mouth, throat, and stomach. This rapidly increases in intensity until it becomes an intense, burning pain. In some cases the pain is accompanied by a sense of constriction of the throat and of impending suffocation. The act of swallowing is performed with difficulty, and later the voice becomes fainter and husky, and sometimes completely extinguished. Within ten or fifteen minutes violent and persistent vomiting begins in almost every case. The vomited matters are most frequently of a "coffee-ground" character, and separate on standing into two layers: the upper a clear, yellowish, and strongly acid liquid; the lower a thick, red-brown sediment of altered blood. Occasionally true hæmatemesis is observed. In cases in which the poison has been taken in small quantity and in dilute solution, the vomited matters may be free from blood. In some cases persistent vomiting and pain, and later persistent purging of a bloody material are the only symptoms, and they may continue, with or without intermission, for five, six, or seven days. Death finally occurs from exhaustion in from five to ten days.

When very large doses have been taken (30–60 gm. = ℥ i.–ij.), the patient, after vomiting, may go into a state of collapse and die within five minutes.

The lips, mouth, and fauces are, shortly after the poison has been taken in solution, reddened, swollen, and painful. Later they become paler, and finally, sometimes within an hour, of a dirty, ashen-white hue, either throughout or in patches. The tonsils and uvula are much swollen. There is severe thirst.

Soon the symptoms due to the true poisonous action of the acid are added to those caused by its immediate corrosive action upon the alimentary canal. The countenance is pale, anxious, and haggard, the upper lip trem-

Digitized by Microsoft®

bling, the lower jaw relaxed. The surface is bathed in a cold, clammy perspiration. The fingers are semiflexed and rigid, and the nails blue. The eyes are glazed and the pupils contracted. There is sometimes persistent hiccough. The pulse is small and thready, sometimes intermittent or imperceptible. There are general numbness and a sense of tingling or cramps in the upper and lower extremities. Abdominal pain is no longer complained of, although the abdomen may remain tender to pressure; but the patient suffers violent lumbar pains, shooting down into the lower extremities. The respiration is quick and labored. The skin in some cases is marked with an exanthem resembling that of roseola. The urine is frequently retained, and that removed by the catheter contains albumin in large quantity, epithelium, granular or hyaline casts, and crystals of calcium oxalate. Sometimes, in cases of recovery, the urine remains purulent for several weeks.

www.jibtool.com.cn

Sometimes there are violent spasms of a tetanic character; more rarely delirium. In cases of recovery, spasmodic twitchings may continue for a month.

In exceptional cases (usually, though not always, cases in which a small dose has been taken) the patient rapidly becomes stupid, somnolent, and unconscious. This condition has been known to pass into one of coma, terminating in death (Tidy: *Lancet*, 1872, ii., 41).

Like the mineral acids and alkalies, oxalic acid may cause death secondarily, after partial recovery, by starvation, due to extensive destruction of gastric and intestinal mucous membrane. This was observed in an early case by Fraser (*Edinb. Med. Journ.*, xiv., 1818, p. 607), in which death by inanition followed in fourteen days from the effects of a dose of ℥ ss. (15.5 gm.) of the acid.

The immediate cause of death in oxalic-acid poisoning may be, therefore, either collapse, or paralysis of the heart, or inanition.

Duration.—The duration of a case of oxalic poisoning is usually short if it terminate in death; but if the patient recover the illness is generally protracted through several days. Of 22 cases ending in death, 9 died within half an hour, 3 in from one to twelve hours, 3 in from twelve to twenty-four hours, and, 7 in from two to fourteen days. Of 14 cases terminating in recovery, in which the time of discharge is mentioned, 3 recovered within one day, 4 in from one to five days, 4 in from five to ten days, and 3 in from ten days to three months. The shortest recorded duration of a fatal case is three minutes, the longest fourteen days.

Lethal Dose.—The following tabulation of 51 cases will illustrate the difficulty of fixing this quantity definitely:

Quantity of Oxalic Acid Taken.	Recovery. Cases.	Death. Cases.
Undetermined	5	11
4.00 gm. = (ʒ i.)	1	1
7.75 gm. = (ʒ ij.)	3	1
11.66 gm. = (ʒ iij.)	1	1
15.50 gm. = (ʒ iv.)	6	2
23.33 gm. = (ʒ vi.)	0	2
27.22 gm. = (ʒ vij.)	0	1
31.00 gm. = (℥ i.)	7	7
38.85 gm. = (℥ i¼)	1	0
46.65 gm. = (℥ iss.)	1	0
	25	26

From this it will be seen that one-half of those who have taken over 4 gm. (ʒ i.) have died; and that the deaths and recoveries are nearly evenly balanced with all doses below 30 gm. (℥ i.).

Treatment.—The first indication, and one which admits of little delay, is the neutralization of the acid in such a manner as to bring about the formation of an insoluble oxalate, and thus prevent further corrosion and absorption. For this purpose the alkaline carbonates are useless, because, although they neutralize the acid and thus prevent further corrosion, the salts formed are soluble and as poisonous as the acid itself. The old direction to "scrape the wall" and administer the scrapings, was well enough so long as whitewashed walls were in vogue; but to administer the scrapings of a modern plastered wall is of no benefit, as the calcium sulfate so given is incapable of neutralizing oxalic acid, or of converting it into an insoluble salt. The best antidote is syrup of lime, or a similar preparation of magnesia. Precipitated chalk is more frequently available and may be given, as the corrosion is not sufficiently extensive to render the generation of gas dangerous. For the same reason the introduction of the stomach tube and lavage are not attended with the same degree of risk of perforation as exists in corrosion by the mineral acids. Emetics are rarely called for, as persistent vomiting is one of the most characteristic effects of the poison. In the rare cases, however, in which vomiting does not occur as a result of the poisoning, emetics may be given, but only after early neutralization of the acid. In no case should warm water be given with a view to producing emesis; and, until the acid has been neutralized, the amount of liquid of any kind taken by the patient should be as small as possible. Opium may be given to allay pain, and stimulants in the stage of collapse.

Post-mortem Appearances.—The lips, tongue, mouth, and œsophagus are of an opaque, yellowish-white color, sometimes marked with patches of a reddish hue. The stomach is contracted, and in many cases contains a thick, gelatinous, reddish-brown and acid liquid, somewhat similar to the "coffee-ground" material vomited during life. The peritoneal surface of the organ, as well as the mesentery and the greater portion of the peritoneal surface of the intestines, is marked by blood-vessels filled with dark, fluid blood. The mucous surface of the stomach is strongly corrugated, and in most cases presents a uniform, bright red color in the elevations and depressions, except in so far as it may have been changed to brown, or even black, by post-mortem action. In some cases the mucous surface is, either in part or in whole, pale, opaque, or translucent, and marked with a coarse, ramiform vascularity of the submucous tissue. The mucous membrane, where it remains, is soft, pulpy, and easily detached. Although perforation has been observed, it is of rare occurrence. Crystals of oxalic acid, or of hydropotassic oxalate are not frequently found in the stomach, although Lesser figures a case ("Atlas," t. viii., Fig. 1), in which the patient died within ten minutes; and the almost uniformly pale and much contracted stomach was found plentifully lined with crystals of hydropotassic oxalate. Microscopic crystals of calcium oxalate are, however, found in many cases in the stomach and intestines, particularly in cases in which death has followed, not within a few moments, but in the course of from three to six hours. A microscopic examination of a section of kidney reveals the presence of amorphous and crystalline oxalate in the tubules, even in rapidly fatal cases (Lesser, *loc. cit.*, Pl. vii., Fig. 3).

Analysis.—The parts to be examined are the stomach and intestines and their contents, the liver, kidneys, and urine, also vomited matters.

The contents of the stomach and the vomited matters are strongly acid in reaction, unless antidotes have been administered, in which case they may be neutral, or even alkaline.

In a systematic analysis the acid, or its salts, are to be found in the residue of the portion examined for prussic acid and other volatile poisons, or in the aqueous liquid which has been treated with solvents for the separation of glucosids and alkaloids. If oxalic acid or oxalates alone are to be sought for, the materials are to be treated directly as below.

It must be remembered that the acid sought may be present either in the free state, in combination as a soluble oxalate, or, in consequence of the administration of antidotes, as the insoluble calcium oxalate, or the very sparingly soluble magnesium oxalate.

The substance under examination, if acid, is to be first extracted with water, the solution filtered, the filtrate evaporated over the water-bath, the residue extracted

Digitized by Microsoft®

with alcohol, the filtered alcoholic solution evaporated, and the residue redissolved in a small quantity of water. The solution so obtained (No. 1) will contain any free oxalic acid which may have been present. The material left undissolved by alcohol in the preparation of solution No. 1 is next to be treated with alcohol, acidulated with hydrochloric acid, the solution filtered and evaporated, and the residue redissolved in a small quantity of water. This solution (No. 2) will contain any oxalic acid which may have been present in the form of a *soluble* oxalate. Lastly, the substance left undissolved by water in the preparation of solution No. 1 is to be treated with a sufficient amount of solution of potassium carbonate (not hydroxid) to render it distinctly alkaline, and boiled for two hours. The solution is filtered and evaporated, the residue extracted with alcohol acidulated with hydrochloric acid, the solution filtered and evaporated, and the residue redissolved in water. This solution (No. 3) will contain oxalic acid, if it were present in the form of an *insoluble* oxalate.

www.tiibook.com.cn

The tests for oxalic acid are then to be applied to the three solutions.

The urine, contents of stomach, and vomited matters should also be examined microscopically for crystals of calcium oxalate.

The detection of a *mere trace* of oxalic acid can only be of value as corroborative evidence in a case of suspected poisoning by that substance, owing to the normal presence of oxalates in articles of food and in the human economy.

Tests.—1. A solution of a calcium salt produces, in neutral or alkaline solutions, a white precipitate which redissolves in hydrochloric acid.

2. Argentic nitrate solution produces a white precipitate which dissolves in ammonium hydroxid solution and also in nitric acid. If the liquid containing the precipitate be boiled, the latter does not darken. If the precipitate be collected, dried, and heated upon a strip of platinum foil, it explodes.

3. Lead acetate solution, in solutions of oxalates which are not too dilute, produces a white precipitate which is soluble in nitric acid, but insoluble in acetic acid.

Rudolph A. Witthaus.

OXAPHOR. See *Oxycamphor.*

OXFORD MINERAL SPRING.—New Haven County, Connecticut. Post-Office.—Oxford.

Good hotel within one-half mile. This spring has been well known to residents of the neighborhood for many years, but it has only recently been brought to the attention of the public. Its medicinal properties are supposed to have been known to the Indians, as arrow heads and other evidences of aboriginal life are frequently found near it. The spring yields about one and a half gallons of pure, sparkling water per minute. An analysis by Prof. George F. Barker, of the Sheffield Scientific School, in 1873, resulted as follows: One United States gallon contains: Sodium chloride, gr. 0.35; sodium sulphate, gr. 0.49; potassium sulphate, a trace; lithium sulphate, a trace; magnesium sulphate, gr. 0.62; calcium sulphate, gr. 1.61; iron carbonate, gr. 0.91; silica and insoluble matter, gr. 1.33; organic matter, gr. 1.22; loss in analysis, gr. 0.10. Total, 6.18 grains.

The path of the stream can be easily traced by the abundant bright yellow deposit of hydrate of iron. In the short time since this water was brought before the public it has risen high in popular favor as an invigorant and general tonic. It is useful in conditions of debility and anæmia, and in stomach, liver, and renal disorders, etc. The water is used commercially, and is said to be acquiring an extensive sale.

James K. Crook.

OXYCAMPHOR—($C_8H_{14}.CO.CHOH$), a product of the oxidation of camphor—is prepared by reducing camphor orthoquinone with zinc powder and acetic, sulphuric, or hydrochloric acid. It is a white crystalline powder of bitterish, peppery taste, and without odor. It fuses at 204° C. (400° F.), and is soluble in fifty parts of cold water and freely in hot water, alcohol, ether, chloroform, and the oils. Its two-per-cent. solution coagulates albumin, reduces hæmoglobin, and is strongly bactericidal.

To this drug is attributed the special power to overcome dyspnœa by diminishing the excitability of the respiratory centre in the medulla. Physiological experiments with 0.5-per-cent. solutions and clinical usage by Ruttner, Ehrlich, Marlier, and others have demonstrated that oxycamphor tends to lessen the frequency of the respirations, to increase their depth, to slow the pulse, and slightly to increase the blood pressure. It improved the breathing in cases of tuberculosis, bronchitis, emphysema, Bright's disease, anæmia, and heart disease.

Exposed to light and moisture the powder becomes a soft, slimy, sticky, yellowish mass. It keeps fairly well, however, in tablet triturates made with sugar of milk, and is stable in fifty-per-cent. alcoholic solution. This solution, known as *oxaphor*, is given with much water in dose of 0.5–1.0 c.c. (♏ viij.–xv.).

W. A. Bastedo.

OXYGEN.—Oxygen is not recognized in the United States Pharmacopœia as a drug, but yet is used in medicine to a certain extent, generally by inhalation, either of the pure gas, or of the same mingled with from one to four volumes of atmospheric air or of nitrogen monoxide (nitrous oxide gas). Oxygen is a colorless, odorless, and tasteless gas, and is, when pure, distinctly irritant to sensitive parts. Its main medical interest centres upon the phenomena which follow the inhalation of the gas in greater concentration than is the case in the atmosphere. Continuously inhaled, pure, the irritant effects of oxygen are considerable; mice immersed in an atmosphere of pure oxygen die after three days with congested and inflamed lungs. With inhalations too short to excite local mischief, the question naturally arises whether an atmosphere abnormally rich in oxygen does or does not tend to determine abnormal absorption of the gas into the blood, and so a quickening of the oxidations concerned in vital processes. Opposite opinions have been held on this question. The one view (Regnault and others) is that with healthy lungs the blood normally takes from the ordinary atmosphere all the oxygen that it is physiologically capable of absorbing, so that the presentment to it of an air containing an increased proportion of the gas can have no effect on the absorption rate. But a considerable number of experiments and observations of various kinds seem to oppose this view, and lead to the belief that crowding the lungs with oxygen does also crowd the blood with the gas. Thus, during oxygen inhalations granulation tissue has been observed to grow quickly ruddier in hue (Demarquay), expired carbon dioxide to double in amount (Allen and Pepys, Limousin), and excreted uric acid to lessen in quantity, presumably by undergoing oxidation within the system (Kollman). Whichever answer to the question be the true one, no marked symptom pointing to any serious derangement of physiological processes occurs when a moderate inhalation is practised by one in health. The gas, even when pure, is pleasantly respirable, and from fifteen to thirty litres (from four to eight gallons, about) can be inhaled with little other obvious effect than a feeling of general warmth and nervous exhilaration, with occasionally a little giddiness and quickening of the pulse rate. But while the effects in health are comparatively negative, it is far otherwise when an oxygen inhalation is undertaken by one suffering for want of a sufficiency of oxygen because of some impediment to the full exercise of the respiratory function, such as may be caused by asthma, emphysema, cardiac disease, croup, diphtheria, etc. In such case the distress, because of the insufficiency of the air supply, tends to be compensated by the higher oxygenation of the same, and the dyspnœa may be greatly abated, or even, for the time, wholly abrogated. And the relief may persist, of course in keeping with the character of the case, for a longer or shorter time after discontinuance of the inhalation. Similar relief by respiration

Digitized by Microsoft®

of oxygen is afforded in cases of asphyxia from irrespirable or noxious gases, such as carbon monoxide or the poisoned air of sewers.

The therapeutic applications of oxygen are, first in importance, the administration of the gas by inhalation for the relief of dyspnœa or asphyxia in the circumstances above described. Inhalations have also been practised with the view of quickening the processes of physiological chemistry and so determining better nutrition in chronic cachectic states, such as anæmia, chlorosis, tuberculosis, etc. The results of this latter therapeusis, however, have not been very striking. Under any circumstances the existence of ulceration or active inflammation within the air passages had better be accepted as contraindicating oxygen inhalation, unless the gas be well diluted. In appropriate cases, from four to sixteen litres (one to four gallons, about) may be inhaled at a sitting, two or three times a day, pure or diluted with air, from one to four volumes, according to the urgency of the case. The gas must be known to be pure, in the chemical sense of the word, and is best administered by means of the bags devised for the giving of nitrous oxide gas. But whether the gas be drawn from a bag or from a gasometer, the inhalation should be by means of a mouthpiece so fitted with valves that the products of expiration shall not pass into the apparatus to mingle with the gases to be respired. In order to obtain dilution with air the simplest expedient is to leave the nostrils open to inhale the atmosphere, while the mouth inhales oxygen.

Oxygen has been administered also by passing the gas into the stomach or the rectum, and with reported prompt relief of dyspnœa, the same as when given by inhalation. Four rectal injections of five litres each are said to have been absorbed in an hour. Oxygen has also been used locally for the vivifying of tissues disposed to ulceration or gangrene, with reported benefit. The practice is certainly not a common one in the United States. The gas is applied in jet upon the affected parts.

Oxygen is supplied for medical use in iron cylinders, generally condensed so that a cylinder holding from one hundred to two hundred gallons is of a size easily handled and stored. From such reservoirs a bag or gasometer is charged for the individual inhalations. Where these cylinders are not procurable, oxygen may be obtained by the usual procedure of heating potassium chlorate with admixture of a little manganese dioxide—this addition in some way determining the decomposition of the chlorate at a lower temperature than would otherwise be required. The manganese compound must be free from adulteration with carbon (such as occurs in some commercial samples by the accidental or intentional addition of pounded coal), else a dangerous explosion may result. It is best, therefore, to test an untried sample by heating a little of it with a little potassium chlorate in a test tube, where the small scale of a possible explosion will do no serious mischief. For the making, the mixed substances are heated in a closed retort or flask, from which a tube leads through an intervening wash bottle, containing caustic soda solution, to a gasometer or jar filled with water and inverted in a pneumatic trough, or to the bag from which the inhalations are made. The first portions of gas that come over should be allowed to escape before connection is made with the wash bottle. And this wash bottle is an all-important feature of the apparatus, the passage of the oxygen through soda being necessary to free the gas from contamination with carbon dioxide and chlorine. The connecting tube of the apparatus should be of good size, since the gas, when once it begins to disengage, comes over in great volume. For the same reason the heat should carefully be watched and regulated during the operation, to avoid too furious action. For each litre (about one quart) of oxygen required, 3.46 gm. (about gr. liiss.) of potassium chlorate will be needed. The salt must be well powdered, and mixed with one-eighth of its weight, or thereabouts, of powdered and pure black oxide of manganese. *Edward Curtis.*

OXYQUINASEPTOL.—(Diaphtherin—$C_6H_4[HOC_9H_6NHO]_2SO_2$)—a registered compound introduced as a powerful antiseptic for surgical purposes, but which has not been much employed. It was reported upon by Prof. R. Emmerich, of Munich, at the Eleventh Congress for Internal Medicine, held at Leipsic in 1892.

It forms in amber-yellow transparent hexagonal crystals, which, when powdered, are soluble in one part of water, also soluble in dilute alcohol, very sparingly soluble in absolute alcohol. It melts at 185° F. without decomposition, but is not altered chemically at 212° F.

It is recommended as an antiseptic dressing in surgical practice, and for the treatment of ulcers, wounds, etc. A solution of one-half to one per cent. is said to be sufficiently strong for a lotion or to saturate dressings. Locally it has been employed in solutions as strong as fifty per cent. without any injurious effect.

The sole drawbacks are said to be a tendency to act on instruments, causing a black deposit, and a tendency to discolor the skin and clothing. *Beaumont Small.*

PACHYAKRIA. See *Acromegaly.*

PACIFIC CONGRESS SPRINGS.—Santa Clara County, California.

Post-Office.—Saratoga. Hotel and cottages.

Access.—Stages connect at Los Gatos with Southern Pacific trains leaving San Francisco morning and evening. Time, three hours and fifteen minutes.

These springs obtain their name from their resemblance to the well-known Congress Spring at Saratoga, N. Y. The Santa Clara Valley is celebrated for its excellent climate and dry, pure, and invigorating air. A large and commodious hotel and several cottages have been established at an elevation of 735 feet above the sea level. The springs are located about one hundred feet farther up the mountainside. The drives about these springs are among the finest in the State. There are on the premises several springs which flow in great profusion. The waters belong to the alkaline-chalybeate class. They are valuable for table purposes. The following analysis was made by Anderson in 1888:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	115.76
Sodium carbonate	120.42
Sodium sulphate	12.95
Potassium carbonate	2.06
Magnesium carbonate	26.34
Magnesium sulphate	14.17
Calcium carbonate	16.03
Calcium sulphate	14.19
Ferrous carbonate	13.87
Alumina	4.50
Silica	3.98
Organic matter	Trace.
Total	344.27

Free carbonic acid gas 44.17 cubic inches. Temperature of water, 50° F.

It will be observed that this water is much less densely mineralized than is that of its New York namesake. The Saratoga Congress Spring contains over 700 grains of solid ingredients to the United States gallon and over 392 cubic inches of carbonic-acid gas. The California Congress waters are, however, much more strongly chalybeate than are those of Saratoga. Their action is decidedly tonic, owing to this large infusion of iron. They are also mildly aperient (from the presence of Glauber's and Epsom salts), diuretic, and anti-acid (from the presence of alkaline carbonates). The springs have gained considerable celebrity in the treatment of anæmia, dyspepsia, liver and kidney troubles, irritability of the bladder, rheumatism, gout, and cutaneous affections. The waters are shipped to all parts of the coast.

PACINIAN CORPUSCLE. See *End-Organs, Nervous.*

PACINIAN CORPUSCLES, PATHOLOGY OF.—Very few observations have been made upon the occurrence of pathological changes in the Pacinian corpuscles.

Virchow noted the possibility of the development of the so-called lamellated fibroma from Pacinian corpuscles, but regarded such origin as being of the nature of a pathological curiosity.

Osler (Proceedings of the Pathological Society of Philadelphia, 1886) reported a case of hemorrhagic pancreatitis in which the Pacinian corpuscles were enormously swollen and œdematous and the neighboring tissue was infiltrated.

Przewoski (*Arch. f. path. Anat. u. Phys.*, Bd. 63) describes five cases of œdema of the Pacinian corpuscles which occurred in mitral insufficiency, in chronic nephritis, in emphysema, and in two cases of chronic pulmonary tuberculosis. In the first two cases general œdema was present, but not in the other three. He claims to have been the first to observe this condition.

Rattone (*Archivio per le scienze mediche*, Torino, vol. ix.) also describes a case of local œdema of the Pacinian corpuscles. In a case of scoliosis, in which no other pathological changes of note were found, the Pacinian corpuscles about the pancreas showed an extreme grade of œdema. He, as did Przewoski, at first took the cyst-like bodies to be cysticercus cysts, but microscopic examination showed them to be Pacinian corpuscles. In a case of fibroma of the mamma, occurring in a young male, he found a much compressed Pacinian body. The chief symptom of the case had been agonizing neuralgic pain, and Rattone believes that this was caused by the changes produced in the Pacinian corpuscle through pressure. There were no evidences of inflammation in or about the corpuscle.

The most extensive observations yet made upon the pathology of the Pacinian corpuscle are those reported by the writer (*Phil. Monthly Med. Jour.*, February, 1899). In nine cases pathological changes were found in Pacinian corpuscles embracing the following conditions: congestion, œdema, hemorrhage, changes in vessel walls, acute and chronic inflammatory processes, mucous and colloid degeneration, hyaline deposit, calcification, and necrosis.

In one case of pulmonary gangrene great numbers of hyaline or cystic bodies, varying in size from a pinhead to a small cherry, were found in the mesentery, particularly in the neighborhood of the pancreas and semilunar ganglia. The majority were transparent, jelly-like, and fluctuating, suggesting parasitic cysts. Microscopical examination showed these to be Pacinian corpuscles in various stages of cystic change. The interstitial tissue of the lamellæ contained large cyst-like spaces in which a mucin- or pseudomucin-like substance was present. These changes were confined to the corpuscles, and were apparently primary. In some of the corpuscles the presence of congestion, small hemorrhages, and small-celled infiltration would appear to justify the diagnosis of a primary inflammation (Pacinitis) of the Pacinian corpuscle.

In a case of chronic parenchymatous nephritis, mitral insufficiency, and general œdema, a similar condition of œdema and cystic change was found, which was regarded as secondary to the general œdema.

In four cases hyaline change of the Pacinian corpuscles was found: in two cases in the peritoneum and mesentery, in the other two in the region of the prostatic plexus. The hyaline bodies showed transition stages to an appearance similar to the lamellated fibroma, as described in the literature. In two other cases similar hyaline bodies were found, but they were so changed that their genesis could not be determined.

In a case of femoral thrombosis chronic inflammatory changes were found in and about the Pacinian corpuscles present in the vessel sheath. The process was regarded as an extension from a chronic inflammatory process involving the sheath of the vessels and the vessels themselves.

In a case of hemorrhagic pancreatitis necrosis, œdema, and hemorrhage were found in the Pacinian corpuscles in the neighborhood of the pancreas. These changes were regarded as secondary to the pancreatic disease, the marked liquefaction necrosis of the nerve structure being due to the action of pancreatic ferments. The involvement of the Pacinian corpuscles and nerve trunks may be the immediate cause of death, as suggested by Osler.

Since the report of these cases the writer has observed four other cases in which pathological conditions of Pacinian corpuscles were found. Œdema and cystic degeneration were observed in the corpuscles in the neighborhood of the pancreas, in a case of valvular disease of the heart with general œdema, and in a case of colitis without general œdema. In a scirrhous carcinoma of the mammary gland a much compressed Pacinian corpuscle was found, completely surrounded by carcinoma tissue. In contrast to the case observed by Rattone this patient had never suffered pain. In a second tumor of the mammary gland, a cystadenofibroma, a much compressed Pacinian corpuscle was found extending across a large cyst filled with serous fluid. Though surrounded on all sides by fluid, the corpuscle showed no change beyond that of compression. The tumor in this case was painful.

It would appear from the above cases that œdema or cystic change is the most common primary, as well as secondary, pathological condition of the Pacinian corpuscles. The exact significance of this condition cannot at present be stated; nor in the primary cases is the genesis of the condition clear. In these cases the œdema is probably to be referred to some local circulatory changes, probably to changes in the blood-vessels of a sclerotic or inflammatory nature. In the other [illegible]es the secondary nature of the affection is clear.

Inasmuch as the physiology of the Pacinian corpuscles is still in doubt, the clinical significance of these changes cannot at present be known. The presence of large numbers of the corpuscles about the pancreas would indicate that they serve some important sensory function, probably relating to intra-abdominal pressure; and we are justified in assuming that any extensive disease of these bodies would produce important disturbances and give rise to clinical symptoms. The intense abdominal pain occurring in acute pancreatitis may be explained by the involvement of the Pacinian corpuscles and the nerve trunks in the vicinity of the pancreas. As Osler has suggested, death in these cases may result from shock caused by such involvement. That compression of the Pacinian corpuscle does not always give rise to severe pain is shown by the case of scirrhous carcinoma of the mamma. This case may, however, be explained by the assumption that the nerve trunks had been destroyed by carcinomatous infiltration, the more resistant corpuscle remaining preserved. The paucity of observations and our lack of knowledge regarding these structures make desirable more careful investigations as to their physiology and pathology.

PAGOSA SPRINGS.—Archuleta County, Colorado.

Post-Office.—Pagosa Springs. Hotel and boarding-houses.

Access.—Viâ Denver and Rio Grande Railroad to Amargo, N. M., thence twenty-eight miles by daily stage over a good road to the springs.

This resort is located in a picturesque, heavily wooded mountain region, at an altitude of about seven thousand feet above the sea level. Bear, elk, deer, and wild turkeys abound in the neighboring mountains, and it is said that a basket of trout may be taken at any time without going beyond the village limits. The country is new, but is fast being developed, and hundreds of people from different parts of the United States camp out in the

Digitized by Microsoft®

neighborhood every summer in order to avail themselves of the salubrious climate and many other attractions to be found here. There is considerable snow in January, February, and March, but during the remainder of the year the weather is clear and beautiful. The summer temperature reaches 90° F. at times, but owing to the bracing atmosphere no discomfort is felt. The nights are always cool. There is but one mineral spring at Pagosa. It is situated on a small elevation and from it the water issues through crevices in various directions. The water supply is quite inexhaustible, as it is estimated that the combined currents from the spring would form a stream three feet deep and six feet wide. Dr. H. G. Haxley, of the springs, furnishes us the following analysis, supposed to have been made under the auspices of the United States Government when it maintained a fort at this point:

PAGOSA HOT SPRINGS.

ONE UNITED STATES GALLON* CONTAINS:

Solids.	Grains.
Sodium chloride	61.81
Sodium carbonate	83.27
Sodium sulphate	150.21
Calcium carbonate	41.76
Magnesium carbonate	6.65
Lithium carbonate	3.28
Potassium carbonate	2.80
Iron protoxide	.16
Manganese protoxide	.11
Calcium fluoride	.30
Calcium phosphide	.03
Silica	.71
Total	351.09

Temperature of water, 155° F. Elevation, 7,000 feet.

* Converted from grams per litre.

The waters are said to possess valuable properties in the treatment of rheumatism, gout, syphilis, and anæmic conditions. Dr. Haxley informs us that he has seen obstinate cases of chronic rheumatism cured or greatly benefited by a two weeks' course of the hot baths.

James K. Crook.

PAIN.—From a restricted philosophical view pain may be regarded as a reaction of the organism, in part or as a whole, to harmful influences; giving a warning in consciousness that some activity prejudicial to the health of the tissues is operative.

The movements of expansion and contraction in protoplasm, the biologists say, are primordial expressions of the pleasure-pain sense; expanding in response to pleasure-giving (healthful) and contracing in reaction to pain-giving (harmful) impulses. These reactions are considered the germ of the idea which by numerous multiplications, complications, and added phenomena have come to make the many-sided figure of the human pleasure-pain sense.

The pain of trauma, in a bruised bone, or the discomfort of a mechanical process, as the pressure of an exudate or transudate, the irritation of an inorganic or organic toxic agent, the pain of ulceration or of necrosis—these are of the types of painful sensations, viewed in a narrow sense, which the physician most often is called upon to treat. But there may be pain in consciousness connected with more complex processes than those just mentioned. The pain of fear, of anxiety, of dread, of anger, even the peculiar pain of the "sick soul" and the ecstatic states, and of other and various emotional conditions, are no less real pain than those of an irritated or injured sensory nerve. Even these manifold and complexly intricate emotional states, however, are posited by the terms of some descriptive psychologists as the results of organic visceral reactions, mostly represented in the sympathetic nervous plexuses and in the extra-cortical or subliminal mental activities.

Of the intricacies and the extraordinary width, breadth, and depth of the pleasure-pain sense only a most extensive study of the ancient and current literature of anthropology, neurology, psychology, and sociology can give an adequate idea, and the present discussion is limited in scope to the narrow field of that which may be termed pain in the common-sense view of the term—the reaction of the sensory nervous system to a prejudicial activity. It will be limited to the painful sensations of the periphery (the epiblastic substances—the skin and external mucous membranes), of those organs and surfaces which are formed by involution of the primary epidermal structures—as the intestinal canal, the bladder, the pleuræ; further, to those pains which occur in the mesoblastic structures—the muscles, the bones, the viscera, etc.

VARIETIES OF PAIN.—From simple discomfort to agony the gradations of pain are many, but a few types seem to be associated with recognizable types of lesion. Two types of pain may be distinguished at the outset—*acute* and *chronic*—indicating in a general way, first, the more violent reaction of the sensory nervous system to an irritant; and, secondly, that of the more prolonged and habitual protest of nature against the harmful influences of a chronic process. Acute pains usually call for immediate diagnosis, if not immediate treatment; chronic pains, as a rule, demand a study of the more involved and intricate processes of nature.

Pain, again, is spoken of as *periodic, recurrent, alternating*, or *continuous*.

As to character, *acute darting* pains are characteristic of the neuralgias, myalgias, and neuritides—such pains are frequently *paroxysmal* or *remitting* in type, coming and going with great suddenness and leaving no trace of their presence, save at times a certain sense of soreness after frequent attacks. Such pains, moreover, are distributed usually in definite anatomical areas, which fact is of the utmost importance in their diagnosis and treatment. In many instances this type of pain is recognized as shifting in its distribution. At one time the nerve distribution in the foot is affected; again, the same nerve area of the thigh, then the leg representation; again, the painful sensations may be distributed over a definite segment area; on one side or on opposite sides of the body.

Colicky Pains are characteristic of affections of the hollow viscera. The stomach colic of poisoning and of cholera morbus, the abdominal colic of flatulency, of distention and obstruction of the intestine, the tenesmus and pain in the ureter and bladder from urethritis, pyelitis, cystitis, etc., are the results of the cramp-like muscular activities of these organs, usually engaged in the process of ejecting, or trying to eject, a harmful occupant. In the diagnosis of these pains the sense of muscular effort is often present in the patient's consciousness and is a useful guide. Careful questioning of a discriminating patient will often reveal much. In the treatment of these conditions the carrying out of nature's indications is rational. Thus, at the present time, catharsis and enteroclysis are more frequently employed for the initial stages of cholera morbus, diarrheas, and dysenteries than are narcosis and muscle paralysis by opium and similar drugs.

Boring or *growing* pains are deep-seated, illy defined pains frequently found in visceral disease. The bones, the muscles, the meninges, the spinal column, the liver, or other deep-seated viscus may be involved. Aneurisms, new growths, and other lesions in these more remote localities are often the cause of *dull* pains. It is usually advisable to regard them at their worst if regrets of faulty diagnosis are to be avoided. Many of the brilliant diagnoses of the specialist may be anticipated by the family practitioner, if sufficient consideration is given to all dull pains of a persistent chronic or remittent nature. The so-called growing pains may be classed in this category and too frequently prove to be precursors of acute or chronic joint lesions, which on development entail much misery and suffering on the young. *Movement* pains are those which are increased by motion of the joints or of the muscles and are indicative of some lesion in these structures.

Digitized by Microsoft®

Pain Appreciation.—If pain be regarded as a reaction, evidently two factors, at least, are involved in its appreciation. The character or intensity of the inducing agency and the individual's susceptibility. Since each individual's own experience is the only guide to the physician's estimation of the intensity of the painful feeling, much judgment and sympathy are needed correctly to gauge the patient's susceptibility. Pain to many is but an incident. They are either anæsthetic or stoical, either really feeling little or able to control their expressions of pain; others, again, are hyperæsthetic or exaggerational; either they really are extremely susceptible or they possess little or no control over their feelings. At all events the grade of the patient's own feeling is the true measure of the pain for themselves, but it may not be a useful guide in the diagnosis of a disease process.

It has become popular, since the studies of Lombroso and his school, to generalize regarding pain susceptibilities among individuals in certain occupations or professions, or among the peoples of a country. Thus the Teutons are reputed to be relatively non-susceptible; that thieves, prostitutes, and the like are anæsthetic. Such generalizations are founded on the most flimsy evidence and are based purely on half-truths at best. Moreover, the question of control over one's expressions of pain is rarely taken into account by many of these students.

Pain that is acute and severe in character usually causes a well-known picture of contracted muscles, dilated pupils, cold wet hands and feet, a picture closely resembling and indeed inducing at times the well-known act of fainting.

Pain Location.—For the most part the feeling of pain is referred to the diseased area, and when lesions are found to be superficial and within reach it is easy at once to distinguish their true nature and to locate them correctly, and then to apply the proper treatment. When no superficial lesion is found, the question arises whether the pain sensation is in direct relation to an adjacent organ or whether it is a referred sensation from a more remote viscus.

Of the facts which help to a correct judgment the grade of pain intensity is one of the most important. Those pains which are less intense and more illy defined are more liable to be referred pains from a more remote area.

By the researches of Dana and Head* the mapping of areas of referred sensations has become an almost definite matter. Head has shown that a diseased viscus very frequently, if not always, sends sensory impulses to the spinal cord, which impulses are felt as irregular pains, usually dull, at times very acute, in the skin area supplied by the sensory nerve of the spinal-cord segment related to the viscus segment. By means of the work of this author and others many of the earlier charts illustrating referred pains are being revised, and more definite conclusions are now possible, although as yet many of the ascertained facts have more importance in neurological than in general diagnosis.† *Smith Ely Jelliffe.*

PALISADE WORMS. See *Nematoda*.

PALM BEACH, FLORIDA.—This popular and fashionable winter resort is situated in Southern Florida on the east coast, in latitude 26° 57', about two hundred and eighty miles south of Jacksonville. It lies upon a narrow strip of land between Lake Worth and the Atlantic Ocean. The vegetation at this latitude is naturally tropical and luxuriant, and art has added to the natural beauty by parks, gardens, and paths running through groves of palms and tropical trees. Flowers abound, and such tropical fruits as the banana, pineapple, guava, tamarind, and mango are found here. Indeed, nature and art have combined to render this spot peculiarly attractive and fascinating. The accommodations are luxurious and consequently expensive. There are two large hotels affording every comfort, and several smaller and less expensive ones. There are also numerous fine private residences. Many means of recreation are offered the visitor: bicycling through the many beautiful paths; fishing,

FIG. 3728.

rowing, sailing, shooting, surf bathing, swimming in a large salt-water pool, and golf upon the fine and extensive links. Hot salt-water baths are to be had in some of the hotels. Palm Beach is easily and comfortably reached direct by railway from Jacksonville. One is referred to the article upon *Florida* in this HANDBOOK for an extended consideration of the climate of Florida, including this region. In this article will be found the climatic data for Jupiter, which is only seventeen miles north of Palm Beach, and which therefore has essentially the same climate as that of Palm Beach. The average mean temperature (Fahrenheit) for the months of December to March inclusive is: December, 67.2°; January, 63.4°; February, 66.7°; March, 68.8°. The maximum temperature for the same months is: December, 82°; January, 80°; February, 84.7°; March, 85.5°. Minimum, December, 41°; January, 38.5°; February, 39.8°; March, 44.8°. The average relative humidity is 82 per cent. The average number of clear and fair days is: December, 23.9; January, 24; February, 22.1; March, 27.1. The average precipitation is: December, 2.88 inches; January, 3.43; February, 2.72; March, 2.59.

The distinguishing characteristics of the winter climate of Palm Beach are warmth, sunshine, equability, and moisture. It is a warm, moist, marine climate. Such a climate is well suited for elderly and feeble persons, convalescents of a certain kind; for persons affected with neurasthenia or with chronic bronchitis, and for the valetudinarian in general, but not for those who are affected with pulmonary tuberculosis. For one who desires to escape the inclemency and strain of a northern winter and live an outdoor existence in the midst of at-

Digitized by Microsoft®

tractive surroundings, and who, moreover, is able to pay for luxurious accommodations, Palm Beach can unqualifiedly be recommended. Further, it is easily and comfortably reached from the North. Good medical service is at hand, which is a matter of the first importance in a health resort. The season extends from December to March.

www.libtool.com.cn

Sixty-seven miles south of Palm Beach is *Miami*, the terminus of the East Coast Railway and the port of departure for Nassau, Havana, and Key West. It is a town of about three thousand inhabitants. "The Royal Palm," a large and luxurious hotel, is situated here in the midst of a large tropical park. The climate is essentially the same as at Palm Beach, and much the same sort of outdoor life and amusements are afforded the visitor here as at the former place. *Edward O. Otis.*

PALMYRA MINERAL SPRINGS.—Jefferson County, Wisconsin.

Post-Office.—Palmyra Springs. Hotels and sanitarium.

Access.—Viâ Chicago, Milwaukee and St. Paul Railroad to Palmyra, 118 miles north of Chicago and 20 miles west of Waukesha. The sanitarium stage meets trains.

Palmyra is a pretty little town of 1,000 inhabitants, nestling in the foothills of the famous Kettle Range of Wisconsin. The location is 850 feet above tide-water, and it combines many of the features sought after by the summer seeker for health or recreation. This entire section is favored with a salubrious climate, and is altogether free from malaria. The soil is dry, sandy, and porous, overlying glacial deposits of gravel, which affords the best natural facilities for through drainage. The scenery here is noted for its tranquil beauty and loveliness. In his attractive brochure on "Summer in the Northwest" Mr. W. J. Anderson informs us that the beautiful little Spring Lake, or Palmyra Lake, as it is generally called, "may be classed as one of the gems of Wisconsin. Its bottom is covered with mosses, ferns, and other aquatic plants, which in mid-summer bloom and blossom as a garden. It is fed by numerous mineral springs in the vicinity, and affords an enticing prospect for the angler or the lover of boating." Seven miles distant is the Scuppernong trout pond, which is said to contain millions of trout of all varieties and sizes. Many other beautiful lakes are within easy driving distance, over excellent roads. The Palmyra Springs Sanitarium is delightfully situated on the margin of Palmyra Lake, of which it commands a charming view. This is a substantially built brick structure, four stories in height, containing spacious halls, wide verandas, and all the modern accessories for the health and comfort of its occupants. There are facilities for the administration of electricity in its various forms, massage, etc. The baths embrace salt, shower, shampoo, Turkish, Russian, and natural mineral-water baths, the rooms being spacious and luxuriously furnished. All kinds of facilities for indoor and outdoor diversions are at the option of the guests. Directly opposite the sanitarium is a forty-acre forest of native oaks—the "Sanitarium Grove." Its winding walks and shaded nooks add no little to the attractiveness of the place. At a distance of one mile and a half from the sanitarium is the great Geyser Spring. It is thirty-eight feet in depth and fifty feet across the surface, and supplies ten million gallons of water per day. The water is soft, pure, and palatable, and is believed to possess remedial value. The mineral springs at Palmyra are very numerous. A cluster of half a dozen in the spring park, which could all be covered by a canvas forty feet square, are quite dissimilar in taste, of varying temperature, and of different analysis. One spring is slightly thermal, having a temperature of 72° F.; another, ten feet distant, is a little cooler (62.5° F.); while others vary in temperature from 50° to 52° F. Back of the sanitarium, and four hundred feet from it, is another group, known as Magnesian Springs. They are remarkably pure and free from organic matter. Following are analyses of three of the springs, No. 1 being by Prof. W. S. Haines, of Rush Medical College, Chicago, and Nos. 2 and 3 by Prof Bode, of Milwaukee:

Spring No. 1.—One United States gallon contains: Sodium sulphate, gr. 0.94; potassium sulphate, gr. 0.23; calcium bicarbonate, gr. 15.70; magnesium bicarbonate, gr. 10.94; magnesium chloride, gr. 0.18; iron bicarbonate, gr. 0.5; calcium phosphate, a trace; alumina, a trace; silica, gr. 0.70; organic matter, a trace. Total, 28.74 grains.

Spring No. 2.—One United States gallon contains: Sodium chloride, gr. 0.21; sodium sulphate, gr. 0.64; sodium bicarbonate, gr. 0.16; calcium sulphate, gr. 0.30; calcium bicarbonate, gr. 9.86; magnesium bicarbonate, gr. 7.91; iron bicarbonate, gr. 0.6; alumina, gr. 0.19; silica, gr. 0.61; organic matter, gr. 0.35. Total, 20.29 grains.

Spring No. 3.—One United States gallon contains: Sodium chloride, gr. 0.43; sodium sulphate, gr. 0.40; sodium bicarbonate, gr. 0.18; calcium sulphate, gr. 0.80; calcium bicarbonate, gr. 12.84; magnesium bicarbonate, gr. 10.14; alumina, gr. 0.22; silica, gr. 0.90. Total, 25.91 grains.

These waters all possess mild diuretic and antacid properties. The water of Spring No. 3, being entirely free from organic matter, is well adapted for carbonating and bottling. The numerous topographical, climatic, and other advantages of Palmyra render it a suitable resort for a large variety of ills and ailments. The spring waters exert a beneficial influence, especially in rheumatism and dyspepsia, although their use is also extended to functional hepatic disorders, the early stages of Bright's disease, and to eczema, pityriasis, and other skin troubles. *James K. Crook.*

PANACEA SPRINGS.—Halifax County, North Carolina.

Post-Office.—Littleton.

Access.—These springs are situated three and a half miles from the town of Littleton, at an altitude of 380 feet above the sea-level.

The location is in a beautiful valley surrounded by picturesque hills covered with rocks of immense size, and still clothed in their primeval forest growth of gigantic oaks. The meteorological conditions which prevail here are of a salutary character, there being neither long droughts nor excessive rains. The springs are fifteen or twenty in number and flow about five hundred gallons of water per hour. The following analysis was made some years ago by Dr. H. B. Battle, of the State Experiment Station. The bases and acids only are given: One United States gallon contains: Iron, gr. 2.18; alumina, gr. 0.32; calcium, gr. 1.11; magnesium, gr. 0.20; manganese, gr. 0.01; potassium, gr. 0.70; sodium, gr. 2.23; hydrochloric acid, gr. 0.82; suphuric acid, gr. 0.42; phosphoric acid, gr. 0.53; silica, gr. 1.18. Total, 9.70 grains. (Carbonic acid, large amount; not determined.)

It is evident that the acids and bases would unite in the form of carbonates, chlorides, sulphates, and phosphates.* The waters are very useful in chronic diarrhœa and the debility which usually accompanies the disease. They are highly recommended in the debilitated states attending uterine and ovarian diseases and in restoring anæmic and puny children. *James K. Crook.*

PANARITIUM ANALGICUM. See *Morvan's Disease.*

PANCREAS, ANATOMY AND PHYSIOLOGY OF.—1. Gross Anatomy.—The pancreas is an elongated gland of a reddish-yellow color. The size is somewhat variable in different individuals, but the gland is usually from

* According to E. E. Smith, M.D., Ph.D., of New York, to whom we have submitted this analysis, the combinations would result as follows. In one United States gallon there would be: Sodium chloride, gr. 1.31; sodium sulphate, gr. 0.68; sodium bicarbonate, gr. 0.93; potassium bicarbonate, gr. 1.02; calcium bicarbonate, gr. 4.85; magnesium bicarbonate, gr. 1.21; manganesium bicarbonate, gr. 0.03; iron bicarbonate, gr. 3.98; iron phosphate, gr. 0.82; alumina, gr. 0.31; silica, gr. 1.18. Total, gr. 16.32.

Digitized by Microsoft®

five to six inches in length, from half an inch to an inch in thickness, and weighs from two and a half to three and a half ounces (60 to 90 gm.).

The pancreas, like the liver, is moulded in shape by the organs with which it is in relationship, so that it is irregularly prismatic in shape, especially in its middle portion or body.

www.libtool.com.cn

The pancreas lies in the loop of the duodenum and is hence deeply placed in the abdomen, stretching across the posterior abdominal wall nearly transversely at the level of the first and second lumbar vertebræ, and is almost concealed by the stomach which lies in front of it. Regionally the pancreas lies almost completely in the epigastrium, but the tip of the free end or tail, which comes into contact with the inner surface of the spleen, lies in the left hypochondrium.

For the description of relationships, it is usual to consider the gland as consisting of head, neck, body, and tail, although these parts are not very clearly marked off naturally from one another.

The larger rounded right extremity of the gland forms the head, which accurately fits into and fills the concave

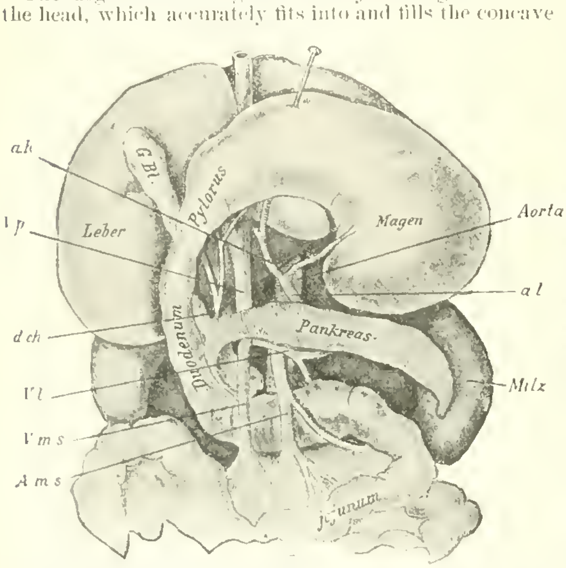

FIG. 3729.—Diagrammatic Picture Showing the Relations of the Pancreas to the Stomach, Duodenum, and Blood-vessels. (After Koerte.) *a.h.*, Arteria hepatica; *V.p.*, vena portæ; *d.ch.*, ductus choledochus; *a.l.*, splenic artery (art. lienalis); *V.l.*, splenic vein; *V.m.s.*, superior mesenteric vein; *A.m.s.*, superior mesenteric artery; *G.Bl.*, gall-bladder; *Leber*, liver; *Magen*, stomach; *Milz*, spleen.

side of the sharp curve formed by the second and succeeding parts of the duodenum. The neck is a portion about an inch in length which curves upward, forward, and to the left, from the anterior portion of the head, to unite it to the body and tail at about a right angle. In this angle are placed the superior mesenteric vessels, which lie in front of the head and are covered, as they pass upward toward the cœliac axis and portal vein, by the neck, which lies in front of these main trunks. The body and tail, which together measure from four to five inches, cannot really be differentiated from each other, the tail being merely the extremity of the body which turns upward toward the spleen.

The inferior vena cava, left renal vein, and aorta lie behind the head of the gland, and the origin of the superior mesenteric artery, the crura of the diaphragm, the splenic vein, left kidney, and suprarenal gland are the chief posterior relations of the body. In front, the pancreas is separated from the overlying pylorus and stomach by the lesser omental sac, and the lower portion of the head of the gland is crossed by the transverse colon and its mesocolon. The transverse mesocolon is attached posteriorly to the lower border of the gland and splits here into two layers, one being reflected upward, over what is known as the anterior surface of the body of the pancreas, while the other passes back over the narrow inferior surface and is then reflected downward, so leaving the posterior surface of the body free from peritoneal investment.

The pancreas is richly supplied with blood from three different sources, which freely anastomose with one another, viz.: 1. By the *superior pancreatico-duodenal* artery, a branch of the *gastro-duodenal* and hence of the *hepatic* artery, which curves round between the head of the pancreas and the duodenum. 2. By the *inferior pancreatico-duodenal*, a branch of the *superior mesenteric*, which courses round the head of the pancreas in the direction opposite to that of the superior pancreatico-duodenal and finally communicates with it. 3. By the *splenic artery*, which in its wavy and tortuous course toward the spleen, grooving the upper border of the pancreas, gives off to that gland many small twigs called the *pancreaticæ parvæ*, in addition to a larger branch near its termination, the *pancreatica magna*, which penetrates the gland and passes back from left to right parallel and close to the chief pancreatic duct.

The main *pancreatic duct* or *canal of Wirsung* runs deeply embedded in the substance of the gland, somewhat nearer the lower than the upper border, from left to right throughout the length of the gland. It is easily distinguished by its white glistening appearance, and the best guide for finding it is the artery which, as above described, runs parallel and close to it. It commences by the union of many small ducts from the lobules of the tail, and, being joined by ducts from the lobules on all sides, increases in size until near its termination at the duodenum, where it measures about one-tenth of an inch. It follows the course of the gland described above, bending downward, backward, and to the right, as it courses through the neck, and passing toward the posterior part of the head where it enters, in common with the bile duct, into the second part of the duodenum, between three and four inches below the pylorus, upon a slightly raised papilla.

A second duct, called the *accessory duct* or *duct of Santorini*, is found in the majority of bodies. This duct is usually much smaller and runs from near the orifice of the main duct to open separately about an inch nearer the pylorus; but in exceptional cases it may be large and take on the functions of a main duct, the extremity of Wirsung's duct being then much smaller than usual. The presence of two ducts arises from the development of the gland as two separate outgrowths from the duodenum.

The smaller of these two outgrowths arises close to the common bile duct, and its original duct forms at a later period the proximal end of Wirsung's canal. The other larger growth arises nearer the pylorus, and the accessory duct of Santorini is formed from the proximal end of its duct. At about the sixth week of development the two ducts fuse, and, the upper duct afterward developing less rapidly, the main pancreatic duct comes to be formed of the central end of the lower duct and the peripheral parts of both the others.

2. MINUTE ANATOMY.—The pancreas is a compound racemose gland which, in its general arrangement and in the appearance of its cells, closely resembles a serous salivary gland. It may be distinguished, however, by the longer, tubular, and somewhat convoluted alveoli, which are often cut in oblique or longitudinal section and then present the appearance of long columns of cells lining the central ducts. This appearance is never evident in salivary gland sections, because their alveoli are not elongated. The ducts also serve to differentiate the pancreas from the salivary glands, for they are much less numerous in the former and the cells lining them do not show any of that longitudinal striation which is present in the cells of the ducts of the salivary glands.

The ultimate branches of the ducts which pass to the individual alveoli are very narrow and are lined by flattened cells.

Digitized by Microsoft®

The alveoli in the loaded condition of the gland are compactly filled by the charged cells so that no distinct lumen is visible, but after active secretion the cells shrink considerably in size and the lumen becomes obvious.

By special methods of treatment, such as injection under pressure backward from the main duct, or perhaps better by the Golgi method of staining with silver chromate, it can be shown that intercellular canaliculi exist which branch off from the lumen of the alveolus and pass between the constituent cells. The Golgi method, when the result is good, further demonstrates intracellular canaliculi which penetrate into the cells themselves and drain off the secretion from their interior.

www.libtool.com.cn

The secreting cells present characteristically different appearances according to whether the gland has been resting and has hence become charged with secretion, or whether it has been recently active and as a result is exhausted of those materials which contribute the solids of the secretion. These materials are deposited in a granular form during the period of rest, and are hence visible under the microscope, and give by their amount an indication of the condition of the gland.

Even in the fully charged condition of the gland the granular deposit never quite fills the cell, a clear finely striated outer zone always being left, which takes stain readily and hence appears deeply colored in prepared sections as compared with the central granular zone.

In the fully charged cell about three-fourths of the cell substance lying toward the lumen is completely obscured by a thick granular deposit which hides the nucleus and the outlines of the cells so that the lines of division are invisible in fresh sections.

The first effect of secretion is an increase in volume of the cells, probably due to water and salts being taken up from the surrounding lymph; but this is quickly followed by a diminution in size, accompanying which there is a rapid diminution in the amount of granular deposit present in the cells. The granules become fewer in number in the central part of the cells toward the lumen, where they are still present, and the outer granule-free zone becomes greatly increased in width and comes to occupy nearly the whole cell. These changes are shown in hardened and stained sections by the greater amount of cell which becomes deeply stained.

As a result of the gradual clearance of the granules from the protoplasm the cell nucleus and its outlines become more clearly visible. These granules seen in the cells do not consist of deposits of the enzymes found in the secretion of the glands, which are described below, but probably of other substances which form precursors of these, the so-called zymogens.

The zymogens are inactive until they have been changed into the free enzymes, as is shown by the fact that neutral extracts of the fresh gland are almost inactive, but become active when treated by dilute acetic acid (one per cent.), or a dilute solution of sodium carbonate (two per cent.) in presence of oxygen.

Recent research has further demonstrated that the fresh pancreatic juice as it flows from the gland duct contains a large percentage of its zymolytic material in the inactive form of zymogens and that it is only in the intestine itself that the change into active enzyme is completed (*vide infra*). In addition to the nucleus a body called the *paranucleus* can be demonstrated histologically in the pancreatic cells. This structure surrounds the nucleus of the cell and is shown by its property of staining more readily than the rest of the cell protoplasm. It is supposed to arise from the nucleus by a process of extrusion, and the view has been advanced that the zymogen granules are manufactured in this part of the cell.

3. Secretion.—The rate of secretion of the pancreatic juice varies with the state of digestion, being most rapid during the earlier periods after a heavy meal and then gradually diminishing. During prolonged inanition the flow practically ceases. It commences toward the end of the next following meal and attains a maximum rate within the first two hours; it then falls off rapidly up to the end of the fifth hour. A secondary increase in the rate then occurs which attains its maximum at about the tenth hour, but is never so high as the first maximum; after this the flow once more falls off and practically comes to a standstill in the eighteenth hour after the meal. The richness of the secretion in ferments is inversely proportional to the rate of flow, the more rapidly secreted fluid being more diluted with water.

These variations in the rate of secretion are probably in part under the reflex control of the nervous system and in part are due to chemical stimulation of the pancreatic cells, by a substance secreted by the cells of the duodenal mucous membrance and carried in the blood to the pancreas.

Regarding the reflex nervous influence upon the secretion, it is probable that the *afferent* channels are connected up to the medulla from the mucous membrane of the stomach and duodenum; at any rate it is an experimental fact that chemical or electrical stimulation of these surfaces causes a flow of pancreatic juice. The chief *afferent* nerve affecting the pancreatic secretion is the vagus.

This fact is rendered somewhat difficult to demonstrate, in the first place by the important disturbances of the cardiac mechanism, and other organs, which follow stimulation of the vagus, and secondly by the fact that the vagus contains both excitatory and inhibitory fibres for the pancreas, and hence the net effect of stimulating the nerve upon the pancreas varies according to the relative excitability of the two kinds of fibres. At times a stoppage of secretion results and at other times an increase in the rate of flow. Until this had been demonstrated many contradictory experimental results regarding the action of the vagus in this respect had been published by different observers.

Pawlow and his pupils first clearly demonstrated that the vagus can act as an excitatory nerve for the pancreatic secretion. These observers got rid of the disturbing influence upon the heart by severing the vagus three or four days before placing the cannula in the duct of the pancreas to observe the rate of secretion and stimulating the peripheral end of the vagus. The cardiac fibres are the first to degenerate and become completely inexcitable at a period when the excitatory fibres of the pancreas are still active. Apparently the inhibitory fibres to the gland cells also suffer early degeneration, for in all cases a positive result of increased secretion was obtained. Similar results were obtained by stimulation of the thoracic vagus below the place of exit of the cardiac fibres from that nerve. Popielski later discovered that the action of the vagus depended upon the rate of secretion which was already going on at the moment when the vagus was called into activity. This observer utilized the discovery of Dolinski, that application of acid solutions to the duodenal mucous membrane causes a copious flow of pancreatic juices (*vide infra*), to study the effects of stimulation of the peripheral end of the vagus during active secretion, and found that a stoppage of secretion was the invariable result.

It is probable, then, from these experiments that the vagus contains secreto-inhibitory fibres for the pancreas, in addition to secreto-motor fibres as shown by Pawlow.

The action of injection of fluids of acid reaction into the duodenum in provoking an outflow of pancreatic juice is a subject which at the present time is exciting a good deal of attention, and although the matter is still *sub judice*, many interesting results have already been obtained.

Popielski found that the effect was still obtained even when both vagi and sympathetics were divided. He further found that the effect was obtained when the stomach was separated from the intestine above the level of the pylorus, but *not* when the section of stomach from intestine was carried out below the pylorus, and from these experiments he came to the conclusion that the action was due to a local nervous mechanism, the nerve

Digitized by Microsoft®

cells for which lay in the intestinal wall close to the pylorus.

More recently still Bayliss and Starling have discovered that an exceedingly copious flow of pancreatic juice is evoked when an extract of mucous membrane of the duodenum is made with a dilute acid, and then neutralized, filtered, and injected into a vein. This effect follows, according to these observers, even when all nerves to the pancreas have been carefully severed. The result is obtained only by using extracts of the mucous membrane of the duodenum or of the upper end of the jejunum and is not given by exactly similar extracts from other parts of the intestine. The substance giving this effect is not an enzyme or a proteid body, since it is not destroyed by boiling in acid solution. The name of *secretin* has been given to the body by its discoverers, but it has not yet been isolated.

From the foregoing description it is obvious that *secretin* is quite distinct from the peculiar enzyme termed *enterokinase*, which has recently been shown by Delezenne, to exist in extracts of intestinal mucous membrane or in the *succus entericus*. This enzyme can be obtained from *any part* of the intestinal mucous membrane, and, like all enzymes, can be destroyed by boiling solutions containing it.

It acts upon the pro-ferments present in the pancreatic juice, and converts them into the active ferments. Fresh pancreatic juice collected by means of a cannula inserted into the pancreatic duct is practically inert when tested by its action upon fibrin; but when a solution of *enterokinase*, or, in other words, *succus entericus*, or an extract of intestinal mucous membrane, is also added to the mixture the fibrin is then rapidly attacked and dissolved.

Bayliss and Starling regard the *secretion* elicited by the action of acid upon the mucous membrane of the duodenum as being due to a chemical stimulation of the pancreatic cells by *secretin* taken up by the blood from the columnar cells of the duodenum and carried to the pancreatic cells, and not to any nervous action either central or local. According to these authors the main regulation of pancreatic secretion takes place by chemical means through the medium of the blood stream, which acts as a carrier of the stimulating chemical products.

Thus, upon this view, the cells of the mucous membrane of the duodenum during a period of rest, corresponding to the period when the stomach is empty, store up a precursor of secretin which may be termed *prosecretin*. On the passage of acid chyme from the stomach into the duodenum, the cells discharge secretin into the blood stream, and this body being carried to the pancreatic cells induces secretion of alkaline pancreatic juice.

The pancreatic juice so secreted is almost inert, so far as action upon proteid is concerned, until it has become mixed with the *succus entericus* in the intestine. Here the action of Delezenne's *enterokinase* plays a complemental part, changing the pro-ferment into active ferment, for Bayliss and Starling find that the activity of the secretion produced by the injection of solutions of *secretin* into the blood stream is greatly increased by the addition of extracts of intestinal mucous membrane.

It is obvious that the amount of pancreatic flow can thus be nicely regulated to the amount of digestion performed, for the stimulus to secretion will be proportionate to the quantity of acid gastric chyme thrown into the duodenum to cause evolution of secretin from the duodenal cells, and again the stimulus to secretion will be automatically removed when the quantity of alkaline pancreatic juice secreted is sufficient to neutralize the acid which gives the stimulus.

It is a discovery of high importance to our knowledge of pancreatic secretion that a material can be extracted from the duodenal mucous membrane, and peculiar to it alone, which is capable of evoking a copious flow of pancreatic juice, but a few words may judiciously be offered in criticism of the view of the authors that the process is a purely chemical one, and that this method is the most important and naturally occurring one by which pancreatic secretion is regulated.

In the first place, the experiments of Pawlow and Popielski, quoted above, undoubtedly prove that the pancreas possesses a nervous mechanism which is capable of regulating its secretion both in the direction of excitation and in that of inhibition, and this even while a strong application of acid is being made to the duodenum. It is also obvious that no such treatment of the cells of the duodenal mucous membrane with acids can normally occur in the process of digestion as takes place when they are extracted in a test tube with acid. In fact, at the height of pancreatic secretion, the reaction of the contents of the duodenum is normally alkaline, or they possess an acidity due to dissolved carbonic acid only, for the acid of the gastric juice is neutralized at once by the mixture of pancreatic juice and bile into which it is received. Hence there never can be any free acid in the duodenal cells, which must be still less acid than the contents of the intestine, so that any flow of *secretin* from these cells into the blood which may occur cannot be caused by an acid reaction.

Again, it is exceedingly difficult to prove that *secretin* acts directly on the gland cells and not through the central nervous system, even admitting that this substance is normally secreted into the blood stream. For it is experimentally impossible to prove that all the non-medullated nerves passing to the pancreas have been severed; a convincing proof of the peripheral action of *secretin* can in fact be given only by showing a secretory effect of this substance when perfused through an excised pancreas, and this has not yet been given.

In whatever way this peculiar substance found in the cells of the duodenal mucous membrane may eventually be shown to act, there is no doubt, however, that its discovery has awakened a new line of thought as to the mode of secretion of pancreatic juice and probably of other secretions, for there is no reason why the pancreas should be peculiar in this respect. We have also here another beautiful example of that interdependence of one organ in the body upon another, and of the usefulness of the products of the metabolism of one cell for the life work of another, situated in a different part of the body, and apparently not even remotely connected with it.

4. Chemistry of the Pancreatic Juice.—It is impossible in the present state of development of the experimental technique for obtaining pancreatic juice to give any reliable figures as to the quantitative composition of that fluid. The irritation set up by the necessary operations for the collection of the secretion causes the flow, within a few hours, of a paralytic secretion, which is many times more diluted and consequently poorer in organic constituents than that which flows within the first few hours. For this reason it is also impossible to obtain any information experimentally as to the average quantity secreted in the twenty-four hours, and as the tables of total quantities and quantitative composition are quite illusory they are not here quoted.* The secretion obtained immediately after the production of a temporary fistula of the pancreatic duct is a clear, viscid fluid of strongly alkaline reaction, equivalent to 0.2–0.4 per cent. of NaOH, due to the presence of carbonates and phosphates of sodium. It undergoes spontaneous coagulation in the cold, and being very rich in coagulable proteids (eight to ten per cent.), which cannot be distinguished from serum globulin and serum albumin, it undergoes heat coagulation and sets to a solid white mass when heated to 75° C. If kept in a water bath at a temperature of 40° C., its own coagulable proteids undergo digestion by the trypsin present (*vide infra*) into albumoses and peptones, and the secretion is then no longer coagulable by heat. Alcohol precipitates both the proteid and the enzymes.

The inorganic salts present are practically identical with those of blood serum.

* See Schäfer: "Textbook of Physiology," vol. i., p. 366 *et seq.*

Digitized by Microsoft®

White blood corpuscles showing sluggish amœboid movements are present in the fresh secretion.

Traces of leucin have been detected in the fresh secretion, but tyrosin is absent. The most important constituents of the pancreatic juice from the point of view of the physiological chemist are the enzymes to which it owes its powerful digestive action upon all three classes of foodstuffs.

www.libtool.com.cn

There are four enzymes known to be present. These possess in each case all the general reactions which are characteristic of this class of bodies, and hence need not here be detailed (see article on *Enzymes*), and accordingly only the peculiarities of each will be recorded.

No complete separation of these enzymes has as yet been accomplished, that is to say, no one has succeeded in obtaining from the mixture present in the pancreatic juice solutions which contain one enzyme only. Hence the belief that each specific action of the pancreatic juice upon a foodstuff is due to a separate enzyme rests upon the partial proofs, first, that there is no known example of a single enzyme which acts upon two different varieties of foodstuff, and, secondly, that in certain cases, according to the method of extraction used, extracts can be prepared from the gland which are relatively rich in one enzyme and poor in another, although this has not been done for all four. For example, from the pancreatic tissue, after completely drying by alcohol, the diastatic enzyme can be extracted by anhydrous glycerin, while the proteolytic enzyme does not pass into solution.

It is hence extremely probable that four distinct substances or their precursors are present in the gland cells and secretion which have been named as follows: (1) Amylopsin, a diastatic enzyme; (2) steapsin, or pialyn, a steatolytic or fat-splitting enzyme; (3) trypsin, a proteolytic enzyme; and (4) an unnamed enzyme which has the property of curdling milk.

It has been clearly demonstrated that trypsin is present in the gland cells, and also to a large extent in the fresh secretion before it is acted upon by the *succus entericus* in an inactive form, which is known as *trypsinogen*. It is at present unsettled whether steapsin and amylopsin possess similar precursors.

There are two views as to the action of the complementary enzyme called *enterokinase* of the *succus entericus*. One view is that this first attaches itself to the proteid, and renders it in a catalytic fashion more easily attackable by the pancreatic enzyme. The other and more probable view is that the enterokinase acts upon the trypsinogen and sets free trypsin which then attacks the proteid.

Amylopsin.—This can be extracted from the fresh gland by most extractives, such as chloroform water, twenty-five-per-cent. alcohol, to which a trace of acetic acid has been added, fifty-per-cent. glycerin, saturated solution of sodium chloride, saturated boric-acid solution.

Its action upon starches is very rapid, and closely resembles that of other diastatic enzymes. The action is hydrolytic, and leads to the formation of a mixture of achroödextrins and maltose. One part of amylopsin (impure) is capable of hydrolyzing over forty thousand times its weight of starch (see article on *Digestion*).

The action is at a maximum at a temperature of 30°–45° C., decreasing gradually as the temperature is lowered down to 10° C., at which it is stopped, as long as the temperature is kept at that level, but recommences on warming. The temperature of destruction is about 60 to 70° C.

Amylopsin acts best with a neutral reaction or in presence of an excessively minute trace of acid, the optimum according to Melzer coinciding with 0.01 per cent. of hydrochloric acid. By greater amounts of acid than this, not only is the activity lessened, but the ferment is itself rapidly destroyed; it is less susceptible to the fixed alkalies withstanding the action of one per cent. of sodium carbonate, but is rapidly destroyed by free alkalies.

Steapsin.—This enzyme is exceedingly unstable, and hence great care is required in obtaining active extracts from the gland substance. In any case, a good deal of the enzyme is lost in the process of extraction, and hence as shown by Rachford, the fresh pancreatic juice is always more active than any extract of the gland, and should be used in experimenting upon the action of this enzyme. It was formerly believed that this ferment acted only upon a small fraction of the fat of the food, because the action of extracts of pancreas upon fats was so slow and incomplete; but this arises from the great loss of activity in the process of extraction, and it is now known that the steapsin has sufficient power to split up the entire fats (Rachford), and it is probable that fats are taken up in solution (see article on *Digestion*).

That the action is truly enzymic is shown, first, by its stoppage on boiling; and, secondly, by its taking place when bacteria are excluded by the presence of antiseptics.

If extracts of the gland containing steapsin are desired, the *fresh* gland must be taken and extracted with a very dilute (1 to 1,000) solution of sodium carbonate, or a ninety-per-cent. solution of glycerin, containing 1 per mille of sodium carbonate.

Such solutions, or the fresh pancreatic juice, act upon neutral fats, hydrolyzing them, and forming free fatty acids and glycerin. A similar hydrolyzing action has been noted upon other synthetically prepared esters.

The action is increased by the presence of bile (Rachford). The effect here is probably a physical one, the bile salts or bile acids dissolving the fatty acids which are a product of the hydrolysis, and so allowing fresh portions of neutral fat to be attacked.

The optimum temperature is 38° C., and at this temperature the action is twice as rapid as it is at 18° C.

Trypsin.—This enzyme acts upon proteids more powerfully and completely than any other known to us, forming in succession alkali-albumin, deutero-albumose, peptone, and a large number of amido-acids. Primary albumoses do not seem to be formed, or, if they are formed, they at once pass into more completely hydrolyzed forms, and the action is both more rapid and complete than is that of pepsin. The ferment can be extracted by any of the usual extractives from the gland. It is insoluble in strong alcohol or glycerin, and the latter of these two reagents has been utilized for its differentiation from amylopsin.

According to Sir William Roberts its activity goes on increasing with the temperature up to 60° C., and it is destroyed at a temperature of 75° to 80° C. These figures do not agree with those of Biernacki, who found it to be destroyed at a temperature of 50° C. when in solution in five-tenths per cent. sodium carbonate, and when in neutral solution at a temperature of 45° C.

Trypsin acts best in an alkaline medium, the usual optimum given being that of a one-per-cent. solution of sodium carbonate. It, however, can act in a neutral solution or even in the presence of a faintly acid reaction, provided no free inorganic acid is present. A small amount of hydrochloric acid, combined with proteid, does not stop its action, but much acid, *even when combined with proteid*, has a destructive effect.

The Milk-Curdling Ferment.—The presence of a milk-curdling enzyme in the pancreas was first discovered by Kühne, and has since been confirmed by other observers.

More recently the subject has been re-investigated by Halliburton and Brodie, who found that the coagulum produced by this enzyme differs considerably from that obtained by the action of the rennin of the gastric juice. Thus, instead of a jelly-like coagulum which is obtained in the water bath at a temperature of 35°–40° C., a finely granular precipitate is obtained by the action of pancreatic juice or pancreatic extracts, which does not at this temperature interfere with the fluidity of the mixture. But on cooling to the temperature of the room a coherent curd is formed; if this be now heated to body temperature it again becomes fluid, and on cooling a second time it again sets to a clot, and this process can be repeated indefinitely. Further, the coagulation by means of the pancreatic enzyme differs from that by rennin in that it is not prevented by excess of ammonium oxalate, and hence does not require the presence of calcium salts.

Digitized by Microsoft®

The use of this pancreatic enzyme is difficult to understand, since any milk taken by the mouth would be coagulated in the stomach by the rennin there present. A similar difficulty exists regarding the purpose of rennin in the gastric secretion of fishes and other animals from whose food milk is absent, as also regarding the presence of milk-curdling ferments with the juices of certain plants. A possible explanation is that such ferments may have a less obvious action upon other forms of proteid, a fact which yet remains to be discovered. *Benjamin Moore.*

www.libtool.com.cn

PANCREAS, DISEASES OF THE.—The great importance of diseases of the pancreas was not generally recognized by the medical profession until within comparatively recent times, but that pathological alterations of the organ not uncommonly exist was known to all of the older pathologists. That changes in the pancreas sometimes occur in individuals who have diabetes mellitus was first recognized by Cowley in 1788, but prominence was not given to the matter until 1877 when Lancereaux's work was published, and the relation between the two conditions has been recently definitely proven by the experimental work of von Mering and Minkowski. Spiess in 1866 recognized hemorrhage into the pancreas as being a frequent cause of sudden death, and Zenker some years later accentuated this relation; but its great importance was first fully recognized by Draper, who particularly directed attention to it in 1886. In 1889 Draper's fellow-townsman, Fitz, in a most admirable paper, opened up a new field to the clinician in bringing together a great mass of isolated facts concerning pancreatitis, and coordinating them in such a masterly manner that since this time inflammations of the organ have been brought within the list of those diseases which may be diagnosticated. Several years before the appearance of the article by Fitz, Senn, of Chicago, very thoroughly reviewed the subject of pancreatic cysts. In the article that follows the writer wishes particularly to express his indebtedness to the various papers upon this subject written by Fitz, to the chapter on these diseases in Osler's "Practice of Medicine," and to the recent monograph upon the subject by Koerte.

Fatty and Hyaline Changes in the Pancreas, and Amyloid Infiltration.

Fatty Changes.—The fatty alterations that occur in the pancreas may be divided into (*a*) fatty degeneration, and (*b*) fatty infiltration.

(*a*) In many acute diseases, especially in those accompanied by high temperature, *fatty degeneration* occurs in the pancreatic cells. Happily, the condition is one that passes away with its cause, and is not generally supposed to give rise to serious or permanent change in the organ. There is no symptomatology of the condition.

(*b*) *Fatty Infiltration.*—This condition is frequently observed in obese individuals, and is not generally believed to produce any serious interference with the functions of the organ, though cases of diabetes have been reported in which this lesion was present in the pancreatic tissues to a marked degree. In these instances it is likely, as in a case recently observed by the writer, that the fatty changes were secondary to interstitial pancreatitis and that they were not responsible for the diabetic condition.

Hyaline Degeneration.—In a very interesting paper Opie has recently called attention to the fact that diabetes sometimes occurs in which the only alteration found post mortem is hyaline degeneration of the islands of Langerhans in the pancreas. Whether or not there is any connection between the two conditions cannot as yet be stated with certainty.

Amyloid Infiltration.—Amyloid infiltration of the coats of the blood-vessels of the pancreas occurs in those conditions in which this material is being produced in the body. So far as is known it does not give rise to any serious alterations of the pancreatic functions.

Pancreatic Hemorrhage.

Pancreatic hemorrhage is a condition that occurs to a slight degree in quite a number of different affections, but the term is here limited to those sudden and profuse extravasations of blood into the organ that are commonly known as pancreatic apoplexy.

Etiology.—In the vast majority of instances those suffering from severe pancreatic hemorrhage have passed middle life, and the disease appears particularly to affect corpulent individuals. In many instances those who have had the disease have been addicted to the continuous use of alcohol. It commonly occurs also in those who have previously suffered more or less with "indigestion," and in many cases there appear to have been previous mild attacks. It is more common in males than in females. In some instances it has followed injury. As to the exact nature of the condition of the blood-vessels that predisposes to this disease we are still in great ignorance, careful microscopic studies being much needed to elucidate this rather obscure morbid state. It has been assumed by some that syphilitic disease of the blood-vessels is the most common cause of the malady, but adequate proof of this has not as yet been brought forward. That minute hemorrhages occasionally occur in the pancreas as the result of chronic induration of the organ there can be no question, and extravasations of a similar kind are occasionally found in connection with obstructive diseases of the circulation—such as are produced by organic heart lesions, emphysema, and tumors pressing upon the inferior vena cava. Recently Chiari has shown that minute hemorrhages are sometimes produced in the pancreas by what appears to be post-mortem digestion of portions of the organ.

Morbid Anatomy.—In cases of severe hemorrhage into the pancreas the entire organ may be blood-stained, and be either of an almost black, dark purple, or brownish-red hue. In by no means all instances, however, does the gland as a whole present this appearance, as all degrees of hemorrhage are met with from the complete infiltration of the organ to single, minute ecchymotic spots situated in some part of the substance of the gland. In the affected region the pancreas is usually distinctly increased in size, though in some instances it appears to be normal in bulk. The organ may be of normal consistence, distinctly softened, or quite friable. It is of interest to note that in no instance has any one succeeded in finding the blood-vessel from which the hemorrhage came. Under the microscope the tissues of the pancreas may present a practically normal appearance, though, especially in obese individuals, more or less fatty infiltration is generally present. Blood in various stages of disintegration is found both within the interstitial tissues of the organ, and within its parenchyma in the diseased regions. In some instances the tissues of the pancreas present evidences of extensive necrotic change, as was observed by the writer in one instance in which the nuclei of all of the cells in the affected areas entirely failed to take basic stains. It not uncommonly happens that the hemorrhage does not remain confined to the pancreas, but extends into the surrounding retroperitoneal tissues, even so far as the left kidney, and it occasionally forces its way into the fat of the omentum and mesocolon.

Symptoms.—The disease comes on in almost all instances with extraordinary suddenness, the individual having usually been in perfect health previously, though in rare cases the condition is preceded by slight prodromal pains in the upper part of the abdomen. In most instances the pains are confined to the region of the pancreas, but in some cases they may be diffused throughout the abdomen, and have been sometimes mistaken for colic in the beginning. Following the pain there are usually nausea and vomiting of a most persistent kind, and occasionally there is an urgent desire to defecate. Along with these symptoms a profound depression of the vital powers invariably occurs; the pulse is small, feeble, and exceedingly rapid. There is pronounced and oftentimes urgent dyspnœa, the patient tosses from one side of the bed to

Digitized by Microsoft®

the other, is bathed in cold perspiration, the countenance exhibits great anxiety, and there is every symptom of impending dissolution. In a comparatively short time the abdomen not uncommonly becomes swollen, and tenderness develops in the epigastric region. The temperature is either normal or subnormal. Constipation is quite frequent. If the hemorrhage is at all extensive the patient rapidly grows worse, and death usually occurs within a few hours. There can be no question that recovery sometimes follows the milder forms of the disease.

Diagnosis.—Pancreatic apoplexy is distinguished by the sudden onset, with excruciating pains in the epigastric region, nausea and vomiting, and rapid collapse. It is differentiated from intestinal obstruction by the sudden onset, and by the extreme urgency of the symptoms. In biliary colic the history, the absence of excessive vomiting, and symptoms of collapse serve to distinguish between the two conditions. In gastric and duodenal ulcer perforation is preceded by frequent attacks of severe pain in the epigastric region, tenderness over the site of the ulcer, and the vomiting of blood. Moreover, ulcer generally occurs in anæmic young women.

Prognosis.—In all cases of severe hemorrhage death follows in a very short time, the patient not, as a rule, surviving longer than two or three hours. On the other hand, when the amount of blood effused is small, recovery may occur, though in these cases the condition very quickly becomes one of pancreatitis. Patients have survived even very severe hemorrhages, as is conclusively shown by the fact that recovery has occurred in several instances in which the diagnosis was made by an exploratory incision.

Treatment.—The nature of the lesions in this disease makes it, of course, impossible for drugs in any way to influence the local condition, and the treatment is therefore necessarily entirely of a symptomatic kind. Morphine should be given to relieve the pain, and the collapse should be treated in the usual way by the application of warmth, and by the hypodermatic injection of strychnine and atropine. For the reason that death in this condition cannot be produced merely by the loss of blood, but is brought about by the pressure exerted upon the surrounding nerve structures, it has been suggested that free incisions around the pancreas might relieve this condition, and thus be the means of saving the patient's life.

Acute Pancreatitis.

There are at least three more or less separate and distinct varieties of acute inflammation of the pancreas: (*a*) the acute hemorrhagic, (*b*) the acute suppurative, and (*c*) gangrenous pancreatitis, each of which demands separate consideration.

(*a*) Acute Hemorrhagic Pancreatitis.—By the term acute hemorrhagic pancreatitis is meant that condition of the pancreas in which the hemorrhagic lesion is accompanied by evidences of so-called inflammation. This condition cannot be clearly separated from that of simple pancreatic hemorrhage, the latter merging insensibly into the former.

Etiology.—This disease is much more commonly observed in persons past middle life than in the young, but instances have been reported in which the malady occurred in children, the sufferer in one instance being only nine months old. It is more common in males than in females, though the number of recorded instances of the disease is not as yet sufficiently great to determine its relative frequency in the two sexes with certainty. It occurs more commonly in obese individuals than in those who are lean. In quite a large percentage of the recorded cases the subjects have been alcoholics. Like pancreatic apoplexy this condition has been frequently observed to occur in individuals who had previously suffered for a greater or less length of time with derangements of the digestion, and in some cases there has been a clear history of previous attacks of the malady. It is also noteworthy that many of those who have had the disease had previously suffered for a period of years with unmistakable symptoms of gall-stones and inflammatory states of the gall-bladder. In view of the fact that in conditions of this kind bacteria are always present in the gall-bladder and ducts, the investigations of Hlava, Williams, and Flexner, who produced experimental inflammations of the pancreas by the injection of various bacteria, seem to be of special significance.

Morbid Anatomy.—In acute hemorrhagic pancreatis the pancreas presents much the same macroscopic appearances that it exhibits in pancreatic apoplexy. The organ, wholly or in part, is almost black, of a purple hue, or of a dark red color, and in the affected regions is considerably swollen. The tissues of the gland are in some instances softened and quite friable. The amount of hemorrhage varies in different instances. It may be confined to the head, body, or tail of the organ, or may be diffused throughout its entire extent. Not uncommonly the hemorrhage extends into the retroperitoneal tissues, and is frequently found present in the omentum, mesentery, and mesocolon. The spleen may be enlarged. Within the pancreas itself there are not uncommonly found small areas of a dull whitish opaque appearance that are made up of fat which has undergone a peculiar chemical alteration. This change in the fat is known as *fat necrosis*, and is dependent upon the fat-splitting ferments elaborated in the gland. Williams describes the appearance as follows: "Frozen sections of the white necrotic nodules showed them to be made up of coarse granules and masses, globules and crystals, and a small amount of masses of brown pigment. Many of the opaque masses were about the size and shape of fat cells, and evidently represented altered fat cells. The surrounding tissues were mildly congested; a few small extravasations were noted; the fat cells appeared normal. Sections of the same embedded in celloidin, and stained with hæmatoxylin or carmine, give similar results." It is notewothy that tetroxide of osmium is not reduced by the structures composing these necrotic tissues. It has been shown by Langerhans that the areas of fat necrosis are made up of a substance that results from the combination of lime with certain fatty acids. Osler speaks of a case in which death was the result of Bright's disease, and in which the lobules of the pancreas were entirely isolated by areas of fat necrosis with extensive deposition of lime salts. In hemorrhagic pancreatitis it very frequently happens that areas of fat necrosis are found in the fatty tissues of the omentum, mesentery and mesocolon, and in the adipose tissues situated behind the gland. It should be remarked, however, that minute areas of fat necrosis are sometimes found in the living human being where there is no disease of the organ, and Chiari has shown that post mortem there are often found in the pancreatic tissues minute alterations that appear to be the result of auto-digestion —alterations which bear a close relation to the necrosis that occurs in the fatty structures. Balser, who first accurately described the condition in man, has also shown that it not uncommonly occurs in the fatty tissues around the pancreas in healthy swine. This observation has been recently confirmed in this country by Williams, who has also shown that it occasionally occurs in the abdominal adipose tissues of the cat. It is very interesting to note that experimental fat necrosis in connection with hemorrhage into the pancreas has been produced artificially by a large number of investigators, among whom are to be especially mentioned Hlava, Langerhans, Hilderbrand, Dettmer, Williams, Flexner, Rosenbach, and Opie. These investigators have shown that the condition may be induced in dogs and other animals by the injection, into the pancreas or its ducts, of bacteria, acids or alkalies, by ligation of the organ, by simply injuring it or by injuring it and at the same time infecting it with bacteria, and by the introduction of sections of fresh pancreas into adipose tissue.

Symptoms.—The initial symptoms that usher in an attack of acute hemorrhagic pancreatitis are those of pancreatic hemorrhage. There is a sudden onset with ex-

www.libtool.com.cn
Digitized by Microsoft®

cruciating pain in the upper part of the abdomen, vomiting, and all indications of collapse. However, in some instances the disease does not begin with such violent symptoms, there being a period of days or even weeks during which there are slight, oftentimes colicky pains in the abdomen, combined with a certain amount of tenderness; constipation is, as a rule, present. The temperature, which in the beginning may be normal or subnormal, becomes somewhat elevated as the so-called inflammatory phenomena develop in the diseased organ; but, as a rule, the fever does not go above 103° F. About the time that the fever begins, chilly sensations are not uncommonly complained of, and even pronounced chills are occasionally encountered. The pulse is always rapid, and as a fatal termination is approached, it becomes weaker and weaker, and finally uncountable. The respiration is almost in all instances shallow and decidedly hurried. In most cases after the disease has existed for a short time the abdomen becomes distinctly swollen, and is exceedingly tender in the epigastric region. In some instances it has been possible to feel the swollen pancreas through the abdominal walls, though this cannot, as a rule, be accomplished.

Diagnosis.—Although this disease was always overlooked until a comparatively short time ago, the diagnosis, thanks to the brilliant work of Fitz, has been recently made in a large number of cases. Where a previously healthy person is suddenly seized with intense pain in the upper part of the abdomen, with nausea and vomiting, and with pronounced symptoms of collapse, this disease should be always suspected. Of all the conditions simulating acute hemorrhagic pancreatitis, acute intestinal obstruction is perhaps the one that may be most readily mistaken for it; but the former malady may be distinguished by the suddenness of the seizure, by the pronounced symptoms of collapse, and by the absence of distention of the intestine in the early stages. The further fact is of importance that obstruction of the small intestine in the region of the pancreas is very infrequent, and the patency of the large intestine can be always readily determined by inflation. Biliary colic may also be mistaken for pancreatitis, but may be generally distinguished from it by the history of previous attacks, by the situation of the pain, and by the absence of pronounced symptoms of collapse. It should, however, be remembered that several instances of pancreatitis have been recorded in which the patient had previously suffered from biliary colic. In the later stages of acute hemorrhagic pancreatitis inflammatory exudates collect in the lesser omentum to such an extent that the condition somewhat resembles that of pancreatic cyst, but the history of the case and the pronounced septicæmic state that often occurs in connection with it will serve to make the diagnosis clear. In case of doubt the physician may resort to aspiration, which will determine the true nature of the condition with certainty. The symptoms that occur in connection with perforation of the stomach or duodenum, resulting from ulcer, somewhat resemble those which are found in this disease; but generally the two may easily be distinguished by the history of severe pain following the taking of food, the vomiting of blood, and the increased secretion of hydrochloric acid that are so characteristic of the former conditions. Irritant poisons might give rise to some of the symptoms usually observed in pancreatitis, but the history of the case and the absence of the evidences of corrosive action in the mouth and throat and the character of the vomit, will generally serve to make clear the true nature of the condition.

Prognosis.—Although acute pancreatitis is a very fatal disease, there are numerous instances on record in which recovery occurred even from the severer forms of the malady. If the patient survive the first few days of the disease there is always hope for ultimate recovery, though even in these cases a death from septicæmia and exhaustion generally occurs in from two months to a year. In the latter stages abscesses in and around the pancreas not uncommonly occur, and inflammatory exudates often collect in the lesser omentum to a considerable extent. In these instances laparotomy and the establishment of proper drainage are absolutely essential to the preservation of the patient's life, and as we learn to make the diagnosis with more certainty there can be no doubt that fatal terminations will become less and less frequent. Cases have been recorded in which diabetes followed the disease.

(*b*) Acute Suppurative Pancreatitis.—Acute suppurative pancreatitis is a condition that fortunately is rarely observed, it being much less frequent than the hemorrhagic form. Pus may be diffused throughout the organ, or it may be localized. Not uncommonly the neighboring viscera are secondarily affected, and the abscess may perforate into the stomach, into the small intestine, or into the peritoneal cavity. Secondary abscesses in the lesser omentum have in a number of instances been produced, and thrombosis of the portal vein has been noted. The spleen is often enlarged. This disease has in some instances followed injury; but in quite a number of cases, further than that the patient had previously suffered with disturbances of the digestion, the origin of the affection was not apparent. It should also be remembered that this condition may be encountered as a sequel to the acute hemorrhagic form of the malady.

The *symptoms* of this disease are by no means so characteristic as those that are encountered in the hemorrhagic form of the affection; although there is always more or less pain localized in the region of the organ, it is never so intense, and does not come on with such suddenness as in the hemorrhagic form; and vomiting, although quite common, is not so persistent. Intense pain in the sciatic nerves may occur. Patients suffering with this disease very quickly develop the symptoms of sapræmia or septicæmia, usually having irregular rises and falls in temperature, profuse sweats, and chills, and they present the profound depression of the general system that is so characteristic of blood poisoning. In a number of cases it has been possible by palpation to discover, in the region of the pancreas, the presence of a tumor; and this discovery, whenever it can be made, is of the utmost importance from a diagnostic standpoint. Jaundice and sugar in the urine have been noted in some instances.

(*c*) Gangrenous Pancreatitis.—Gangrenous pancreatitis usually follows the acute hemorrhagic form of the disease, and may be partial or complete; it has been known also to follow the suppurative variety of the affection, and has in some instances resulted from injury.

Under these circumstances the pancreas becomes totally or in part necrotic, and the diseased parts are soft, have a foul odor, and present a dark, slaty appearance. In many instances the diseased tissues have completely sloughed away from the remains of the organ; they then commonly lie along with masses of pus and broken-down tissue in the cavity of the omentum. Notwithstanding the extremely dangerous situation in which a patient must, under these circumstances, be placed, instances of recovery after operation are not wanting; and Trafoyer and Chiari have reported cases in which sloughs of the pancreas made their way into the cavity of the intestines, and were discharged from the bowels.

As this condition is usually secondary to acute hemorrhagic pancreatitis, its early *symptoms* are those of this disease. After the necrosis in the tissues occurs there follow septicæmic symptoms, in combination with tenderness in the upper part of the abdomen and evidences of a tumor-like mass in the same situation.

Treatment.—The treatment of acute hemorrhagic pancreatitis in the beginning is that of pancreatic apoplexy. The agonizing pain requires the exhibition of full doses of morphine hypodermatically, and the symptoms of collapse should be treated by the subcutaneous injection of strychnine, atropine, and whiskey, and by the application of external warmth to the body. Following this the treatment should be entirely symptomatic. The diet should be relatively free from fat. The administration of portions of raw pancreas, with the food, has been recommended by some, as the food is in this way brought

Digitized by Microsoft®

more or less in contact with the pancreatic juices which are so necessary for proper digestion. Diastases are also useful if they be administered immediately after food is taken, as they take the place of the pancreatic juices in a measure. In the suppurative and gangrenous forms of the affection laparotomy offers the best hope for the ultimate recovery of the sufferer. In the latter stages of all forms of the disease the patient requires a supporting, nourishing diet, with the administration of stimulants and tonics.

Chronic Pancreatitis.

By the term chronic pancreatitis is meant the gradual increase of the fibrous and elastic tissues that are normally found in the pancreas, this change resulting in the compression and ultimate destruction of a greater or less amount of the glandular structure of the organ. Such a chronic inflammation is a matter of very great importance, inasmuch as it is very commonly associated with diabetes mellitus.

Etiology.—Birch-Hirschfeld showed, a number of years ago, that chronic fibroid thickening of the pancreas not uncommonly results from congenital syphilis, and his conclusions have been recently confirmed in a most admirable article by Schlesinger. It has been also assumed by some that acquired syphilis is likewise capable of inducing chronic induration of the organ, but its causal relation to the present disease has not as yet been conclusively shown. Quite a number of cases have occurred in those who have been addicted to alcohol, and the inference therefore seems justifiable that this habit may in some way predispose to this morbid state. There seems good reason to believe that catarrhal conditions of the duodenum, leading to changes of a similar kind in the common and pancreatic ducts, give rise in some instances to this affection, and we have abundant proof that closure of either of these ducts by means of gall-stones, pancreatic calculi, or in other ways, results in chronic indurative change in the organ. Experiments on animals have also shown that ligation of the duct of Wirsung is followed by an increase in the fibrous structures of the gland. "Fibrous thickening of the pancreas is even associated with ulcer of the stomach or duodenum, tumors of the stomach or suprarenal capsule, aneurism of the aorta or cœliac axis, or with disease of the spine" (Fitz). Dilatation and obstruction of the pancreatic duct is not uncommonly the result of chronic induration of the organ. The writer has recently recorded a case in which diabetes quickly followed mumps, and the theory was suggested that an acute pancreatitis was in this case produced by the poison of this disease, and that subsequently chronic changes occurred, giving rise to glycosuria.

Morbid Anatomy.—Fibroid thickening of the pancreas is most frequent in the head of the gland, but the disease may be limited to other parts of the organ, or may involve it throughout. Opie has recently written a number of interesting articles upon the subject of chronic induration of the pancreas, and he recognizes two different varieties of the disease: (1) Interlobular pancreatitis, characterized by the proliferation of fibrous tissue between the lobules which are invaded from the periphery; and (2) interacinar pancreatitis, where the newly formed fibrous tissue is more diffusely distributed between the lobules and individual acini. This writer asserts that the interlobular form of the disease is that variety which follows occlusions of the pancreatic duct, and, although the parenchyma of the gland is in a large measure replaced by fibrous tissue, the islands of Langerhans are for the most part unaffected, and diabetes is but rarely observed. In the interacinar form of the malady the areas of Langerhans are on the other hand quickly destroyed, and in these instances diabetes always occurs. It was suggested many years ago by Laguesse, and later by Schaefer and Diamare, that Langerhans' bodies exert the important function of controlling carbohydrate metabolism, and Ssobolew has recently brought forward as experimental proof of this the fact that after feeding animals with carbohydrates in considerable quantities the cells of the islands became more granular than usual. There is therefore some experimental evidence that Langerhans' islands are in some way associated with the assimilation of carbohydrates. There is even stronger pathological proof of this relation in the human being. The experiments of von Mering and Minkowski, by which the close relation of diabetes mellitus to alterations of the pancreas was so clearly shown, are so well known, and have been so frequently cited, that it does not appear necessary to consider the matter at length in this article. In all cases in which the fibrous change has advanced to any great extent the pancreas is found distinctly diminished in size, and its surface is more or less roughened and nodular; on the other hand, where the changes are not so pronounced the organ may be but little smaller than normal, and its surface may be comparatively smooth. On section its consistence is found to be considerably increased, and its tissues are, as a rule, even paler than normal. The subperitoneal tissues surrounding the pancreas are in some instances likewise thickened. Fatty changes are oftentimes extreme, and, as in a case recently observed by the writer, the entire organ may present the macroscopic appearance of a mass of ordinary fat, though on microscopic examination the fibrous tissues are found to be greatly increased. In some instances these fatty alterations are not so extreme, there being merely small yellowish spots scattered throughout the organ. In some cases hæmatoidin crystals, crystals of fatty acids, and calcareous granules are found scattered throughout the substance of the gland.

The fibrous changes not uncommonly result in constriction of the pancreatic ducts at various points, causing them to appear dilated and tortuous, though this does not always occur.

Symptoms.—Progressive loss of flesh and strength and the various indications of alteration in the digestion are the symptoms that are most commonly observed in chronic pancreatitis. There are usually loss of appetite, belching, pyrosis, nausea, and a sense of weight and fulness in the epigastrium, and occasional vomiting. Diarrhœa very commonly exists, and the fæces are frequently fatty, and may be colorless even when no jaundice exists. The sclerotic changes have in some instances compressed the common duct, in which case jaundice, of course, supervened. In connection with the influence of the pancreatic secretion on the chemical changes occurring in the fatty foods ingested the observations of Mueller are very interesting. He has shown in three cases of pancreatic disease that the fat contained in the fæces was by no means decomposed to such an extent as is the case in health. He found that normally 84.3 per cent. of the fat contained in the stools is split up, forming free fatty acids and soaps; and in a number of instances this percentage was practically that found in the discharges of individuals suffering from other diseases than those of the pancreas. On the other hand, in instances in which the pancreatic secretion does not reach the intestine he found that on an average only 39.8 per cent. of the fat occurred as fatty acids and soaps. It is, of course, obvious that such a pronounced variation from the normal must occur only in those instances in which there is suppression of the greater part, or all, of the pancreatic secretion, and that in cases in which the stenosis of the pancreatic duct is only partial, the proportion of altered fat in the fæces will be considerably greater. It is therefore clear we cannot assume that the greater part of the fat will appear as such in the stools in all cases of pancreatic disease. Notwithstanding this, an analysis of the discharges will probably be found of value in obscure cases. The examination is conducted as follows. The fæces are heated at a temperature of 100° C. until thoroughly dried, and then finally are pulverized. This powder is then treated with alcohol, acidulated with hydrochloric acid, and boiled. This causes the soaps to become again free fatty acids, the neutral fats remaining unaltered. The mass is then thoroughly dried, and is treated with ether for three days in a Soxhlet apparatus. The ethereal extract is then filtered and evaporated, dissolved in abso-

Digitized by Microsoft®

lute ether, again filtered, dried, and weighed. This determines the amount of neutral fat, and both the free fatty acids and those that were in combination forming soaps. A weighed portion of this mass is then dissolved in warm alcohol containing a small amount of ether, and a few drops of an alcohol solution of phenolphthalein are then added, and the solution is titrated with caustic potash in alcohol. From the results of this titration we estimate the amount of free fatty acids present in the entire residue, and this, subtracted from the total weight of the mass, gives the amount of neutral fat.

www.libtool.com.cn

Since the time of Cowley it has been known that diabetes mellitus is not uncommonly associated with alterations in the pancreas, and a large number of observations made within recent times show beyond question that the relation is not an accidental one, and that diabetes is in many cases the result of disease of this organ, interstitial pancreatitis being the lesion most commonly found. The brilliant investigations of von Mering and Minkowski have shown experimentally that diabetes may be produced in the dog and other animals by the extirpation of the pancreas, and instances are not wanting where the removal of the organ in man has resulted in severe glycosuria. The theory has been suggested by Minkowski that the pancreas elaborates "a glycolytic ferment" by means of which the sugars are chemically changed in the body, and that when the pancreas is removed or destroyed, this ferment being no longer present, glycosuria results. It has been thought by others that this experimental diabetes is the result of disturbed tissue-metamorphosis produced by the absence from the intestine of the pancreatic juices—a view supported by the fact that diabetes may follow ligature of the duct of Wirsung. Despite the fact that diabetes frequently follows organic alterations in the pancreas, it is but proper to state that this condition by no means always results; and, further, that there are on record many instances of diabetes in which no changes could be found in this organ. It is of interest to note that Picenti and Gerhardi have claimed that the percentage of indican in the urine is much lowered in diseases of the pancreas.

Diagnosis.—The diagnosis of this disease is exceedingly difficult, for it never gives rise to symptoms that are in any way characteristic. The condition may, however, be suspected when the patient is found to suffer from long-continued derangements of the digestion, loss of strength and flesh, in combination with the presence, in the fæces, of an increased amount of fat, which, according to Mueller, exists in a state of free neutral fat, and not broken up into fatty acids. In conjunction with these glycosuria, when present, is of course of great importance in deciding the true nature of the disease, though it should never be forgotten that this condition may occur when the pancreas is in no way affected. For the reason that salol is not decomposed in the intestine in the absence of the pancreatic juice, the failure of carbolic acid to appear in the urine after the administration of full doses of this drug would be strong presumptive evidence of either the total destruction of the secreting structure of the organ or of the occlusion of its duct.

Prognosis.—As regards recovery the prognosis is, of course, hopeless, for we are acquainted with no means by which the process in the pancreas may be cured or even stayed. However, on account of the fact that the disease progresses very slowly, and that great destruction of the parenchyma of the organ is necessary before pronounced symptoms are produced, those suffering with the affection generally survive for a considerable period of time.

Treatment.—The treatment of chronic pancreatitis necessarily resolves itself into seeing that the patient lives under proper hygienic conditions, takes a sufficient amount of outdoor exercise, and gives the necessary attention to the diet. Inasmuch as fats and starches are digested by the secretion from this organ, it is of much importance that these articles be eliminated in a large measure from the diet of the sufferer, and the necessity for a precaution of this kind is often accentuated by the coexistence of glycosuria. It is practically impossible entirely to withdraw carbohydrates from the dietary. The administration of some diastatic ferment with the food is of decided value, or small pieces of raw pancreas may be substituted, inasmuch as it has been shown that the digestion of foods and starches is greatly promoted by its use under these circumstances. Other symptoms have to be treated as they arise.

Pancreatic Calculi.

Calculi are occasionally formed in the pancreatic ducts where they may remain, or from which they may be discharged through the duct of Wirsung and common duct into the duodenum.

Etiology.—Pancreatic calculi are occasionally encountered post mortem, and there are several instances in which the passage of the stones through the ducts into the duodenum has been diagnosticated in life. The condition, however, is one which is rarely encountered, being much less frequent than cholelithiasis. Concerning the causation of this affection it is generally assumed that catarrhal changes in the ducts most frequently give rise to it, but in all probability it may be also associated with the lithæmic diathesis.

Morbid Anatomy.—The calculi are usually quite small, being, as a rule, not larger than a grain of sand, though instances have been recorded in which stones of this kind were more than an inch in diameter. There may be only a single calculus or there may be large numbers, more than one hundred having been found in a single instance. They are usually rounded or oblong, but they may be quite irregular in form. In many instances their surfaces are smooth, though they may be decidedly roughened. They are usually of a light color, and consist generally of carbonate of lime, though they may be composed of phosphate of lime, or a stone may consist of a combination of the two. In some instances they consist of organic material.

In cases in which the calculi become impacted either in the duct of Wirsung or in the common duct, great dilatation of these canals results, and these distentions may be so increased in size that they present the appearance of being cysts. As a result of the stoppage of the pancreatic duct chronic interlobular pancreatitis is sooner or later produced, and in rare instances suppuration of the organ occurs. Fistulous openings have sometimes resulted, the dilated ducts communicating with the stomach, duodenum, or peritoneal cavity. The irritation produced by these stones is supposed by some to lead to the development of cancer.

Symptoms.—In the few instances in which the passage of pancreatic calculi has been diagnosticated during life, the symptoms came on somewhat suddenly with severe pain in the epigastric region, somewhat to the inner side of the left mammary line. From this point the pain generally extended around the border of the ribs on the left side to the spine, and later radiated into the left shoulder. During the height of the attacks vomiting has been noted, and in the case of Cipriani there were salivation, polydipsia, glycosuria, fatty diarrhœa, fever, and great weakness. Following the attacks thirst and hunger have generally been pronounced. In the case just referred to, there were repeated attacks, and the diagnosis was confirmed by the finding of a stone in the fæces. In the case reported by Poliakoff the patient complained of severe pain in the abdomen for two and a half months, the pain being sometimes accompanied by vomiting. The sufferer developed hunger and thirst, and sugar was found in the urine. The symptoms are not, however, in all instances so characteristic, for in the case recorded by Minnich the patient could not distinguish between attacks of pancreatic and those of biliary colic, he having previously repeatedly suffered from the latter affection.

In those instances in which the calculi lodged in the duct of Wirsung, causing retention of the pancreatic secretion and secondary changes in the organ, the symptoms

Digitized by Microsoft®

www.libtool.com.cn

that followed resembled those which occur in chronic pancreatitis. There are similar digestive disturbances, accompanied by loss of flesh and weight, and diabetes occasionally develops. The fat in the fæces is generally increased, and is not split up into fatty acids to the same extent as in health. Microscopic examination of the fæces will frequently show the presence of much undigested food, unaltered muscle fibres being especially numerous. In those instances in which the ducts become greatly dilated a tumor may be occasionally felt in the region of the pancreas, and when this can be done the presence of such a tumor may be considered of the utmost diagnostic importance.

Diagnosis.—The diagnosis of pancreatic colic is made by noting that the patient is suddenly seized with severe pain in the left epigastric region, the pain radiating around the lower border of the ribs to the spine on the left side, and oftentimes passing up into the left shoulder. Vomiting and glycosuria in some instances have accompanied the passage of the stone. After about two hours the pain usually ceases suddenly, and the patient develops marked hunger and thirst. From biliary colic the condition may be usually distinguished by the facts that in the former condition there is tenderness in the region of the gall-bladder, and that the pain is not confined in such a pronounced way to the left side of the body. It cannot be questioned, however, that a diagnosis between the two cannot always be made with certainty. From acute pancreatitis it is distinguished by the facts that the vomiting is not so severe, that the symptoms of collapse are not so pronounced, and that the pain ceases in the course of a comparatively short time.

In those instances in which the excretory duct of the pancreas is occluded, the symptoms will resemble those of chronic interstitial pancreatitis, though the relation of a calculus to the condition may be inferred when there is a previous history of possible pancreatic colic.

Prognosis.—In pancreatic colic the prognosis is good, as under proper exercise and diet the condition that lies at the bottom of the attacks may usually be entirely relieved.

In those instances in which the concretions have lodged in the excretory duct of the organ, the prognosis is much more unfavorable, as sooner or later chronic interstitial pancreatitis develops. In some cases, however, recovery has followed as a result of the establishment of fistulous communications with the neighboring viscera and the consequent discharge of the stone.

Treatment.—For the relief of the intense pain that accompanies the passage of a calculus, morphine should be freely administered subcutaneously; and, if necessary, ether or chloroform may be given. The application of heat to the abdominal wall may be also of considerable service. In the case of Cipriani the patient recovered under the internal administration of hydrochloric acid, a vegetable diet, baths, and gymnastics. It has also been asserted that the hypodermatic injection of 1 c.c. of a one-per-cent. solution of pilocarpine three times a week has resulted in the disappearance of attacks of pancreatic colic. After the stone has lodged in the excretory duct of the organ medical treatment is, of course, no longer of avail; but it seems highly probable that recovery in these instances would frequently follow intelligent surgical intervention.

The treatment of chronic interstitial pancreatitis resulting from the stoppage of the excretory duct of the gland is entirely symptomatic, and is in every way similar to that already recommended for a pancreas which is chronically indurated as a result of any cause whatever.

Pancreatic Cysts.

By the term pancreatic cysts is meant the presence in the organ of collections of fluids due to a variety of different causes. Fitz thinks that many reported cysts of the pancreas were circumscribed collections of fluid wholly outside of the organ.

Etiology.—Pancreatic cysts occur with about equal frequency in the two sexes, as of 121 cases of the disease operated upon by surgeons, Koerte found that 61 were males, 56 females, and in 5 the sex was not mentioned. The affection is rather more common after middle life than before, though instances have been reported in which the disease occurred in an infant six months old. As several cases have been reported in very young children, it is highly probable that pancreatic cysts are occasionally congenital, though the more frequent cause is beyond doubt the obstruction of the excretory duct of the gland. Trauma is also recognized as a frequent etiological factor in the production of cysts of the pancreas, as out of 121 cases collected by Koerte, in 33 instances the lesions had followed blows or injuries. Retention cysts which have developed from the smaller ducts of the gland—through their becoming occluded either by a constriction or by the pressure exerted by a calculus or by a tumor of some kind—are sometimes encountered. In a remarkable case reported by Durante a cyst resulted from the obstruction of the duct of Wirsung by a round worm. Parasitic cysts are sometimes likewise found. It is highly probable that in many of those instances in which pancreatic cysts are supposed to have followed injury the condition is really one of inflammation of the tissues surrounding the organ, with the accumulation of inflammatory products.

Morbid Anatomy.—Cysts may occur in any part of the pancreatic tissues, though they are most commonly encountered in the body and tail of the organ. They vary in size from those that are merely microscopic to enormous collections of liquid, an instance having been recorded in which the tumor contained fourteen quarts of fluid. The cysts may be single or multiple. Their walls are, as a rule, smooth, but in some instances papillary new formations spring from them. The inner walls of the cysts are lined by cylindrical epithelium. The fluid is usually of a clear grayish hue, and is slightly opaque, though not uncommonly it is clear and of a straw color; in a few cases, however, and particularly in those of a traumatic nature, it may be blood-stained. The reaction of the liquid is alkaline, the specific gravity varying from 1.010 to 1.024. In many instances the fluid will emulsify fat, convert starch into glucose, and digest albuminous substances, though not uncommonly, especially in older cysts, these properties are entirely wanting. Under the microscope the fluid is found to contain leucocytes, epithelial cells, cholesterin, and small drops of fat.

In many cases the tumors gradually increase in size at the expense of the parenchyma of the pancreatic structures, and this is sometimes so extreme that the gland may be practically destroyed. As the cyst enlarges it usually pushes the stomach upward and the transverse colon downward, though the latter viscus may lie directly in front of it. In rare instances the cyst lies above the lesser curvature of the stomach and pushes the organ downward; and in other cases it develops below both the stomach and the transverse colon. In some instances the walls of the cysts are firmly attached by adhesion to neighboring viscera. The cysts may rupture into the peritoneal cavity, into the stomach, or into the intestines.

Symptoms.—In quite a number of instances the first evidence of the existence of a pancreatic cyst has been the detection of a tumor-like mass in the abdominal cavity, although, as a rule, before these cysts reach a noticeable size other symptoms manifest themselves and first direct attention to them. In the traumatic cases there are usually in the beginning inflammatory symptoms, consisting of pain, vomiting, and more or less pronounced collapse. In all varieties of these cysts usually the most pronounced symptom is pain, which may occur in attacks lasting only a short time, or may be persistent and continued for weeks, months, or even years. The pains are present in the region of the pancreas, and, as in other affections of this organ, they have a tendency to radiate toward the left side, and into the left shoulder. Not uncommonly these painful paroxysms are accompanied by symptoms of deranged digestion, and

Digitized by Microsoft®

as the disease progresses the patient loses in weight and strength. As the cysts enlarge they appear as localized prominences in the upper portion of the abdomen, usually in the left hypochondriac region, though they may be present below the navel. The tumors are globular in shape, smooth, and offer considerable resistance. In most instances they are but slightly movable, and are not, as a rule, affected to any great extent by the respiratory act, but instances have been recorded in which they were pedunculated and could be moved into almost all parts of the abdominal cavity. The cysts are, of course, dull on percussion when not covered by the stomach or intestine. The pulsation of the abdominal aorta is not uncommonly transmitted, though the cysts are never expansile. On auscultation a systolic souffle may be distinctly heard in some instances. The tumor by its pressure may seriously interfere with the functions of neighboring organs in addition to its destructive action on the pancreas itself. The pressure in some instances has been so extreme that symptoms of intestinal obstruction have occurred, and jaundice in some cases has been produced. Sometimes the cyst diminishes in size, as in a case reported by Halsted, in which the girth of the abdomen decreased to the extent of twelve inches in ten days. If the entire gland be destroyed, or if its duct be so compressed that the pancreatic juices cannot be discharged, the fæces may contain considerable quantities of fat, glycosuria may be present, and the amount of indican in the urine may be decreased. Salivation, as in other diseases of the pancreas, is sometimes noted.

Diagnosis.—Cysts of the pancreas should be suspected in all cases in which successive attacks of severe pain occur in the epigastric region, especially if they be accompanied by pronounced symptoms of collapse. The diagnosis, however, must always remain problematical until a tumor is discovered in the affected region, in which case, conjoined with the symptoms just referred to, the probability of pancreatic cyst should always be considered. Should doubt exist, aspiration may be resorted to, and the fluid obtained tested for pancreatic ferments; but it should always be remembered that in quite a proportion of cases the fluids that occur in these possess no digestive properties, and on the other hand that other liquids sometimes do. From aneurism the cysts may be differentiated by the fact that even when they show pulsation it is non-expansile, and that in the knee-elbow position it entirely disappears. Collections of fluids in the pancreas may be mistaken for ovarian cysts, but may be generally diagnosed by the facts that in the latter condition the increase in the abdomen is from below upward, and that on aspiration the contents of the tumors are rarely blood-stained, do not emulsify fat, and contain no digestive ferments. Cysts of the gall-bladder differ in that they are continuous with the liver, and that on puncture the fluid found corresponds to bile rather than to the juices elaborated by the pancreas. Solid tumors may be distinguished by the fact that they contain no liquids. Cysts of the lesser peritoneum, or mesentery, are differentiated with great difficulty from like collections of fluid occurring in the pancreas, but the absence of digestive properties in the liquids removed from these situations, and the lack of symptoms indicating interference with the proper performance of the functions of the pancreas may serve to make the diagnosis clear.

Prognosis.—Cysts of the pancreas not uncommonly exist for long periods of time without producing any serious results, but they may cause marked disturbances by pressing upon the neighboring organs. Diabetes is sometimes produced by them, though this is comparatively rare. The particular danger is rupture of the cyst into the neighboring cavities.

Treatment.—Of one hundred and one cases collected by Koerte, which were opened and drained, four deaths followed as a direct result of the operation, and one case ultimately ended fatally from infection of a fistulous tract resulting. In fourteen cases the cysts were extirpated, with twelve recoveries.

New Growths of Pancreas.

Tumors of the pancreas are exceedingly rare, but the neoplasms that occur in the organ are in most instances malignant. Of the tumors that develop in the gland carcinoma is the most common, but sarcoma, adenoma, lymphoma, gumma, and tubercle are occasionally encountered. For the reason that most of the tumors that occur in the organ belong to the group of carcinomata, and inasmuch as the symptoms of other tumors of moment are practically identical with those occurring in this form of the disease, cancer will be alone considered.

Carcinoma of the Pancreas.—Notwithstanding the great amount of work that has been recently done upon the subject of the etiology of cancer, there is as yet no satisfactory explanation of its causation, and we shall therefore have to be contented with pointing out that carcinoma of the pancreas usually occurs between the ages of thirty and fifty, and that it appears to be rather more frequent in men than in women. The rarity of the condition is evident by the fact that in 36,541 post-mortems the disease was found in only 174 instances.

Morbid Anatomy.—Carcinoma of the pancreas may occur in any part of the organ, but its most frequent site is in the head of the gland. The tumor may be very soft, or, when containing much fibrous tissue, of almost cartilaginous consistency. In some instances the neoplasm is circumscribed and remains confined to one part of the organ; but in other cases it is diffused throughout the entire substance of the gland. It may be very small or quite large, sometimes attaining the size of a cocoanut. The disease does not remain confined to the pancreas, but is prone to extend into the surrounding tissues, notably into the walls of the duodenum. The lymph nodes in the vicinity are sooner or later involved, and secondary nodules may occur in the spleen or liver.

Symptoms.—Until the tumor reaches such a size that it can be palpated, the diagnosis of cancer of the pancreas is exceedingly difficult, and is indeed generally impossible, as the symptomatology of the disease in its incipiency is apt to be vague and misleading. In most cases the first manifestations of the affection are disorders of the digestive functions, which in the course of weeks or months are followed by paroxysms of epigastric pain, not uncommonly accompanied by nausea and vomiting. As the tumor increases in size the common duct is in most instances compressed, with the result that jaundice of an intense and persistent kind is induced, and on account of the retention of the bile the gall-bladder is generally greatly dilated. Jaundice sometimes develops slowly, and in other instances with suddenness. On account of the absence of the pancreatic and biliary secretions the fæces are apt to be white, and in rare instances to contain an increased amount of fat. The fæces when examined microscopically are apt to exhibit many undigested muscle fibres, even in instances in which constipation exists. In some cases the urine is found to contain sugar, and indican is said by some to be considerably diminished in amount. As the tumor increases in size it sometimes causes obstruction of the duodenum, with the result that the stomach and upper part of this viscus become considerably dilated. If it be very large it may impede the portal circulation with the production of ascites, or by pressure upon the inferior vena cava dropsy in the lower extremities may be developed. In rare cases hydronephrosis has been produced in the left kidney as a result of the compression of the left ureter. After the tumor becomes quite large it may be felt, especially if perfect relaxation of the abdominal muscles be brought about by the means of general anæsthesia. It should, however, be remembered that the tumor must be quite large in order that this may be accomplished, for it has not been palpated in more than ten per cent. of all cases in which the disease was undoubtedly present. If carcinoma exist the tumor is deeply seated, and is but slightly movable. It may or may not be tender. In some instances the neoplasm causes hemorrhage into the peritoneal cavity or into the intestine, and this may be so profuse as to

Digitized by Microsoft®

cause death. In the beginning the appetite and general health may be but little changed, and, indeed, increased hunger and thirst may occur, especially if diabetes exist. As the disease progresses the patient, as is usual in all forms of carcinoma, becomes anæmic and loses flesh, which condition may be extreme in the latter stages of the affection. The temperature is apt to be somewhat below the normal.

www.libtool.com.cn

Diagnosis.—Carcinoma of the pancreas is most likely to be mistaken for carcinoma of one of the neighboring viscera—the liver, the transverse colon, the pyloric end of the stomach, or the duodenum. From carcinoma of the liver it is distinguished by the facts that in the former condition the disease is in almost all instances secondary to cancer of some of the other abdominal viscera, that it is often associated with enlargement of the liver, and that an ascites frequently exists. The tumor in cancer of the liver is situated somewhat higher up than are those of the pancreas, and it is, as a rule, more easily movable. In both diseases jaundice occurs, but is much more common in cancer of the pancreas. In cancer of the transverse colon obstinate constipation as a result of the obstruction usually exists, and this is generally associated with the production of a large amount of indican, quantities of which appear in the urine. In these cases the tumor is more superficial, and is more frequently movable, and the disease is not accompanied by jaundice. In cancer of the pyloric end of the stomach there is commonly a history of intense pain developing an hour or so after taking food, and examination usually reveals the fact that the stomach is greatly dilated, contains much lactic acid, and but little hydrochloric acid. Not uncommonly it will be found that the patient suffering with this malady has vomited blood freely, and jaundice is not so apt to be present. From cancer of the duodenum it is practically impossible to distinguish carcinoma of the pancreas, as the two conditions commonly give rise to symptoms in every way similar. Cancer arising in either of these situations is, moreover, very apt to extend to the other. The symptoms of cancer of the pancreas that are of greatest diagnostic importance are the presence of a deeply seated but slightly movable tumor in the situation normally occupied by the head of the gland, the existence of intense and persistent jaundice, pain in the affected region, rapid emaciation and loss of strength, diminished excretion of indican in the urine, and especially the presence of sugar in this excretion. The absence of the pancreatic juice in the intestine, according to Mueller, results in the diminished splitting up of the fats ingested, and this, if true, in all probability will prove of much value in enabling us to make the diagnosis in obscure cases. For the reason that salol, when taken by the stomach, is decomposed only in the presence of the pancreatic secretion, the absence of carbolic acid in the urine after the administration of full doses of this drug points to obstructive lesions of the excretory ducts—a condition which is usually present in carcinoma of the organ.

Prognosis.—When surgical interference is not invoked, death in practically all instances results from carcinoma of the pancreas, but the practicability of removing tumors from this organ has been recently clearly shown; and in cases in which the diagnosis can be made early enough, the operation would offer some hope for the life of the patient.

Treatment.—As we have no drugs that act specifically on carcinomatous processes, treatment is to be entirely of a symptomatic kind. Diastases and small pieces of raw pancreas may be administered with the food with advantage, but the only effect that can follow this is an improvement in the digestive functions. In the early stages an operation may be the means of saving the patient's life, as, according to Koerte, recovery has followed in several cases of this kind after the removal of the tumor.

PANCREAS. (SURGICAL.)—ANATOMICAL CONSIDERATIONS.—The pancreas lies transversely across the upper part of the abdominal cavity, behind the stomach, on a level with the first and second lumbar vertebræ, and three inches above the umbilicus. The head is contained in the loop of the duodenum, the body lies on the crura of the diaphragm. To the left the posterior surface is in contact with the left kidney and suprarenal capsule. The tail touches the lower part of the inner surface of the spleen. Its average length is from five to six inches, and it weighs from two and a half to three and a half ounces.

The blood supply is from the splenic artery and from the inferior mesenteric and hepatic by the inferior and superior pancreatico-duodenal arteries. The blood is returned into the portal vein by means of the splenic and superior mesenteric veins.

The lymphatics terminate in two glands which lie on the superior mesenteric artery. The nerves are branches of the solar plexus which accompany the arteries entering the gland.

The pancreas is a compound racemose gland, soft in texture, and of a pinkish-cream color (Morris [1]).

The secretion of the pancreas is carried by short canals or ducts to the main duct, the duct of Wirsung, which they join at nearly right angles. The duct of Wirsung turns down through the head of the pancreas and opens into the second portion of the duodenum, together with the common bile duct. The lesser duct, or duct of Santorini, collects the secretion from a portion of the neck and head of the pancreas, and opens into the duodenum 2.5 to 3.5 cm. nearer the stomach. Brewer [2] states that the older anatomists were wrong in teaching that the duct of Santorini, or smaller duct, usually atrophied; according to him it is practically always present in the human subject.

The pancreas is developed between the two layers of the posterior mesentery from two offshoots from the intestinal tube just below the gastric dilatation. Brewer [2] calls especial attention to the fact that the pancreas is at this time completely invested by peritoneum, "and only becomes a retroperitoneal organ by the absorption and conversion, into areolar tissue and fat, of the several layers of the posterior mesentery." He then draws attention to the fact that the areolar tissue surrounding the pancreas is continuous with that surrounding the left kidney and the areolar tissue lying behind the colon on the left side.

ACCESSORY PANCREAS.—Tieken states that fourteen cases of accessory pancreas have been reported. This results from lack of fusion of the separate diverticulums. These accessory glands may be found in the walls of the stomach or duodenum, or in the mesentery. It has been suggested that these accessory glands may cause diverticulums of the intestine. They have

Digitized by Microsoft®

been found at the tips of such processes. The "pancreas minus" is merely an accessory pancreatic lobule springing from the head of the main gland and it usually extends along the wall of the duodenum. Hyatt

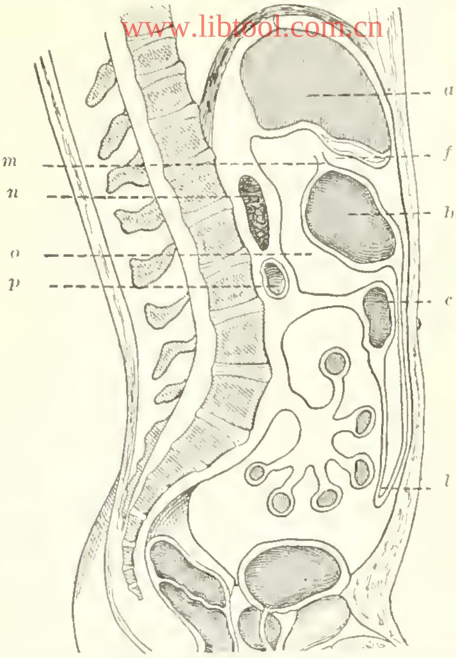

FIG. 3730.—Shows the Normal Relations of the Pancreas to the Stomach, Colon and Peritoneum, as they Appear in a Longitudinal Antero-Posterior Section of the Trunk. (From Kehr.) *a*, Liver; *b*, stomach; *c*, transverse colon; *f*, foramen of Winslow; *l*, omentum; *m*, omentum minus; *n*, pancreas; *o*, bursa omentalis; *p*, duodenum.

speaks of a partial division of the gland by the mesenteric vessels during development. The most important surgical anomaly is described by Tieken as follows: The neck was of normal size, the head somewhat enlarged. "From the head two bands of glandular substance extend forward in such a manner as to surround the lower part of the descending duodenum, forming a complete ring about its circumference. . . . The duodenum is greatly constricted at this portion, and admits the tip of the index finger with difficulty. . . . The duodenum above the constriction is greatly dilated, forming a sacculation nearly one-half the size of the stomach." Similar cases have been reported by Ecker,[10] Auberg,[11] Symington,[12] and Genersich.[13]

"The anatomical relations of the common bile duct and the duct of Wirsung are well known. The common bile duct descends toward the duodenum alongside the head of the pancreas, occasionally embedded in its substance, and comes in contact with the duct of Wirsung, beside which it lies for a short but variable distance before entering the wall of the intestine. The two ducts penetrate, side by side, the coats of the duodenum, and after passing obliquely a distance of about 2 cm. and causing a papilla-like elevation of the mucous membrane, unite to form a short cavity—the diverticulum of Vater. Near its termination at a point where the two ducts are in contact, the common duct becomes constricted, and it is here that a foreign body passing downward, tends to lodge" (Opie[3]).

Both ducts may enter the duodenum independently of each other and the hepatic duct. In one case the duct of Santorini entered the stomach.

The pancreas is a fixed organ and does not descend during forced inspiration. Nevertheless, it has been found in diaphragmatic hernias, in congenital umbilical hernias, and in Band's[4] case the duodenum, pancreas, and a portion of the ileum and colon were invaginated into the descending colon.

Total extirpation of the pancreas in animals is usually followed by true diabetes, and partial extirpation by temporary or alimentary diabetes.

Persistence of fat in the stools in the absence of jaundice and diarrhœa is an indication of disease of the pancreas, particularly when accompanied by great emaciation.

TRAUMATISM.—The pancreas, from its position, is seldom injured alone. The liver, stomach, and transverse colon lie in front, and if the liver should happen to be enlarged and if the stomach and colon should be full at the time when the injury occurred, the pancreas could hardly escape a frontal attack. It might possibly be injured from behind from a penetrating wound or from a fractured vertebra. On the other hand, the pancreas, as mentioned by Robson,[5] is soft in consistence and easily bruised. The lobules are not well supported as in the parotid. Blows upon the abdomen or a kick or a fall against a hard object may, under certain circumstances, injure the pancreas. Robson relates the case of a butler who slipped and fell against a knife board projecting from the end of a table at which he was working. The blow was not severe, the man did not even fall to the ground, but acute hemorrhagic pancreatitis followed and the patient died. An exploration for peritonitis followed by an autopsy, revealed the true cause of death. Generally the neighboring organs, the stomach, colon, liver, spleen, and lungs are injured at the same time.

The diagnosis of injury to the pancreas alone is impossible. It can only be inferred from the nature of the accident and from symptoms of shock and hemorrhage. After the abdomen is opened, injuries to neighboring organs will probably be found in addition to that of the pancreas. If the pancreas is torn, an attempt should be made to close the rent by stitches. Hemorrhage may be controlled by gauze packing. It is obviously inadvisable to ligature the superior mesenteric artery. Repair may take place; cysts may subsequently develop. Gangrene of the pancreas has followed injury to the parenchyma.

Perforating wounds of the pancreas are not common. Koerte has collected six cases. They generally result from gunshot or stab wounds, and are nearly always fatal from the complications, such as injuries to the stomach, spleen, lungs, or liver. A definite diagnosis can be made only by an exploratory incision. If the compli-

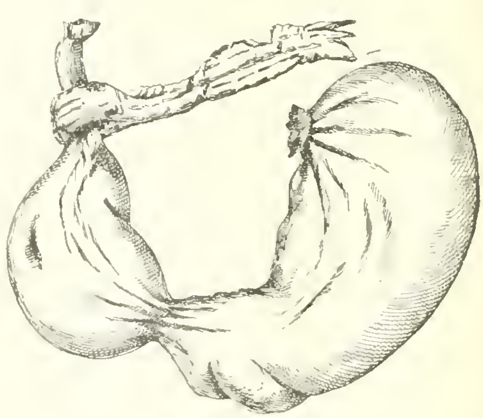

FIG. 3731. Annular Pancreas with Sacculation of the Duodenum. (From Tieken.)

cating injuries and the condition of the patient permit, the wound in the pancreas might be closed. The most perfect asepsis should be attained.

Prolapse of the pancreas is difficult to understand, but cases are reported by Kehr.[4] The tail is the most movable part of the organ. It may be replaced and main-

Digitized by Microsoft®

tained in position, until adhesions have formed, by sterilized gauze packing.

As hemorrhage of the pancreas (or pancreatic apoplexy), acute hemorrhagic pancreatitis, and fat necrosis, are affections which belong to the domain of the physician rather than to that of the surgeon, the reader is referred, for information with regard to them, to the article immediately preceding this.

www.libtool.com.cn

Necrosis of the Pancreas.—Necrosis or gangrene of the pancreas may result from different causes. The whole gland may necrose, but more frequently the necrosis involves only a portion. The tail and body are often involved in this process. In other cases the affected areas are numerous and small. The necrotic area may be infolded by peritoneum and ultimately an abscess may form at this point. In two cases reported by Chiari recovery ensued after a portion of the pancreas had been passed per rectum. "In other cases the pancreas is converted into a dark, slaty-colored mass lying nearly free in the omental cavity or attached by a few shreds" (Osler).

The causes of necrosis are to be found in inflammatory suppuration and hemorrhagic conditions of the pancreas itself. It may arise from infections entering from the intestine or through a perforating ulcer of the stomach, as in a case reported by Chiari.[20] Syphilitic disease of the blood-vessels and arteriosclerosis are also assigned as causes. Fitz and Koerte have reported about forty cases. A fatal ending is common.

Symptoms.—Many pathological lesions of the upper abdominal region are closely simulated by necrosis or gangrene of the pancreas. A very careful study of the clinical history may throw light on the case. Perforating ulcer of the stomach, gall-stone colic, or perforation of the bile passages may give rise to similar symptoms. A diagnosis of intestinal obstruction has been made on several occasions and laparotomies have been performed without, of course, revealing any obstruction. Pain, tenderness, vomiting, and collapse are present in severe cases, and later, with the formation of pus around the necrotic area, there will probably be an intermittent temperature, a dry tongue, and a feeble pulse. If the patient survives there may develop such complications as peritonitis, pulmonary embolism, metastatic pleurisy, pericarditis, leptomeningitis, and pyæmia. The different courses taken by the pus after abscess for mation will be referred to under Suppurative Pancreatitis.

Diagnosis.—A definite diagnosis is possible only after a portion of the necrotic pancreas has been passed per rectum or found by exploratory incision. Kidney lesions might be excluded by an examination of the urine.

Treatment.—During the acute stage but little can be done except to relieve pain; and, if collapse is present, stimulants may be administered judiciously. After encapsulation and pus formation have taken place, surgical interference may be indicated. The abscess may be approached from behind, through the loin or through the pleura, or by an anterior incision through the abdominal wall. Some patients remain well, but diabetes has occasionally developed a year or two afterward.

Acute Suppurative Pancreatitis.—In 1688 Blancard reported finding small abscesses in the pancreas of a child that had died of variola, and cases have been described in increasing number during recent years. Osler[14] has analyzed 46 cases; of these 28 were men and 11 were women. The age was given in 30 cases. The greatest number occurred between the ages of twenty and fifty, the largest number, 11, between twenty-one and thirty. There may be one or innumerable abscesses. Several small ones may coalesce and form one large abscess. In 24 cases there was a single abscess and in 14 numerous small ones (Osler).

The causes are divided, by Dieckhoff, into three groups. In the first the infection is brought to the pancreas by the blood stream; in the second, the infection comes from some adjacent focus, as, for example, the base of a stomach ulcer which has become adherent to the pancreas before perforating; in the third, the infection passes in from the duodenum through the ducts of Wirsung or Santorini. It is now quite generally thought that the cause is an infection. The colon bacillus, first found by Welch in the pancreatic ducts, and many varieties of micro-organisms, are now known to be present in the pus. In some cases there is a history of gastroduodenal derangements and of pancreatic and of biliary calculi. Thrombosis of the portal and splenic veins with abscess formation in the liver and spleen are not uncommon. The spleen may not be enlarged even when the splenic vein is obliterated. Inflammation of the peritoneum in the immediate neighborhood is common, that of the peritoneum below the transverse colon rare. When that covering the diaphragm is involved the inflammation may extend to the pleura and pericardium (Fitz).

The abscess formation is seldom confined to within the capsule of the pancreas. Outside the pancreas the pus may collect between the layers of the mesentery or omentum, or in the lesser peritoneal cavity (the foramen of Winslow being closed), or it may extend back into the loins. Sometimes it burrows down behind the descending colon to the pelvis (Koerte). Fat necrosis is rare in suppurative pancreatitis (Fitz).

Symptoms.—The onset is generally sudden and characterized by severe pain in the epigastrium. The pain and tenderness may be referred to one or the other side of the median line if the lesion is limited to the tail or head of the organ. In some cases there is no pain. Vomiting is usually present. There may be constipation or diarrhœa, sometimes colliquative. The temperature varies. Absence of fever is rare. Chills are frequently present. According to Fitz more or less jaundice is present in one-fourth of the cases. Albumin and sugar in the urine are sometimes found, but fat in the stools seldom.

Koerte in four of his cases observed a grayish-brown discoloration of the skin. In one case Bloodgood[22] observed a leucocytosis of 19,000, tumor formation, blood and pus in the stools.

Diagnosis.—The diagnosis of an abscess confined within the pancreas is impossible. The symptoms are not distinctive. The discovery of a tumor in the pancreatic region is suggestive. If by inflating the stomach and transverse colon it can be demonstrated that the tumor lies between them and is free from either, it would be evidence of pancreatic origin. The absence of any clinical history of gastric or duodenal ulcer and the presence of a history of gall-stones would be suggestive. Fluctuation is seldom to be directly made out. If there is bulging in one loin and an examination of the urine gives no evidence of kidney lesion, Koerte thinks it might be justifiable to use an exploratory needle. The diagnosis is generally made by an exploratory incision.

Kehr[23] states that in the great majority of cases the course is chronic. Cases are reported which have run a course of nearly a year. On the other hand, some cases are very acute and end fatally within a few days. Abscess may be said to be always fatal unless the pus escapes spontaneously into the stomach or intestine, or is evacuated by the surgeon. Koerte[24] emptied these abscesses through an incision in the loin and in other instances by anterior incision. The lumbar incision is to be chosen when there are indications that the pus is near the kidney. The anterior incision should generally be made in the middle line. If, however, a palpable tumor lies to one side, the incision is best made over the prominence. If the anterior wall of the sac is adherent to the anterior abdominal wall the cavity may be washed out and packed with gauze; otherwise great care should be taken to prevent the spread of infection by careful packing with sterilized gauze pads. If possible the wall should be sutured to the abdominal incision. If this is not feasible careful packing with gauze around a large drainage tube, or the building of a drainage canal from omentum, is the only resource. The operations are very simple. If, however, the abscess is confined within the capsule of the pancreas, the operation, as remarked by Boeckel,[25] is more delicate, laborious, and restrained; delicate, because the pancreas is deeply situated and is surrounded by numerous important vessels the wounding or ligaturing of which might prove

Digitized by Microsoft®

fatal (superior mesentericus); and restricted, because only a small portion of the pancreas can be removed with safety and freedom from the danger of a fatal diabetes.

CHRONIC PANCREATITIS.—Although suppurative pancreatitis may run a slow and chronic course, the term chronic pancreatitis is used to designate a hardening of the pancreas, with enlargement or shrinking. Perhaps the terms hypertrophic cirrhosis and atrophic cirrhosis would be appropriate. A part or the whole of the gland may be involved. Opie[26] recognizes two varieties. In the interlobular form the inflammatory process is localized chiefly at the periphery of the lobule; in the interacinar the process is diffuse, involving the lobules and separating individual acini. Of great interest is the relation of chronic pancreatitis to the islands of Langerhans and the occurrence of diabetes. The islands of Langerhans, as defined by Opie, are composed of cells having the same origin as those of glandular acini, but forming structures which are independent of the secreting apparatus, and in intimate relation with the vessels. In the splenic end of the cat's pancreas they have a definite position within the lobule, each of which contains one of those structures. In the human pancreas they are more numerous in the splenic extremity than elsewhere. Opie claims that prolonged stimulation of the gland does not, as claimed by Lewaschen, transform groups of acini into islands of Langerhans.

In the interlobular variety of chronic pancreatitis the islands of Langerhans do not usually suffer, nor do they when the infective agents come by way of the ducts with which they are not connected. In the intralobular or interacinar variety they may atrophy as the result of pressure. In this way the presence or absence of sugar in the urine in diseases of the pancreas may perhaps be explained.

Etiology.—The causes of chronic pancreatitis are not satisfactorily determined. They are probably varied. Undoubtedly localized indurations may arise from lesions of the neighboring organs, such as ulcer of the stomach or duodenum. A general involvement of the gland may result from hæmatogenous infection, from a mild form of acute pancreatitis, from diseases of the blood-vessels, or from obliterating endarteritis. Opie[26] reports two instances of congenital syphilitic pancreatitis in which the patients died respectively three and four hours after birth. In one of the cases it was believed that the disease represented an active stage of a chronic inflammatory process; in the other the process was more advanced and was no longer active. The islands of Langerhans were surrounded by newly formed stroma, but in neither case were they invaded by it.

Clinical experience would seem to indicate that in the majority of cases the condition arises from an infection entering through the ducts, secondary to a gastroduodenal catarrh and a complete or partial stasis of the flow of the pancreatic secretion. Numerous operating surgeons have noticed the frequent association of pancreatitis with cholelithiasis. The pancreatic duct may be completely or partially obstructed by a gall stone or a pancreatic stone; the result may be either a narrowing or an obstructive dilatation. The enlargement and hardness found at the operating table have often given rise to a diagnosis of malignant disease. Alcohol has been thought to be a cause. The disease seldom occurs in drunkards, and when it does it is probably secondary to a gastroduodenal catarrh. It may follow mild traumatism.

Pathological Anatomy.—The characteristic picture is the fibrous thickening of the connective tissue generally throughout the gland or only in limited areas. The head of the pancreas may be much enlarged and of stony hardness. In other instances the gland is diminished in size from contraction of the interstitial tissue. The surface is sometimes smooth and sometimes nodular and of a gray color. There may be an associated condition of fatty or calcareous degeneration. The duct of Wirsung may be dilated, tortuous, or of normal appearance.

Symptoms.—There are no pathognomonic symptoms of chronic pancreatitis. Its presence has usually been discovered during operations or in the autopsy room. Disorders of digestion, pyrosis, vomiting, pain and tenderness in the epigastrium, constipation or diarrhœa, and emaciation are the symptoms usually present and they are certainly not distinctive. There may or may not be some elevation of temperature. Icterus may be present if the common bile duct is pressed upon. Sugar may be present in the urine. Fat in the stools is rare and lipuria still more rare. Walker has shown "that the absence of pancreatic secretion from the intestine, although bile were present in the intestinal canal, led to pale-colored stools." Mr. Cammidge has found "that if the urine of patients suffering from pancreatic disease be boiled for a short time with an oxidizing agent and then the phenyl hydrazin test performed, an abundant crop of delicate yellow needles arranged in sheaves and rosettes was produced" (Robson[5]). A histological examination of the blood may show marked diminution in the number of blood plates. The presence of a hard, palpable, immovable tumor in the region of the pancreas would be a very important symptom.

Prognosis.—The prognosis is grave. Many patients, however, known to be the subjects of chronic pancreatitis, live for years in good health, and the same remark is true of patients who have lost a part of their pancreas through suppuration and necrosis. Experiments upon animals harmonize with clinical experience; some animals can live with one-tenth of their pancreas. The association of syphilis, arteriosclerosis, or obstructive heart lesions would render the prognosis less favorable.

Treatment.—"The treatment of chronic pancreatitis is by abdominal section and drainage; but in this case the drainage is indirect and is obtained by draining the gall-bladder by cholecystotomy, cholecystenterostomy, or duodenocholedochotomy. The exact line of treatment cannot be determined until the abdomen is opened, and for this purpose I prefer, as in all my gall-bladder operations, a vertical incision through the upper part of the right rectus, splitting that muscle to whatever extent is necessary in order to obtain a good view of the diseased region, and to afford plenty of room for manipulation.

"If merely cholecystotomy on a distended gall-bladder is necessary, an incision of one or two inches will suffice; but if the gall-bladder be contracted or if the ducts have to be attacked, an incision of from four to six inches will be required; and if the several layers of the abdominal wall are sutured separately, there is no fear of subsequent hernia. This I can affirm by ample experience. It saves much unnecessary dragging on the parts when operating on the common duct or duodenum to have a free incision, and there is no retractor equal to the hand of a skilled assistant, who with a flat sponge interposed between the spread-out fingers of his left hand and the viscera, will at the same time afford the operator a good view of the field of operation, and with his right hand help in the further steps of the operation.

"If the right costal margin or the edge of the liver be obstructing the view, another assistant may with advantage retract it either by digital manipulation or by means of a wide retractor with a long handle, so that he can stand back a little and avoid embarrassing the operator.

"As a matter of experience I seldom find a second assistant necessary. A sponge in the pouch to the right of the common duct, and one pushed down over the right kidney, help to catch all escaping fluids and to keep the peritoneum clean. When the ducts or the duodenum are opened, sterilized gauze pads are employed to mop up the fluid as it escapes, but none of these is allowed to remain even temporarily in the abdomen. When there are gall-stones present they should be removed, unless the patient is too ill to permit of the complete operation; but in every case drainage must be secured, if possible by cholecystotomy, as in nearly all my successful cases. Moreover, the drainage must not be stopped before the bile has become healthy, and not before the greater amount of bile is being passed by the bowel, which will be certain to occur as soon as the swollen pancreas has subsided, if the duct be otherwise clear of obstruction.

www.libtool.com.cn
Digitized by Microsoft®

"It might be thought that cholecystenterostomy would be the ideal operation in these cases, but experience says that it is not; for instance, in one of my cases the operation brought so much relief that a cure was being anticipated, yet in the third month relapse occurred and death ensued, apparently simply owing to closure of the new opening between the gall-bladder and duodenum. In one of Mr. Barling's cases in which the gall-bladder was joined to the duodenum, he states 'that although the symptoms were relieved, enlargement of the pancreas persisted.'

"Possibly in some cases the manipulations of the indurated tumor may have detached calculi impacted in the pancreatic duct, and thus led to a subsidence of the pancreatitis, then to an opening of the common duct by the relief of tension, and so to a cure of the patient. The simulation of malignant disease of the head of the pancreas by chronic interstitial pancreatitis would make one hesitate to decline operation in any case of distended gall-bladder, where the patient is in a condition to bear it, or even in any case of chronic jaundice without distention of the gall-bladder, where the general strength is deteriorating as, though it should be recognized that if the disease be really malignant, very little good will be done, and life may even be shortened or only prolonged for a short time; yet if the disease prove to be chronic pancreatitis, a real and permanent cure may be brought about. If a calculus be felt embedded in the head of the pancreas or impacted in the pancreatic duct, it may be reached through the second part of the duodenum by laying open the papilla and exploring the duct, or by dividing the peritoneum passing between the duodenum and hepatic flexure of the colon, and then cutting through the overlying pancreas on to the concretion. If the papilla common to the bile and pancreatic ducts be incised in the duodenum, it does not require suture; and in the cases in which I have explored the ducts by the duodenal route there has been no serious hemorrhage. The anterior duodenal opening only requires closing by a mucous and serous suture. Drainage of the right kidney pouch for from twenty-four to forty-eight hours is advisable, though not always necessary, and this is best done by a stab wound at the most dependent part.

"The result of treatment in this class of cases has been most encouraging, as out of twenty-two cases operated on only one died directly from the operation, and in that case the patient's life was only very slightly shortened, since he was reduced to the last stage of exhaustion before surgical operation was sought. Of those recovering from operation, with the exception of two who died a few months later, complete and perfect recovery ensued. These results contrast very markedly with the surgical treatment of cancer of the pancreas, where nearly half of the cases operated on have died directly as the result of the operation, and in those who have survived life has only been prolonged for a comparatively short time."

The above is from Mayo Robson's address before the American Surgical Association in 1901.

Another very important point has been raised by Mr. Robson, and that is the tendency to troublesome hemorrhage during operation in cases of chronic pancreatitis, particularly when associated with jaundice. This was at one time thought to be due to the cholæmia. The suggestion that it is due to the glycerin set free in fat necrosis is not generally accepted. He has found the exhibition of chloride of calcium most useful as a prophylactic. He administers calcium chloride in thirty- to sixty-grain doses, thrice daily, for from twenty-four to forty-eight hours previous to operation; and by enema in sixty-grain doses, thrice daily for forty-eight hours afterward. This he nearly always finds successful in correcting the hemorrhagic tendency.

The close association of pancreatitis and angiocholitis is confirmed by Ferguson, of Edinburgh, who observed in cases of death that he could express a few drops of pus from the duct of Wirsung. It would seem that the indirect drainage of the pancreatic ducts was as rational and successful as drainage of the bile pasages in infective conditions. Kehr has suggested an anastomosis between the intestine and the duct of Wirsung. The technique would be very difficult.

Cystic Tumors of the Pancreas.—Cysts of the pancreas are rare; their nature and origin are obscure. It may be said that probably the majority are retention cysts. The most common cause is generally thought to be chronic indurative pancreatitis. The connective tissue in some part of the gland so presses upon or so distorts the excretory duct that the outflow from a part of the gland is arrested. Senn thinks that in addition there is an alteration in the character of the secretion whereby it becomes no longer absorbable. Another cause may be the obstruction of the duct of Wirsung from pressure of neighboring organs, as for instance from a stone in the common bile duct, or from an obstructive swelling of the duodenum at the point where the duct enters. A catarrhal inflammation of the duct of Wirsung may cause obstruction. A new growth in the head of the pancreas may act similarly.

Minier suggests that cystic degeneration may occur in the pancreas in much the same way that it does in the kidney, testicle, and mammary gland. That cysts may result from hemorrhages into the pancreas is not yet proven. The frequent finding of blood in the cyst contents has suggested this cause. It is probable that small hemorrhages may be entirely absorbed, leaving only a pigmented stain (Orth). On the other hand, it is quite probable that hemorrhages may occur into cystic tumors, and it is generally thought that most bloody cystic tumors of the pancreas are in origin retention cysts. Trauma is also assigned as a cause. Cysts are more frequent in the tail than in the body or head of the pancreas. In an analysis of 134 cases Osler[14] found in 90 cases that the situation was not given; in 14 that the whole pancreas was involved; in 15 the tail; in 11 the head; in 4 the body. Koerte[27] states that of 121 cases operated upon by surgeons, 60 were in males and 56 in females; in 5 the sex was not given. Sixty-six of the cases occurred in the fourth decade.

There may be multiple cysts. This should be borne in mind when considering the prognosis and possibility of recurrence. Pancreatic cysts vary greatly in size. Those found in autopsy rooms are usually comparatively small. Surgeons report, however, that some of the cysts contain from 1 to 20 litres. The fluid is generally of a light-brown coffee or reddish-brown color, seldom clear (Osler). Gussenbauer found in the fluid altered red and white blood cells and pigment. Fresh blood has also been found. The chemical reaction as a rule is alkaline, but may be neutral or acid, with a specific gravity of 1.007–1.028.

The lining of the cyst wall may be smooth or sacculated; it is generally surrounded by blood-vessels. In developing the cyst may assume very variable relations to adjacent organs, particularly the liver, stomach, and transverse colon. It may lie behind and push forward the stomach; it may project between the stomach and liver; it may appear between the stomach and transverse colon, or lie behind the colon. The displacement of these organs is sometimes very great. In one instance the transverse colon was pushed down behind the symphysis pubis. Besides the displacement and dragging of the viscera mentioned, other serious complications may arise from the pressure of the tumor. The common bile duct may be so pressed upon that jaundice results. Pressure may cause obstruction of the duodenum or ureter, and cases are reported of pressure resulting in ascites.

There are no symptoms which can be called characteristic of cystic tumor of the pancreas so long as it remains small and not palpable. As might be expected, from what is known of its etiology, there is generally a history of indigestion, of indiscretion in eating and drinking, and occasionally of trauma. Pain in the epigastric region is common, its severity depending on the situation of the tumor and its rate of growth. There may be nausea and vomiting. The vomitus may contain blood if it occurs subsequently to rupture of a cyst into the stomach. If

Digitized by Microsoft®

rupture into the intestine occurs, blood may appear in the stools. There is sometimes very great and rapid loss of weight. Pancreatic salivation (increased flow of saliva) is rare. Sugar in the urine would indicate very extensive

www.libtool.com.cn

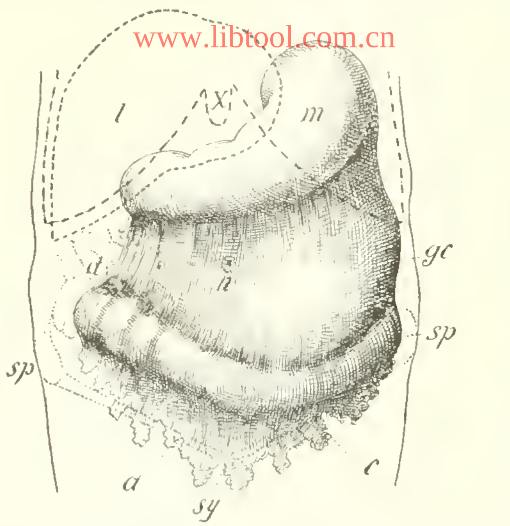

FIG. 3732.—Showing the Appearances which were Presented, in a Case of Large Pancreatic Cyst, when the Abdomen was Opened and its Contents Freely Exposed to View. The cyst, in its growth, had forced its way forward between the stomach and the colon, and was putting the ligamentum gastrocolicum upon the stretch. (After H. Kehr.)

cirrhosis of the gland. Fat in the stools is seldom found. Icterus may result from pressure. The development of a palpable tumor is the most suggestive symptom. The discovery of ferments in the sac contents is noted.

Diagnosis.—Clearly a cyst of the pancreas can be recognized only after it has reached a size that can be palpated. A palpable cyst is the most easily diagnosed of all the diseases of this deeply situated gland. The presence of a fixed fluctuating tumor in the median line above or below the umbilicus should certainly suggest pancreatic cyst.

The first fact to be clearly established is the relation of the tumor to the adjoining viscera, especially to the stomach, colon, and intestines. The inflation of the stomach and colon with air or gas will give great assistance in the determination of this relationship. If the cyst has passed forward between the stomach and colon, pushing before it the gastrocolic omentum, a clear percussion note should be heard above and below the tumor if it is a large one; and if it is small, the distended stomach and colon may meet together in front of it. If the tumor projects forward below the liver and above the stomach, the dull percussion note of the liver may be continuous with that of the tumor. The difficulty of differentiating a pancreatic cyst thus placed from a distended gall-bladder or an echinococcus cyst, or other fluid collection connected with the liver, would be very great, and probably could be accomplished only by examination of the contents removed by a Pravaz syringe. Possibly by examining the patient in the erect position, a line of tympany could be found between the liver and cyst. A pancreatic cyst would not move during inspiration or expiration.

If the tumor projected forward below the colon, the dull note of the tumor should be easily elicited between the tympany of the colon above and that of the small intestines below.

It may grow behind and push forward the stomach, or it may pass forward between the layers of the mesocolon, in which case the stomach or colon would lie immediately in front of the tumor. When so situated it is generally possible, after inflation, to establish the mobility and freedom of the stomach or colon from involvement in the body of the tumor.

The differential diagnosis between a cystic tumor of the pancreas and a solid tumor of the spleen should not be difficult. To differentiate a cyst springing from the tail of the pancreas from an echinococcus cyst of the spleen—the only cystic growth involving the spleen—may be very difficult, and perhaps impossible except by an examination of the cyst contents.

Great difficulty may be found in differentiating between a pancreatic cyst and hydronephrosis. In hydronephrosis the bulging is generally in the lumbar region. There may also be a history of renal colic, of the passage of a renal calculus or blood, or other urinary derangement. An examination of the urine may throw light on the case. A cystoscopic examination of the bladder might show that no urine was entering from that side.

From large ovarian cysts the history should show that the growth began low down and laterally. Cysts of the mesentery are movable. Aneurisms of the aorta or its branches are pulsating and expansile.

The aspiration of cysts for diagnostic purposes is a questionable procedure. There is always a danger of puncturing a flattened-out overlying viscus, of wounding some abnormally placed vessel—and the walls of a pancreatic cyst are sometimes very vascular,—or of permitting the escape of infective contents,—as, for instance, hooklets in the case of echinococcus cysts,—or of pathogenic organisms. An exploratory incision is now so safe that it is to be recommended as an almost universal rule in place of puncture. When the fluid is obtained, its examination may be far from satisfactory. The ferments may be present, but diastatic and fat-emulsifying ferments occur in various other exudates. The only positive sign would be the presence of the ferment which digests fibrin and albumin, and it is often absent. The presence of blood would be very suggestive. It occurs, however, in ovarian cysts with a twisted pedicle. Küster thinks the presence of fat globules is characteristic of

pancreatic cyst. "A remarkable feature often noticed has been the transitory disappearance of the cyst. In Halsted's case the girth of the abdomen decreased from

Digitized by Microsoft®

forty-three to thirty-one inches in ten days, with profuse diarrhœa. Sometimes the disappearance has followed blows" (Osler).

Prognosis.—The rapidity of the growth of pancreatic cysts is difficult to ascertain, because the date of their commencement can seldom be determined. They are

www.libtool.com.cn

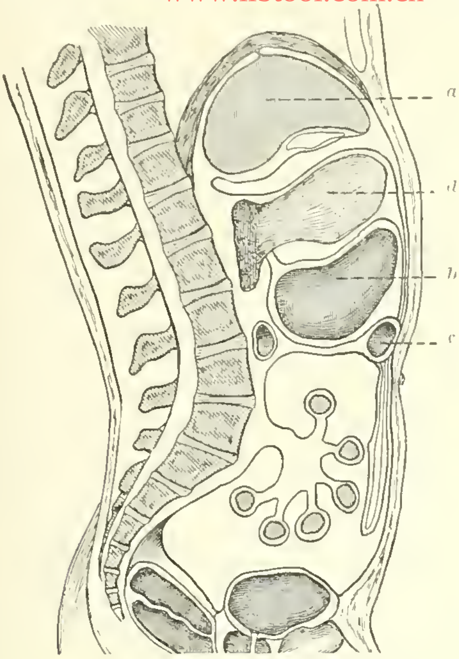

FIG. 3734.—Shows the Relations which the Pancreatic Cyst Bears to the Neighboring Organs in a Smaller Group of Cases. (From Kehr.) *a*, Liver; *b*, stomach; *c*, transverse colon; *d*, pancreatic cyst.

probably of slow growth as a rule. When following trauma or acute inflammatory processes, however, they may develop into palpable tumors in two or three weeks. Their duration is also uncertain; instances of their being present for thirty or forty years are reported. They sometimes rupture spontaneously into the stomach or intestine, as evidenced by the vomiting, or passage by rectum, of a quantity of bloody fluid. Their occasional disappearance and reappearance may possibly be explained by the assumption that in this way they periodically empty themselves into the stomach or intestine. Echinococcus cyst of the spleen is very rare. One case is reported by Heller. Rupture of a pancreatic cyst may occur into the peritoneal cavity.

Treatment.—Medical treatment is useless. Preventive treatment can influence only the most common cause of cyst development, viz., chronic indurative pancreatitis. The surgical methods which have been adopted are, puncture, application of caustics to the cystic cavity, emptying of the cyst and stitching of the cyst wall to the abdominal incision at one or two operations, opening and drainage of the cyst through a lumbar incision, and excision of the cyst wall, partially or wholly.

Puncture of the sac is to be condemned for the reasons given in the paragraph on diagnosis, and because it is insufficient.

The application of caustic to the interior of the sac wall in the case reported proved fatal.

The method which has been employed in the greatest number of cases is that first adopted by Gussenbauer, viz., the opening and emptying of the sac followed by immediate suture to the edges of the abdominal incision and drainage by means of gauze or drainage tube, or both. The incision is best made over the most prominent part of the tumor. The cyst wall should be very carefully uncovered, as far as possible, by blunt dissection. Great care should be exercised in the ligature of overlying vessels, that none essential to the blood supply of the colon are interfered with. The wall of the sac is sometimes very thin and must be handled gently.

After carefully protecting the peritoneum by the placement of sterile gauze pads, the cyst may be incised or punctured with a trocar having a tube attached to convey the fluid into a receptacle. After the cyst wall is stitched to the abdominal incision the cavity should be packed with strips of plain sterilized gauze; iodoform gauze is to be avoided, as there is a possibility of iodoform intoxication. The fluid that escapes tends to irritate and digest the skin. This should be prevented by a liberal use of zinc ointment. Boeckel[25] reports ninety-nine cases treated by this method, with ninety-two recoveries and seven deaths.

The subsequent history of these cases in some respects is satisfactory. The nutrition improves wonderfully and quickly, although pancreatic juice may continue to flow from the wound. There is sometimes great difficulty in getting the fistula to close. If it does not close in five or six weeks it may remain open for years. When the opening persists, closure may be effected by the application of nitrate of silver or chloride of zinc.

The above method carried out in two stages has not been adopted in as many cases, but the results have been very good. Boeckel[25] reports sixteen cases and sixteen cures.

Drainage through a lumbar incision is indicated only in those cases in which the cyst lies far back in the loin. An anterior exploratory incision may show this to be the best route by which to approach the tumor.

Complete excision of the sac wall, while perhaps the ideal method, is possible only when the sac wall is well

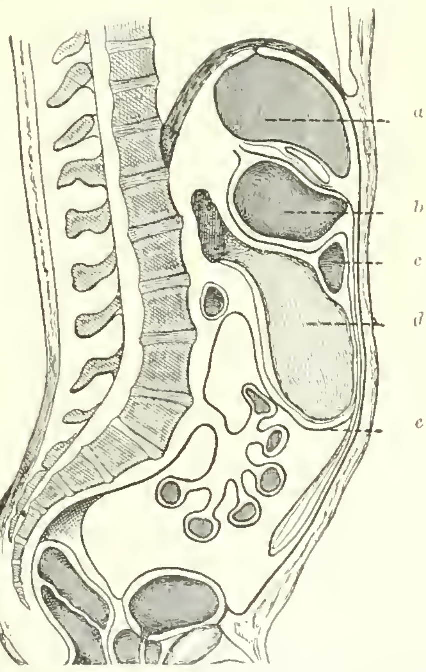

FIG. 3735.—Represents a Case in which the Pancreatic Cyst has Developed between the Laminæ of the Mesocolon, coming Forward between the Transverse Colon and the Small Intestines. (From Kehr.) *a*, Liver; *b*, stomach; *c*, transverse colon; *d*, pancreatic cyst.

defined and not too closely united by adhesions to the neighboring organs. If the cyst is pedunculated, its total extirpation might be indicated. The difficulty arises in dealing with the adhesions, the blood vessels, and the point of origin from the pancreas. The vessels are generally numerous and large. Another great diffi-

Digitized by Microsoft®

culty is to avoid injuring or tearing vessels essential to the nourishment of the colon. Koerte has collected 21 cases with 6 deaths. In 7 cases the difficulties were so great that the operation could not be completed; of these, 4 died. Boeckel reports 25 cases of total or partial excision, with 21 cured and 4 deaths. If the sac is excised, the space from which it has been removed should be packed with gauze and drained through the abdominal

www.libtool.com.cn

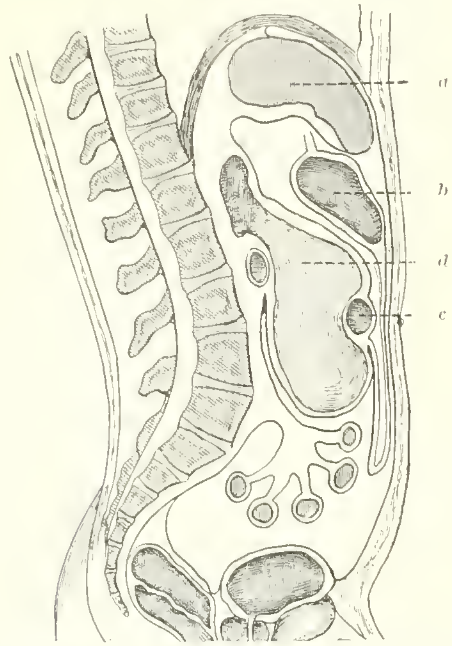

Fig. 3736.—Shows the Cyst Developed Between the Laminæ of the Transverse Mesocolon. The colon lies directly in front of the cyst. (From Kehr.) *a*, Liver; *b*, stomach; *c*, transverse colon; *d*, pancreatic cyst.

incision, or through a stab wound in the loin. It may be said that excision should be undertaken in favorable cases only, when adhesions are absent or are easily separated by blunt dissection, and when the blood-vessels involved in the sac wall are small and unimportant. It is certainly a much more grave operation than the simple incision and drainage of the sac.

Tumors of the Pancreas.—Tubercle, gumma, lymphoma, and sarcoma may occur in the pancreas, but they are very rare. Primary carcinoma of the pancreas is stated by Willigk and Lebert to occur in about six per cent. of all cases. It is more frequently found in the head than in the tail or body of the gland. The most common variety is scirrhus.

The *symptoms* are at first exceedingly indefinite. Later, fatty diarrhœa and vomiting occur, with tenderness on pressure over the gland. Jaundice is an early symptom, and is more persistent and less variable from day to day than when due to stone. The stools are persistently clay-colored. In obstruction from stone the color may vary. Diabetes is seldom present. An important diagnostic point, according to Courvoisier and Ecklin, is the condition of the gall-bladder. In stone the gall-bladder is usually small and shrunken, while in carcinoma it may be very much distended and palpable as a tumor. When stone and carcinoma exist together the difficulties in diagnosis are very great. An examination under an anæsthetic should be of great assistance. Emaciation is rapid and extreme. A palpable tumor is seldom found until the disease and its attendant emaciation are well advanced. The examination of the stomach contents, together with the comparatively good functionating power of that organ, should enable one to exclude carcinoma of the stomach. The tumor sometimes becomes adherent to the stomach, and in some cases the disease has perforated the stomach wall. Hæmatemesis might give evidence of this complication.

Treatment.—The treatment of carcinoma is most difficult and unsatisfactory. In the primary course of the disease the diagnosis is wellnigh impossible. If the disease is localized in the tail, its removal may in favorable cases be feasible; but extirpation of the whole gland, even if the patient recovered from the operation, would be followed by a fatal diabetes. Extirpation of the head of the gland presents technical difficulties that are almost insurmountable. There is the danger of injuring the vessels necessary for the nourishment of the colon, duodenum, and spleen; and if both of the pancreatic ducts are tied, diabetes and atrophy of the remaining gland tissue follow. There is also the difficulty of dealing with the common bile duct. Cholecystotomy may give relief from the icterus; and if there is great pressure on the duodenum, a gastro-enterostomy would relieve the obstructive symptoms, vomiting and inanition. Koerte reports ten cases of operation on solid tumors of the pancreas with six recoveries.

Pancreatic Calculi.—Pancreatic calculi may be single or multiple. They are composed of carbonate of lime and phosphates. In shape they may be round, oval, or angular, and in color an opaque white. Osler states that in one thousand autopsies at the Johns Hopkins Hospital there were two cases. In 1885 Johnston collected thirty-five cases in the literature. They had been found in the pancreatic ducts and in pancreatic cysts and abscesses.

As to their *ætiology* but little is known. They may result from inspissation of the secretion or from an obstruction in the ducts, or be due to some undetermined action of bacteria. Probably, as in the liver, both slowing or obstruction in the outflow of the secretion and bacterial infection are etiological factors.

The results are found in the gland itself. They are: inflammatory indurations, cyst and abscess formation, a predisposition to the development of malignant disease, and obstruction to the common bile duct from pressure upon, or the blocking of, the ampulla of Vater at the duodenal opening.

A definite *diagnosis* is seldom possible. The pain could not be differentiated from gall-stone colic. Pain in the left hypochondrium is thought to be suggestive of pancreatic calculus. Pain, vomiting, fatty stools, diabetes, and the passage of carbonate of lime stones would render the diagnosis probable. Carbonate of lime calculi, however, are sometimes formed in the intestines.

A stone might be removed from a cyst or abscess or from a dilated duct. If jaundice is present and the obstruction cannot be found and removed, cholecystotomy would be indicated. *George E. Armstrong.*

PANCREATIN.—Pancreatinum. "A mixture of the enzymes naturally existing in the pancreas of warm-blooded animals, usually obtained from the fresh pancreas of the hog (Sus scrofa Linné; class, Mammalia; order, Pachydermata). A yellowish, yellowish-white, or grayish amorphous powder, odorless, or having a faint, peculiar, not unpleasant odor, and a somewhat meat-like taste.

"Slowly and almost completely soluble in water, insoluble in alcohol.

"Pancreatin digests albuminoids, and converts starch into sugar; prolonged contact with mineral acids renders it inert.

"If there be added to 100 c.c. of tepid water contained in a flask, 0.28 gm. of pancreatin and 1.5 gm. of sodium bicarbonate, and afterward 400 c.c. of fresh cow's milk previously heated to 38° C. (100.4° F.), and if this mixture be maintained at the same temperature for thirty minutes, the milk should be so completely peptonized that if a small portion of it be transferred to a test tube and mixed with some nitric acid, no coagulation should occur.

"Peptonized milk, prepared in the manner just described, or even when the process is allowed to go on to the development of a very distinct bitter flavor, should not have an odor suggestive of rancidity."

The pancreas contains four distinct enzymes which are known by their action: the proteolytic—trypsin; the diastasic—amylopsin or diastase; the milk-curdling; and the fat-splitting. No one of these ferments has been isolated. The proteolytic enzyme converts proteids with equal or greater facility than pepsin, but it differs from pepsin in respect to the media in which it exerts its activity, and also in respect to the final products of its action. Trypsin bears no relation to an alkaline medium which corresponds to the dependence of pepsin upon acid; it acts with equal facility in a neutral or a faintly alkaline medium. Alkalies, more particularly sodium carbonate or bicarbonate, up to one per cent. of the digesting mass, are generally stated to be most favorable to the action of trypsin: the writer, however, has not found in digestion in vitro that sodium bicarbonate in 0.1 per cent. to 1 per cent. has given better results than parallel tests in which the alkali was omitted, while more than traces of free alkali were found unfavorable. Trypsin in antiseptic solutions (with thymol) containing as small an amount as 0.1 per cent. anhydrous sodium carbonate, has been found to undergo rapid deterioration at ordinary room temperature. While the pancreas juice obtained from living animals is alkaline, the pancreas gland, as soon as it may be conveniently treated upon removal from the recently killed animal, will be found to give an acid reaction. Aqueous infusions, glycerin or hydro-alcoholic extract, from such gland are invariably acid to litmus, and the acid present in these solutions does not in the slightest degree interfere with the pancreas enzymes in vitro; this acidity is reasonably to be attributed to nucleic acid, and undoubtedly the proteid is bound up in the cell with acid. The ash is invariably acid, containing phosphoric acid and potash, presumably acid phosphate. Minute percentages of mineral (0.03 per cent. HCl) and organic (0.25 per cent. acetic) acids do not interfere with the action of trypsin, but have been observed slightly to enhance it. Furthermore, the latent mother ferment, trypsinogen, is developed by the influence of the acid constituents of the gastric juice, and probably likewise of foodstuffs, for in the treatment of the gland itself it is found that the addition of minute amounts of organic acids yields the ferment in an active form from the trypsinogen. Trypsin, however, is very sensitive to more than traces of free mineral acid, 0.1 per cent. to 0.15 per cent. HCl destroying it immediately, and subsequent neutralization failing to revive it. So far, therefore, as may be gathered from these facts there is no evidence in support of the impression which has gained so much credence—that pancreatin depends upon an alkali for activity or in any way bears such a relation to an alkali as pepsin does to acid.

Trypsin converts native proteids into soluble and diffusible forms of albumoses and peptones which differ in no known way from those derived from peptic action, and causes by prolonged digestion a further cleavage of these proteids into simpler nitrogenous bodies—the amido-acids, leucin, tyrosin, etc., and hexone bases, ammonia, etc. Recent researches have led to the opinion that the development of these proteids into these crystalline bodies is essential to their complete utilization in nutrition.

Trypsin exhibits a special affinity for the digestion of certain native forms of proteids—fibrin, muscular tissue, both raw and cooked; these are promptly digested by the trypsin, whereas its action upon coagulated egg albumen is very slow in comparison with that of pepsin.

The products of peptic digestion (those intermediary between raw proteid and true peptone, syntonin and albumoses) are likewise, after neutralization, quickly converted into peptone by trypsin. Rapidity of action seems to be the natural function of trypsin. It exhibits a peculiar affinity for the casein of milk, as natively existing in milk, peptonizing this proteid with great celerity without the intervention of an alkali.

Certain differences in the physical phenomena observed in tryptic and peptic digestion have led some to suppose that trypsin exerts a peculiar erosive action. The swelling of tissue, the gelatinous character which fibrin almost instantly assumes under pepsin acid digestion, is not to be accounted for by any peculiar action of the pepsin itself; it is due to the influence of the hydrochloric acid which combines with raw proteins to form syntonin—this being very penetrable by the enzyme. In fact, one is struck with the similarity in adaptation to digestion, between gelatinous starch and this swollen, gelatinous fibrin. Boiled albumen presents no visible difference in its digestion with trypsin or with pepsin, for the acid does not swell the coagulated albumen. Trypsin (like pepsin) acts only by effecting the solution of the surface exposed—by conversion into more soluble forms.

A peculiar effect of trypsin upon milk is the conversion of casein into a form which becomes coagulable at the boiling point. This partially peptonized casein has been termed "metacasein," which, upon more complete conversion, loses its coagulability. This behavior of milk has been suggested (Roberts) as a convenient means of testing the activity of pancreatin, simply by ascertaining under certain conditions the time at which this "onset" point of conversion occurs. This is an extremely interesting reaction, and significant of the peculiar nature of casein, which, unlike other forms of native proteid, is not coagulable by heat, probably owing to its peculiar combination with inorganic constituents, losing this characteristic, after a certain amount of digestion and again becoming non-coagulable like other peptonized proteids. By rendering milk slightly alkaline by the addition of sodium bicarbonate or potassium bicarbonate, this metacasein reaction is prevented, and the milk then at any period of peptonization may be heated to the boiling point without curdling.

The starch-converting ferment of pancreatin, commonly known both as amylopsin and as diastase, very rapidly liquefies starch paste, converting starch into maltose. Raw or uncooked starch is similarly converted, though less rapidly, the action being proportionate to the diffusion of the starch, to the surface presented to the digestive ferment, completely cooked gelatinous starch being with great facility brought into complete contact.

The products of pancreas digestion of starch are apparently identical with those of diastase from other sources—the achroo-dextrins, dextrins, and maltose. Amylopsin is extremely susceptible to the influence of chemical reagents. Its action is not enhanced in the slightest degree in alkaline media; indeed, it is greatly enfeebled by free alkali; it is also weakened by acids (mineral and organic) beyond a very slight percentage. Acids which tend to promote the development of trypsin exhibit no corresponding behavior on amylopsin. In vitro, in neutral media, or as found in its normal association with the acids of the pancreas gland or in extracts or

Digitized by Microsoft®

infusions therefrom, amylopsin exerts enormous energy in the conversion of starch. It no doubt exists preformed in the pancreas gland, and there is ground for the belief that it differs in its constitution from the proteolytic enzymes.

www.libtool.com.cn

The fat-splitting or emulsifying ferment of pancreatin (steapsin or lipase) is the most delicate of the enzymes; it is rapidly destroyed by all acids, except the fatty, and by strong alcohol. Steapsin rapidly liberates the fatty acids, and this can be very readily observed by the addition of a few drops of a neutral solution of pancreatin to a neutral solution of butter in ether, to which a little litmus has been added. The nature of the ferment, its susceptibility, and the so far insuperable difficulty of separating it in any degree from the other ferments of the gland, complicate its study and have precluded the establishment of accurate, conclusive data concerning it.

The coagulating ferment behaves in a manner similar to that of the rennet. When added in a sufficient quantity to pure milk at a temperature of 100° F., the characteristic milk curd is almost instantly formed. This casein curd, however, is not permanent, and cannot be separated so freely as that obtained by the action of rennet; if the milk be maintained at an ordinary temperature the trypsin will rapidly attack the casein, and by stirring the mass, solution can be readily effected.

The milk-curdling ferment often escapes detection owing to the rapid peptonizing action of trypsin upon the casein.

Although pancreatin is officially defined as "a mixture of the enzymes naturally existing in the pancreas," no official test is given for other than the proteolytic ferment, and this is determined by its action on milk under conditions which are approximate to those commonly employed in the preparation of peptonized milk. The provision against the development of rancidity in peptonized milk is especially important, for pancreatin, which produces this result, is distinctly objectionable,—it yields a milk which is unfit for food, especially for the sick.

The term "pancreatine" in the past has been applied to indefinite preparations of the pancreas and more often identified with the emulsifying ferment—the function of the gland which was first observed and thought to be its chief and important characteristic. The official adoption of this title, however, now makes it applicable only to a product which contains all the pancreas enzymes. This of course is in distinct opposition to scientific nomenclature of the enzymes, for the term might best be applied to some one particular ferment, in conformity with the use of pepsin for the proteolytic ferment of the stomach.

"Pancreatine" was originally applied to the starch-converting agent of the pancreas juice by Bouchardat and Sandras, to the ferment obtained by them from infusion of pancreas with water and precipitated with alcohol.

The pancreatic enzymes, certainly the proteolytic, amylolytic, and curdling, are freely soluble in water, and are readily extracted from the gland by infusion, by dilute glycerin, by hydro-alcoholic menstrua. It is not possible, however, to prepare a liquid extract of the gland which will retain for any lengthy period all the several, chief enzymic properties of the pancreas. Whatever the reaction of the mingled ferment solution may be whether due to the fresh gland acid constituents or to added acid or alkali, the diastase especially loses its activity. This will either be due to unfavorable reaction or to the influence of the trypsin, should the conditions be favorable for its action. The pancreatic liquors (originally suggested by Roberts) have not been found by any means so effective and agreeable and convenient for general purposes, especially for the peptonization of food, as the extract in a dry form. The activity of pancreatin, whether in a dry or a liquid form, simple or in combination with other agents, is readily tested by applying it to the digestion of proteids in an alkaline medium (a procedure which differentiates tryptic action from that of pepsin); and its effect upon starch may be tested by the very simple method which establishes the presence of diastase,—by its action on starch mucilage at 100° F. The proteolytic ferment may be tested upon fibrin or milk, using the United States Pharmacopœia test. Negative reaction in any respect with these tests is absolute evidence of the absence of the ferment which is thus to be indicated.

Pancreatin is so susceptible to change and enfeeblement that it should not be prescribed in solution with soluble chemical agents—mineral acids or alkalies. Pepsin-acid solutions are particularly incompatible with pancreatin; even that degree of acid which is suitable for the preservation of the pepsin weakens the activity of the pancreatin, and this is increased by the influence of the pepsin, under the commercial conditions to which a pharmaceutical product must be submitted, and for which it must be suitable by a reasonable degree of permanency. Alkaline agents are indicated and freely prescribed with pancreatin, and this is best accomplished in dry mixtures—tablets, capsules, powders, etc. While in certain conditions, for instance, in the peptonizing process, the salts of the alkalies (sodium bicarbonate, etc.) fulfil a useful purpose, alkaline solutions of pancreatin do not retain their activity at ordinary temperature; they are suitable only for immediate use.

The liquid preparations of the pancreas gland, therefore, should as a rule be prescribed alone, separate from the remedies to be used in association. In the dry form, however, complete freedom of combination of any remedy indicated is afforded, for the dry enzymes are very stable.

The whole relation of the enzymes of the different digestive glands mixed in artificial solutions may perhaps best be summed up by this fact: that the ferment for which the reaction of the solution is most favorable will exert an injurious action upon the other enzymes; in other words, the *active* enzyme-proteid will convert the other enzyme-proteids which are in the unfavorable environment.

Therefore, from a pharmaceutical standpoint, we have to keep strictly to the ascertainment of conditions which are favorable to the extraction and production of these enzymes in a form of reasonable stability, and to the avoidance of incompatibles, these being simply agents which are positively known to injure the ferment in vitro; and to the adoption of certain definite standards of activity, and the development of proper methods for utilizing their digestive properties either in laboratory operations or in the artificial digestion of peptonized food for the sick. It must be ever considered that these data do not by any means offer a clear picture of, or arbitrary conclusion as to, the relation of the enzymes in the whole digestive scheme, where the enzymes in natural association are mingled under exceedingly complex conditions; first as to the influence of the constituents of the juices on the several enzymes thereof; secondly as to the influence of each secretion in its entirety upon the other, and as to the influence of the food constituents in their native form and as converted by gradual and successive digestive changes.

The study of the enzymes in vitro and of the entire digestive secretions warrants the conclusion that the ferments bear a different relation to, and influence upon, each other when mixed together simply with water and with reactions obtained by acids or alkalies, than they do in their physiological interaction. For instance, pancreatin will continue to act in an alkaline medium in the presence of food, and pepsin will continue to act for a long time in the presence of acid albumin, while aqueous solutions of these ferments of the same degree respectively of alkalinity and acidity by simple exposure to ordinary conditions of temperature are rapidly deteriorated.

Pawlow, after his recent elaborate and original studies of the digestive secretions, calls especial attention to the importance of his experiments concerning the "interaction of the digestive juices." He says: "Hence the chemical agencies of digestion form an alliance of a complicated nature in which the individual members are linked together mutually to relieve and support each other"; and he insists that it is indispensable in physio-

Digitized by Microsoft®

logical inquiry to bring into view the "whole train of normal occurrences"; that "to constantly remember that all parts of the organism work together sheds a bright light over the special field under review."

No official method is given for pancreatin. It is commonly obtained by mechanical and chemical means—by the precipitation of an infusion, or a mixture of the pancreas gland with water freed as much as possible from the fat and connective tissue by mechanical means, this mixed with alcohol in excess, and the precipitate collected, expressed, and dried. Pancreatin is also prepared from the animal pancreas by freeing the gland in so far as possible from connective tissue and fat by careful trimming, reducing to pulp, passing through a sieve, desiccating and powdering, and further purifying by extraction with suitable solvents of fat, coloring matter, etc.

A liquid diastasic extract of the gland may be obtained by treating the pancreas as soon as possible after removal from the animal, the gland meanwhile kept refrigerated, in which state the trypsinogen remains unchanged; rapid extraction and clarification yield the amylopsin in an exceedingly active form, and by repeated filtration an agreeable, efficient pharmaceutical product is finally obtained.

Pancreatin as a remedy in intestinal indigestion is usually administered in two- to five-grain doses, about three and a half hours after meals and at bedtime, in capsules or tablet form. It is also given with soda bicarbonate (ten grains) an hour or so before breakfast or at bedtime, taken in a glassful of water as hot as can be conveniently sipped, say, 115°–130° F., this particularly in catarrhal conditions and in biliousness. Pancreatic extract with oxgall, ipecac, and bismuth has gained repute in disorders of intestinal digestion. The elixir or essence of amylopsin is much used as a remedy in salivary or intestinal indigestion; in the former case it is given immediately before food, or mixed at table with farinaceous food. Inasmuch as the full pitch of gastric acidity does not appear until about half an hour after eating, this diastase certainly has the same physiological conditions for its activity as that normally mingled with the food in the saliva. The diastasic essence is given at the completion of stomach digestion to promote intestinal starch digestion.

In the artificial reinforcement by pancreatic ferments, the essential consideration is obviously to protect them from action *in gastro;* and clinical experience, with the various expedients used, has shown that the pancreatic ferments exert distinctly beneficial action.

The pancreatic ferments are peculiarly and happily fitted for the preparation of partially or completely digested foods for the sick; under their influence and by very simple means and methods, the chief and complete foods of almost every variety are readily peptonized in the household. These foods may be so prepared as to convey the ferments in an active form, thus promoting further digestion, or the digestive agent may be destroyed at any desired stage by raising the temperature of the food to 160° F., or, more simply, to the boiling point.

Special products and devices, such as peptonizing tubes, are much used; milk, either cold or by the warm process, is thus adapted to the varying requirements. The peptonized milk gruel deserves more extensive use, as the simultaneously converted farinaceous foods—wheat, arrowroot, etc.—increase the nutritive value and convey a very agreeable taste, masking that of the milk. Porridge of oatmeal, wheat, etc., is easily made more digestible by adding, at the proper temperature, a small quantity of the diastasic essence to a portion as served at the table; for the aged and for infants this is an efficient method. (See also article on *Dietetics.*)

Trypsin as a surgical solvent is peculiarly serviceable in cases in which acid is undesirable or alkali necessary; in such situations, and where fluid cannot readily be kept in contact, the trypsin powder is preferable, adhering as it does to moist surfaces, and being thus exceedingly active; in nasal diseases, in diseases of the throat, urethra, etc., the trypsin powder is successfully applied. By its use in diphtheria, great relief is often afforded to the distressing local manifestations, in addition of course to the specific constitutional treatment. The pancreatic extract has been used with marked success as a solvent in abscess cavities of the liver, hip joint disease, etc.

Trypsin is used as the essential agent in the preparation of an artificial human or humanized milk from cow's milk, for the reason that cow's milk proteids, under the regulated influence of the enzyme, become practically identical in solubility with the proteids of human milk; in consequence of this change a cow's milk mixture with percentage composition adjusted to the standard of human milk becomes notably thinner, of a grayish-yellow color, and acquires a marked resemblance to human milk in physical and physiological characteristics and deportment with all reagents. This milk so converted by trypsin gives minute, diffusible coagula with gastric juice, and with acid of normal gastric percentage; it corresponds in digestibility in vitro to human milk with pepsin and acid, and is not coagulated by rennet. The enzyme itself, as the physiological factor in the process, is instantly destroyed by simply heating the milk to 160° F. or by boiling it after the enzymic action has been utilized; the enzyme thus becomes so much inert proteid, so minute in amount as to be a negligible quantity in the food and quite incapable of in any way influencing the digestibility of the milk.

This use of the enzyme in infant feeding is based on the unquestionable postulate, confirmed by all data, chemical, physiological, and clinical, that the radical difference in digestibility and deportment between cow's and human is milk attributable to the nature of their respective proteids—largely casein in cow's milk, and soluble, non-coagulable peptone-like proteids in human milk; it is also based upon comparative analyses and observations of this humanized milk and many specimens of average, normal human milk. Theoretical objections based upon presumed defects in this method, as presenting a food unnaturally digestible or conveying a digestive agent, are obviously erroneous in view of the foregoing facts. The enzyme may, however, be so used as to secure a degree of digestibility beyond the normal where this is required, by simply prolonging the subjection of the casein to the proteolytic agent or the enzyme administered in the food, by chilling the milk instead of pasteurizing or sterilizing it when the desired degree of digestion is accomplished. In fact, this is like the use of the enzyme as a means of aiding the digestion of mother's milk itself by giving pancreatin in a few one-grain doses immediately after nursing.

Benjamin T. Fairchild.

PANCREON is a combination of pancreatin with tannic acid, said by Gockel to possess the tryptic, amylolytic, and emulsifying powers of pancreatin, but to be unaffected by the gastric juice. Out of 100 gm. of albumin subjected to the action of 1 gm. of pancreon for fifteen minutes at 40° C. (104° F.) in a weak alkaline medium, 85 gm. were digested. The dose of pancreon is 0.3–0.5 gm. (gr. v.–viij.) three times a day.

W. A. Bastedo.

PAPAW JUICE.—*Papaya. Carica.* The milk juice obtained from the nearly ripe fruit of *Carica Papaya* L. (fam. *Papayaceæ*).

This interesting plant is the well-known melon tree of tropical America, now widely introduced into other tropical countries. All of its parts contain a latex or milk juice, which is more abundant and more milky in the nearly ripe fruit than elsewhere. This milk juice possesses a bitterish and very acrid taste, is irritant to mucous membrane or to the abraded skin, and has considerable detergent power. It possesses the property of peptonizing albuminous substances, after the manner of trypsin, and of softening an additional portion which is not truly peptonized. By reason of its possessing this property, it has been largely used in its own home for application to tough meat to render it more palatable and

Digitized by Microsoft®

www.libtool.com.cn

digestible, a fact which has led to its examination by chemists and physicians with a view of determining its availability for use as a digestant. Its digestant principle has eluded isolation, as have all similar substances. It has been found possible, however, to concentrate the activity in a peculiar extract called caricin (Moncorvo), papain (Wurtz), or papayotin (Peckolt), which is extracted with water, the solution filtered and the filtrate precipitated with alcohol, and perhaps again dissolved and reprecipitated for somewhat further concentration. The fresh juice, which consists largely of water, yields also considerable resin, divisible into two portions, nearly five per cent. of a kind of caoutchouc, a little fat, malic acid, leucin, tyrosin, and other unimportant matters. The leaves, from which the papain can also be obtained, yield the crystalline alkaloid *carpaine* ($C_{14}H_{25}NO_2$), which is most abundant in the young leaves, constituting about one-fourth of one per cent. of their weight when dried. The seeds, which are pungent and which are used for their tænicidal properties, contain a resin which shares the pungency, though the latter is said to be due to a volatile principle allied to the volatile oil of mustard.

Action and Uses. Since about the year 1880, great attention has been given in Europe and America to attempts to employ papain as a digestant. Reports as to the energy, and even as to the manner of its action, vary most widely, even when presented by careful experimenters, and the conviction is forced that the market preparations employed by them must have differed in character. It appears very likely that some of these preparations were mixtures of different digestive ferments, the results being such as might be expected from an admixture to the papain of pancreatin or pepsin. Much of the information which has been supplied to physicians, and which has found its way into professional journals and books, has been smuggled under the guise of scientific literature from interested commercial sources.

It has been definitely established that as a digestant papaya is wholly proteolytic. It disintegrates, softens, and liquefies albumen in the form of white of egg, musculin, fibrin, and casein, and considerable of the product is peptonized. This action takes place in an alkaline or neutral medium. Davis (1893) and Hobein (1894) have shown that it is inactive in an acid medium, the papain employed by the second-named authority having been prepared by himself from papaya. Fairchild, using specimens the identity and purity of which were authenticated by himself, has fully confirmed this conclusion. Nevertheless, some eminent authorities claim that there is a slight activity in acid media. Dr. Lafayette B. Mendel, who takes this view and who has made special researches in this direction, has furnished us with the following account of the products of papain digestion:

"The products of the reaction of papain with proteids consist in large part of proteoses. Peptones—*i.e.*, compounds not precipitable with ammonium sulphate, but still giving the biuret reaction—are also formed. The papain proteoses resemble the related products obtained by gastric digestion. Regarding the occurrence of further products of proteolysis, such as leucin, tyrosin, tryptophan, and other characteristic derivatives of tryptic digestion the evidence is somewhat uncertain. Underhill and the writer have usually failed to find leucin, tyrosin, and tryptophan in appreciable quantities, at least under conditions in which they are readily formed in large quantities by other tryptic enzymes. Emmerling has succeeded in isolating small quantities of these substances from the products formed after very prolonged digestion, although even under such conditions proteoses predominate. Papain accordingly resembles trypsin in dissolving proteids in media of various reactions, thus differing from pepsin; its resemblance to the latter lies in the similarity of the products formed by the two enzymes. Harlay has made comparable observations with the enzyme of the related *Carica hastifolia*. Kurajeff has found that commercial preparations of papain induce the formation of peculiar proteid precipitates in solutions of proteoses such as the widely used 'Witte-pepton.' The reaction corresponds with that described for rennin as 'plastein formation,' by Danilewski and his co-workers. The importance of this proteid-clotting or precipitating function of enzymes can only be conjectured at present. Thus it may play a rôle in proteid synthesis and regeneration; and the significance of such an enzyme in plants at once becomes apparent. On milk papain preparations exercise a clotting or curdling action. Whether these properties are all due to the same enzyme, or whether more than one unorganized ferment is present in the plant, are questions which have not yet been settled."

Riedel, who in 1894 made a very elaborate series of experiments to determine the most favorable conditions for the activity of papain, concluded that the most favorable temperature was about that of the body; that one part of papain to one hundred of albumin was the most favorable proportion; that the more concentrated the papain solution the greater the activity, and that the capacity of papain for digesting egg albumen was about one hundred times its own weight. The answer to the last question depends naturally upon the degree of concentration of the papain; yet it has been found impossible to carry this concentration more than a little way. The activity of a definite portion of the dried papaw juice itself is much greater than that of the papain extracted from it; a single instance is recorded in which such a juice, very carefully prepared, digested one thousand times its own weight. The difficulty is that this action is extremely variable; so much so that it is not at all probable that commercial dried papaw juice could ever be brought to a uniform standard of strength.

As a general statement, it may be said that a good average sample of papain is capable of digesting from fifty to one hundred times its own weight of albumen, under favorable conditions. It is also very noteworthy that it loses its power rapidly upon being kept. If kept with ordinary care in well-stoppered vials it will ordinarily have but little value at the end of a year.

As to whether papain possesses any diastasic action in the conversion of starch, we have also discordant reports, but are obliged to conclude that it has none. As to its milk-curdling power, it certainly possesses a small and variable degree; but this is of a peculiar character, the process and the coagulum differing distinctly from those resulting from the use of rennet.

Papaya is a powerful irritant to denuded tissues and to mucous membrane. So powerful is this action that if a large amount be taken into the stomach in concentrated form it acts as an irritant, or even as a caustic emetico-cathartic poison. Applied to a raw surface it acts as an escharotic, and is very apt to be followed by putrefactive processes. Papain, prepared as above described, is less active in this direction, though still irritant. Desjardins states that the irritant property is almost completely destroyed by boiling, which also produces a new substance, having a powerful lumbricidal action, similar to that of the seeds.

The principal native use of papaya has been stated above. Owing to its locally stimulant action, it has also been used as a cosmetic, to remove pimples and similar roughnesses from the skin, and to produce a smooth, healthy surface. Its irritant properties have been utilized in the form of caustic applications to cancerous and other morbid tissues, but the practice cannot be considered good. Its dissolving action upon albuminous substances has been utilized by applying it to diphtheritic membranes. For this purpose a five-per-cent. solution, preferably made alkaline with 0.5 per cent. of bicarbonate of soda or potash, is applied at short intervals with a brush, or in the form of a spray. The results appear to be highly irregular and uncertain. A similar solution, but twice as strong, is applied to warts, corns, and other cutaneous indurations. Almost its entire use in Europe and America is for internal administration as a digestant, either alone or combined with other ferments. Owing to its irritant effect it should be administered when the

Digitized by Microsoft®

stomach is full of food, and dilution with milk-sugar or other neutral substance is desirable. Opinions differ widely as to the dose, but the best evidence is in favor of the use of a considerably larger dose than that of official pepsin. Where there is an irritable condition of stomach or bowels, the dose should be reduced, and the drug should not be used in case of an inflammatory condition of those organs.

Allied Drugs.—The juice of the fruit and leaves of the pineapple has similar properties and uses, already referred to under *Bromeliaceæ*. *Henry H. Rusby.*

PARA-ACET-AMIDO-PHENOL ETHYL CARBONATE, a tasteless, white, crystalline powder, insoluble in water and readily soluble in alcohol, is administered in dosage of 0.5 gm. (gr. viij.) as an antipyretic, analgesic, and hypnotic. *W. A. Bastedo.*

PARA-CHLORALOSE. See *Chloralose*.

PARACHOLIA.—The term used by Pick to designate the hypothetical secretion-anomaly by which the bile leaves its accustomed channels and passes into the blood, giving rise to icterus. By a number of recent writers icterus is regarded as due to a diseased condition of the liver cells, the process being analogous to the secretion of albumin in diseased conditions of the kidney cells. Normal liver cells should secrete bile into the bile vessels, and urea and sugar into the blood capillaries. According to Minkowski it is, therefore, not without analogy that the liver cells in diseased conditions should give off the bile into the blood-vessels. Such a process is designated by him as *parapedesis*. Liebermeister and Pick also explain many forms of icterus as due to functional disturbances of the liver cells, either with or without evident anatomical changes, the former designating such a disturbance as *diffusion* or *akathectic icterus*, the latter as *paracholia*. Pick believes that the pathogenesis of the obscure forms of icterus may be explained by this hypothesis. He accordingly distinguishes three classes: *nervous paracholia*, *toxic paracholia*, and *infectious paracholia* (*Wiener klin. Wochen.*, 1894). *Aldred Scott Warthin.*

PARADISE SPRING.—Cumberland County, Maine. Post-Office.—Brunswick. Hotels and inns.

This spring is located about one mile from the centre of the village of Brunswick and five hundred feet from the Androscoggin River. It is reached by way of the Maine Central Railroad to Brunswick, and thence by Jordan Avenue. The country about the place is level—a sandy plain, covered by pines extending to beautiful Casco Bay, three miles distant. Concerning the meteorological conditions prevailing about Brunswick, we are indebted to Prof. Leslie A. Lee, of Bowdoin College, for the following description: "The climate of Brunswick is peculiarly agreeable. Fair weather predominates, the annual number of cloudy days averaging not more than eighty-six in a long period of years. The prevailing winds are from the southwest during the summer and from the northwest during the winter. On this account the air is much drier than would be expected from the proximity of the village to the sea, and fogs rarely occur."

Scattered throughout the town are large areas of pine forests, which give a resinous and balmy quality to the air. The average annual temperature is 44.40° F., rising to an average of 65.11° F. in the summer, and falling to a mean of 22.63° F. in the winter. The temperature of the spring water is about 45° in summer and 43° F. in winter. The outflow of water is abundant, being estimated at twelve thousand gallons per day. The following analysis was made by Prof. Henry Carmichael, of Bowdoin College: Reaction neutral. One United States gallon contains: Silica, gr. 0.38; iron oxide, a marked trace; calcium sulphate, gr. 0.06; calcium carbonate, gr. 0.07; magnesium carbonate, gr. 0.06; sodium chloride, gr. 0.02; sodium carbonate, gr. 0.36; potassium chloride, gr. 0.04. Total, 0.99 grain.

A more recent analysis by State Assayer Franklin C. Robinson shows a somewhat larger proportion of solids, viz., 1.05 grains per United States gallon of inorganic salts. The water is remarkably free from organic matter, containing, according to Robinson's analysis, but 0.07 of a grain per United States gallon. This organic matter was found by examination to be of vegetable origin, only a minute trace of nitrogenous material being detected. The water is excellent for table use, and has been supplied to the students of Bowdoin College for some time past. It is used commercially. *James K. Crook.*

PARAFFIN INJECTIONS. See *Reparative Surgery*.

PARAFFIN-XYLOL is a solution of 1 gm. of paraffin in 10 c.c. of xylol, and is used as an antiseptic varnish for the hands in surgical operations. *W. A. Bastedo.*

PARAFORM—paraformaldehyde, triformol, trioxymethylene $(HCOH)_3$—is a polymer of formaldehyde occurring as a white, insoluble, crystalline powder. It tends to decompose slowly with the production of formaldehyde gas, and, when acted upon by heat, as in some of the formaldehyde generators, may evolve the gas rapidly and in large quantities. On account of its slow and steady evolution of formaldehyde, it is used by physicians as an intestinal antiseptic and by dentists for disinfecting cavities. The dose is 0.5–1 gm. (gr. viij.–xv.). Unna prescribes: ℞ Paraform 2 gm. (gr. xxx.), ether 2 c.c. (♏ xxx.), and flexible collodion 15 c.c. (℥ ss.) as the best application for pityriasis versicolor, erythrasma, and other saprophytic skin diseases. Meuse uses a three-per-cent. paraform collodion as a slow caustic for warts and other small cutaneous growths.

Paraform enters into the composition of eka-iodoform. *W. A. Bastedo.*

PARAISO HOT SPRINGS.—Monterey County, California. Post-Office.—Paraiso Springs. New Cottages.

Access.—Take 8:15 a.m. Southern Pacific train from the corner of Third and Townsend streets, San Francisco, reaching Soledad station at 1:43 p.m. Thence by stage a drive of one hour and a half to the springs.

"Paraiso Springs," says Mr. E. S. Harrison in his history of Monterey County, "were the property of the Mission Soledad, which lies about five miles northeast of the springs. The title of the present owner was obtained from the Church of Rome, to which a patent was granted by the Mexican Government in 1778. In the records of the Mission Soledad the healing and invigorating qualities of these waters are duly set forth. The springs are situated in a picturesque alcove of the Santa Lucia Mountains on the western border of the Salinas Valley, about one hundred and fifty miles south of San Francisco. The altitude of the location, being nearly one thousand feet above the valley, renders the atmosphere dry, bracing, and invigorating. Below the resort, and for miles beyond, the eye scans the fertile valley, traversed by the grand Salinas River and Arroyo Seco, and the far-away Gabilan Mountains, forming a picture of great charm and glory. The commodious hotel and cottages combine all the luxury and comforts that can be found anywhere. On the premises are several valuable springs flowing about two thousand gallons of water per hour, and consisting of sulphur, soda, and iron waters. The temperature of the springs varies from 100° to 118° F. We give below the analyses of the waters of the two principal springs, the Paraiso Sulphur Spring and the Great Paraiso Hot Soda Spring.

The Paraiso Sulphur Spring.—According to the analysis made by Dr. Anderson in 1889, one United States gallon contains: Sodium chloride, gr. 2.76; sodium carbonate, gr. 1.15; sodium sulphate, gr. 37.10; potassium sulphate, gr. 0.83; magnesium carbonate, gr. 6.09; magnesium sulphate, gr. 2.19; calcium carbonate, gr. 0.89; calcium sulphate, gr. 4.40; ferrous oxide, gr. 0.73; silica, gr. 2.55; organic matter, gr. 7.35. Total, 66.04 grains. Gases: carbonic-acid gas, 2.04 cubic inches,

Digitized by Microsoft®

sulphureted hydrogen, 9.25 cubic inches Temperature, 114° F.

This is said to be one of the best bathing waters on the coast.

The Great Paraiso Hot Soda Spring.—One United States gallon contains: Sodium chloride, gr. 3.37; sodium carbonate, gr. 5.06; sodium sulphate, gr. 34.60; potassium chloride, gr. 0.32; potassium sulphate, a trace; magnesium carbonate, gr. 0.75; magnesium sulphate, gr. 1.10; calcium carbonate, gr. 1.30; calcium sulphate, gr. 6.45; ferrous carbonate, gr. 0.89; alumina, gr. 0.56; silica, gr. 2.90; organic matter, gr. 4.15. Total, 61.45 grains. Free carbonic-acid gas, 2.95 cubic inches. Temperature of water, 118° F.

www.libtool.com.cn

Qualitatively this water closely resembles the famous Carlsbad Sprudel water, but is less highly mineralized. Thousands of visitors, invalids, and pleasure-seekers visit Paraiso Springs yearly, and the excellence of the mineral waters, the salubrity of the climate, and the picturesqueness of the location bid fair to make Paraiso one of the most prominent health resorts in California.

James K. Crook.

PARAKERATOSIS. See *Cornification.*

PARALDEHYDE.—Parethylaldehyde: $3(C_2H_4O) = C_6H_{12}O_3$. Paraldehyde is a polymeride of common ethylic aldehyde, producible by the action of a considerable number of substances upon such aldehyde. Paraldehyde is, at ordinary temperatures, a liquid, colorless, of a burning taste and powerful and penetrating ethereal odor. It dissolves in 8.5 parts of cold water and in 16.5 parts of boiling water. It mixes in all proportions with alcohol, ether, and fixed or volatile oils. At 0° C. (32° F.) paraldehyde solidifies to an ice-like crystalline mass, or may crystallize in distinct prisms. It should be kept in well-stoppered, dark amber-colored bottles, in a cool place. Paraldehyde is peculiar among ethereal bodies for possession of the property of determining *sleep*, with a minimum of by-effects. The sleep produced by the medicine seems a quite perfect imitation of natural slumber, since the subject under the influence of the hypnotic is as easily awakened as from ordinary sleep. No worse derangements occur from the medicine than a little dryness of the throat and thirst, and a trifling reduction of pulse rate and arterial tension. The most disagreeable circumstance attending the use of paraldehyde is a persistence of the taste of the drug upon the palate, and of the odor in the breath, often for a number of hours after the taking. Also it may disorder the stomach. The sleep produced by a perfectly legitimate dose of paraldehyde may begin within fifteen minutes after the swallowing, and last five, six, or seven hours. The medicine is used exclusively for the procurement of sleep, and is applicable, without special contraindication, for any case in which that therapeusis is proper. A quantity of from 2 to 4 gm. (from ♏ xxx. to lx.) is the average dose, and the same is best given dissolved in 30 gm. (fl. ℥ i.) of an aromatic water, sweetened.

Edward Curtis.

PARALYSIS.—The term paralysis, in its more limited sense, denotes complete or very pronounced loss of muscular power. The term paresis is sometimes employed to designate lesser degrees of loss of power. Paralysis is the result of functional or organic changes in the nervous system (central or peripheral), but in a comparatively rare group of diseases it is due to primary changes in the muscular fibres (pseudohypertrophic paralysis and allied forms).

Loss of muscular power may vary widely in its distribution. When confined to a single limb or part of a limb, it is known as monoplegia; when it involves one side of the body it is called hemiplegia. If the hemiplegia is present on both sides of the body, the term diplegia is used. Paraplegia is paralysis of both lower limbs (usual form), of both upper limbs, or of all the limbs.

In ascertaining the existence of paralysis of any part of the body, we must not be satisfied with merely noting the absence or diminution of motion in the suspected part. We must also make sure that there is no mechanical obstruction to motion, such as ankylosis, fracture or dislocation, and that it is not inhibited by pain. Furthermore, the patient must be in a condition to understand our directions. Even when the patient is profoundly comatose, we may usually diagnose the existence of paralysis by noting the increased resolution and flaccidity of the parts when compared with the corresponding ones on the opposite side of the body.

Various instruments, called dynamometers, have been devised to test the amount of muscular power, but they are unnecessary for practical purposes and for the most part unreliable. If the paralysis is very marked, the loss of function is forthwith noticeable. If the loss of power is not so pronounced, the patient is directed to overcome the resistance to various movements offered by the physician. For example, in order to test the power of the quadriceps femoris the patient is directed to flex the thigh on the abdomen, against the resistance offered by the physician. This is then compared with the resistance offered on the healthy side (it must not be forgotten that the right limbs are usually somewhat stronger than the left). In cases of paraplegia we must rely upon our knowledge of the degree of resistance which should be offered normally, taking into consideration the muscular build and habitus of the patient, his general nutrition, intelligence, etc.

We must always be on our guard against mistaking paralysis for the immobility due to painful affections. For example, a case of acute articular rheumatism in a child was sent to us with the diagnosis of paraplegia, the apparent paralysis being due merely to the pain in the joints.

We must next determine whether the paralysis is functional or organic. Functional paralysis is usually hysterical and the general condition of the patient exhibits the evidences of that neurosis. Hysterical paralysis rarely affects individual nerves. It generally involves muscles in functional groups, not according to strict anatomical distribution. Some symptoms are usually found which point directly to a non-organic origin. For example, in the recumbent posture the paralyzed legs may be capable of certain voluntary movements, or they may be moved involuntarily during excitement, while on attempting to walk the loss of power may appear absolute. Furthermore, hysterical paralysis is often preceded by undoubted hysterical seizures, and it may change very rapidly in degree. Sensory disorders are very common and, like the loss of motion, are not confined strictly to the anatomical distribution of individual nerves. They consist very often of hemianæsthesia, accompanied by concentric narrowing of both fields of vision.

The differentiation of peripheral from central paralyses is usually not a difficult matter. The muscles affected in the peripheral forms are supplied by one or more nerves, and a knowledge of the functions of the muscles will enable us to recognize these nerves. As the majority of the motor nerves are mixed in character, the distribution of the attendant sensory disturbances will aid still further in localizing the lesion. In mild cases there may be no change in the electrical reactions of the muscles; in severer cases there may be all possible gradations between simple diminution of electrical irritability and complete degeneration reaction. The latter is also observed, however, in certain forms of spinal-cord disease.

Atrophy of the muscles is common in peripheral paralysis, but extremely rare in cerebral paralyses; it is a constant symptom of diseases of the anterior horns of the spinal cord.

Paralysis of spinal origin usually takes the form of paraplegia, and is attended not infrequently by interference with micturition, defecation, and the sexual function. The limbs may or may not undergo atrophy, and they exhibit the degeneration reaction, according as the anterior horns are implicated or not. The patella reflexes may be lost, but if the lesion is situated high up in the cord, the tendon reflexes as well as the cutaneous reflexes may

Digitized by Microsoft®

be greatly exaggerated. Contractures are apt to develop, and are perhaps more pronounced than in any other forms of disease.

Cerebral paralysis is usually hemiplegic in character, and its onset is generally attended by symptoms of apoplexy; sensory symptoms are subsidiary. Hemianæsthesia is sometimes present at the beginning of the seizure, but usually disappears in a few days. The paralyzed muscles rarely undergo atrophy and the electrical reactions are unchanged. Contracture of the muscles develops after a while and, like the paralysis, is more marked in the upper limb.

www.libtool.com.cn

In the majority of cases the diagnostic features described above will enable us to locate the lesion which has produced the paralysis, but in exceptional cases a probable diagnosis alone can be made, after giving due weight to the attendant symptoms, etiology, etc.

The prognosis and treatment of paralysis will depend upon the primary disease, and will be considered in the various special articles. *Leopold Putzel.*

PARALYSIS AGITANS.—(Synonyms: Shaking palsy, Parkinson's disease.)

Etiology.—Paralysis agitans is one of the diseases of advancing years, and the large majority of cases develop after the age of forty to forty-five years. It is a mistaken idea, however, to regard it as an indication of senility. In a few exceptional instances the disease has begun at a much earlier period, and cases have been reported at the age of twenty, seventeen, twelve, and even three years. It is very often difficult to determine the exact period at which it begins, because the inception is usually very gradual and is often unnoticed by the patient.

Unlike other neuroses, heredity plays a very slight part in this affection. Only a few cases have been reported in which other members of the patient's family suffered from this or some other form of nervous disease.

Paralysis agitans is a rare disease. Among 4,600 patients under my observation, during a period of eleven years, at the Clinic for Nervous Diseases in the Bellevue Outdoor Department, there were 30 examples of paralysis agitans, 19 of which occurred in males, 11 in females.

It has been said that the Anglo-Saxon race is especially predisposed to the disease. At all events there can be no doubt that reports of cases are comparatively rare in the otherwise very prolific German literature on nervous affections. We may also state, with regard to New York, that the disease is frequently mistaken here for senile tremor or multiple cerebrospinal sclerosis.

Prominent among the exciting causes stands emotional excitement, usually of a depressing nature, such as fright and anger. Several cases of this kind were observed among the inhabitants of Metz and Strasburg during the sieges experienced in the Franco-Prussian war. Lorain (*Arch. de Méd.*, vol. i., 1875, p. 214) reports the following striking example: A girl, aged seventeen, was frightened by the bursting of a shell in the cellar in which she had taken refuge during the siege of Paris. This was followed immediately by tremor of the right arm, which soon extended to the rest of the body. At the end of five years she was still suffering from paralysis agitans.

Long-continued worry and grief appear to act in the same way as sudden emotions.

Living in damp rooms, or protracted exposure to wet and cold, is also said to give rise to the disease, and in our experience this has seemed to be the most efficient of all the etiological factors. Some patients inform us that the tremor began immediately or shortly after catching cold, from a single exposure to wet or cold, but it is doubtful whether there is any real connection between the two events.

A number of cases have been reported in which the disease had a local origin in an injury to the arm or leg (sometimes, perhaps, as the result of a peripheral neuritis). In such cases the tremor begins usually in the injured part, but then spreads to the rest of the body and pursues the ordinary course of paralysis agitans.

Ball claims that paralysis agitans and insanity are associated more frequently than is commonly believed. The insanity, according to this writer, is always of a depressive character, generally melancholia, with suicidal impulses and numerous hallucinations. In some cases a condition of dementia and of "demi-stupor" predominates.

Clinical History.—When the disease begins slowly, as usually happens, it is sometimes preceded by prodromes. These consist of wandering pains in different

Fig. 3737.—Position of the Body in Paralysis Agitans. (From Seiffer: "Diagnostik u. Therapie d. Nervenkrankheiten.")

parts of the body, occasional formication, or a feeling of weakness in the parts that are attacked at a later period by the tremor. In some instances the tremor does not remain constant after its first appearance, but subsides at times until again provoked by some exciting cause. In rare cases the disease begins suddenly, as we have seen in the section on etiology, and may spread quite rapidly to the entire body.

In the majority of cases tremor first appears in an arm or leg (usually the former), and then extends to the other limb on the same side. After a longer or shorter time (sometimes several years) it spreads to the other side of the body, generally attacking the latter in the same order. The head and trunk may also become involved. Charcot claimed that the apparent tremor of the head was always the result of the transmission of the movements of the trunk and limbs. This has been disproven by numerous cases, and several instances have fallen under our own observation. In rare cases the tremor first attacks the arm of one side and the leg of the opposite side, or it assumes a paraplegic form, involving both lower limbs. But sooner or later it extends to the rest of the body.

Coincidently with the tremor (in some cases even preceding it) the muscles of the body acquire a certain degree of rigidity, and the body assumes a peculiar, almost pathognomonic, position, as shown in Fig. 3737.

The motor power of the limbs remains comparatively unchanged for a long time, even for many years, but in the last stages general paralysis sets in. Sensation is unaffected throughout the entire course of the disease. The

Digitized by Microsoft®

reflexes are unchanged. Unless life is terminated by some intercurrent disease, the patient finally lapses into a condition of mental hebetude, becomes bedridden, and loses power over his limbs; then the functions of the bladder become impaired, bedsores develop, and finally death ensues.

We will now enter into a more detailed examination of the various symptoms.

www.libtool.com.cn

The tremor, which is one of the most striking features of the disease, and the one from which, in fact, it derives its name, consists of very quick, uniform, and limited excursions of the affected parts during repose. There are usually four or five oscillations in a second. In the first stages the patient is able to control the tremor for a time by an effort of the will, or by executing a voluntary movement of the parts. But, as the disease advances, this power is diminished, and, finally, while the patient may, for a very brief interval, moderate the severity of the tremor, a voluntary effort is soon followed by increased violence of the movements. The tremor subsides during sleep, but the patients are very restless at night and do not remain long in one position. The cessation on voluntary effort was regarded by Charcot as a pathognomonic differential sign, distinguishing the disease from the tremor of multiple sclerosis. But Westphal has reported a case in which the tremor of sclerosis presented the same characteristics as that of paralysis agitans; and a similar case, in which an autopsy was obtained, has come under my own observation. Magnan has also reported a case of paralysis agitans, in which the movements did not occur unless the patient performed some voluntary act which required a certain degree of attention on his part. As a rule, the fingers and forearm are the parts most affected; next follow the foot and leg. In the large majority of cases the head also presents rhythmical movements, but these are generally conveyed from the trunk and limbs. In not a few cases, however, certain of the facial muscles, particularly of the lips and chin, present tremulous movements similar to those of other parts. In still rarer cases the tongue, when protruded, also presents oscillatory movements, but these are never so pronounced as in other muscles.

Rosenberg has reported a rare case of tremor of the velum palati and epiglottis. The laryngoscope showed that the vocal cords came together, promptly on phonation, but the tension of their edges changed, the gap between them being sometimes linear, sometimes a broad ellipse. The body of the vocal cords showed twitching movements, which had the same rapidity as the general tremor. When the patient was directed to hold a note as long as possible, a rhythmical change from high to low pitch became noticeable.

The appearance of the body, when the disease is fully developed, is highly characteristic, and, indeed, almost pathognomonic.

The face has a peculiarly stolid, rigid appearance. The eyes have a dull, lack-lustre look, and their movements are slow, as if the muscles were rigid like those of the face and rest of the body. Two cases have been reported in which so called ocular lateropulsion was observed. The patients, while reading, experienced a certain amount of difficulty in directing the gaze from the end of one line to the beginning of the next line. This is most noticeable if the reading matter is arranged in columns. When they have arrived at the end of a line, the eyes involuntarily seek the corresponding line in the next column, because the ocular muscles cannot be moved with the normal rapidity.

The facial muscles have lost their emotional play almost entirely, and the face therefore looks as if covered with a mask. At times the muscles of the mouth and chin present tremulous movements similar to those observed in the extremities. The mouth is sometimes kept slightly open, and the saliva may dribble constantly in advanced cases. Speech is slow, labored, and extremely monotonous. It sounds as if the muscles of speech had to overcome some unusual resistance before the words can be enunciated. The speech is unchanged by emotional excitement, and, if we may use the expression, appears to be covered by a veil. According to Buzzard, the piping voice of old age is really a symptom of paralysis agitans, and not of senility. In certain cases the words sound as if they were jolted out of the patient's mouth, like the conversation of an unskilful rider while on horseback.

The head is held forward, and the chin may even be closely approximated to the sternum. The muscles of the neck are usually rigid and offer considerable resistance to passive motion. Three cases, I believe, have been reported in which the head was drawn backward instead of forward. A fourth one has come under my observation. In some cases the muscles of the neck present independent tremor, but their movements are usually conveyed from the trunk. In the latter event the head will remain quiet if the movements of the body are forcibly restrained. The trunk is generally in a condition of anteroflexion, as shown in Fig. 3737. The arms are usually drawn slightly forward, and the elbows are slightly separated from the side of the chest. The forearms are strongly flexed, partly pronated, and they ordinarily lie across the abdomen. These parts are in a state of constant tremor, though this is not so vigorous as in the hands. The fingers are usually flexed, the thumb is adducted, and also very slightly flexed. The thumb and index finger are continually moving to and from one another, as in the act of writing, or making pills; the other fingers are in a condition of constant fine tremor. In other cases the position of the fingers resembles that of arthritis deformans, but the joints are not swollen as in the latter disease.

The lower limbs are moderately flexed at the thighs and knees, and the latter are drawn inward. The feet are in the position of equino-varus. The toes are extended at the first phalangeal joint and flexed at the other phalangeal joints.

The patient's gait is also very characteristic. Upon attempting to rise from a chair a certain amount of difficulty is experienced, as if he were compelled to overcome some resistance. He stands still for a moment, as if to steady himself, and then makes short, shuffling steps. The gait gradually increases in rapidity, and may soon pass into a sort of slow dog-trot. In many cases the patient loses his balance and falls, unless supported. Others measure with the eye the distance between the starting-point and their objective point, and learn to regulate their muscular effort in such a way as barely to reach their destination in safety. This so-called festinating gait has been attributed by most writers to the forward displacement of the centre of gravity of the body, so that the body is, as it were, hurried along in order to catch the centre of gravity. This explanation is insufficient, as is shown by the phenomena of propulsion and retropulsion. In some cases, if, while the patient is standing still, slight traction in a forward direction is exercised upon his clothes, he will be irresistibly impelled to move forward in the peculiar manner described above (propulsion). In rare cases, if the traction is exercised backward, the patient will move in this direction in a similar manner (retropulsion). In still rarer cases, the patient exhibits a tendency to move to the side (lateropulsion). In retropulsion, indeed, he is moving in a direction opposite to that of the action of the centre of gravity. Retropulsion and propulsion have also been regarded as forced movements, like those produced by irritation of the cerebral peduncles.

The muscular power of the patient is not much diminished until he becomes bedridden, but he is very easily tired by muscular exertion. Furthermore, an unusually long time elapses before the patient is able to execute any voluntary movement, and when this has been begun it cannot be discontinued as abruptly as in health. This may be readily detected by directing the patient to squeeze one hand firmly and rapidly, and comparing this action with that of a healthy individual. Although the difference is often quite decided, the dynamometer may fail to reveal any real loss of power.

Paralysis Agitans.

Many patients suffer constantly from a feeling of heat in the skin, or from sudden flashes of heat. In addition, they complain of an indefinable internal restlessness which impels them to change position very frequently. This is often very distressing at night, since many of the patients are unable to turn voluntarily from side to side on account of the rigidity of the muscles of the trunk.

www.libtool.com.cn

The cutaneous and tendon reflexes and sensation are unaffected, but in a few cases increase of the knee-jerk has been reported. The sufferer may complain occasionally of pains in the limbs, but the pains are felt chiefly in the back. As the disease advances, the muscular power of the patient is gradually impaired, and finally he is compelled to remain in bed. Then bedsores may develop, the sphincters of the bladder and rectum become paralyzed, and the patient dies of exhaustion. In these cases the mental powers are also apt to undergo very marked deterioration.

Probably in the majority of cases, however, death is the result of intercurrent diseases, among which pneumonia seems to play an important part.

In rare cases paralysis agitans runs its course without tremor. Such patients present all the other evidences of the disease—muscular rigidity, characteristic position of the body, festinating gait, speech disturbances, the sensation of superficial heat, etc.—but the tremor is entirely absent, or is observed only at times to a mild degree.

Within the last few years a few autopsies have been made with the aid of the most approved methods of examination. Kelscher found that the ganglion cells of the cord were strongly pigmented, with granular degeneration in places; degeneration of the nerve fibres, particularly in the posterior columns and in the peripheral nerves; in places the muscular fibres exhibited atrophy and fatty or hyaline degeneration. The interstitial tissue in the cord, the peripheral nerves, and the muscles was increased; the glia of the spinal cord, especially in the cortical layer and around the vessels, was thickened, particularly in the posterior and lateral columns. The walls of the vessels showed thickening, in places miliary aneurisms and hemorrhages.

Sander found, in addition to glia proliferation in the white substance, a similar condition in the gray matter throughout the cord; this was most pronounced in the anterior horns and in Clarke's columns. There were marked arteriosclerotic changes in the finest vessels, with periarteritic and endarteritic processes. In the parts most severely affected there was distinct degeneration of the medullary sheaths of the nerve fibres.

Dana found connective-tissue proliferation in the region of the oculomotor nucleus, very marked atrophy of the cells of the nuclei of the ninth, tenth, and eleventh nerves, and slight atrophy in the facial nucleus; also thickening of the spinal pia mater, dilatation and thickening of the walls of the vessels, especially in the anterior horns of the cord, with atrophic changes in the ganglion cells.

It is very probable that all of the changes found in these autopsies are non-specific in character. They are similar to the senile changes which are commonly found in the central nervous system, and which have also been observed in chronic alcoholism.

Nor must it be forgotten that not a few carefully observed cases have shown entirely negative findings. Hence the disease must still be regarded as a functional neurosis.

Diagnosis.—When the disease is fully developed the diagnosis is extremely easy. But in its early stages it may be mistaken for multiple cerebrospinal sclerosis, senile tremor, or toxic tremor, especially after mercurial poisoning.

Multiple sclerosis is distinguished by the following symptoms: The tremor is coarser and not so rhythmical as that of paralysis agitans, and, with the exception of very rare cases, it occurs only during the performance of voluntary movements. The characteristic position of the body and the peculiar appearance of the face are wanting, while nystagmus, diplopia, and various other cerebral symptoms of serious import are present.

Senile tremor may be as uniform and fine as that of paralysis agitans, but it generally begins in the muscles of the head and neck, and is uninfluenced by repose or motion. The head may be bent forward, but rather as the result of bowing of the back. The patient does not suffer from the peculiar restlessness of paralysis agitans, and the muscular rigidity incident to the latter is wanting. There are also other evidences of senility in the general condition.

In mercurial tremor, examination will always show that the affection has been preceded by the buccal symptoms of mercurial poisoning. The disease is also attended by greater impairment of muscular power and general prostration. The tremor is much more marked during action than during repose. In severe cases it is said to be attended at times with profound deterioration of the mental faculties. This affection appears to be extremely rare in New York, and the very few cases which have come under my observation have occurred in looking-glass makers.

Post-hemiplegic chorea sometimes appears as a fine muscular tremor, and at first sight may be mistaken for paralysis agitans, especially in view of the fact that there is considerable restoration of muscular power in the paralyzed side before the tremor begins. In addition, there is always rigidity of the affected parts. But the clinical history shows that the disease began with an apoplectic attack, and, in addition, the tendon reflexes are always exaggerated. Finally, the subjective symptoms of paralysis agitans are wanting.

Prognosis.—No authentic case of recovery from this disease has been heretofore reported. Indeed, recovery might be looked upon as convincing proof of an error in diagnosis.

During the first stages of the disease temporary remissions sometimes occur, but after a time it shows slow but uninterrupted progress.

The patients usually die of an intercurrent disease, and in many cases life does not appear to be shortened by the malady. Cases have been reported in which it continued for more than thirty years.

Treatment.—The most that can be hoped for from treatment is to produce a certain degree of palliation of the symptoms. In our own hands slight benefit has been derived, in a few cases, from the use of galvanism, nitrate of silver, hyoscyamine, and prolonged rest in bed. Electricity has been employed by me in the form of the constant current of moderate strength, one electrode being placed on the upper cervical spine, the other on the lower dorsal region; sittings three times a week, each one of from five to ten minutes' duration. This plan of treatment must be continued for a long time in order to produce any good results whatever. Nitrate of silver may be given in pill form for a year or more consecutively, but it is well to intermit its administration from time to time. The dose may vary from gr. $\frac{1}{6}$ to gr. $\frac{1}{4}$ t.i.d.

Hyoscyamine sometimes produces very rapid and brilliant temporary results in diminishing the tremor. Even when the tremor is very violent and widespread, it may subside almost completely in a few days. The initial dose should not exceed gr. $\frac{1}{100}$, but this may be gradually increased until the physiological effects are produced. But unfortunately the good effects of this remedy cease as soon as it is discontinued, and it does not seem to us to be entirely safe to give it continuously in sufficient doses for any length of time.

Absolute rest in bed may also exert a favorable influence, but it is very difficult, on account of the great restlessness of the patient, to secure his consent to prolonged treatment in this way. Suspension has been employed in treatment, but its effects appear to be very fleeting, and in some cases it produced harmful results. In the majority of cases we are finally compelled to resort to morphine in order to relieve, in a measure, the sufferings of the patient. *Leopold Putzel.*

PARALYSIS, ARSENICAL.—Paralysis due to arsenical poisoning is not very rare. The larger number of cases have the appearance, and are, doubtless, mere instances of multiple neuritis. Most text-books do not allude to arsenical paralysis otherwise than by simply mentioning arsenic as one of the causes of multiple neuritis.

Etiology.—Usually the paralysis results from acute arsenical poisoning, the poison being taken either designedly or by accident. The paralysis corresponds in some measure to the intensity of the general poisoning. Not infrequently the paralysis follows the repeated administration of the drug. It has been observed after the ordinary medicinal doses: for instance, after taking from three to ten drops of Fowler's solution three times a day for a number of weeks. In these instances the paralysis is usually of a mild grade. A few years ago there was quite an epidemic of arsenical paralysis in some British towns, Liverpool, Manchester, and other places, which occurred in drinkers of beer, the examination of which revealed the presence of arsenic. In these instances the alcohol may also have played a part in producing the paralysis, but the sufferers were mostly moderate drinkers, and the pain attending the paralysis was more severe than that usually found with alcoholic neuritis.

Paralysis occurs, but less frequently, from the external use of arsenic (salves, baths, etc.), and from contact with fabrics (wall paper, carpets, and artificial flowers) which contain arsenic. Barton reports two cases, in husband and wife, with paralysis following acute poisoning, the man having for some years been rubbing a mixture of four parts of arsenic and three parts of plaster-of-Paris into the skins of animals and birds, while his wife cleaned the room twice a week. Similar cases, from dealing in stuffed birds, working with arsenical draperies, or living in rooms where there were draperies or wall paper containing arsenic, have been reported.

Symptomatology.—In cases of acute poisoning the paralytic manifestations appear shortly after the disappearance of the severe gastro-intestinal disturbance. Paralysis of twenty-four hours' duration immediately after the ingestion of the arsenic has been spoken of, but must be rare or must escape detection. The onset of the paralysis occurs usually from several days to several weeks after the poison has been taken. It is commonly preceded by sensory symptoms, tingling, numbness, intense pains, etc. The paralysis itself begins more or less gradually. Not uncommonly its onset is not observed, but when the acute symptoms have subsided and the patient attempts to get out of bed, it is found that he cannot walk or cannot hold anything in his hands. Occasionally the paralysis is complete, or at least no longer progressive, at an early period but usually some weeks elapse before it reaches its greatest intensity. Almost always, when observed from the beginning, it has been found to commence at the distal ends of the extremities, the fingers and toes, usually first in the lower extremities, and thence extend upward The parts below the knees and elbows are most profoundly paralyzed. In bad cases the muscles of the thigh are also paralyzed, and not infrequently the trunk is more or less paretic. The extensor muscles—the radial group in the upper and the anterior tibial group in the lower extremities—are, as a rule, most profoundly affected When the paralysis is complete the paralyzed muscles are quite flaccid, and we find wrist-drop, foot-drop, etc. At a later period there are very frequently contractures, more or less strong, affecting particularly the least paralyzed muscles. Tremor, often fibrillary in character, is not infrequently observed in the affected muscles. The paralysis just described, affecting the four extremities, the lower more than the upper, is that usually found. In rare instances it is otherwise distributed; sometimes in hemiplegic, and more rarely in monoplegic form. In almost all instances we find great loss of flesh and a general wasting, in addition to pronounced atrophy of the paralyzed muscles. The electrical reactions are those of peripheral paralysis. The reaction of degeneration becomes more or less pronounced a few days, or a few weeks, after the occurrence of the paralysis. At a later period, if the paralysis be profound, all electrical reactions may cease. In some instances slight changes in the electrical reactions may be observed before there is any manifest paralysis, particularly in so far that it requires a stronger faradic current than usual to produce muscular contractions. In lighter cases such electrical responses, especially in the anterior tibial group of muscles, may be the only indication of incipient paralysis.

The sensory symptoms are at times even more pronounced than the motor paralysis. These symptoms are paræsthesiæ of various kinds, tingling, numbness, coldness, etc.; pains, tenderness, and anæsthesiæ. As a rule the tingling and numbness, and very frequently the pains, precede the paralysis. The pains are often intense and constitute the most distressing symptom of the disease. They are usually described as burning, cutting, boring, etc., and are often accompanied by sudden starts, cramps, or spasmodic movements of many muscles of the body. They are usually more or less paroxysmal, and are likely to be worse at night and to keep the patient awake. They occur most frequently in the feet and hands, sometimes appear to be in the joints or bones, and occasionally are in the course of the nerves. Tenderness of the affected muscles is also a common and prominent symptom. The tenderness may be so great as to make the handling of the patient extremely painful. In some instances the tenderness is observed to be in the course of the nerves, but generally it is so diffused that it is hard to state that it is especially over the nerve tracts. Often hyperæsthesia or hyperalgesia is observed, although this may be only an expression of the great tenderness. Loss of or impaired sensation, anæsthesia, is also a common symptom. It is found most frequently in the feet and hands, and especially in the finger tips and toes or soles of the feet, although it corresponds somewhat to the extent of the motor paralysis. Rarely it occurs only in the distribution of certain nerves. Anæsthesia is found in all bad cases of paralysis, and not infrequently in mild cases. Loss of tactile sensation is most common; the loss of the senses of temperature and of pain is also common; and muscular sense is not infrequently impaired. The knee-jerks are usually abolished. This is often true even when the paralysis is slight. Vaso-motor and trophic symptoms, such as œdema, particularly in the feet, profuse perspiration, loss of nails and hair, pigmentation of the skin, herpes, and muscular atrophy, are common.

On the other hand, the cranial nerves and bladder are very rarely affected. In some instances the pulse is more rapid than seems consistent with the patient's general condition; a fact which may be due to an affection of the vagus or of the cardiac ganglia.

As has already been stated, usually several days or several weeks elapse before the disease reaches its acme. Then after an interval, which may be of only a few days' duration, but which sometimes runs into months, the patient begins to improve. The anæsthesia begins to disappear before the motor paralysis. It disappears in the reverse order of its appearance; first from the trunk and the upper part of the extremities, remaining longest in the fingers and toes. The motor paralysis disappears in the same manner: first in the upper part of the extremities, then in the muscles below the knees and elbows. The flexors usually improve more rapidly than the extensors, until finally the only motor symptoms which remain, in the mild cases, are paralyses of the extensors of the feet and toes, and of the extensors and small muscles of the hand. At a late period there are liable to be contractures in the still paralyzed parts. The pains also become modified in intensity after the lapse of some time, but unfortunately they are likely to persist with a greater or less degree of severity throughout the whole course of the disease. The vaso motor and trophic symptoms (œdema, pigmentation of the skin, etc.), usually disappear at a comparatively early period. The whole duration of the disease is extremely variable. Alexander puts it as from eight days to a number of years. It may be stated in general that mild cases usually get well within

www.libtool.com.cn
Digitized by Microsoft®

six months, possibly in an even shorter time, whereas in severe cases one or two years elapse before there is complete recovery, or, in those cases in which a cure remains incomplete, before there is a definite cessation of improvement.

In some cases of arsenical paralysis muscular incoordination, ataxia, is a more prominent symptom than paralysis, and to this group of cases the term pseudotabes has been applied. The pains, anæsthesia, absence of knee-jerks, together with the ataxia, make that term seem very appropriate.

www.libtool.com.cn

The disease so far described is that following acute arsenical poisoning. In some cases following chronic poisoning the symptoms are much the same, only the onset is likely to be less sudden and the symptoms less severe. In other chronic cases the symptoms are very slow in appearing, and may have been in part masked by those of gastric irritation. The pains are likely to be proportionately greater, and the paralysis slight in degree. But, even when the paralysis is slight, the changes in the electrical reactions are likely to be found. In such instances the motor manifestations may be rather like those of ataxia than of paralysis. Sometimes a sense of profound prostration is the only indication of motor impairment.

There is another class of cases in which the poisoning appears to have been exceedingly slow and insidious. The symptoms in these cases are usually very obscure, and the cause is commonly to be found in arsenical wall papers or the like. Among the symptoms are, gastro-intestinal irritation, neuralgia, headache, insomnia, general prostration, mental depression, impairment of memory and mental endurance, and epileptiform convulsions. As this article is devoted to the subject of arsenical paralysis no further attention will be given to this class of cases.

Pathology.—In the larger number of cases examined only neuritis was found. In a few instances disease has been found in the central nervous system, in the spinal ganglia, in the cord, and even in the brain. Experiments have been made on various animals, but the results are not all in accord. In some instances neuritis only, in others, inflammation in the spinal ganglia, in the anterior cornua of the cord, and in other parts of the central nervous system was found. The probability is that the peripheral neuritis and the affection of the central nervous system, when present, occur at the same time, but that neuritis is the more frequent and of a higher grade of intensity. The clinical picture indicates that the characteristic condition in most instances is multiple neuritis, and if further pathological changes are present they do not contribute to the symptoms presented.

In those rare instances of incontinence of urine, etc., and those with profound and lasting paralysis, the symptoms are probably due to central disease.

Diagnosis.—When it is known that the patient has been poisoned with arsenic, as is usual in acute cases, the cause of the resulting paralysis is apparent. When there is no such knowledge, the history of severe acute gastro-intestinal disturbance preceding the kind of paralysis just depicted should be almost enough to make the diagnosis certain. The picture of the paralysis is fairly characteristic. The four extremities are usually affected, the lower ones being more often and more extensively involved than the upper ones. The paralysis is always greatest in the digital extremities and is attended by atrophy and altered electrical reactions. In addition there are the intense pain and extreme tenderness, and the absence of knee-jerks, of bladder symptoms, and of bed sores.

When the paralysis is less marked, and the whole array of symptoms less conclusive, the greater prominence of the sensory symptoms and the presence of altered electrical reactions in the slightly paralyzed muscles (in this instance it requires a very careful examination to reveal such reactions) may arouse a suspicion of the true condition.

The cases with ataxic gait may suggest locomotor ataxia as the correct diagnosis, and Seeligmueller mentions a case of his own which was falsely looked upon as one of locomotor ataxia. The severe pains and lost knee jerks heighten the resemblances of the two diseases. But with careful examination such errors will rarely occur, for it will usually be found that the difficult gait is rather paretic than ataxic; and, furthermore, symptoms on the part of the bladder and the eyes (such common and early manifestations in locomotor ataxia) are absent.

In cases of chronic poisoning the detection of arsenic in the urine may assist materially in the diagnosis. In acute cases the arsenic has usually been eliminated before or soon after the paralysis appeared.

Prognosis.—Mild cases may get well in a few months, though rarely in less than six; but when there has been profound paralysis, recovery cannot be expected in less than one or two years.

In not a small proportion, possibly in one-fifth, of the cases of extensive paralysis, complete recovery does not take place.

Treatment.—The treatment is that of multiple neuritis.

Philip Zenner.

PARALYSIS, DIPHTHERITIC.—This is paralysis which occurs during or after diphtheria, and is due to changes in the nerves or muscle fibres.

The statistical frequency of diphtheritic paralysis has varied greatly according to different writers. The American Pediatric Society's collective investigation[7] showed that it occurred in 9.7 per cent. of all cases of diphtheria. This is rather low, some figures running as high as twenty-five per cent. or even higher. It is probable that at least ten per cent. of all cases of diphtheria in private practice, properly treated, may be expected to show this complication.

Etiology.—That the pathological lesions upon which the symptoms of diphtheritic paralysis depend are due to the action of the poisons of the disease on certain of the tissues there can be no question, since both the lesions and the symptoms have been produced experimentally in animals by the injection of the toxins.[1,2] Paralytic symptoms may follow diphtheria of all degrees of severity, and instances in which it has complicated cases so mild that the causative sore throat has been unnoticed or forgotten by the patient are sometimes seen in large clinics. As to whether it is more common after the severe cases than after the mild ones there is a difference of opinion. Gowers[3] and Henoch[13] believe that its frequency does not depend upon the severity of the original disease. Goodall[8] and De Gassicourt believe that it does. The former reports a series of cases which seem to show that its frequency is greatest in the cases showing the most extensive membrane.

The influence of the antitoxin treatment upon the frequency of the paralysis is also a matter of doubt. Certain statistics have shown that the use of this remedy has been followed by an increased number of cases of paralysis; but such studies are misleading, since under the use of this method there are many severe cases of diphtheria which recover and have paralysis,—cases that would otherwise die before the time at which the palsy generally begins. It is said that the condition is comparatively rare among cases in which the larynx is the part mainly affected by the diphtheria. Males appear to be slightly more susceptible than females. As to age, Gowers[3] agrees with Landouzy that adults are much more frequently affected. Goodall[8] and Ross[14] find that it is relatively more common in children.

Pathology.—Lesions are found in the central nervous system, in the peripheral nerves, and in the muscles, but there is no doubt that the dominant lesion—the one upon which the clinical picture, at least so far as the peripheral palsy is concerned, mainly depends—is degeneration of the lower motor neurones, *i.e.*, peripheral neuritis. According to J. J. Thomas and others who have made careful studies of the nervous system, using modern histological methods, the process is one of fatty degeneration, which begins in the myelin sheaths. The axones afterward become beaded, break up and disappear. Both

Digitized by Microsoft®

motor and sensory nerves are affected. These changes would appear to be much more frequent than the palsy, since they are very generally found at autopsy, even though no paralysis has been noted before death. In all of Thomas' cases the vagus nerve showed more or less marked degeneration. Others have observed the same thing, as well as similar changes in the cardiac plexus, the fifth cranial nerve, the muscles of the larynx, and elsewhere.

www.libtool.com.cn

The effect of the toxic substances is not confined to the peripheral nerves, as there is a diffuse parenchymatous degeneration of the nerve fibres of the spinal cord and brain. Several observers, notably Bikeles, have found that these changes were most marked in the posterior columns and in the posterior nerve roots, a fact of interest in connection with those cases which show ataxia as a symptom. As to the effects on the nerve cells opinions differ, some authorities even considering that the characteristic symptoms are due to primary degeneration of the motor nerve cells in the anterior horns, rather than to changes which are primary in the peripheral nerves. The weight of evidence is strongly against this view, however, and the changes in the nerve cells are probably of relatively slight importance and degree. The brain and cord often show hyperæmia, and in rare cases myelitis or hemorrhages, the latter sometimes being severe. But the symptoms in most cases depend on changes in the peripheral nerves rather than in the central nervous system.

Of the muscles, the one in which the changes are of the greatest clinical significance and in which they have been most carefully studied is the heart. According to Councilman, Mallory, and Pearce[6] degeneration in the myocardium is one of the most common conditions found in diphtheria. The simplest form is fatty degeneration, which is found in the majority of all cases, and which seems to precede the more advanced forms of degeneration which lead to complete destruction of the muscle fibres. In these there is destruction of the sarcous elements, which become swollen, broken up, and converted into hyaline masses. The degeneration may become so extensive as to account fully for the impairment of the heart's action. Acute interstitial lesions are also found, and occasionally cardiac thromboses and less important vascular lesions.

Changes are also observed in the skeletal muscles. It is probable that, as Baginsky[3] believes, the paralysis of the palatal muscles represents a myositis due to the direct effects of the membrane in their close proximity, rather than a neuritis. But we must also remember that the vagus nerve, which supplies these muscles, is almost always involved. Councilman, Mallory, and Pearce[6] observed marked fatty degeneration of the tongue, diaphragm, and various muscles of the extremities, and they conclude: "It seems probable that in all cases where fatty degeneration of the heart and nervous system has occurred, a similar change will be found in the skeletal muscles."

The changes produced in the nervous system by diphtheria are thus summed up by Thomas:[4] "(1) A marked parenchymatous degeneration of the peripheral nerves, sometimes accompanied by an interstitial process, and hyperæmia and hemorrhages. (2) Acute, diffuse, parenchymatous degenerations of the nerve fibres of the cord and brain. (3) No changes, or but slight ones, in the nerve cells. (4) Acute parenchymatous and interstitial changes in the muscles, especially the heart muscle. (5) Occasional hyperæmia, or infiltration, or hemorrhage in the brain or cord; in rare cases severe enough to produce permanent troubles, such as the cases of multiple sclerosis and of hemiplegia which have been observed. Finally, the probability that the cases of sudden death from heart failure in diphtheria during the disease or convalescence are due to the effects of the toxic substances produced in the disease upon the nerve structures of the heart." The changes produced in the nervous system, then, involve chiefly the lower (spino-muscular) segment of the motor path.

The SYMPTOMS in the ordinary peripheral form of paralysis may begin as early as the fourth day, while the patient is still ill and while the membrane is still present, or they may be delayed for many weeks. The usual time is from one to three weeks after the disappearance of the membrane.

The distribution of the paralysis may be judged from the following figures of the American Pediatric Society's[7] 189 collected cases: Throat, 124; extremities, 22; eyes, 11; respiratory muscles, 5; heart, 32; neck, 1; general, 8. Ross[14] collects 171 cases, distributed as follows: Palate, 128; eyes, 77, of which 54 involved the muscles of accommodation; legs, 113; arms, 60; trunk or neck, 58; respiratory muscles, 33. In Goodall's[5] 125 cases the palatal muscles were involved 102 times, the ciliary muscles 56 times, the legs 52 times, the external ocular muscles 26 times, the arms 21 times, and the pharyngeal muscles 11 times. Obviously the throat is the region most often affected and the eyes and extremities next. When the extremities are involved the disease is characteristically more common in the legs than in the arms, which, in severe cases, are involved later.

The symptoms begin gradually, and usually a number of different parts are involved successively, improvement taking place in one while the disease advances in another. It most commonly begins in the throat, and the palate may be the only part affected. As a result of the involvement of the palate the nasal cavity is not shut off from the nasopharynx in swallowing or in speaking. The child is observed to regurgitate its food, a symptom which may become so severe that deglutition is impossible. The voice becomes nasal in character. Extension to other muscles of the throat and mouth may lead to inability to blow, whistle, suck, or gargle. The muscles are bilaterally or rarely unilaterally involved. Paralysis of the constrictors of the œsophagus is evidenced by the entrance of food into the glottis. Cough, hoarseness, aphonia, and paroxysms of dyspnœa are seen when the larynx is involved. There may be difficulty in articulation or in protruding the tongue. Facial paralysis is rare, as is also paralysis of the tongue or œsophagus.

When the eyes are involved dimness of vision for near objects is noted, and is due to loss of the power of accommodation from paralysis of the ciliary muscles. The patient usually first complains of dimness of vision. The failure of accommodation reaches its height in a few days and generally lasts two or three weeks. The pupil may be dilated. Ophthalmoplegia externa—squint or double vision—and ptosis are rarer. Sometimes most or even all of the muscles of the eyes become paralyzed. Involvement of the hearing, taste, and smell are recorded, but are rare.

When the extremities are involved there is gradual loss of power, beginning almost always in the legs, afterward extending to the arms in severe cases or even to the trunk and neck, so that in the worst cases the patient becomes a helpless mass. But such cases are rare, and the loss of power is seldom absolute. The distribution is usually symmetrical. In contrast to the alcoholic form of neuritis subjective sensory symptoms are ordinarily slight. There may be numbness, tingling, hyperæsthesia, or anæsthesia; but in most cases these symptoms cause little distress. According to Gowers[3] anæsthesia is always most severe toward the extremities of the limbs, and he mentions cases in which sensation was lost only in the finger-tips. As in all forms of degeneration of the lower motor neurone, the muscles become flabby and atrophy occurs. The knee-jerks are commonly lost, and lost reflexes are sometimes the only evidence that the nerves of the extremities are involved. It is said that in some cases they are retained. During convalescence there may be increased knee-jerks and ankle clonus.

The electrical reactions are variable; according to Northrup so much so that they are of little value in diagnosis or prognosis. As a rule they are altered, the muscles showing decreased reaction to faradism with the reaction of degeneration, and the nerve trunks showing

Digitized by Microsoft®

decreased irritability to both currents.[3] The bladder and rectum are rarely involved.

Reference has already been made to the occurrence of ataxic symptoms in diphtheritic paralysis, and to the view of Bikeles, which explains them as due to degeneration of the posterior columns of the cord. These symptoms are clumsiness in the use of the limbs and unsteadiness in walking. The gait is sometimes distinctly ataxic as in true tabes. The Romberg symptom is prominent. Lack of knee-jerks and sluggish pupillary reactions complete the picture, which, however, is often masked by the muscular weakness.

One of the most serious complications of diphtheritic paralysis is extension to the muscles of respiration. It occurred in 33 of Ross' 171 cases,[14] and 21 times in 275 cases reported by Meyers.[17] Either the diaphragm or the intercostals may be involved. The average time of onset in Meyer's cases was the thirty-seventh day, but it occurred as early as the eleventh and as late as the fiftieth. Dyspnœa is a marked symptom, and is seen in the form of asthma-like paroxysms or in spasmodic attacks due to the accumulation of mucus. There are anxiety and mental distress with a sense of impending suffocation. When the diaphragm is involved abdominal breathing is reversed, the abdomen sinking in on inspiration, and *vice versa*.

The symptoms of cardiac paralysis occurring in diphtheria are of the greatest importance, owing to their frequency, seriousness, and bearing upon questions of treatment. Their exact cause is a matter of doubt. Changes are found at autopsy both in the myocardium and in the nerves controlling the heart. As has already been said, the myocardium may show degeneration sufficient to account in full for all the symptoms. Some, however, believe that the nerve changes are primary. Thomas and Hibbard,[10] in an exhaustive investigation of the subject of heart failure in diphtheria, favor Hesse's view,[18] that heart failure results directly from the effects of the poisons of the disease rather than from the degenerative processes which they cause in the tissues; but they consider that these toxins act through the nervous mechanism. It seems probable that the origin of the heart symptoms may be due either to changes in the myocardium or to changes in the nerves controlling the heart, or to the effects of toxins on the nerve centres. In any given case the exact cause of heart failure can be stated only after death, but it seems fair to suppose that those due to the direct effect of the diphtheritic poisons will occur early in the disease, just as they do in other acute conditions, while those due to organic degenerations may occur later.

Cardiac symptoms are observed in diphtheria at a relatively early date as compared with the other palsies; according to Woodhead,[15] mostly between the fifth and tenth days. The average in Meyer's cases[17] was the seventh. But sometimes they arise late in convalescence. Occasionally they are overlooked, and sudden death after slight over-exertion takes place in a case apparently well. As a rule, some abnormal condition of the pulse first calls attention to the heart. It is unusually rapid or unusually slow, or oftener it is irregular or intermittent. The heart, when mapped out by percussion, generally shows some enlargement. Systolic murmurs, most of which are temporary, may be heard. Pallor, cold extremities, dyspnœa, and cardiac distress are noted. Vomiting is an important symptom, whose occurrence, unless otherwise explained, in diphtheria should always call attention to the heart. Its association with cardiac failure is supposed to depend upon the common relationship of the vagus nerve to both the heart and the stomach. Death may occur within twenty-four hours after the onset of cardiac symptoms, or, as has already been said, it may take place suddenly without warning. In most of the heart cases there is evidence of paralysis elsewhere.

Brodie,[19] as a result of animal experimentation, and Biernacki[20] from clinical observation, consider that the fall of blood-pressure occurring in diphtheria is a result of paralysis of the muscular walls of the vessels. It is a question, however, whether the action is local or central, and to what extent impairment of the heart's action is responsible for the phenomena noted.

There are other forms of paralysis which are sometimes associated with diphtheria, but they occur more rarely and they need but brief mention. One is sudden cerebral hemiplegia, due generally to embolism, more rarely to hemorrhage or thrombosis. Meningitis is sometimes a sequel of diphtheria, and cases of multiple sclerosis have been reported by Schönfeldt. The paralytic symptoms which they cause could hardly be mistaken for the common form.

Diagnosis.—This depends on the recognition, during an attack of diphtheria or in convalescence from the same, of a peripheral neuritis or, in some cases, of a myositis. The most significant peculiarities of the diphtheritic form of neuritis are the frequency of involvement of the throat and eyes, the process often beginning in the former, the symmetrical distribution, the tendency to involve the legs before the arms, the slightness of sensory symptoms, and the frequency of cardiac manifestations.

In making the differential diagnosis other forms of peripheral neuritis must be excluded, especially in cases in which the causative diphtheritic infection has escaped recognition, in which more than one cause is present, or in which the palate and eye symptoms have been slight or lacking. The chief forms of neuritis to consider are those due to alcohol and to lead. Alcoholic neuritis is rare in children, does not involve the throat, and has more prominent sensory symptoms. Other evidences of alcohol are usually present. Lead palsy begins generally in the arms, involving the extensors and giving the characteristic wrist-drop. It is usually associated with other evidences of lead poisoning, such as the blue line on the gums, the cachexia, colic, traces of lead in the urine, and granular degeneration of the red corpuscles of the blood. Other forms of neuritis may be ruled out on similar lines. Mixed forms occur, but in such cases, apart from questions of prophylaxis, the cause is rather of academic than of practical importance. Cases of diphtheritic paralysis showing marked ataxia may be mistaken for tabes dorsalis. The post-diphtheritic disease, however, develops more rapidly; true lightning-like pains are not experienced; and the loss of motor power with atrophied and flabby muscles is absent in true tabes. Acute poliomyelitis is also of importance. Here the onset is more acute, paralysis is not symmetrical, and the sensory symptoms are lacking. Hysterical palsy seldom involves the palate, as diphtheritic paralysis almost always does. In hysteria the knee-jerk is retained. The greatest difficulty arises in cases in which a true diphtheritic paralysis is combined with hysteria.

Prognosis.—This will depend upon the site of the paralysis, the severity of the case, and the previous condition of the patient. Of Goodall's 125 patients 17 died: 4 in the acute stage of diphtheria; 6 fatal cases were cardiac, 4 respiratory, 2 vomiting and cardiac, 1 convulsions.[5] Of Ross' 171 patients 45 died: 8 from intercurrent diseases, 8 from sudden syncope, 10 from heart failure, 14 from respiratory paralysis, and 2 from the aspiration of food into the trachea.[14] According to Gowers, the sooner the paralysis begins after the diphtheria the greater the danger to life.

Paralysis of the extremities of itself causes little danger to life, and recovery may be predicted, even though it may be months before power is completely restored. The duration is often from six to eight weeks. The loss of knee-jerks is generally the last sign to disappear. In the throat cases there are two sources of danger. The first is that arising from the frequency with which palatal involvement is associated with heart symptoms. The second danger arises from the difficulty of deglutition, patients dying from inanition on this account, or from the aspiration of food into the trachea with resulting asphyxia or bronchopneumonia. In respiratory cases the outlook is always more dubious. Meyers[17] reports 21 patients affected with diaphragmatic palsy, of whom 11

Digitized by Microsoft®

died, this being 13.7 per cent. of all deaths from diphtheritic paralysis in his series.

Cardiac paralysis is even more fatal. Statistics are of little value, as different observers vary so greatly in the criteria upon which they base their diagnoses. All 32 cases collected by the American Pediatric Society [7] were fatal. Hibbard [11] reports 47 per cent. of deaths in cases with irregular pulse. Vomiting during convalescence from diphtheria generally means heart failure, is an unfavorable sign, and occurred in over half of Hibbard's fatal cases. According to Burrows [12] it is especially to be feared when it occurs in a patient whose heart is irregular, or who presents other evidences of nerve degeneration. A very slow pulse is also unfavorable, especially in children. The patients may die within twenty-four hours of the onset of cardiac symptoms, or later during an exacerbation. Sudden death from heart failure without previous symptoms may occur in the acute stage, or it may suddenly and unexpectedly terminate a case after convalescence has appeared to be completed.

Treatment.—The varying results of statistical studies as to the effect of antitoxin have already been mentioned in connection with the subject of etiology. It seems probable that the early and vigorous use of antitoxin in any given case will decrease the likelihood that this complication will occur, but only in so far as it lessens the severity and duration of the causative disease. That this view is correct is proven on the experimental side by the work of Ransom,[1] who shows that doses of the toxin capable of producing paralysis in animals are neutralized in this respect by antitoxin injected simultaneously and modified, though not prevented, by large enough doses given from fifteen to twenty-two hours after those of the toxin. On the clinical side the report of the London Clinical Society [21] shows that the frequency of paralysis as a complication of diphtheria is less when antitoxin is used on the first two days of the disease than when its use is delayed. After the injury to the nerves or muscles has been done, it is not probable that antitoxin will have any effect in restoring them to the normal condition. The same conclusions probably hold in regard to the heart manifestations. In other words, antitoxin, given early and in large doses, has some value as a prophylactic in preventing the paralytic complications of diphtheria.

On the peripheral neuritis no form of treatment has much effect. The case should be managed like a neuritis from any other cause. Rest, careful nursing, liberal diet, tonics, massage, and electricity are of some value. Strychnine is much used, but its influence in restoring the degenerated nerves and muscles to their normal condition is at least questionable. In palatal, and especially in pharyngeal and laryngeal cases, great care should be taken in feeding the patient to prevent the entrance of food into the larynx. The œsophageal or nasal tube may be used if needed, great care being taken to avoid introducing it into the larynx and to get the end well below the glottis. In some cases it will be better to feed by the rectum. Forced feeding had better not be delayed in hope that the child will begin to eat, especially in cases in which the patient is much debilitated by a severe attack of diphtheria. Proper and sufficient nourishment is of importance both in the treatment of the general depressed condition and in that of the paralysis.

One precaution should be insisted upon. Every case of diphtheria should be watched closely for the occurrence of cardiac or respiratory symptoms, especially when evidences of palatal paralysis are present. Thomas and Hibbard [10] advise that every case of diphtheria, however mild, should be kept in bed till the throat is clear, and, if there has been any prostration, for at least two weeks more. After four weeks with no heart symptoms there is little danger. If heart symptoms arise, the greatest care must be taken to keep the patient quiet, morphine being used for this purpose if needed. Careful feeding is of importance. Medicines are of value only in meeting special symptoms. Alcohol, digitalis, and strychnine may be of service. In the respiratory cases strychnine is the most valuable remedy. Electricity may also be used. *Ralph C. Larrabee.*

PARAMUCIN.—Mitjukoff has obtained from the mucoid contents of ovarian cysts a mucin-like substance, which differs from *pseudomucin* and *mucin*, chiefly in the fact that without previous boiling with dilute mineral acids it will reduce an alkaline solution of copper. ("Ueber das Paramucin," *Arch. f. Gyn.*, Bd 49, 1895.)
Aldred Scott Warthin.

PARAMYOCLONUS MULTIPLEX.—(Synonyms: Myoclonus multiplex, Myoclonia, Polyclonia.) Originally described by Friedreich [1] in 1881, this disorder has been recognized by clinicians in Germany, France, Italy, England, and America. Its existence as a disease has been questioned, some asserting it to be a variety of hysteria, others of chorea. Still others cut the Gordian knot by claiming that both a true form and a hysterical form of the disease exist. However, the preponderance of authority as well as of evidence at the present day appears to favor its validity as a clinical entity.

It is a rare disease. Gowers [2] states that he was able to collect but fifty-two cases in the literature up to July, 1895, of which only thirteen were considered by him true examples.

One of the best accounts of the disease accessible to American readers is that of Starr,[3] which is also accompanied by a bibliography.

The disease is characterized by paroxysms of clonic muscular contractions, shock-like, bilateral, and symmetrical as regards the two sides of the body. The individual contractions are frequent, varying in rate from thirty to one hundred or more per minute. The duration of the paroxysms may vary between five or ten minutes and some hours. Likewise the frequency of paroxysms in a day may vary from one or two to twenty or more. The muscles affected in typical cases are the intrinsic truncal muscles and those connecting the trunk and extremities; those moving the face, hands, and feet being seldom, if ever, affected (see Fig. 3738). In one case observed by the writer,[5] the diaphragm and laryngeal muscles were involved at times, causing short, sharp, involuntary exclamatory sounds.

Negative characteristics are: consciousness is not affected; mental defects are absent as a rule, but, if present, are transient; voluntary movements of the face, hands, and feet are not abolished, even during a paroxysm, though the muscular power is much reduced; elec-

Digitized by Microsoft®

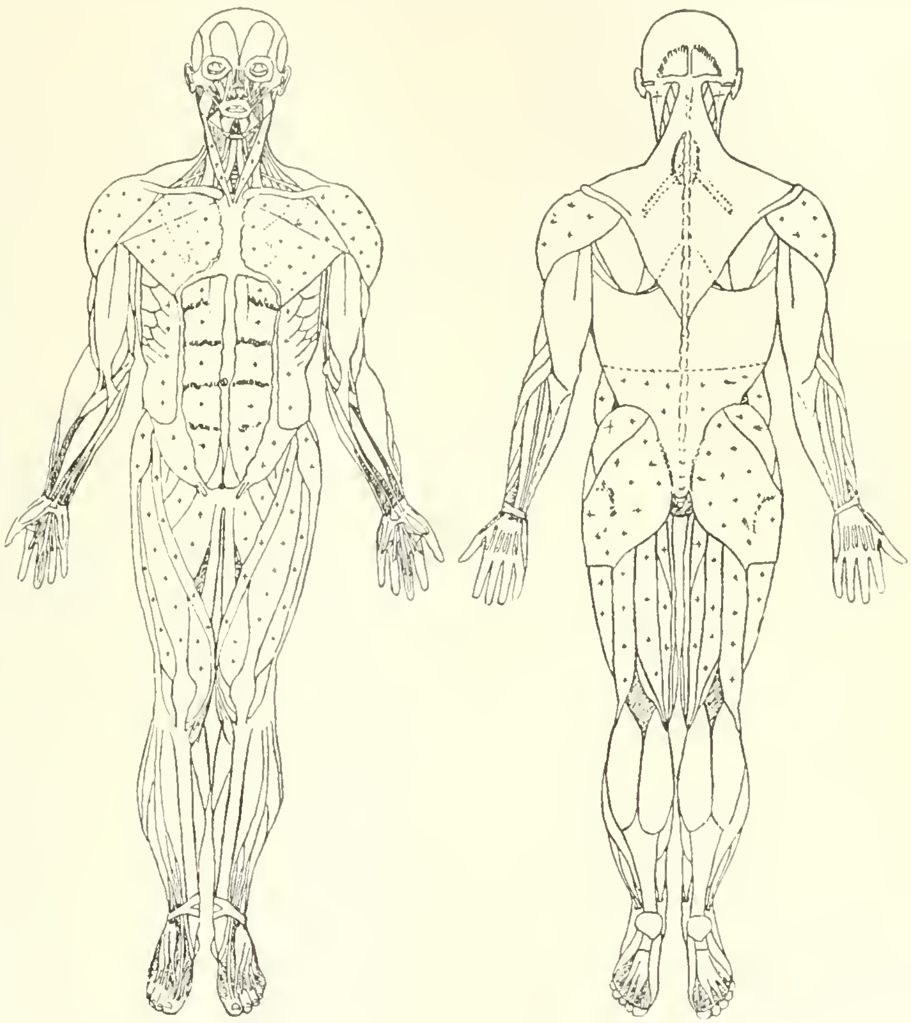
trical changes of degenerative significance are absent, as is fibrillary twitching. Sensation is not diminished or lost, but a decided hypersensibility to sound and touch has been observed by the writer in one case.[5] A profound sense of fatigue was also noted in that case. The convulsive movements cease during sleep, and are brought on, or, if present, increased in violence by emotional excitement, by irritation of the skin, by cold, etc., and by manipulative procedures generally.

www.libtool.com.cn

Oppenheim[4] recognized a hysterical type as distinguished from the true form, but admits the difficulty of separation.

Unverricht, Weiss, Kreiver, and Sepilli (quoted by Oppenheim) describe cases of a familial type and associated with epilepsy (*loc. cit.*).

CAUSATION. — The patients are usually neurasthenic. A majority of cases reported were of the male sex. The ages of patients have varied between thirteen and forty-eight. Mental worry, fright, injury, and physical strain are accredited causes. Of two cases reported by the writer one was attributable to mental worry combined with la grippe. The other was distinctly due to fright. A third case, observed by the writer through the kindness of Sir William Gowers, followed a fall from a considerable height without palpable injury. Fry's case[6] was due to overexertion, Starr's[3] to strain in lifting. Removal of the thyroid in dogs is said sometimes to cause symptoms of this disease.



A.—Front View. *B.*—Rear View.

FIG. 3738.—*A* and *B*. Paramyoclonus Multiplex. Distribution of myoclonic spasm indicated by plus marks.

The PATHOLOGY is unknown. Autopsy in one case (Schultze) revealed no nervous changes. Friedreich, who was the first to describe the disease, believed it to be based on overexcitability of the spinal motor elements. Some have surmised that the cause of the faulty action lies in the muscles themselves or in an abnormal state of the nerve endings. To the writer its psychic antecedents, marked hemiplegic preponderance at times (in one case); its aggravation by mental and emotional states; the marked, though transient, mental changes in two cases; and the heightened muscle reflexes, would all suggest that the disease is to be viewed as the visible expression of a state of "*inhibitory insufficiency*," probably cortical in seat.

DIAGNOSIS.—This is to be based on "the sudden shock-like character of the muscular contractions, their bilateral symmetry, and the comparative freedom of the extremities." (Gowers.[7]) This view is also concurred in by Walton[8] in a recent paper on the myospasms in general. Hysteria is ruled out by the absence of the stigmata and of the characteristic emotional state. There appears to be no tendency to simulation or desire for sympathy in paramyoclonus. Chorea is excluded by the non-involvement of the face and hands. Dubini's "electrical chorea," a disease endemic in a certain locality in Italy, is to be separated by its unilateral beginning, nerve and muscle degeneration, and a fatal termination in a few months.

The PROGNOSIS is variable, according to different authors. Friedreich reported that some of his patients recovered. Oppenheim considers the prognosis grave. In all the American cases reported to date the patients have recovered. Relapse may occur, but does not preclude ultimate recovery.

The duration may vary from three or four months to a year or more. In one of the writer's cases the convulsions ceased on the one hundred and second day, but recurred in twenty-four hours, to disappear again in eight days. There has been no recurrence to date (four months). In the case reported by Starr (*loc. cit.*) the patient recovered in about a year, as did also the patient in the first case reported by the writer.[5]

TREATMENT.—The drug treatment followed has been

Digitized by Microsoft®

so diverse as to suggest that it has had little to do with the recovery. Chloral, bromides, hyoscine and other sedatives, arsenic, quinine, thyroids, and galvanism have all been followed by improvement and recovery. The factors of rest, feeding, and time would appear to be the important ones. Sedatives may be used to mitigate the severity of the spasm and promote the patient's comfort.

Nutrient medication, in the form of glycerinophosphates, iron preparations when indicated, and supporting measures generally, are advisable.

F. W. Langdon.

PARAPHIMOSIS. See *Sexual Organs, Male, Diseases of.*

PARAPLEGIA.—The term paraplegia specifies a symptom, not a disease. It indicates, in the first place, an impairment of motility, namely, akinesis or paralysis, and secondly, paralysis of a certain distribution. Thus, it is customary to indicate a paralysis involving one of the extremities by the term *monoplegia*, a paralysis of both extremities on one side of the body, that is to say, of longitudinal or unilateral distribution, by the term *hemiplegia*, while a transverse distribution or symmetrically bilateral paralysis of the body is classified as a *paraplegia* (para, Gr. παρα, side by side). Usually, the lower extremities and the caudal portion of the body are the parts involved. The term is not restricted, however, to paralysis of these parts alone, but may be applied to the involvement of any transverse section of the body. When the upper extremities are involved, the term *cervical paraplegia* is applied. In this condition, usually, though not always, paralysis extends to all parts below—caudad. The term *hemi-paraplegia* refers to paralysis of one lower extremity, accompanied by anæsthesia of the opposite member. It is, strictly speaking, a crural monoplegia. The term double hemiplegia is synonymous with cerebral paraplegia, both indicating a paraplegia of intracranial origin, involving the cerebral motor tracts. The term ocular paraplegia has been used, rarely, to indicate paralysis, in both eyes, of symmetrical ocular muscles. The term diplegia is to be preferred in cases in which a single pair of nerves on each side is paralyzed; as facial diplegia, instead of facial paraplegia. Jaccoud introduced the adjective *paraplegiform* to indicate bilateral disturbances of motility other than true paresis or paralysis, but which resemble the latter in disturbance of locomotion; as, for example, that produced by incoordination, and spastic conditions.

In paraplegia (it being defined as paralysis of a certain distribution) we have an important symptom of various pathological conditions, forming by its association with other symptoms some of the most striking clinical pictures of disease. Its proper study involves the consideration of the localization of function, the impairment of which produces paraplegia; the nature of the pathological process causing such impairment; the variations in disturbance of function due to involvement of different segments of the body; the other symptoms which may accompany it; and the diagnostic and prognostic significance of the grouping of such symptoms, together with indications for remedial measures.

From this standpoint paraplegia forms a convenient centre from which may be analyzed a great number of diseases of the nervous system, mostly of spinal origin, but also including some cerebral and peripheral nervous affections. As we have a motor impairment to consider, the motor tracts of the nervous system must be called to mind. From their periphery in the motor end-plates they pass through the mixed peripheral nerves, the anterior roots of the spinal cord, the root zones in the anterior columns, to the anterior cornua of the cord, where the motor nerve fibres are supposed to terminate in cells arranged in groups or scattered through the gray matter of this portion, and by means of which they form reflex connections with sensory nerve tracts, commissural connections with the motor tracts of the opposite half of the cord, and with different levels of the cord above and below; and, in addition, connection with the motor tracts in the lateral columns of the cord known as the crossed pyramidal, cerebral, or voluntary tracts, and the direct pyramidal tracts in the anterior columns. After decussation of the crossed pyramidal tracts in the medulla, both crossed and direct tracts pass through the anterior (ventral) portion of the pons, continue through the crura cerebri, then upward, forming a part of the internal capsule, and on to the so-called cortical motor areas. Associated tracts through the cerebellum, the cerebral ganglia, and the nuclei of the cranial motor nerves complete the system. In order to produce paraplegia, not only must some part of this motor system be affected, but the lesion must be symmetrically bilateral, must involve both halves of this duplex system. The general division may be made, therefore, into peripheral, spinal, and intracranial (cerebral) paraplegia. The divergence of the right and left motor tracts in their peripheral and cerebral por-

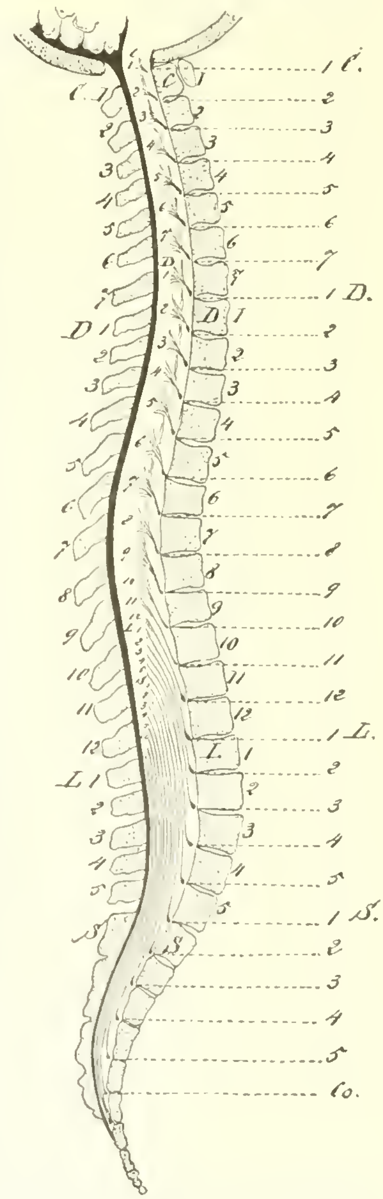

FIG. 3739.—Diagram Showing the Relations of the Spinous Processes to the Bodies of the Vertebræ, and of these to the Points of Origin of the Spinal Nerves. (From Gowers.)

Digitized by Microsoft®

tions, and their approximation in the spinal cord, medulla, and pons, admit of their frequent bilateral involvement from lesions in the latter regions, and but rarely in the first-named divisions. Consequently, the lesion producing paraplegia is usually a spinal-cord lesion. Yet it is possible to have a tumor develop in the longitudinal fissure www.libtool.com.cn between the hemispheres, which will involve the motor areas for the legs in each hemisphere, thereby producing a symmetrical and bilateral paralysis of the lower extremities, namely, a cerebral paraplegia. On the other hand, it is now well known that a peripheral paraplegia may be produced by a multiple neuritis involving the peripheral nerves of both lower extremities in such a symmetrical manner as closely to resemble spinal-cord lesions. Compression within the spinal cord of the bundle of peripheral nerves known as the cauda equina may also give rise to paraplegia. In the latter case, and also in multiple neuritis, we have the phenomena which attend irritation or destruction of a mixed nerve, namely, motor, sensory, and trophic disturbances in the parts supplied by the nerves involved. But motor, sensory, and trophic disturbances may also occur when the lesion is in the spinal cord, provided it be extensive enough to involve both motor and sensory tracts, and at a level from which the upper or lower extremities receive their motor innervation, namely, the anterior cornua in the cervical and lumbar enlargements. Lesions between these enlargements, or above the former or below the latter, do not produce the trophic disturbances which result in degeneration of peripheral motor nerves of the extremities, and the consequent atrophy of the muscles which they supply; although voluntary power and sensation may be lost through interruption of the cerebral motor and sensory conducting tracts traversing the section of the cord involved by disease.

Myelitis affecting the entire transverse area of the cord, but limited in its longitudinal extent to some portion between the cervical and lumbar enlargements, commonly known as transverse dorsal myelitis, furnishes an example of this form; while involvement of the lumbar enlargement will serve as a type in which motor degeneration and atrophy are added. Similar results may follow a meningitis, or meningo-myelitis involving the sensory and motor nerve roots or root zones at the level of the lumbar enlargement. Paraplegia, unaccompanied by loss of sensation, may be conceived of in case the meningitic or myelitic process remains limited to the anterior periphery of the cord, or to the anterior horns of the lumbar enlargement, by which the motor tract would be involved and the sensory tracts escape implication.

A similar process affecting the cord at its cervical enlargement alone might produce bilateral paralysis of the upper extremities without involving the lower extremities, as long as the myelitic process did not extend deeply enough to invade the pyramidal tracts in the lateral columns. Should it so extend, however, the lower extremities would exhibit paraplegia without loss of sensation and without muscular atrophy; while with a complete transverse lesion at the cervical enlargement loss of sensation in all parts below the upper extremities would be added, but still without degenerative atrophy in the lower part. The meningitic process might be extensive enough to involve both cervical and lumbar enlargements, affecting chiefly the anterior periphery of the cord, producing a paraplegia involving both upper and lower extremities with muscular atrophy in both, and even a transitory loss of sensation; or the gray matter of the anterior horns may be involved throughout the cord on both sides, as in poliomyelitis anterior, with similar results. Finally, we may have involvement of the cerebral (pyramidal) motor tracts in the lateral columns of the cord at any height, cutting off voluntary innervation to all parts supplied below the lesion, but without producing trophic disturbance.

L. L.*, lateral limiting layer; *A.-L. A. T.*, antero-lateral ascending tract, which extends along the periphery of the cord. (From Gowers.)

These examples show the necessity of keeping before us a mental picture of the topographical anatomy of the nervous system, and a recollection of the functions of the different tracts to the extent known, in all our attempts to localize a lesion from the symptoms found. The disturbances which accompany the bilateral paralysis constituting paraplegia will vary (1) *according to the level of the lesion* through interference with the visceral, vaso-motor, sensory, and reflex functions of the segment involved; (2) *according to the extent of the lesion transversely in the cord*, through involvement of different functional tracts and centres; and (3) *according to the predominance of an irritative, or of a destructive pathological process* constituting the lesion, producing increase, diminution, or perversion of function. The first and second factors concern the localization of the lesion, the third its nature and course. To aid in the consideration of the former, diagrams and tables are given, and a brief résumé of certain anatomical and physiological data.

The spinal canal is longer than the cord, the latter terminating in man at the upper border of the second lumbar vertebra. The exits of the several spinal nerves do not, therefore, correspond to their levels of origin in the cord, nor do the bodies of the vertebræ correspond to their spines. Gowers' diagram (Fig. 3739), showing the relations of the segments, nerves, and bodies of the vertebræ to the spinous processes, together with the table (Fig. 3741) showing the functions of the different segments, are valuable aids to diagnosis. The cervical enlargement corresponds to the lower five cervical spines; the lumbar enlargement to the tenth, eleventh, and twelfth dorsal, and first lumbar spines.

The ascending tracts of the spinal cord are (1) the antero-lateral ascending tract of Gowers, supposed by him to conduct painful sensations; (2) the direct cerebellar tract, whose function is unknown; and (3) the posterior columns, which conduct tactile and muscular sensations. Fibres serving the latter function, it is thought, occupy part of the median division of the posterior columns (columns of Goll), and do not decussate, while other sensory fibres do. The external columns (columns of Burdach) include the posterior root zones and fibres having a short course up and down the cord, probably decussating at higher levels, or connecting different levels of the cord. The ascending tracts degenerate upward from the

Digitized by Microsoft®

level of a destructive lesion. The descending tracts are the direct and crossed pyramidal tracts, concerned in the transmission of cerebral impressions downward to the motor centres in the anterior horns. They diminish in size downward, going chiefly to the cervical and lumbar enlargement; the direct tract mostly to the former. The remaining portions of the lateral column and the lateral limiting tract are supposed to contain commissural conductors of motor impulses between different levels of the cord on the same side. The anterior roots originate in the gray matter of the anterior cornua as already described, traverse the anterior columns (anterior root zones), and go to the muscles. In connection with the sensory roots through the gray matter, they constitute the "reflex arcs," interruption of either the motor or sensory division of which abolishes reflex action in that segment. Destruction of any portion of the motor division from the muscles to the cells of the anterior cornua, including the latter, besides producing paralysis and abolition of reflex action, also causes atrophy in the muscles and the corresponding motor tracts up to the point of lesion, which is characterized by the electrical reaction of degeneration. This does not follow a lesion of any other part. Destruction of the pyramidal tracts causes a degeneration of the column downward from the point of lesion, but this does not usually go beyond the connections of these tracts with the cells of the anterior horns. Atrophy, and the reaction of degeneration are absent. The reflex arc is not only preserved, but reflex excitability is increased. Impairment of voluntary power, and exaggerated motor reflexes frequently amounting to clonic or tonic spasm, characterize lesions of these tracts. Lesions of the cervical region may be accompanied by disturbances of respiration, of the cardiac functions, of the cilio-spinal centre (radiating fibres of iris), and by vaso-motor phenomena, showing either increased or diminished functional activity, as the lesion is irritative or destructive. Lesions in the lower segments of the cord interfere with certain functions of the bladder, the rectum, the sexual, and the vaso-motor apparatus in a similar manner, serving as aids to localization.

As disturbances of the bladder and rectum are usually important features in the paraplegic state, their complex functions should be referred to. Each of these organs has two sets of muscles, which are opposed to each other in action—the detrusors, which expel the excretions, and the sphincters, which oppose expulsion. Besides the local nervous apparatus which are found in the walls of all hollow muscular organs, and which probably constitute a reflex apparatus between the mucous membrane and the subjacent muscular, vascular, and glandular apparatuses, in a manner not fully known, these organs have their opposed muscular movements represented in the cord by motor centres situated somewhere between the origins of the second and fifth sacral nerves, and a reflex arc is established through sensory fibres from their mucous membrane and muscles. In addition to this there are sensory connections (posterior columns) with the brain, and voluntary paths from the brain (pyramidal tracts), by which a certain amount of control is obtained over the sphincters and detrusors, the mechanism of which is but imperfectly understood. The important facts for pathology are that, as in the involvement of other motor organs, lesions above the motor centres in the cord simply cut off the sensory impressions from these organs to the brain when the ascending tracts are destroyed, and interrupt voluntary impressions to them when the pyramidal tracts are destroyed. In the former case, there is no consciousness of the necessity of micturition or evacuation, and therefore no attempt to restrain it. In the latter, there is consciousness of the necessity, but inability to resist the expulsion. When both paths are cut off there is neither desire nor power to expel the excretions—involuntary and unconscious evacuations take place through the reflex mechanism in the cord; but when the lesion destroys the motor centres of the bladder and rectum, expulsive power and the power of the sphincters are lost, and the retention of excretions results, except evacuation due to the mechanical expulsion of liquid fæces and the dribbling of urine.

In most of the examples given to illustrate the question of localization of the lesion, destructive lesions have been assumed—that is to say, abolition or diminution of function, rather than the intensified activity of an irritative lesion. It should be borne in mind, however, that in most cases, before a pathological process becomes destructive, an irritative stage has existed; and that the irritative and destructive stages may so vary in their course and duration that both processes go on at the same time in different areas involved by the lesion. Thus paralysis may be preceded by clonic or tonic spasm; anæsthesia, by pain and by paræsthesia; abolition of reflex action, by an exaltation of the reflexes; vaso-motor paresis and failure in nutritive processes, by functional exaltation. Or, as instanced in paraplegia from transverse myelitis, between the focus of disease, in which function is lost, and the healthy portion, there is usually a region of increased activity—an irritated zone. The balance between these opposite conditions, which shade into each other, and the degree and extent of each, will vary with the nature and rapidity of the pathological process producing it.

FIG. 3741.—Table Showing the Approximate Relation of the Various Motor, Sensory, and Reflex Functions of the Spinal Cord to the Spinal Nerves.

Concerning the nature of the pathological process, the common division into structural and functional will serve our purpose; meaning, by the latter, that in which no perceptible change exists—abnormal variations in those molecular movements which constitute functional activity, and which are, therefore, dynamic rather than static in character. This class comprises many of the defects due to unstable molecular conditions, partly

Digitized by Microsoft®

Paraplegia.

inherited, partly acquired, and frequently dependent upon imperfect nutritive processes in the neural tissues, either assimilative or excretory. From this extreme, we have a gradation into coarser forms of molecular derangement, and, finally, into those in which the microscope, or the eye alone, distinguishes derangement in structure. Taking the latter first, as being more tangible, we find that nearly all structural neural disease begins in non-neural tissues. True, we may have direct traumatisms, as cutting, crushing, and compression of neural tissues; and there may be degenerative processes originating primarily in nerve fibres and cells, and direct toxic effects from organic or inorganic poisons conveyed by the nutrient fluids; but there is a larger group of disorders which are secondary to inflammation, acute or chronic, in the connective-tissue structure which forms the framework or support of the neural elements, or to vascular disease, such as hemorrhages, thrombosis, embolism, or proliferative occlusion.

Leaving the consideration of these elementary propositions, we pass on to consider the actual clinical forms of disease which result in producing paraplegia.

Taking the disease which most frequently produces paraplegia, myelitis, as a type, let us study its most common form—namely, transverse dorsal myelitis. This name implies that the entire transverse area of the section is more or less involved in the inflammatory process, and does not include the more limited centres of myelitis, termed *focal* lesions, which may be located in one-half of the cord, and rarely produce paraplegia; though this may result when independent foci involve motor tracts of the anterior horns or root zones, at the same level, or the pyramidal tracts even at different levels. Where several myelitic foci exist, the term *disseminated focal myelitis* is used. While the term "transverse" implies that the longitudinal extent of the lesion is limited, this is not construed in a narrow sense, and may be properly applied when the lesion invades both the lumbar enlargement and the dorsal segments. When the entire length of the cord is involved, the term *diffuse myelitis* is applied; this may be general—*i.e.*, involving both white and gray matter—or may be limited to the latter, when the term *diffuse poliomyelitis* (myelitis of gray matter) is used. The term poliomyelitis anterior indicates that the anterior cornua alone are invaded; while the term *central myelitis*, or *diffuse central myelitis* (according as it is local or general), is applied to poliomyelitis originating about the central canal and invading any portion of the remaining gray matter. Other adjectives are in use—such as *hemorrhagic myelitis*, when secondary to a hemorrhage within the cord; *compression myelitis*, when secondary to compression of the cord, as from tumors, inflammatory exudations, and fractures or dislocations of the vertebræ; *meningomyelitis*, when the inflammatory process invades the membranes and cord. The terms acute, subacute, and chronic prefixed to these various terms, specify whether the onset has been sudden, gradual, or slow.

1. Acute Transverse Dorsal Myelitis (involvement of any segment of the cord between the cervical and lumbar enlargements).

Symptoms.—Paraplegia resulting from this disease is usually characterized by the rapid onset of motor weakness of the lower extremities, preceded by numbness and painful tingling in the extremities; formication and other paræsthesiæ, moderate or severe; pain in the back and limbs, of a boring, tearing character; irregular twitching of muscular fasciculi; painful tonic spasm (cramps), and tremor of some of the muscles of the extremities; besides, in many cases, general febrile symptoms, usually of a moderate grade, and in rare cases eclampsia, particularly in young subjects. The motor weakness may be hours or days in reaching its highest degree, and this may be gradual, or by a succession of sudden accessions with intervals of partial recovery. Before it becomes complete the gait is similar to that of double hemiplegia of cerebral origin, for it is due to involvement of the pyramidal tracts. The superficial (skin) and deep (tendon) reflexes of the extremities are preserved, and the paralyzed muscles respond to such reflex excitation and also to electrical stimulation; the reaction of degeneration is absent, and the muscles of the extremities do not undergo atrophy except from disuse. Later, the reflexes become increased, often to a high degree. Spastic conditions and contractures may follow, and frequently become permanent. The lower trunk muscles may be involved and flaccid, showing diminished response to faradic excitation; there is retention of urine at first, followed by incontinence from reflex action. The sphincter ani is also cut off from cerebral control.

The pulse is usually rapid. Sensation is rapidly lost; anæsthesia takes the places of the painful paræsthesia, though frequently a condition of hyperæsthesia exists, particularly in the distribution of the nerve coming from the limit of the lesion, where it may form a zone producing the sensation of constriction about the trunk. The dorsal spines may also be sensitive to pressure at this level, but the pain and hyperæsthesia are not increased by active or passive movement. All sensation in the parts supplied from below the upper margin of the lesion may be cut off. If recovery takes place, sensation is usually regained before motion. Death may result from general exhaustion, though myelitis limited to the dorsal region is the most favorable form for recovery. If it extends to the cervical region, respiratory failure may follow; or if it invades the lumbar enlargement, bedsores, cystitis, and nephritis may hasten death. The course and duration, as well the acuteness of onset, are very variable. Months may elapse before recovery takes place; or sensation may be partially recovered, and there may be some return of power, but with spastic conditions which may persist for years. But some patients recover so completely and rapidly that after a few months no trace remains, except an increased patellar tendon reflex.

When the myelitic process involves the lumbar enlargement, either primarily or by the extension from the dorsal region, we have—

2. Acute Transverse Dorso-Lumbar Myelitis.—Here additional phenomena are present, due to the destruction of the motor and reflex connections for the muscles of the lower extremities, and for the bladder, rectum, and sexual apparatus. In place of increased reflexes we have both skin and tendon reflexes abolished. The reflex functions of the bladder and rectum are lost, as already described. Alkalinity of the urine, cystitis, and suppurative nephritis may follow. The muscles of the extremities are flaccid, undergo atrophy, and after a time the reaction of degeneration is found (frequently not before a week or two after paralysis).

Trophic disturbances in the skin and subcutaneous tissues, in the form of bedsores, frequently occur over the sacrum and the buttocks, and sometimes suppuration in the pelvic cellular tissue. The skin of the extremities is often œdematous, livid, and, in late stages, subnormal in temperature, although at the onset it may be supernormal—it may be dry or moist.

3. Acute Transverse Cervical Myelitis.—In this form the lower extremities and pelvic viscera are affected as in the dorsal variety; and, in addition, changes occur in the upper extremities similar to those described in the dorso-lumbar variety for the lower extremities—namely, trophic changes in the muscles and nerves, and in the electrical reaction and the reflexes; besides, vaso-motor, pupillary, cardiac, and respiratory disturbances occur; painful rigidity of the cervical muscles, pallor or flushing of the face and neck, contraction or dilatation of the pupils, and slowness or rapidity of the pulse, according to whether the irritative or destructive stage prevails. Optic neuritis has been found associated. Priapism is a more frequent condition in this than in the dorso-lumbar variety. The upper extremities are paralyzed first. If the process remains strictly a central myelitis, the lateral column will not be invaded and the lower extremities will not be involved. Should the section involved lie

Digitized by Microsoft®

above the cervical enlargement, the upper extremities would be affected like the lower ones—namely, preserved and exalted reflexes, and absence of trophic changes in the muscles. Respiration, deglutition, articulation, and the diaphragmatic functions (origin of phrenic nerve) may exhibit great disturbance, death usually resulting from respiratory failure.

www.libtool.com.cn

The morbid anatomical changes which constitute the basis of these symptoms are the result of irritative and destructive inflammatory processes in the cord; the irritative stage being represented by hyperæmia, exudation from the vessels, proliferation of lymphoid elements, minute capillary extravasation, and frequently by hemorrhage from small arteries. Later, the myelin of the medullated fibres undergoes swelling, granular degeneration, and disorganization. The axis cylinders and nerve cells may become swollen, opaque, or granular, some undergoing complete disorganization—this representing the stage of destruction. The latter process may continue until complete softening occurs, showing, on section, a softened or liquefied state, and, under the microscope, the débris of nerve cells, broken cell processes, myelin drops, lymphoid bodies, red blood cells, and the so-called granule cells—bodies many times the size of lymphoid elements, filled with highly refractive granules. When the process stops short of complete disorganization and a more chronic stage is reached, and also in the earlier stages of chronic myelitis, the neuroglia proliferates, forming more numerous and thicker bands, the walls of the vessels are thickened; lymph spaces may be obliterated or choked with lymphoid cells; so-called spider cells (Deiter's cells), larger connective-tissue cells, with larger and numerous processes, are scattered through the tissues, and the so called corpora amylacea are numerous.

This condition is known as sclerosis. It presents a grayer appearance in unstained sections; deeper red with carmine, and a paler color with the Weigert process, than the normal tissue. The naked-eye appearance, where the cord has undergone softening, has been divided into red, yellow, and white softening, representing successive stages during which the extravasated red blood cells are being absorbed. The more vascular parts of the cord are usually the first to undergo softening. These are on either side of the central canal in the gray matter, the process usually extending outward to the white columns, frequently along blood-vessels or connective-tissue trabeculæ. The appearances of softening or sclerosis on section are often quite irregular, particularly in the white matter.

Simple Softening of the Cord is met with, probably due to occlusion of the vessels from arteritis, embolism, or thrombosis. There are fewer signs of an active inflammatory process, white or yellow softening being found. It is characterized by the absence of marked irritative symptoms, which precede the destructive stage of the inflammatory variety.

Hemorrhagic Myelitis is characterized by a more sudden onset of the paraplegia than occurs in the inflammatory form, frequently becoming complete in a few minutes. The occurrence of traumatic conditions, as concussion, injuries to the vertebræ, etc., will frequently lend support to this diagnosis. The later changes are similar to the forms already described. A hemorrhage may be so small and so located as to produce only unilateral paralysis at first, as in the anterior cornua, paraplegia recurring later from a more general myelitis, secondary to the hemorrhage.

Compression Myelitis presents the usual features of a transverse myelitis, except that paraplegia may be preceded for a longer time by irritative symptoms than in the common inflammatory form, as compression is usually slow, being due to tumors in the membranes, or to vertebral disease. In its common form it is known as *the paraplegia of Pott's disease*. The paraplegic symptoms are those due to irritation of the sensory and motor nerves at their exit from the membranes, which may present pachymeningitis, or from the vertebral foramina, giving rise, chiefly, to bilateral pains in the trunk or upper extremities, in the course of the sensory nerves involved, and being frequently accompanied by hyperæsthetic or anæsthetic areas. Herpes zoster sometimes occurs. The reflexes and the functions of the sympathetic may be disturbed (pupillary, vaso-motor, sweating), and even muscular paresis and atrophy of the upper extremities follow, from this cause. The chief diagnostic features are evidence of localized bone disease, curvature, spinal tenderness on movement, and reflex muscular spasm at the region involved on flexure of the spinal column. Paraplegia, when it does develop, may appear suddenly. The distribution of the paralysis is usually that of the dorsal or cervical varieties, and presents the variations in localization of lesion described for these conditions.

It is considered one of the most favorable forms of myelitis as regards a partial recovery.

In Compression by Tumors pain is such a prominent feature that Cruveilhier was led to characterize the paralysis which it produces as *paraplegia dolorosa*. The pain is lancinating, at first intermittent, but finally becoming constant, and increased by movement. It is of a more severe character than the pain of vertebral caries. All varieties of localization may be presented, and all possible variations in mode of onset, and in slowness or rapidity of course, depending on the location, size, and rapidity of growth of the neoplasm, various symptoms becoming prominent according as different functional tracts are chiefly involved. Sarcomata (including gliomata) are the most frequent; gummata and tubercle are about equally common, while carcinomata and hydatids are among the neoplasms occasionally found.

Meningo-myelitis may result from an extension of the myelitic process outward to the membranes, or of a meningitic process into the cord.

Meningitis, both acute and chronic, may produce paraplegia by involving the anterior roots. When the entire circumference of the cord is involved, the sensory roots being also affected, we have a condition similar to involvement of a mixed peripheral nerve.

The lancinating pains, constrictive bands, muscular rigidity, and convulsive twitching are greater than in simple myelitis, and usually serve to distinguish one from the other. In cervical meningitis the paraplegia will be confined to the upper extremities, as the pyramidal tracts will be free unless there develop a meningo-myelitis, when these tracts may be involved.

As numerous examples have already been given, it will be unnecessary to review all the possibilities that may follow, or to consider all the varieties of meningitis. With a clear appreciation of the anatomical relations and functions, the extent and location of the lesion may be concluded from the symptoms, or *vice versa*. *Traumatisms* may also be left out of consideration, after what has been said on compression myelitis.

Poliomyelitis Anterior (infantile and adult spinal paralysis) may produce a paraplegia; usually, however, the lesion in this case being limited to the anterior cornua and their neighborhood in the anterior columns, certain cell groups succumb, while others survive, leaving an irregular distribution, not symmetrically bilateral, and therefore not paraplegic. The anterior group of one leg is most frequently involved. Nearly one-half the cases are monoplegic, and when bilateral the paralysis is frequently not symmetrical. It should be stated, however, that often during the first hours, and sometimes days, of this sudden paralysis, there is complete paraplegia, the trunk and all four extremities being involved; but it is distinguished from transverse myelitis by the absence of marked sensory or vesical symptoms, and by abolished reflexes. The statement concerning the unsymmetrical distribution of the paralysis also applies to the subacute form of this disease, and in fact to chronic degeneration of the anterior cornual cells, which produces progressive muscular atrophy.

The condition known as Landry's acute ascending paralysis, and also the lateral amyotrophic paralysis of Charcot, which may produce paraplegia, are so rare as to warrant no more than their mention.

Digitized by Microsoft®

The paraplegiform affection due to the ataxia of tabes dorsalis may give place to a true paraplegia by an extension of the degenerative process to the anterior cornua, producing muscular atrophy, or, in the form combined with sclerosis, by involving the pyramidal tracts, it may develop spastic and ataxic paraplegia.

Spastic Paraplegia results, as we have seen, from the symmetrical involvement of the pyramidal tracts in any part of their course, and is usually secondary to a transverse myelitis, or to a transverse lesion of the pyramidal tracts in their intracranial portion, or, particularly in infants, to arrested development of the cortical motor areas, in both hemispheres. It is sometimes termed double hemiplegia. It may affect chiefly the arms, or the legs, and has the usual characteristics, namely, spastic movements, exaggerated reflexes, and absence of sensory and trophic changes. Primary sclerosis of the pyramidal tracts in the cord is a rare condition, if it occurs at all.

www.libtool.com.cn

Intracranial tumors, by pressure upon the crura and pyramidal tracts in the pons and medulla, or in the cerebellum, may produce paraplegia or paraplegiform symptoms, in some cases being ataxic rather than paretic, or a combination of both.

Paraplegia from Multiple Neuritis is characterized by both motor and sensory impairment involving all the extremities, and ascending the members from periphery to trunk, also by pain, hyperæsthesia, tenderness of the nerve trunks to pressure, trophic changes in the muscles, the reaction of degeneration, œdema of the extremities, the absence of visceral disturbances (bladder and rectum), and the absence of a constriction band. It is most common in those addicted to alcohol, but is also a manifestation of certain endemic diseases, such as beriberi or kakki.

Pseudo-hypertrophic Paralysis produces a form of paraplegia somewhat similar to poliomyelitis anterior, and is considered by some to be a form of that affection, by others to be a connective-tissue disease of the muscles. The increase in size of the muscle (usually the calves) and its hardness, serve to distinguish it from ordinary poliomyelitis anterior.

There are several forms of paraplegia usually classified under functional disorders of the nervous system, namely, hysterical paraplegia, paraplegia depending upon idea, reflex paraplegia, malarial paraplegia, anæmic paraplegia, alcoholic paraplegia, and toxic paraplegia.

Hysterical Paraplegia is a less frequent form of hysterical paralysis than that of hemiplegic or monoplegic distribution. It is less apt to be confounded with paralysis of organic origin than the other varieties, for the reason that hysterical paralysis resembles in its symptoms a lesion of cerebral motor tracts in the brain and cord, rather than one in the remaining portion of the motor tract in the cord and peripheral nerves. The reaction of degeneration is absent in hysterical paralysis. Atrophy may be present, but it is that form which is dependent upon disuse. The volume of the muscles may be reduced in such cases, and may give a feeble reaction to electrical excitation; but, what is of the utmost importance, *faradic excitability is preserved, and the contractions are quick.* The skin and muscles may be cold, livid, and flabby, resembling paralysis from peripheral or cornual disease, and contractures may form as in degeneration of the pyramidal tracts, though in many cases the muscles and skin appear normal, except that voluntary control is lost. The tendon reflexes are rarely lost; usually they are increased, sometimes excessively so. The bladder and rectum are not usually affected, though voluntary control over these organs may be lost. Thus, paraplegia from transverse myelitis of the lumbar enlargement would not be confounded with hysterical paraplegia on account of the absence in the latter of trophic and electrical changes in the muscles and nerves, bedsores, and atrophic changes in the bladder; but the latter might closely resemble paraplegia from transverse dorsal myelitis in which these signs are absent. The presence of a constriction band at the level of the segment involved, and the sensory, motor, or reflex disturbances in this zone would exclude hysterical paraplegia. Hysterical paralysis of all the extremities might simulate cervical paraplegia of myelitic origin, but would be differentiated from it by the presence of trophic changes in the muscles of the upper extremities, and by the vaso-motor and visceral symptoms which accompany organic lesions of this region. Again, the onset and course of the two classes of disease are usually sufficient to distinguish one from the other. The irritative stage of most acute or subacute organic diseases of the cord, in which pain, hyperæsthesia, and slight motor irritation precede the paretic and anæsthetic period, is not usually present in hysterical paraplegia. In the latter, sudden development of the paraplegia, and sudden variations in its distribution and intensity, often serve to indicate it. Anæsthesia and analgesia may have a distribution inconsistent with the lesions producing paraplegia of structural origin.

It must not be forgotten that hysteria may accompany organic lesions, and should not, therefore, be taken as proof of the hysterical nature of the paralysis, unless organic lesions can be excluded.

Paraplegia Dependent upon Idea is a form described by Dr. J. Russell Reynolds. Though closely allied to hysterical paralysis, it may be independent of hysteria, hypochondriasis, and simulation, though frequently associated with functional debility, anxiety, and a morbid imagination. "Many cases of paraplegia following railroad accidents," says Reynolds, "may be classed under this head; the attention of the victim being influenced in the most unfortunate manner by the stories of friends, inquiries of his physician, the talk of his attorney, and the sober face of the company's physician." Pain, distributed in a manner inconsistent with the anatomical relations, on the supposition of an organic lesion; spasm, which, however, is sometimes relaxed in a remarkable way when the patient's attention is directed elsewhere; and paralysis, which is rarely complete, and almost identical with a voluntary attempt not to move the parts, or to move them with care, as in simulation, are the chief features of the affection. The removal of the morbid idea, *i.e.*, that the patient is paralyzed, or has a severe disease, results in improvement or cure. An award for damages has also frequently proven a valuable therapeutic agent in such cases.

Reflex Paraplegia, termed by older writers urinary paraplegia, was shown by Brown-Séquard to follow irritation not only of the genito-urinary tract, but also of the intestines and other viscera in animals. He attributed it to an anæmia of the cord, due to contraction of the blood-vessels, while Charcot considered the motor weakness due to inhibitory action of the sensory irritation. While we must admit the possibility of this form of paraplegia, it should not be forgotten that organic lesions may have been lost sight of, or might be sufficiently slight to be transitory. The positive evidence of some form of peripheral irritation, the removal of which has been followed by recovery, is the only basis on which it should be admitted, and then only in the absence of indications of organic disease.

Malarial or Intermittent Paraplegia is a curious form of poliomyelitis anterior, which recurs with the periodicity of intermittent fever. Alcoholic paraplegia, when not due to multiple neuritis, is a temporary affair, following an alcoholic debauch.

Anæmic Paraplegia follows ischæmia of the cord, from pressure on the abdominal aorta, and from pressure or occlusion of the iliac arteries within the pelvis, or ischæmia of muscles; rare conditions.

The indications for *treatment*, where paraplegia exists, are those adapted to the correction of the various pathological processes concerned in the diseases which we have considered. More than a brief résumé would carry us beyond the proper limits of this work. In the irritative stage of acute meningitic and myelitic processes, rest is the first essential. The reduction of hyperæmia, by means of agents supposed to cause vaso-motor contraction, such as ergot and belladonna, and the relief of pain by means of cutaneous irritation (the actual cautery, blis-

Digitized by Microsoft®

www.libtool.com.cn

ters, sinapisms, cupping, etc.), and also by morphine, may be attempted. The use of cold to reduce inflammation in spinal-cord disease is an uncertain procedure, concerning the real effects of which we know but little.

In the destructive stage of these conditions, when paralytic and anæsthetic phenomena are present, rest may still be an important factor. The use of mercury, and of potassium iodide, may be of service in this period to promote the absorption of exudations.

In later stages and in chronic cases the use of tonics, of iron, strychnine, arsenic, etc., is called for. Nitrate of silver may be indicated. Electricity is usually to be avoided in the irritative stage of an acute affection; or, if used, as for the relief of pain, it should be in the form of a gradually increased galvanic current, avoiding interruption. For the paralysis, the interrupted galvanic and the faradic currents, to produce muscular contractions, and spinal applications of the uninterrupted galvanic current, are of value, as are also massage and passive movements. For anæsthesia, the faradic brush is often serviceable.

Extreme care and cleanliness are essential in all cases of paraplegia, and the avoidance of pressure and irritation over the buttocks and sacrum, on account of the danger and frequency of bedsores. Attention must be paid to the bladder and rectum. Catheterization, conducted with extreme cleanliness, may be necessary, and also antiseptic irrigation of the bladder. Constipation must be prevented by cathartics, enemas, etc. Compression myelitis from caries, dislocations, fractures, and other traumatisms requires appropriate surgical treatment.

W. R. Birdsall.

PARASITES.—A parasite is an organism which lives, temporarily or permanently, within the body or on the surface of some other living thing upon which it feeds. Evidently, then, not only may there be both phytoparasites and zoöparasites, but also that form which is parasitized upon and is known as the host may be equally either plant or animal. Among forms which find in man at some time or in some region a subject for attack, the phytoparasites include the prominent group of bacteria which have received attention elsewhere, and a few fungi of etiological importance, in dermal affections chiefly, which have also been discussed. Here will be given a brief discussion of the animal parasites of man, with especial reference to their biological and etiological relations.

It is important to notice first the wide range in degree of parasitism exhibited and the manner in which the various grades merge into one another, producing a scale of dependence in which almost every stage is represented. Most independent of all are the temporary parasites, like the mosquito, bedbug, or leech, which stay by the individual host only long enough to secure a single meal, and which present clearly the structure and habits of free living organisms. Some leeches suggest most plainly the close relation between the carnivorous and the parasitic habit since they often devour bodily small aquatic forms, but when favored by opportunity extract the blood of larger animals. More dependent are such forms as the fleas which can change their host and often do so, and yet their structure has been highly modified in the loss of wings which are generally characteristic of insects and by the development of powerful leaping and grasping organs. Somewhat further modified in the direction of parasitism are the lice, which, moreover, lack special means for effecting a change of host, and may be included among the list of stationary parasites—*i.e.*, those that remain with a single host constantly, or at least for considerable periods of time.

All of the forms thus far noted are parasitic upon the exterior of the host, and consequently are denominated Epizoa or ectoparasites. All human ectoparasites belong to the group of Arthropoda, and include both mites (*cf. Arachnida*) and true insects (*cf. Insects*). Among the water-living animals, however, soft bodied forms such as flat worms (Trematoda) and unicellular animals (Protozoa) occur as Epizoa. With the gradual assumption of an aërial or terrestrial existence on the part of the host such parasites were necessitated, if they had not already sought more sheltered regions, now at least to abandon the external surface and to colonize internal organs where thin mucous membranes afforded facilities for extracting nourishment similar to those which existed on the thin outer skin of the aquicolous animal. The choanæ, pharynx, gills, lungs, alimentary canal, and even the bladder were thus invaded by forms whose kinship to the ectoparasitic species on these lower animals is too plain to fail of recognition.

The Entozoa or endoparasites of man, however, do not even belong to the same branch of the animal kingdom as the forms ectoparasitic upon him, with the single exception of the rare and aberrant Linguatulids, now usually regarded as highly degenerate arachnids (*q.v.*), though formerly classed with the Cestoda. The human Entozoa include Protozoa, Trematoda, Cestoda, and Nematoda, and many of them are highly modified in adaptation to the parasitic mode of existence, as compared to the related free living forms which, however, are entirely wanting in the second and third groups listed.

The term helminthology has been used as synonymous with animal parasitology, and yet this is a considerable extension of its original meaning. The Helminthes or intestinal worms included the pre-eminently parasitic groups, such as Trematoda, Cestoda, and Nematoda, while the Protozoa, Arthropoda, and even the few parasitic Turbellaria, which are in fact closely related to Trematoda, were omitted. The term became thus one of convenience rather than of scientific accuracy.

It is necessary to emphasize the fact that neither Helminthes nor parasites constitute a group of systematic value. At most the forms are related in a biologic sense and not structurally, for they are comprehended in several distinct branches of the animal kingdom, and a given form is often more closely related to free living species than to other parasitic forms. Even the narrower term Helminthes embraced forms of little similarity to each other and rightly to be distributed with their related free living species into several distinct groups, namely, the Linguatulida to the Arachnida, the Trematoda and Cestoda to the Plathelminthes, and the Nematoda to the Nemathelminthes.

Location.—While the majority of endoparasites inhabit the alimentary canal and its adnexa, there is no organ which is immune to them. The following list of human parasites arranged according to the organ inhabited will serve to indicate the extent of the parasitic habit, and will assist in the identification of a given form. The records given apply only to the human host. Parasites are entered under the normal location of the species, and in the most frequent erratic location only; a few forms of doubtful standing, as human parasites or of uncertain location in this host, are omitted.

* Many species possible (see key under *Nematoda*).

One may recognize among these parasites those which occur in their normal host but in an unusual location, like the brain cysticerci or a liver fluke in a subcutaneous cyst; there are also many of the species listed which cannot be regarded in any way as characteristic of the human host. Such are the occasional parasites which are species of true parasitic habit and can attain normal development in the human host, but ordinarily do not find conditions favorable for their introduction. As an instance of such species may be mentioned *Fasciola hepatica*, the common liver fluke of the sheep, which in many regions of the world is extraordinarily abundant. That it can thrive in the human system is demonstrated by the score or more of cases of its occurrence there definitely recorded; but its infrequence is equal evidence of a general immunity on the part of man, lacking in these particular cases, or of special features in its life history which make the infection of the human host difficult. That the latter is the probable explanation may be inferred from the fact that the cercaria larva, liberated from the intermediate host, encysts on grass, and hence could reach the human alimentary canal only under unusual circumstances. Similar examples may be taken from other groups of parasitic forms, such as the rare occurrence in man of *Strongylus apri*, one of the commonest parasites of the pig in Europe, or of *Dipylidium caninum*, the cosmopolitan tapeworm of both dog and cat, which has been reported only rarely from man.

Such occasional parasites often occur under abnormal conditions; thus a fish nematode, *Ascaris clavata*, was discovered once in the hollow tooth of a man. Here the position was probably accidental, but in other cases it is the result of the action of the parasite itself. So the "red spiders," or "jigger" mites of the Central States bury themselves in the skin of man, although such a position is so clearly abnormal that in fact it destroys the chance of further development and costs the parasite its life. A small leech, *Limnotis nilotica*, common in the Circummediterranean area, is often drawn into the throat of men and other animals drinking at wayside pools. It usually retains its position, causing serious difficulty, until removed by operative interference; hence it has become an occasional parasite of man rather than, as in the case of most leeches, a temporary parasite; or one may regard it as falling in the next following group of accidental parasites. This example shows most clearly the narrow and somewhat artificial limits which separate these groups of parasites from one another. Of the mites also, which have been reported a few times as obtained living from stomach, bladder, and rectum, it is difficult to say whether they are occasional or accidental parasites of man.

There are also rarely forms which commonly occur free living, but which by chance are introduced into some organ in which conditions are such that they can thrive. They become thus accidental parasites, a group difficult practically to distinguish from the last, the occasional parasites, and yet presenting somewhat different biological conditions. The recent discovery by Stiles and Frankland, as well as others, of the vinegar eel, *Anguillula aceti*, as an apparently successful colonizer of the bladder in a female patient illustrates the type under consideration. There is little doubt that this parasite was introduced through the use of vinegar in vaginal douches and effected a successful colonization, possibly by virtue of the trace of albumin present in the urine which furnished it with nourishment. Equally striking is the case of Scheiber, who discovered *Leptodera pellio* in the urine of a female patient in Hungary. This typical slime-inhabiting nematode gained entrance, no doubt, through the application of mud poultices, which are commonly employed by peasants in that region. It should be noticed that such accidental parasites are necessarily confined to those groups of animals which have free-living forms. Such are Protozoa, Nematoda, and perhaps Insecta in the larval condition, while Cestoda and Trematoda, which live only as parasitic forms in some host, would become rather occasional parasites of man should they stray into the human system in some chance manner and find favorable conditions for existence.

Quite distinct from the types just considered are pseudo-parasites, which rank high in clinical importance. Among them one may recognize several very distinct classes. First, those which are actually free-living animals, introduced by accident, usually in food or drink, into the human alimentary canal, exciting there abnormal conditions which induce their more or less immediate and forcible expulsion. Thus Botkin found in the vomit of a Russian numbers of a small nematode which he wrongly believed to be a human parasite. In fact it lives normally in the onion, and its introduction into the stomach with this food excited the untoward symptoms noted. Similarly Blanchard records a case in which coleopterous larvæ were found in the vomit of a child.

That such may be the result of introducing a true parasite from some other host is indicated by several cases, like that of *Ascaris maritima*, which Leuckart described from a single specimen vomited by a child in Greenland, and which this author noted was very similar to *A. transfuga* of the brown bear. In all probability it was ingested with the viscera of some animal (seal?), though it may have been a species which had strayed into this unusual host, only to make its appearance under the circumstances noted.

Of similar import are the cases of *Gordius*, the hair snake, which have been reported from man. In the adult condition this is normally a free-living species, but about a dozen specimens have been taken from man after a supposed sojourn of from a few hours to fourteen days. Some of these have been vomited and others passed per anum. This form has often been passed off upon the physician as a true parasite, and in one celebrated case at least as the Guinea-worm.

In the same way one may find the explanation for other isolated cases of parasitism, even when the parasite is reported to have been passed from the alimentary canal. Thus Cobbold reported that larvæ of *Blaps mortisaga*, the English churchyard beetle, were found in fecal discharges, and many authors have recorded the presence of dipterous larvæ in the alimentary canal.

The majority of such observers have inclined to regard these larvæ as temporary endoparasites, and to consider that they have accommodated themselves to the conditions present in the human host. The cases seem to show that these larvæ live for some time in the canal, and they often appear to evoke serious or even fatal disturbances; and yet the conclusions are open to grave doubt, for Calandruccio experimented extensively on two families of flies to which many of the supposed accidental parasites

belong, and found that the ingested larvæ were regularly and promptly evacuated, dead or dying, and in no case did they secure a footing in the canal.

Among the myriapods about forty recorded cases of pseudoparasitism have been brought together and discussed by Blanchard. In the large majority the animal was taken from the nasal fossæ, though in a smaller number it was actually obtained living from the alimentary canal, where it undoubtedly can exist for a brief time in spite of the untoward environment. The ingestion of such forms is purely accidental, the symptoms are those of helminthiasis in general, and their stay at most is very limited. They never show any evidence of adaptation to the new environment.

In some such accidental fashion other forms are sometimes introduced into various organs not connected with the alimentary system. Thus Trouessart reported the occurrence of a species of detricolous Sarcoptids in the human testicle where the mites formed an old colony in a painless cystic tumor.

In contrast with the living animals of the types noted, the second class of pseudoparasites includes a large number of other structures which have been described as parasites. These may be considered conveniently in a few groups, the first of which includes bodies which are parts of the so-called host animal itself. Thus fragments of the arteria hyaloidea have been described as eye worms (*Filaria lentis, F. oculi humani*, etc.), the organisms of whooping-cough are nothing more nor less than ciliated tracheal cells torn from the wall and found in the sputum in distorted form, while groups of small axillary and inguinal glands, hydatid moles, and Pacchionian bodies from the arachnoid have been frequently put on record as hydatid cysts.

Parts of substances used as food, both of plant and of animal origin, which have not been destroyed by the action of digestive juices are also among the pseudoparasites of man. The radulæ of the common limpet have been reported several times from stools; the seeds of the mulberry were duly baptized as parasitic worms; and plant vessels and other similar undigested structures of peculiar appearance appear periodically as new helminthes. That a differentiation of such structures is not simple appears from the account given by Stiles of the partially digested banana fibres which closely simulate minute tapeworms. Some years ago Leuckart entrapped a group of research students in helminthology with the pulp vesicles of an orange which were found in a fecal examination.

In all of the cases considered above it should be kept in mind that the animals or these other structures actually came from within the human body. There is, however, another class of objects of which this cannot be said.

In determining the nature of unusual forms reported from man it should always be kept in mind that in the absence of positive personal evidence, suspicion in case of neurasthenia at least favors the deceitful introduction of doubtful bodies. In many cases on record such things as earthworms, chicken entrails, etc., have been forcibly introduced into the rectum or vagina, and have been subsequently reported by the attending physician as undoubted human entozoa of a remarkable character! Here as elsewhere the appearance of unusual structures should at once arouse the suspicion of the physician and call forth a most searching examination of the case in all its factors, that any deceit be disclosed, or that in the event of the discovery of some rare parasite all conditions connected with its appearance be put on record for future use. The large number of parasites in other animals which some unusual combination of circumstances may bring into the human system makes it imperative also that any supposedly new species be submitted to the judgment of a specialist before it is described as such. Only in this way can the discoverer avoid adding to the long list of synonyms, which already burden the literature of this subject, and render it so difficult for the investigator not a specialist in this particular line to find his way aright. Furthermore, it is important to preserve the fullest data in regard to any substances associated with the supposed parasite, as well as the food of the patient, whether usual or unusual, since in this way some hint as to its introduction may be found.

Effect upon the Host.—In the belief of the medical profession two hundred years ago there was no disease, real or imaginary, which was not due to the presence and effect of some kind of parasite. Each ailment had its particular "worm" in its characteristic location. This was a direct result of the endeavor to reduce every malady to some definite cause, and of the joining of the unknown sickness with the parasites of which they knew as little. Under the influence of study and of increasing knowledge regarding the parasites such a theory was seen to be untenable, and the movement in the opposite direction began, a tendency which may be said by this time to have passed its height.

It is true that internal parasites are very widely distributed, and that scarcely any individual is entirely free from them. They are, however, usually present in limited numbers, and are believed to be harmless if infrequent or of small size. This does not seem to be strictly correct, for while it is doubtless true that the effect of a single parasite, or even of a considerable number of minute size, is small and difficult to measure or estimate, it is equally clear that even this is a certain drain on the host. Furthermore, the tax on the host is in proportion not only to the number and size, but also to the habits of the parasites present. Thus there is a great difference whether the parasite is active and growing in the alimentary canal or some other cavity in the body of the host, or passively resting in the midst of the tissue of some organ.

While encysted parasites exercise a continued and sometimes serious pressure on adjacent tissue, yet the draft on the host by free parasites is much the greatest, and manifests itself in three ways. The parasite requires a certain amount of food for its support; this it takes directly from the host, either from that which the latter has digested for its own use, if the parasite be in the alimentary canal, or from material which the host has formed to perform certain work, as in the case of blood parasites, or from the tissue of the host, as in the case of some intestinal worms which feed on the cells composing the wall of the intestine. In any case the host expends at least the extra energy necessary to procure and digest the food taken by the parasite, and this extra labor will be directly in proportion to the amount of food taken, or in general to the size of the parasite and to its fertility.

In the second place the parasite occupies a certain amount of space, and correspondingly reduces the calibre of the tube in which it lives. Unless a considerable number are present this is hardly a practical stoppage for the alimentary canal, although in several recorded cases death has followed occlusion of the canal by a mass of ascarids, and in the case of the blood system a vessel may be closed or a clot formed by the presence of even a very few parasites.

In the third place active parasites will, by their movements, give rise to a certain amount of irritation and inflammation of the membranes over which they move. This is in some ways, perhaps, the most serious trouble which a few parasites can cause, and it is much increased if in the special case the parasite obtains its food at the expense of the tissues of the host, that is, if it tears or consumes the walls of the cavity in which it lives. A secondary, though possible, result of this manner of living is the liability of rupturing some blood-vessel, with consequent serious results, as in the case of certain lung flukes which may chance upon some large blood-vessel and in this way produce even fatal hemorrhage. In the alimentary canal a single ascaris may perforate the wall and induce fatal peritonitis, as has been observed several times in recent years. It is evident, then, that no more than a single active parasite may be dangerous, and that it is always some tax on the domestic economy of its host. Of course, the effect of a microscopic worm in the alimentary canal of an elephant will be so small that it

Digitized by Microsoft®

could hardly be calculated in any way; but this reasoning should not be extended too far. The disturbance produced in the human system by a single tapeworm is sufficient to call for prompt measures to remove it.

Recent studies have demonstrated the presence of hæmoglobin in the alimentary canal of many nematode parasites, the pathological effects of whose activities must be counted much more important than heretofore estimated by reason of this blood-sucking habit. Thus in cases of uncinariasis the amount of blood lost from myriads of minute hemorrhages imparts a characteristic reddish-brown color to the fæces, the intestinal wall becomes seriously affected and affords places of easy attack for any pathogenic germs which may be present. This indirect damage may be very serious in the individual instance, and may include primarily or secondarily undesirable retrogressive or progressive histological changes, inflammatory processes, and disturbances in the circulation.

Another source of danger from parasites is one which has long been surmised but only recently demonstrated. A number of investigators have shown that various Cestoda, Acanthocephala, and Eunematoda contain definite poisons (toxins) which when extracted and employed experimentally affect particularly the nervous system and the formation of blood. The continued formation and giving off of such a substance would explain the apparently excessive results of parasitism in some instances, results which are shown prominently in reflex nervous symptoms such as have been noted under Argas (*Arachnida*), and Tænia (*Cestoda*). In a certain proportion of cases pernicious anæmia is the result of this toxic effect, and is accompanied by a mortality of seventeen per cent., according to one report regarding Bothriocephalus. Whether the poison is elaborated by the parasite or is produced by pathological processes in the worm or by its death, as well as the ground for the variability in the toxic action of different specimens, are questions as yet undecided. It has been shown, however, that extracts from different species of helminthes vary considerably in toxic power. Vaullegrard has isolated two toxic principles, one of which acts upon nerve centres and the other upon muscles, and many symptoms produced experimentally by the injection of these substances are analogous to those manifested in parasitic disease. According to this chemical theory, the troubles caused by parasites are due to the formation of toxic substances more rapidly than their elimination by the host, and their consequent accumulation in the system.

It is noteworthy that eosinophilia has been recorded as a frequent if not universal symptom in parasitic infections. From 15 to 50 per cent. of eosinophiles in trichinosis, 10 per cent. in uncinariasis, 15 per cent. in oxyuris infection, and 20 per cent. in ascarid infection are average figures. The percentage varies greatly and does not appear to be constant, while it is present in other pathological conditions as well.

Life History.—Normal parasitism is related to the life history of the parasite with peculiar intimacy. Among accidental parasites the animal seems to continue the usual method of multiplication under the changed conditions. Thus Oerley was able to colonize *Leptodera pellio* in the vagina of mice where they reproduced normally. But in case of the well-known *Rhabdonema nigrovenosum* of the frog the parasitic generation alternates with a free living generation, and the two are distinguished only slightly in structure but radically in method of reproduction, since the one is diœcious and the other hermaphroditic. In the case of the parasite of Cochin China dysentery also, *Strongyloides stercoralis*, there is a hermaphroditic parasitic generation and a diœcious free-living generation, in which the individuals differ noticeably from the first. Alternation of generation is not infrequent among true parasites, but it usually bears a different relation to the life history, and one which will be clear after the examination of the simpler cases.

In the simplest case which is exemplified by many of the Nematoda parasitic in the alimentary canal the eggs reach the exterior with the fæces of the host, and in them or in water undergo development until after a brief period of growth, either still enclosed in the protecting egg membranes, as is the case in *Ascaris lumbricoides*, the common stomach worm, or as a free-living form in the water, the larva is ready to be reintroduced into the human alimentary canal. Then it undergoes its transformation into the adult, which is usually only growth, and the formation of the reproductive organs which are present in the larva in the form of a single cell or group of cells near the centre of the body, often so insignificant in the undeveloped condition as to escape observation. This type of development may be somewhat complicated by the sojourn of the parasite in one region of the canal, where it passes through the earlier stages of development and becomes sexually mature before seeking its definitive location. Such is the case in the pinworm, *Oxyuris vermicularis*, which grows to sexual maturity in the ileum, while the pregnant females migrate to the rectum in order to make periodic excursions to the perineum for oviposition.

A more complicated development is illustrated by the Guinea-worm, *Filaria medinensis*, in which the embryos set free into the water seek out a new host and enter its body in order to pass through the early stages of development there. After having attained a certain stage of growth in this host the larval parasite is ready for introduction into the final host, in which it reaches sexual maturity, and this change is effected probably by chance. The host in which the sexually mature parasite occurs is known as the primary, while the secondary is that in which the larva is found.

In the extreme case the life history is so modified that the parasite never reaches the external world, but passes from one host to another directly. Here the ultimate extreme of the parasitic habit has been attained. As illustrations of this several species of *Filaria* and *Trichinella* may be instanced. In *Filaria Bancrofti* the adult is parasitic in lymph glands and the embryos are set free in the blood stream. From this they are sucked out into the body of a mosquito and there undergo early development, only to be reintroduced at a later stage into the body of a new host where the mosquito is biting. In *Trichinella spiralis* the encysted larvæ in flesh are set free in the stomach by processes of digestion. They wander into the duodenum, and after attaining sexual maturity the female penetrates a villus and sets free the embryos which, reaching the muscle tissue through the agency of the blood current, encyst there and await transference to a new host. Thus in both cases no part of the life history takes place in the external world, and the transfer of the parasite is dependent upon the carnivorous or blood-sucking habit of the animal which functions in the one case as secondary host and in the other alternately as primary and secondary host, but in different organs.

A still more complicated relation is found in the majority of Trematoda and in some Cestoda when the change of host is associated also with an alternation of a sexual with an asexual generation. In most Cestoda the eggs develop into an embryo which in the secondary host gives rise by metamorphosis to a peculiar larva, the bladder worm; and this after its transfer to the primary host develops into the adult tapeworm. The relation between primary and secondary host here is generally that of food and feeder. Thus the bladder worms of the two most common human cestodes are found in the flesh of cattle and hogs respectively and develop when introduced into the alimentary canal of man into the adult tapeworm. Though somewhat complicated by radical changes in form, the process is generally regarded merely as a metamorphosis. The case is somewhat different in those forms, as, for instance, *Tænia echinococcus*, in which the bladder worm proliferates, forming not a single head merely, but several or many, from each of which when introduced into the proper host there may develop an adult cestode. Here the larva in the secondary host multiples asexually, while the adult in the primary host

Digitized by Microsoft®

reproduces sexually. The change of hosts is accompanied by an alternation of generations or metagenesis.

In the Trematoda one finds the same alternation of generations coupled with change of hosts, only that the asexual generation may be repeated and the life history further complicated by the introduction of a new host, the tertiary, in which a stage of the development is passed. Among those forms of which the life history has been ascertained great difference obtains in detail; of the species parasitic in man the development is as yet known only in part so that the general statement may suffice and reference be made for details to the special account of the group given elsewhere.

Mode of Introduction.—The life history often gives a clew to the means by which the parasite gains introduction into the human host. Thus the discovery of bladder worms or of larval *Trichinellæ* in pork suggested at once the manner of infection, namely, by eating the flesh containing these larval stages without the flesh having been subjected during preparation to conditions such as to kill the larvæ. This method of infection, namely, the introduction of encysted larvæ, is characteristic for the Cestoda. Those species most common as adults in man among civilized nations are obtained directly from articles of food, as *Tænia saginata* from beef, *Dibothriocephalus latus* from fish; other less frequent species as *Hymenolepis diminuta*, *Davainea madagascarensis*, and others of which the larval stages are found in insects (cockroach, beetle, meal worm) owe their introduction perhaps to the chance inclusion of such infected insects in bread, puddings, or other similar articles of food.

Disregard of personal cleanliness on the part of the individual, the habit of biting the finger-nails, and among children the practice of sucking fingers or toes serve to infect such with the eggs or embryos of many parasites or to increase an infection already acquired. In this way there is introduced the larva of *Dipylidium caninum* which lives in the dog and cat fleas, the eggs of *Ascaris canis*, the dog and cat round worm, eggs of *Oxyuris vermicularis* which are deposited upon the perineum of the host, eggs of *Cysticercus cellulosæ* when the adult is present in the same host, and many other species. Contamination of hands with eggs from dirt and consequent infection of the individual is common in children and field laborers, and may introduce any form of which the eggs are capable of causing the direct infection; these forms are *Ascaris lumbricoides*, *Trichocephalus trichiuris*, and other Nematoda.

The introduction of eggs and embryos takes place in the majority of cases, no doubt, through the contamination of the water supply. Almost all the eggs of the helminthes develop in standing water, and primitive methods of obtaining drinking-water from pools afford the best means of disseminating the species. Salads and other foods eaten uncooked serve as further means of infection, especially in those regions where it is customary to use human excrement to enrich the soil, or where the water supply of the village is dependent upon infected sources.

Among the important parasites which reach the human system as eggs in water or on uncooked vegetable food are of the Cestoda: *Cysticercus cellulosæ*, the larva of *Tænia solium*, *Echinococcus polymorphus*, the larva of *Tænia echinococcus*; of the Nematoda: *Ascaris lumbricoides*, *A. canis*, *Oxyuris vermicularis*, *Trichocephalus trichiuris*; of the Linguatulida: *Pentastoma denticulatum*, *Porocephalus constrictus*.

Of those which as larvæ attain the human host in the same manner one may list all the Trematoda parasitic in man, and of Nematoda *Strongyloides stercoralis* and possibly *Uncinaria duodenalis*, though according to the studies of Looss the latter seems to bore its own way actively into the body of the host.

The part played by chance in the introduction of parasites is very large. Grubs, hairworms, maggots, and even tapeworms have been taken from wells and from running water. The same forms occur frequently in various kinds of fruit; others in old or carelessly handled meat, also mites in cheese and fruit; and any or all of these may at times reach the human alimentary canal, where according to their adaptability they become occasional, accidental, or pseudoparasites. Their presence may be made known at once by adverse conditions, or they may remain long undetected so that their source is fully unknown. They may reach peculiar locations, as is shown by the flesh fly maggot taken from an abscess in the middle ear, which it had in all probability reached by active migration through the Eustachian tube, having been introduced into the throat with a piece of meat.

Factors Controlling the Abundance of Parasites.—The life of man in communities led at first to a large increase in the number of parasites and to frequent epidemics; and both of these results were due to conditions resulting from the communal life. Of primary importance is the impure water supply which semicivilized communities are wont to draw from the nearest pool. The minute, well-protected eggs of parasites distributed in fecal matter everywhere (for such communities are not exacting in their demands for the disposition of waste) are carried by rain water and distributed over large areas contiguous to the settlements and contaminate generally the surface water of the district. In case the parasite develops directly, the human host becomes infected by the use of this surface water; and if it is a form requiring a secondary host, the same conditions give it easy access to the forms which serve as such, since these are largely domestic animals. The close relation of the abundance of parasites to the water supply is well illustrated by the case of *Bothriocephalus latus*. This form is very common in a few regions in Europe, all of which are proximate to bodies of water. The intermediate host is a fish, and the very means adopted by civilized communities for removing danger of contamination from waste, namely, the sewage system, became the medium through which the eggs and embryos were carried into the lake. There they found suitable secondary hosts in the fish which subsequently reached the city markets further to infect the populace. The life cycle was complete within narrow geographical limits, and the element of chance which plays a large part in limiting the numbers of parasitic animals was reduced to lowest terms.

The dangers of parasitic infection in communal life, which pays little attention to the amount and character of surrounding surface water, is also illustrated by the spread of malaria, elephantiasis, and yellow fever, which depend upon the abundance of mosquitoes bred in this casual water. It has been abundantly shown that criminal carelessness on the part both of individual and community has multiplied breeding places and contributed materially to the spread of these diseases. Even the invention of protective screens has not been able to cope with these aggravating carriers of disease.

The habit of the isolated individual is also that of the community, even such as may be well advanced in the social scale, namely, to deposit human excrement indiscriminately. This method, which even to-day is practised in some parts of the United States, is well calculated to give to eggs of parasites a maximum opportunity for development. The same opportunity is afforded when the Chinese gardener employs for the enrichment of his garden patch human excrement from the neighboring village.

The same massing of individuals which has made the community more liable to parasitic infection plays its part in the infection of the secondary hosts, especially those which are domesticated animals. If the ground on which cattle are grazing becomes infected by tapeworm eggs, the entire herd may receive bladder worms. The infection of a single hog with trichinæ means the contamination of the entire group if the pernicious habit is followed of feeding to others the remnants of a slaughtered animal. Just here is the chief reason for the strong condemnation which has been visited upon local slaughter-houses. They regularly feed the offal to hogs, and by so doing further the spread of such parasites. In the large packing establishments the requirements of modern

Digitized by Microsoft®

industrial success are met by regulations which cure the evils referred to. All remnants are used and are subjected to processes which destroy whatever parasites may be included. Under these conditions one may safely predict the gradual disappearance of parasites, especially with the co-operation of certain factors not yet mentioned.

www.libtool.com.cn

In addition to municipal features as noted, personal habits play an important part. Cleanliness of person and hands, coupled with careful ablution not only of the person but also of the various articles of food, reduces the percentage of parasitic infection. A simple infection of *Trichocephalus* becomes manyfold greater by the accidental transfer of eggs from the skin near the anus, where they are deposited, to the mouth. The reality of such supposed auto-infection is proved by the high degree of infection among insane and defective classes which are known to exercise little care over personal cleanliness. No doubt many eggs of parasites are introduced on salads and other uncooked foods which are eaten without sufficiently careful cleansing previously.

The employment of footgear and hand coverings is influential also, because it reduces directly the likelihood of infection from eggs of parasites contained in earth, etc., which with uncovered hands become temporarily imprisoned beneath the finger nails of the field laborer. These coverings may also play a considerable part in preventing infection with *Uncinaria* if the observations of Looss are confirmed that the larvæ enter the body by an active migration through the skin, chiefly of the hands and feet, with which they come in contact in the case of field laborers.

Another factor which has tended to reduce the percentage of parasitic infection is the less intimate association of the more highly civilized individuals with domestic animals, especially dogs. The parasites of these animals, and in particular one species, *Tænia echinococcus*, possess great clinical importance for man. Not only is it apparently less frequent than previously, but also its frequence is certainly greatest now in those regions in which the inhabitants live most familiarly with their dogs. It should be noted also that the initial infection of the dog is prevented by keeping from it the offal from slaughtered cattle and sheep.

Probably more influential than any other factor in determining the reduction in degree of parasitism is the use of cooked food. A large part of the flesh food of semicivilized man is eaten raw or only partially cooked, in which condition the larval parasites are capable of development to the adult on reaching the alimentary canal of the new host. Were all animal food eaten only when thoroughly cooked, the common tapeworms and the dreaded *Trichinella* would cease to have clinical importance. The abundance of *Tænia saginata*, the beef tapeworm, where beef is eaten raw, of *T. solium*, the pork tapeworm, where raw ham is a delicacy, and of *Dibothriocephalus latus*, the broad tapeworm, where partly cured fish is eaten uncooked, furnishes the demonstration of the proposition advanced. And so long as pork is eaten uncooked cases of trichinosis will occur, whatever means may be taken to reduce the danger by meat inspection.

That factor which is about to be considered is destined to play the greatest rôle in the limitation of parasitism; it is the intellectual, and by it is brought about the determination of a rational hygiene and its application by the individual. National prejudice or established custom can oppose its introduction only temporarily, and it must ultimately succeed in reducing to lowest terms the parasitic infections of man and the important food animals.

Henry B. Ward.

PARATHYROIDS. (NORMAL AND PATHOLOGICAL ANATOMY.)—In 1880 Sandström discovered the presence of small glandular organs on the posterior surfaces of the lateral lobes of the thyroid. He found these to be of constant occurrence, and from their structure regarded them as embryonic thyroid tissue; he accordingly named them *glandulæ parathyroideæ*. A year later, the same organs were independently discovered by Stieda in embryos of the pig, and by Baber in different animals. The former regarded them as carotid glands, the latter as embryonic thyroid tissue. But little attention was paid to these glands until 1891, when Gley asserted their importance. In the few years immediately following, his statements were supported by numerous observers. In 1895 the first careful study of the minute anatomy of the parathyroid was given by Schaper. Numerous experimental investigations followed, both in normal and thyroidectomized animals, showing the physiological importance of these structures. Various names have been proposed for them: "*epithelial bodies*," "*accessory glands*," "*accessory thyroids*," "*glandules thymiques*," etc.; the original designation *parathyroid* has the advantage, however, that the organs are not thereby confused with the accessory glands having the true thyroid structure.

As to the physiology of the parathyroids and their function no absolute knowledge has yet been obtained. It was first believed that they had a direct connection with the thyroid, and could compensate for it. Later experimental investigations in transplantation and extirpation, as well as in feeding with gland substance, have shown that the parathyroids have a function distinct from that of the thyroid. The loss of the thyroid leads to a chronic disease, that of the parathyroids to an acutely fatal disease. Feeding with gland substance is effective only in case of the administration of the same gland substance as that of the organ affected; thus thyroid feeding is of value only in case of the loss of the thyroid, and parathyroid feeding only in case of loss of the parathyroids. In transplantation, both thyroid and parathyroid preserve their characteristic structure.

The various investigators are not yet agreed as to the embryology of these glands, but it may be regarded as proved that the parathyroid bodies lying outside of the thyroid have an independent *Anlage* in the fourth gill pouch. In some animals there occurs constantly an epithelial body included in thyroid tissue, which probably arises from the third gill pouch. This internal epithelial body occurs so rarely in man that its presence may be regarded as a probable anomaly of development. Further, the parathyroids arise from single symmetrical *Anlagen*, and their occasional multiplicity is to be ascribed to a secondary snaring off.

The parathyroids occur usually in pairs; sometimes one on each side, or two on one side and one on the other. The writer has also found three upon one side. The total number observed has never been greater than four.

In size they vary greatly, but they are usually very small; the average, as found by the writer, being about 7 mm. long, 2–3 mm. broad, and 1.5 mm. thick. The average weight is about 0.2–0.3 gm. They are often almond-shaped, having one end recurved; but the shape not infrequently suggests the spleen. At other times they may be flat, cylindrical, or round. Their color is usually pale brown, but may be brownish-red or bluish, so that they are easily mistaken for hæmolymph glands. They usually lie behind the lower poles of the lateral lobes of the thyroid, separated from the thyroid tissue by connective tissue, their convex surfaces lying in slight depressions on the under surface of the lobes. Not infrequently they are found below the thyroid, even as low as the level of the clavicle. It is often very difficult to recognize the parathyroids at the autopsy; therefore all of the glandular structures in this region should be removed for microscopical examination. It is of advantage, in case the organs are not easily found, to take out the neck organs *in toto* and fix them in formalin. After fixation the dissection of the region behind and below the thyroids usually results in the determination of the exact location and relations of the parathyroids, their brown color becoming more prominent in contrast to the white adipose tissue about them. By following up the branches given off from

Digitized by Microsoft®

the inferior thyroid artery, just before the vessel passes into the thyroid, the parathyroids are usually easily discovered. They derive their blood supply from these branches. Their veins empty into the veins on the surface of the thyroid, or directly into the inferior thyroid vein. But little is known of the nerve supply. Sacerdotti and Anderson have traced nerve fibres along the vessels and between the epithelial cells.

www.libtool.com.cn

The microscopical appearances are those of a gland having a delicate capsule, from which thin connective-tissue septa pass in, supporting the larger blood-vessels, and separating the imperfectly developed lobules. The general appearance of the gland may vary greatly. Often it appears as a single mass of closely placed cells, between which run numerous delicate capillaries, forming a network in the meshes of which lie the cell groups or alveoli. No connective tissue accompanies the capillaries. In other cases the lobular arrangement is much more marked, the cells showing a more decided cord-like or alveolar arrangement. The anastomosing columns may consist of a single row or of several rows of cells, arranged upon the capillaries. In other specimens the cells may be grouped into round follicles. Not infrequently all three types are found in one gland.

The cells vary in appearance, so that three chief varieties may be distinguished. The majority are somewhat larger than those of the thyroid; the nucleus stains deeply, the protoplasm but slightly. The boundaries of these cells are visible as fine lines. Besides these, there are large polygonal cells with deeply staining nucleus, very granular protoplasm which stains deeply, and with sharp cell outlines. The third type of cell is low, columnar, and is arranged upon a basement membrane in such a way that the cells radiate toward the centre of the group, giving it the appearance of a follicle. In the centre of this a definite lumen may often be made out. It usually contains a finely granular substance, but may contain a colloid-like material. Occasionally the follicles are cystic. Between these three types of cells there are all possible transition forms.

Many of the large polygonal cells stain heavily with eosin, resembling closely the acidophile cells of the hypophysis. In others fine fat droplets are often present. The follicular arrangement of the cells is always more marked when the lumen-like opening, containing granules or colloid-like material, is present. The different appearances presented by the cell indicate most probably different stages of functional activity.

The circulation of the gland is sinusoidal in character, the epithelial cells being separated from the blood by endothelium only, connective tissue as a rule not accompanying the capillaries. The secretion of the gland, as clearly shown in a hypertrophic parathyroid obtained by the writer in a case of acromegaly, is into the lymph vessels.

According to Benjamins colloid is constantly present. The writer has not found this to be the case, but has found constantly in the open follicles a finely granular substance. He agrees with Benjamins that the parathyroids are individual and constant organs, differing in structure and function from both the fœtal and the mature thyroid; and that the differences in size, form, and staining reactions represent different stages of functional activity.

Pathology.—Variations in size, shape, and number of the glands occur. Cysts lined with columnar or flattened epithelium may be found near or in connection with the parathyroids, as congenital "rests" of the gill pouch or of a diverticulum of the same. Benjamins suggests that this is an analogue of the *ductus thyreoglossus*, and should be designated as the *ductus parathyroideus*. The writer has observed in one case in man a blind duct, lined with low columnar cells, passing into the parathyroid, its epithelium being directly continuous with that of the gland. Near the entrance of the duct into the parathyroid there were several large cystic follicles containing colloid-like material.

Circulatory Disturbances.—In general venous congestion the capillaries of the parathyroids are dilated; in general anæmic conditions they are collapsed and contain but little blood. Local anæmia may be caused by pressure of strumous thyroids. Hemorrhage, œdema, and inflammation may also be caused by struma.

Retrogressive Changes.—*Pressure atrophy* may be caused by struma of the thyroid. *Fatty atrophy* occurs in old age and in cachexias. Benjamins has observed *hydropic degeneration* in groups of cells, occurring in two cases in which the organ was hyperæmic. The writer has obtained a reaction for *mucin* in the cysts found in one case. He further regards the presence of *colloid material* in such cysts as being of the nature of a degeneration.

Hypertrophy.—In a case of acromegaly with adenomatous tumor of the hypophysis the writer found great enlargement of the parathyroids, the right parathyroid weighing 1.5 gm., the left 1.7 gm.; the right one being nearly 2 cm. long. Both were deep bluish-red. The microscopical examination showed the follicles to be for the greater part cystic, and containing finely granular material staining deeply with eosin. No colloid was found. All transition stages could be observed, from the closed follicle to the cystic ones. The dilated cystic follicles could be seen to possess direct communication with the lymph vessels. The thyroid in this case showed interstitial increase of connective tissue.

Benjamins has seen an interstitial hyperplasia of the connective tissue of the parathyroids in a case of Basedow's disease associated with cirrhosis of the liver.

In struma of the thyroid, according to Benjamins, there is no increase of size in the parathyroids; on the contrary, they are often smaller, and are either normal or show retrogressive changes rather than progressive. These changes are to be referred to the pressure of the enlarged thyroid.

With the exception of the one case mentioned above, Benjamins found no changes in the parathyroids in Basedow's disease.

Benjamins describes a tumor attached to the right lobe of the thyroid, which in structure he regards as closely resembling that of the parathyroid, and regards its origin from the latter as possible.

Functional Relation between Thyroid and Parathyroid.—The evidence at present is against the existence of any close functional relationship between these organs. In conditions of extensive thyroid disease the parathyroids are normal or only secondarily affected. In a case of cretinism with total defect of the thyroid, reported by Maresh and Peucker, the parathyroids were normal. Other disturbances of development of the thyroid occur, in which cases the parathyroids are found to be normally developed. In a case of pigment atrophy of the thyroid Benjamins found the parathyroids normal. According to Vassali and Generali, if the parathyroids be removed at the same time with the thyroid tetany results. If the parathyroid on one side alone be removed, the tetany is transitory. If the parathyroids are not removed, cachexia strumipriva or myxœdema follows.

Whether the case of hypertrophy of the parathyroids in acromegaly is to be regarded as a compensatory hypertrophy on the part of these organs for the hypophysis, or is to be explained as a part of the general hypertrophy occurring in the disease, the writer is not able to decide. The evidences of excessive secretory activity would favor the former view. (See Benjamins, "Ueber die Glandulæ parathyroidæ," *Beiträge zur pathologischen Anatomie*, 31, 1902.)

Aldred Scott Warthin.

PARATYPHOID FEVER.—Up to the time when the Gruber-Durham-Widal reaction came to be used as a routine method in the diagnosis of typhoid fever no hesitation was felt in classing all the cases presenting certain symptoms as typhoid fever; but with the use of this method it has been recently discovered that in some cases the characteristic serum reaction fails. In these it has been found possible to isolate from fæces, urine, blood, and various other situations, organisms which have been carefully described by a number of workers, and which

Digitized by Microsoft®

agree in morphological and cultural characteristics closely enough to be at least classed in one group, if not actually identified with one another. Such organisms have been spoken of as "typhoid-like bacilli" or "paratyphoid bacilli," and the clinical phenomena in such infections may perhaps, from their resemblance to typhoid fever, be suitably spoken of as paratyphoid fever.

www.libtool.com.cn

The disease has occurred, sometimes in small epidemics, in several places in Europe, notably in Paris, Bremen, etc., and has also been observed in American cities. It seems to attack persons of any age, but the average in a number of cases was about twenty-seven years. The symptoms resemble very closely those of typhoid fever—indeed, one cannot point out any symptom of pathognomonic importance, so far as our knowledge yet extends. The onset is, as a rule, with headache and general malaise, with some stupor. There is a continuous, if irregular, high temperature lasting throughout the illness and terminating gradually by lysis, after a duration generally of about four weeks. The spleen is, as a rule, not markedly swollen, and often is not at all palpable. Intestinal symptoms are not characteristic—there may be diarrhœa, or constipation may persist throughout the course of the illness; in some cases there has been intestinal hemorrhage. The blood shows no typical changes—the leucocytes are, as a rule, not increased. Rose spots are very often—indeed generally—present. Various complications, such as bronchitis, abscesses in various localities, slight hemorrhages, etc., have occurred, and in one case (that of Cushing) there was a costo-chondral osteomyelitis from which the organism was isolated.

The prognosis on the whole seems very good, as of twenty-six or more reported cases only a small number were fatal and two or three autopsy records only are at our command. Most of the cases have terminated by lysis—convalescence progressing much as after typhoid fever, while in one or two described by Kurth a sort of crisis occurred.

At autopsy it is found in these cases that there is no intestinal lesion whatever; the Peyer's patches and solitary follicles are not swollen and show microscopically no lesion. The spleen is somewhat enlarged and soft, and on section has a dull, opaque, grayish-pink color. Microscopically there is no great proliferation of the endothelial cells, and no red-corpuscle-carrying cells are seen, although the lymphoid cells of the splenic pulp are more abundant than normal. In one case focal necroses have been described in the liver.

Little characteristic as the symptoms and pathological lesions are, the bacteriological findings are fairly definite and serve well to outline this group of cases. There have been isolated by various workers (Gwyn,[1] Cushing,[2] Schottmüller,[3] Kurth,[4] Johnston,[5] Hewlett,[6] Longcope,[7] and others) bacilli designated under various names and still closely enough related to be classed, with some approach to unanimity, as a group standing half-way in its properties between the Bacillus typhosus and the B. coli, and very closely related indeed to the so-called group of Gärtner, the type of which is the B. enteritidis, a form associated with the epidemics following meat poisoning. Morphologically these paratyphoid bacilli cannot be distinguished from the typhoid. On the ordinary culture media, such as agar, gelatin, bouillon, etc., their growth is practically identical with that of typhoid. In litmus milk they produce, as a rule, acid at first with terminal alkalinity if exposed to the air and they do not clot the milk. Unlike the B. typhosus they ferment glucose with the production of acid and gas, while with lactose media they produce no gas. In these latter respects they most closely resemble the group of B. enteritidis. The production of indol is very slight and even somewhat doubtful.

Far more definite, however, than the results of these cultural methods of differentiation are the serum reactions. It is found that the serum of such a patient will never agglutinate the typhoid bacilli; it will, however, in great dilutions, agglutinate the bacilli isolated from the patient's blood, and sometimes even the bacilli from other cases. Some of the organisms described, however, such as those of Gwyn and Cushing, practically identical as they are culturally, refuse to be agglutinated by one another's sera. Similarly, while it is possible to immunize laboratory animals from each of these bacilli, so that their serum in the greatest dilution will agglutinate the bacilli used, it is often found that the bacilli from another epidemic or from another case will not be agglutinated by this serum. Nevertheless, it seems justifiable to consider these organisms extremely closely related, if not quite identical, and even if, as has been suggested, they are merely the results of altered environment on typhoid or colon bacilli, they have acquired such characters as to secure them a specific value.

To resume, therefore, we have in this recently described group of cases a disease clinically in every respect resembling a mild typhoid fever, but in which the general septicæmia is not as in typhoid associated, so far as we know, with such definite, localized pathological lesions. The serum reaction fails with the typhoid bacilli, but is positive in great dilution with the characteristic bacilli which can generally be isolated from the blood and fæces, and which morphologically and culturally are closely related to the group of B. enteritidis and to the B. typhosus, and from this relation are designated paratyphoid bacilli.

PAREIRA BRAVA.—*Pareira*, U. S. P.; *Pareiræ radix*, B. P. The root of *Chondrodendron tomentosum* Ruiz et Pavon (fam. *Menispermaceæ*).

This drug is derived from a tall woody twiner of Brazil and adjacent parts of tropical South America. It was first introduced to the notice of physicians in Europe about two hundred years ago, and after a period of neglect was again brought forward in the early part of this century. It is very little used at present—at least in this country. During this period several other closely related products from allied genera have been imported as pareira brava, adding much to the botanical confusion in regard to its source. The "false pareiras" appear to have about the same slight degree of usefulness as the genuine.

Pareira occurs in subcylindrical, knotty, and somewhat tortuous, hard, heavy, and tough pieces, of indefinite length and 1–6 cm. (½ to 2½ in.) thick; externally dark brown or blackish, longitudinally wrinkled and bearing transversely elongated protuberances or incomplete annular ridges, as well as constrictions, or occasionally fine fissures; the dried transverse surfaces exhibit several equilaterally concentric circles of interrupted, porous wood wedges, projecting beyond the markedly retracted intervening tissue of the rather large medullary rays; internally pale brown or yellowish-brown, when freshly cut having a waxy lustre; inodorous and bitter.

Of the several spurious pareiras, all have a gray or grayish-brown surface instead of the blackish color of the genuine, and are less, or not at all, knotty and roughened. None cuts with its waxy lustre, and all are lighter in weight and less solid.

Pareira contains from three-fourths to one per cent. of an alkaloid which is probably pelosine, similar to, if not identical with, buxine of box, and biberine of greenheart bark. A little tannin also exists, together with starch, gum, and about eight per cent. of ether-soluble fat.

Action and Uses.—What we know of the constituents of pareira and their actions does not support the therapeutical ideas upon which its use is based. It is known to be a fairly good bitter tonic, and slight anti-periodic properties may be reasonably assumed. Its use, however, is chiefly as a diuretic, and in inflammatory diseases

Digitized by Microsoft®

of the genito-urinary organs, more especially in orchitis. While it does appear to have a slight diuretic action, the idea of its use in this way probably depends upon administering it in decoction well diluted with water. Certainly, the idea of its having the great diuretic value once ascribed to it has been completely abandoned. There is good clinical evidence of a moderate degree of usefulness in the other directions named, although such action is by no means certain or uniform.

www.libtool.com.cn

The Pharmacopœia provides a fluid extract made with ten per cent. of glycerin, of which the dose is a fluidrachm. For its diuretic effects, the five-per-cent. decoction is best employed.

Allied Drug.—The drug which is, in the United States and England, regarded as the principal adulterant or substitute of pareira is that wholly or partly specified in some pharmacopœias, namely, the root of *Cissampelos Pareira* L., a plant of similar habit and growing in the same region, though much more widely distributed, and believed also to grow in India. The root is generally smaller than pareira and is of a brown or gray-brown color; longitudinally much grooved and transversely fissured, and readily losing its bark when kept in stock.

The alkaloid of this drug has been proven to be pelosine. Cissampelos is believed to act much like pareira, though it is more generally used as a tonic.

A number of other tropical American drugs are locally known as "pareira," but they bear no resemblance to the genuine article. *Henry H. Rusby.*

PARIS CHALYBEATE SPRINGS.—Lawrence County, Missouri. Post-Office.—Paris Springs. Hotel and cottages.

Access.—Viâ Kansas City, Fort Scott, and Gulf Railroad to Ash Grove, thence two miles by stage to springs.

The springs are delightfully located in the Ozark Mountains, the surrounding country being interspersed with beautiful glens, green meadows, dense forests, and orchards. The elevation (1,500 feet above the sea level) is sufficient to assure freedom from depressing heat in the summer time. The spring yields about one hundred and twenty gallons of water per hour, having a temperature of 52° F. A qualitative examination showed the presence of oxide of iron in solution, besides the carbonates of lime and magnesia, the chlorides of sodium, potassium, and iodine. A complete qualitative analysis is desirable. Patients suffering from disorders of liver, kidneys, stomach, skin, and nervous system have found great benefit from a sojourn at the springs. The tonic properties of the water have been well shown in the debility of anæmia and in various disorders of the female sexual system. *James K. Crook.*

PARIS, PARISETTE.—A European plant, *Paris quadrifolia* Linn., belonging to the order *Liliaceæ*, and closely allied to the *Trillium*, which is so common as an American wild flower. Experiments with an extract prepared from the entire plant show that it exercises a direct action upon the medullary centres. It at first produces a short period of excitation which is followed by a diminution of sensibility and reflex action, and a slowing and weakening of the respiration and heart beats.

It was suggested that it might prove of value as a substitute for aconite, but it has failed to obtain any recognition as a therapeutic agent. *Beaumont Small.*

PARKER MINERAL SPRING.—McKean County, Pennsylvania. Post-Office.—Gardeau. Hotel and sanitarium.

Access.—Gardeau is a station on the Western New York and Pennsylvania Railroad, four passenger trains daily stopping at this point.

This resort is located in the Alleghany Mountains, on the headwaters of a branch of the Susquehanna River. The elevation here is about 2,000 feet above the sea level. The country in this part of Pennsylvania is still wild and sparsely settled. Dense forests of hemlocks are frequent, and bear and deer may yet be found to reward the hunter's pursuit. Mountain trout streams abound. It is scarcely necessary to add that the climate in this wild and rugged region is bracing and salutary. In 1865 the present mineral well was drilled on the site of an oil spring. At 650 feet a vein of water was struck that flows from the top of the well in an unvarying current of about seventy gallons per hour. After some delay a bathhouse, sanitarium and hotel were built, and the place has developed into a very comfortable and attractive resort. An analysis of the water by Henry Trimble, analytical chemist of Philadelphia, resulted as follows: One United States gallon contains: Magnesium chloride, gr. 109.84; calcium carbonate, gr. 11.95; calcium chloride, gr. 221.92; sodium chloride, gr. 282.55; potassium chloride, traces; silica, gr. 1.33. Total, 627.59 grains. Temperature of water at spring, 50° F.

This is a richly impregnated saline water of the magnesic-sodic-calcic variety. When used under proper medical supervision it ought to exert a very beneficial influence in a variety of disordered states of the physical economy. It should always be taken at first in small quantities. The water has been found to possess active cathartic and diuretic properties. It is also a stimulant to the gastric mucous membrane, promoting the flow of gastric juice and aiding the process of digestion. The best effects of the water will be observed in atonic dyspepsia, torpor of the liver, abdominal venosity, constipation, in nephritis with scanty, highly colored urine, and in irritable states of the bladder. At the resort it is also used in the form of baths in a variety of conditions. The water is bottled and shipped to any desired point. *James K. Crook.*

PARK'S SPRINGS.—Caswell County, North Carolina. Post-Office.—Pelham.

These springs are located six miles east of Pelham, but they do not seem to be used much as a resort. The waters, however, are used commercially, and are highly recommended by physicians of North Carolina and the neighboring States in chronic constipation, dyspepsia, and portal congestion. The following analysis was made not long ago by Prof. Albert R. Ledoux, Ph.D., of the State Agricultural Experiment Station at Chapel Hill: One United States gallon contains Magnesium sulphate, gr. 1.50; sodium sulphate, gr. 1.48; iron oxide, gr. 3.50; alumina, gr. 3.50; uncombined sulphur, gr. 0.15; calcium carbonate, gr. 4.80; silica, a trace; sodium chloride, a trace. Total, 14.93 grains.

In its chemical constitution the water bears some slight resemblance to the well-known Hunyadi-Janos water of Hungary. It is a valuable chalybeate, but must be taken in considerable quantities to secure a purgative action. *James K. Crook.*

PARONYCHIA. See *Hands and Fingers, etc.*

PAROTID GLAND, DISEASES AND INJURIES OF.—I. Injuries.—The parotid gland may be injured from the outside through the cheek or from the inside through the mouth or pharynx. The more common injuries in the reported cases have been the result of blows and sword thrusts and have proved of little importance. However, occasionally hemorrhage, venous or arterial, may be alarming, and if it cannot be controlled by pressure one or more vessels will have to be ligated. The internal and external carotid and the vertebral arteries have been severed in such wounds; when this occurs, if it is found impossible to ligate the arteries in the wound, the common carotid should be at once exposed and tied. Hemorrhage may always be temporarily controlled by pressure. Associated injury to the facial nerve may cause a more or less complete unilateral facial paralysis with areas of anaesthesia, and in such a case an attempt should at once be made to suture the ends of the divided nerve.

An injury to the gland substance is usually demonstrated by the flow of saliva from the wound after the hemorrhage has been controlled. The escape of the fluid

Digitized by Microsoft®

secreted is usually augmented, in such a case, by the movements of the jaws in mastication and by the reflex stimulation caused by the ingestion of food.

Injuries to *Stenson's duct* are important on account of the conditions to which they give rise and of the difficulties which stand in the way of successful treatment. The duct is more often divided or lacerated on the masseter, where it is more fixed, than on the buccinator, where it is moderately movable. The fact of its having been divided is made evident by the flow of saliva from the wound. Occasionally spontaneous healing occurs, but the results to be feared are either the formation of a fistula, the common termination, or the obliteration of the duct, a sequel of more rare occurrence. Stenosis of the duct may lead to the formation of a cyst and eventually, as stated by some authorities, to complete atrophy of the gland.

The *treatment* of injuries to the parotid and its duct demands first of all the control of hemorrhage. Ligation of a vessel in the wound is difficult if it is large, and, if it is not possible to ligate the internal and external carotids singly, the common carotid should be tied. The vertebral artery has been ligated in its first part and also in the vertebral canal after removal of a transverse process. If hemorrhage from collaterals persists, pressure and cold applications will be found sufficient to control it. The possibility of the formation of a fistula and the danger of secondary infection of the gland afford us two special reasons for seeking primary union in wounds of this locality.

Immobility of the head and jaw should be secured with starch or plaster splints, and for a few days fluid food only should be administered through a tube. Talking should be forbidden.

II. Parotid Fistula.—Parotid fistula is a condition in which the normal secretions of the gland escape through an abnormal opening on the side of the face or into the mouth, in the latter case the lesion is of no pathological importance. Among the causes may be mentioned wounds involving the gland or Stenson's duct, either accidental or made during the removal of diseased lymphatic glands or tumors, abscess formation and ulceration following calculus or necrosis of the jaw, and involvement of the gland or duct in a tuberculous or syphilitic process.

In a case of fistula there are usually, on the outside of the cheek, a small opening surrounded by a few granulations and a circumscribed area of reddened and irritated skin. If there is no obstruction in the duct the fistula often heals spontaneously; but at times the fistulous condition is very persistent and obstinately resists treatment.

Slight weeping of the gland from injury to the glandular substance heals spontaneously in a few days.

Treatment.—This consists primarily in removal of the cause of the abscess or ulceration by local and constitutional measures, and the reduction of the lesion to a simple fistula. If the patient is seen soon after the injury has been inflicted a small silver probe may be passed through the orifice of the duct in the mouth and into the proximal portion of the severed duct, and an attempt be then made to suture the ends of the duct with fine catgut sutures, this material being more easily absorbed and less liable to become infected than silk. The sutures should not enter the lumen of the duct. The external wound should then be carefully closed.

If the fistula has existed for some time the edges of the artificial opening may be freshened and closed, in the hope of forcing the saliva into its normal channel.

Another method is to pass a stout thread soaked in balsam of Peru through the fistula into the mouth bringing it out at the angle of the mouth and tying the ends on the cheek. After the lumen is by this means well reëstablished, the duct and external wound may be closed as above. Homer's method is to make a hole with a punch through the cheek into the mouth, this hole including the orifice of the fistula. After this the external wound is closed.

III. New Growths.—There are a certain number of growths which, while they do not involve the substance of the parotid gland, lie in close proximity to it, and should not therefore be passed unnoticed in a consideration of tumors of this region. These, as a rule, lie without the capsular limits of the gland; but at times, particularly when they are of vascular origin, they penetrate the gland substance. These penetrating tumors are sebaceous cysts, dermoids, enlarged lymph nodes, lipomata, nævi, angiomata, and lymphangiomata. They do not differ from similar growths in other regions. The writer has recently seen, in a case of multiple venous angiomata, an angioma occupying the site of the right parotid gland. When the patient was in the recumbent position the tumor was the size of a goose egg and of a deep purplish hue; but with the patient in the erect position the contents were discharged, the tumor entirely disappearing and the skin regaining its normal hue. The left parotid was not similarly affected. These vascular tumors may be removed by pressure, by ligation of the vessels, or by extirpation, the others by extirpation.

Neoplasms of the parotid are very rarely of a single type. Mixed tumors are more common here than in any other part of the body excepting the ovary. "It is not unusual," says Sutton, "in sections from parotid sarcoma to meet with spindle cells, cartilage, myxomatous tissue, and glandular acini in an area two centimetres square." It will be convenient, however, to group these growths according to the tissue which is predominant in each variety and to outline the general characters of each. The neoplasms vary greatly as to their malignancy, but in general it may be stated that the mixed tumors grow rapidly, attain a large size, and tend to infiltrate the adjacent tissues, involving both blood-vessels and lymphatics, thus producing secondary deposits in other parts, and more particularly in the lungs. The growths when small are usually painless; they become painful only when in consequence of their size the pressure on the nerves is considerable, or when the nerve sheath is involved in the process of infiltration. Involvement of the skin with ulceration is characteristic of the later stages of the more malignant varieties. Pressure may cause a facial palsy, occlusion of Stenson's duct, interference with the blood supply of the parts dependent on the carotids, and, when growing deep into the neck, obstruction of the œsophagus and difficulty of deglutition. Facial palsy is more often the result of infiltration than of pressure, and is accordingly more common in malignant growths.

Enchondromata.—Cartilage enters into the formation of nearly all parotid neoplasms. Enchondromata are encountered in two forms: those composed of pure hyaline cartilage, and those in which the cartilage is associated with other tissues. Enchondromata of the first variety are of slow growth, attaining the size of a walnut in the course of several years. It is only in rare cases that they exceed an egg in size. The tumor is firm in consistence with a surface smooth or nodular, at times adherent to surrounding tissues. It is benign, and does not return when removed. Extirpation is usually not difficult. The other variety consists of small masses of cartilage associated with connective, mucous, adenomatous, or carcinomatous tissues. It assumes the character of a mixed tumor, is more malignant than the first variety, grows more rapidly, and tends to recurrence after removal.

Adenomata of the parotid are rare; they are encountered during the period from fifteen to thirty years of age. They have a distinct capsule, and may appear in any part of the gland. They are usually small, painless tumors, easily shelled out. If large they are movable and loosely connected with the parotid tissue. The surface is irregular and nodular, hard in places, but often elastic or fluctuating on account of the presence of associated cysts.

Sarcomata found in this region may be spindle-celled, solid, or cystic. They are rarely pure, and are mixed with cartilaginous, myxomatous, or fibrous growths. They are more common than the carcinomata, and come next to these in malignancy. The soft varieties occur

Digitized by Microsoft®

more commonly in youth, the harder types in middle life. They infiltrate all the surrounding structures, growing deep into the neck, inward behind the pharynx, and backward behind the ear, and involving the sheaths of the blood-vessels. The rapidly advancing ones involve the skin which subsequently ulcerates. A fatal issue follows dysphagia, implication of the pharynx, ulceration into some large vessel, or secondary growths (due to emboli) in more distant organs. They are removed with considerable difficulty and tend to rapid recurrence.

www.libtool.com.cn

Melanosarcomata occur very rarely. They are rapidly growing neoplasms, early involving the entire parotid gland, and invading the neighboring lymphatics and overlying skin, which latter is prone to ulcerate.

Myxomata, when they occur in the parotid, are usually associated with sarcomatous tissue and cartilage. They contain a thick transparent fluid, and may be definitely circumscribed or they may merge gradually into the surrounding structures. They are soft, gelatinous, and fluctuating.

Carcinomata of this region are rare. They belong to the period of advancing years. Their growth is at first slow, but later very rapid. Usually they have no capsule and infiltrate surrounding structures in very much the same manner as do the rapidly growing sarcomata. Secondary infection usually occurs by way of the lymphatics. Carcinomata are the most malignant tumors found in the gland, and they almost invariably recur after extirpation.

Endotheliomata are also rare. They are derived from a multiplication of the endothelial cells lining the lymphatics and blood-vessels. Some of these endothelial overgrowths are succeeded by fibrous tissue, while in others mucoid degeneration takes place.

Fibromata are usually associated with other neoplastic tissues, but have been met with as pure fibrous growths. Many of them contain cysts. They are hard resistant tumors, usually nodular. They should be excised, and when purely fibrous they do not tend to recur.

Lipomata rarely occur as pure growths in this region, but areas of lipomatous tissue are not infrequently found in the mixed tumors.

Rhabdomyomata.—Prudden has reported a case of rhabdomyoma of the parotid. The tumor was composed of muscle fibres, without sarcolemma, irregularly arranged. In this same tumor there were lobules of small spheroidal or polyhedral cells in a well-marked reticulum of an unusual character.

Treatment.—Excision constitutes the proper treatment of parotid neoplasms. The gravity and difficulty of the operation vary with the size and mobility of the growth, the extent of infiltration of the surrounding tissues, the age and general condition of the patient. Removal of the whole gland is a formidable operation. It was first performed by Warren of Boston in 1798. The removal of a tumor should be undertaken at the earliest possible moment, as this offers the greatest hope of a permanent cure. It should not be forgotten, however, that some tumors, especially the melanosarcomata, are often disseminated by operative procedure. In the case of a tumor which is already advanced in growth the possibility of temporary relief from the dangers and discomforts of ulceration and pressure may justify a partial or total removal of the growth. The production of a salivary fistula and the occurrence of facial palsy are complications which may attend the least of these operations, and of this possibility the patient should be warned in advance.

Cysts.—Cysts of the parotid usually occur in association with other tumors, and, according to their extent in relation to the other tissues, they modify the consistence of the tumor.

Less rarely single salivary cysts are met with. These grow slowly, at times attaining the size of a hen's egg, fluctuating, elastic, slightly movable, and not adherent to the skin. They result from the obstruction of Stenson's duct by a calculus or by a stenosis, and they usually represent a dilatation of one of the branches of this duct. They are lined with cylindrical epithelium which in time becomes tessellated. The salivary cysts are filled with clear, amber-colored, slightly viscid saliva; the contents of the simple cysts are more watery. The diagnosis, if doubtful, may be settled by means of an aspirating needle.

Treatment consists in opening the tumor and destroying the lining membrane with zinc chloride (forty grains to the ounce) or with pure carbolic acid. Cysts may be dissected out, but there is danger of injuring the facial nerve. The calculus or other obstruction to the duct should of course be removed.

Cysts due to the dilatation of Stenson's duct have been met with in glass-blowers. These are best left untreated.

Echinococcus of the parotid is exceedingly rare. Schuh reports a case in a woman eighty-three years of age. The tumor increased to the size of a hen's egg, attaining these dimensions in about one year. The tumor is cystic, and the diagnosis from other cysts can be made only by a microscopical examination of the contents of the tumor. Treatment consists in opening the tumor and destroying the walls of the cysts with the curette.

IV. Calculi.—A few cases of calculi of the parotid have been reported. They are less common than concretions in the submaxillary glands. They are the result of a change in the constitution of the salivary secretion which tends to precipitate the carbonates ordinarily held in solution. The calculi vary greatly in size; they may be as small as a grape seed, while one case has been reported in which the concretion weighed 18.6 gm. The chief constituent is calcium carbonate associated with organic substances, variable in amount, which remain after treating the concretions with hydrochloric acid. The calculus may be located in the gland proper or in the duct where it may be felt with a probe passed up the lumen. It occurs as a nodule of variable size and exceedingly hard. Sometimes it obstructs the flow of saliva from the affected side, and may thus produce a cyst, or it may, by the irritation which its presence causes, set up a chronic parotitis. Calculi of this kind should be removed by an incision, to be made from the inside of the mouth whenever this is practicable.

V. Parotitis.—Mumps, or acute infectious parotitis, has been discussed in another portion of this work. (See article on *Mumps.*) Other inflammatory conditions of the parotid gland include chronic idiopathic parotitis, toxic parotitis, and secondary parotitis.

Chronic Idiopathic Parotitis, or sialodochitis fibrinosa, is an affection of unknown cause. It is sometimes associated with xerostomia, and rarely it complicates gout. It usually commences with a catarrhal inflammation of Stenson's duct, which becomes plugged with mucus, and later develops into a chronic interstitial productive inflammation of the gland, the connective tissue replacing to a greater or lesser degree the secretory cells. The lesion is bilateral. The glands of both sides are swollen, firm, slightly elastic, painless, and not tender. The course is very chronic. The supply of saliva is much diminished so that the mouth may become dry and parched, and as a result swallowing and chewing may become difficult.

Treatment is very unsatisfactory, but the ducts should be kept open by frequent expression of the mucous plugs, and every effort should be made to stimulate the secretory function of the glands by the use of galvanism and the administration of pilocarpine and similar drugs.

Raymond Johnson has described five cases of induration and swelling of the parotids, coming on during a meal, due to a collection of saliva and obstruction of Stenson's duct. There was considerable pain during mastication. In one case there were several relapses, in another suppuration ensued. Massage sometimes caused evacuation of the plug.

Toxic Parotitis.—Hypertrophy and inflammation of the parotid have been reported in a number of toxic conditions such as lead, copper, and mercury poisoning, and in uræmic states. Comby reports the occurrence, in a case of lead poisoning, of a symmetrical enlargement of the parotids, soft, painless, and persistent, and running

Digitized by Microsoft®

a very chronic course. In mercurial poisoning the parotids and submaxillary glands become enlarged and tender and the flow of saliva is excessive. Bilateral enlargement of the parotids following the administration of potassium iodide has been reported by Comby, Miss Bradley, Requier, and Villar. In these cases there were also œdema of the eyelids, coryza, inflammation, and salivation.

After the withdrawal of the poison the affected glands usually recover their natural size and function.

Secondary Parotitis.—Next to mumps this is the most common form of inflammation of the parotid. It is associated with many local and general infections, such as maxillary osteitis, inflammation of the temporo-maxillary joint, abscesses, erysipelas, typhoid fever, typhus fever, cholera, diphtheria, smallpox, bubonic plague, yellow fever, cerebrospinal fever, relapsing fever, pneumonia, syphilis, influenza, and gout. Paget has collected 101 cases of parotitis complicating various infectious and functional disturbances of the peritoneal and pelvic organs. Of these, 50 occurred in cases of injury, disease, or temporary derangement of the generative organs, without suppuration. In this list were included cases of pregnancy, childbirth, abortion, pelvic cellulitis, hæmatocele, and operations on the vagina and uterus. In 10 instances the disease developed after the introduction of catheters and sounds in male patients and after blows on the testicle; in 18 the disease was associated with injury or disease of the alimentary tract, involving the stomach, pancreas, etc.; and, finally, in 23 there was disease or injury of the abdominal wall. In these cases the course was, as a rule, rapid and suppuration occurred on the fourth or fifth day. Donkin has reported three cases of unilateral parotitis complicating gastric ulcer, and Pepper has also reported a similar case. Debout d'Estrées has collected the reports of twelve cases of parotitis in gouty subjects.

The route of infection is in many cases obscure, but it is probable that in some cases, as in typhoid fever, it is through Stenson's duct, while in others the metastasis takes place through the blood-vessels and lymphatics. Hanau studied the genesis of five cases of suppurative parotitis which occurred as a secondary process in septic infections. In all these instances the organisms present were staphylococci; they were always found in the abscesses and ducts, while the blood vessels and lymphatics were free. In one fatal case Dietrich found the staphylococcus pyogenes aureus in the ducts, but not in the blood-vessels. The mouth is, without doubt, frequently the direct source of the infection, for in many diseases it offers conditions peculiarly favorable to bacterial multiplication.

In *typhoid* fever parotitis occurs in a variable percentage of cases. Osler reports the complication as occurring 45 times in 2,000 cases in Munich; of 2,000 patients with typhoid fever in the London Fever Hospital, 13 had parotitis; at Basle, of 1,600 cases of typhoid fever there were 16 complicated by suppurative parotitis. Infection is usually through Stenson's duct, and when arising in this manner it is probably not so serious a form as when it occurs as a metastatic process (Osler). Keen has reported two cases in which Eberth's bacillus was recovered from the pus in the glands; in one case there was a mixture of staphylococci. This complication generally begins during the third or fourth week; one case is reported as appearing on the tenth day. It is usually unilateral, but sometimes both glands become infected, coincidently or successively. Suppuration almost invariably ensues.

As a rule, parotitis is seen only in severe cases of typhoid fever; it is in itself a serious complication, the mortality being placed at about thirty per cent. Seven of the Basle cases ended fatally. The complication is said to be less common since the introduction of antipyretic treatment, but it seems to the writer that the attention which has been paid to the care of the mouth in recent years may be the more important prophylactic measure.

In *typhus* fever parotitis occurs in many epidemics to the extent of even twenty per cent. of the cases, being a more frequent and more dangerous complication in this disease than in typhoid fever. Both glands may be affected, but the disease is more commonly unilateral. Suppuration is usual, and the gland breaks down and is discharged in small necrosed fragments. Extensive infiltration and burrowing have caused fatal exhaustion. Pepper has seen death from parotitis after all danger from the original attack of fever seemed over.

Finkler reports 12 cases of parotitis in 55,263 cases of *influenza*. He thinks that in these cases there is probably mixed infection.

Pneumonia is occasionally complicated by parotitis, which is then usually suppurative. Pneumococci have been found in the resulting exudate by Testi and by Fitz. It is a dangerous complication, and the prognosis in these cases is bad.

Parotitis is a rare sequel of *relapsing fever*, *cholera*, *bubonic plague*, *yellow fever*, and *epidemic cerebrospinal meningitis*.

The *symptoms* of secondary parotitis are often masked by those of the primary disease. The parotid region at first becomes hard and swollen; associated with this there is pain on moving the jaw and in swallowing. The area then becomes œdematous, later softening somewhat, and the surface becomes red. At the end of three or four days there is an elastic non-fluctuating tumor. At this point the swelling may begin to subside, but more often it goes on to suppuration. The inflammation may be limited to the gland or it may spread to the surrounding tissues, involving the muscles and the periosteum. The pus burrows beneath the strong fascia for some distance before it points at the skin. The pus may pass downward into the chest, backward along the pharyngeal wall, upward along the sheath of the blood-vessels to the meninges, to the articulation of the jaw, or backward into the middle ear. The blood-vessels may be injured by ulceration, and the facial and jugular veins or the cavernous sinus may become thrombosed. There may be a neuritis with or without destruction of the facial nerve. Rarely the process terminates in gangrene. The pus may discharge spontaneously through the cheek, mouth, or external auditory meatus, more rarely into the œsophagus or anterior mediastinum.

The *prognosis* depends largely upon the condition of the patient at the onset of the complication. In cases in which the patient is much reduced, as in the third week of typhoid fever, a superimposed parotitis is an exceedingly grave matter; in a series of collected cases of this nature the mortality was thirty per cent. If the disease develops after convalescence has been well established, the prognosis is much less grave. Early recognition and evacuation of pus may obviate extensive infiltration and burrowing and distinctly lessen the gravity of the situation. Common sequelæ are induration and enlargement of the glands; less frequently there remains a facial palsy. Death results from general exhaustion, septicæmia, meningitis, or cerebral thrombosis.

The *prophylactic treatment* of secondary parotitis consists in diminishing the danger of infection through Stenson's duct. In typhus, typhoid, and other infectious diseases care should be taken in keeping the mouth clean and as free as possible from bacterial growths. When infection of the gland has occurred, an attempt should be made to obtain resolution or prevent suppuration by the application of ice, leeches, iodine, or mercurial ointment. One should be on the outlook for the formation of pus at all times, and as soon as its presence is recognized it should be evacuated. The gland should be drawn forward and an incision made parallel with the main branches of the facial nerve; the incision should be made well forward so as to avoid injury to the carotid vessels. An efficient drain should be kept in place so that the abscess may heal from the bottom.

VI. XEROSTOMIA, or dryness of the mouth, is caused by a deficient secretion of saliva. It may be physiological in infancy. It occurs in neurotic individuals, partic-

www.libtool.com.cn
Digitized by Microsoft®

ularly in women suffering from hysteria or hypochondriasis. Sometimes a fright may appear to be the main etiological factor, and frequently the cause is entirely unknown. Excessive loss of water by the kidneys, as in diabetes and chronic nephritis, rapid evaporation in mouth-breathers, and febrile diseases often cause a similar condition. It is not infrequent in the aged. Chronic inflammation of the salivary glands and obstruction of their ducts may result in an insufficient supply of saliva and consequent xerostomia. The mouth becomes dry and glazed, and it presents the color of raw beef. The tongue may be parched and deeply fissured, and speaking, mastication, and deglutition become difficult.

In cases due to obstruction of the ducts, relief may be obtained by expressing the tenacious plugs of mucus. In the neurotic cases pilocarpine and the galvanic current have been found helpful; in these cases also general tonic treatment is always of importance, and any causes of reflex nervous irritation should be looked for and removed. Temporary relief may be obtained by moistening the mouth with hot water or with a solution of albolene. Cabot has found that the eating of small pieces of oatmeal cracker gives considerable temporary relief in some cases of xerostomia complicating diabetes.

VII. Ptyalism.—(Synonyms: Salivation, Sialorrhœa.) Ptyalism may be defined as a pathological increase in the secretion of saliva.

In the adult the normal amount of saliva secreted in twenty-four hours is from two to three pints. Pathologically the amount may be increased to ten pints in the twenty-four hours. Such saliva is viscid and glairy; its specific gravity varies from 1.000 to 1.059; it contains little sulphocyanide of potassium and less ptyalin than normally.

Physiologically, the secretion of saliva is increased by the reflex stimulation caused by the taking of food and, in children, during dentition.

Ptyalism is caused by a pathological reflex stimulation of the secretory fibres of the nerves supplying the salivary glands. It is met with in women during pregnancy and at the menstrual period; in psychic disturbances such as hysteria and insanity; in infectious diseases, particularly in rabies and smallpox; in lesions of the medulla and pons. It follows the ingestion of certain drugs, such as mercury, gold, silver, copper, arsenic, lead, pilocarpine, jaborandi, muscarine, potassium iodide, and tobacco. Bohn describes instances, in children, in which the excessive flow of saliva occurred only in the daytime and ceased at night; the cause was unknown, but he believed the ptyalism to be a form of neurosis. Sialorrhœa has been met with in affections of the liver, spleen, pancreas, and genital organs; it is believed to be due to reflex irritation from these parts.

The excessive secretion of saliva necessitates constant swallowing and may interfere with speech, or the fluid may flow from the mouth. In pregnancy it may persist until delivery has occurred. In mercurial poisoning the patient becomes emaciated, the bowels are constipated, and the amount of urine is diminished; the parotid and salivary glands are enlarged and tender. The ptyalism may persist for from one to three weeks after the removal of the drug.

Diagnosis is difficult only when a paralysis exists which interferes with swallowing and thus simulates ptyalism; actual measurement of the amount of saliva will definitely settle the question.

The *prognosis* depends upon the cause and the possibility of its removal.

Treatment consists in the removal of the underlying cause, the use of an astringent mouth wash containing alum, gallic acid, or tincture of myrrh, and the administration of atropine, one-sixtieth of a grain every four hours until there is a sensation of dryness of the throat. In cases of nephritis, the administration of mercurials is especially liable to cause sialorrhœa. During the administration of mercury salivation can be prevented in many cases by keeping the mouth and teeth carefully cleansed; if soreness and tenderness of the gums, tenderness of the teeth on striking, or the "mercurial fœtor" of the breath arises, the administration of mercury should be stopped at once.

PAROVARIUM. (ANATOMICAL.) See *Sexual Organs, Female.*

PAROVARIUM, DISEASES OF.—The term parovarium is applied to a series of from six to eight closed tubules which lie between the two layers of the broad ligament. They radiate out from the ovary toward the Fallopian tube, terminating in a large tubule which runs parallel to and beneath the Fallopian tube.

The pathological changes to which it is liable consist practically of only two varieties, viz.: cystic disease and carcinoma, the latter being secondary to similar disease elsewhere, and so rare as not to merit consideration in so short an article as this.

Parovarian Cysts.—These arise from dilatation of one of the tubules of the parovarium, and are therefore intraligamentous. Frequently they remain so, in which case their removal is an exceedingly grave proceeding, but at times they stretch the ligament to such an extent that they become abdominal with a well-formed pedicle. In the latter case they are freely movable and ovoid in shape, while in the former they are fixed in the pelvis and have often an irregular outline. When pedunculated these cysts have a complete covering of peritoneum; while at the point where they split the layers of the broad ligament only the upper surface is covered by this membrane. This peritoneum is smooth and glistening, and the blood-vessels may be seen beneath it. These cysts are nearly always unilocular and contain, as a general thing, a very thin and limpid fluid; but in the case of older cysts this fluid may be thicker and turbid, especially if any hemorrhage has taken place into the cyst.

The inner surface of the cyst is lined by ciliated columnar epithelium which may be accompanied by some cells of the cylindrical variety. Next comes a layer of connective tissue and unstriped muscular fibres, and lastly comes the peritoneal coat.

Symptoms may be absent in the pedunculated variety until the cysts become sufficiently large to interfere with the heart and respiration, when dyspnœa and palpitation, as well as the swelling of the abdomen, will be complained of. When the cyst is sessile, however, one early gets pelvic discomfort or even pain, and the action of both bladder and bowels will be interfered with.

An abdomino-pelvic examination of the patient, in a case in which the tumor is pedunculated, will give the signs of an ordinary unilocular ovarian tumor, except that the fluidity of the contents will not be so evident in the latter. When the tumor is sessile, however, a fixed and fluctuating mass is felt to one side of the uterus, which is displaced to the opposite side of the pelvis. No hard nodules are to be felt in this mass.

The tumor may rupture, and this may be followed by refilling and repeated rupture, by cure, by hemorrhage, or by sepsis and death.

The *treatment* is removal. In the case of the cyst with a pedicle this is very simple, but when the broad ligament has been split up and the tumor has reached the pelvic floor, the treatment is a difficult matter. Here there is such risk of hemorrhage when one tries to remove the tumor by itself that a clean sweep of the pelvis is advocated by most operators. Hall taps the cyst after hav-

Digitized by Microsoft®

ing opened the abdominal cavity; he then ligates the ovarian arteries—that of the affected side to the outer side of the tumor, and that of the opposite side on the uterine side of the ovary if that is to be left, to its outer side if it is to be removed. The peritoneum is divided across the top of the bladder, which is separated from the uterus. The uterine artery of the healthy side is tied and divided, after which the cervix is divided across. The other uterine artery is then clamped, ligated, and cut. The tumor capsule is incised in front and behind, and the tumor is then shelled out and removed with the uterus. The peritoneal flaps are united by a continuous catgut suture. *F. A. L. Lockhart.*

PARTHENOGENESIS.—(Gr. παρθένος, a virgin, and γένεσις, production.) Parthenogenesis is reproduction by means of unfertilized eggs.

Occurrence.—This means of perpetuating the species occurs normally in several widely separated groups of animals and in a few plants. It was really discovered first in the plant lice, aphids, by Bonnet through a series of experiments begun in 1740; although Albrecht had recorded a single case of parthenogenesis in the silk-moth as early as 1701. In the Aphidæ the eggs which have lasted through the winter hatch in the spring, giving rise to parthenogenic females, which in many species are winged, and in others are without wings. These are viviparous, the eggs developing within the oviduct. After a number of parthenogenic generations sexual individuals are produced, the males being winged, the females always without wings. After copulation the females lay fertilized eggs, which remain dormant during the winter and hatch into asexual individuals in the spring. In this group parthenogenesis is thus combined with an alternation of generations. But sometimes some of the parthenogenic individuals live through the winter, thus producing two parallel cycles of development. In some of the aphids the life history is complicated by the fact that the sexual and asexual generations inhabit different host plants.

Parthenogenesis occurs normally also among the worms—in the liver flukes, larvæ of *Distomum hepaticum*, and in the rotifers. In the Crustacea it is found in certain genera of the Entomostraca, namely, Cypris, Daphnia, Polyphemus, Artemia, Apus, Lepidurus, and Limnadia. The phenomenon is widely distributed among the insects, being especially characteristic of the Hymenoptera—saw-flies, gall-flies, ants, bees, and wasps; the Thysanoptera; and the Aphidæ and Coccidæ,—plant lice and scale bugs. It is found rarely among the moths, as in the genera Apteronia, Psilura, and Solenobia; and in one genus of gnats, Chironomus.

Among plants parthenogenesis is described as occurring in *Chara nitida*, *Thalictrum fendleri* and *purpurascens*, and some fungi, as Saprolegnia.

Classification. The forms of parthenogenesis have been classified by Geddes and Thompson, and later by Delage according to their mode of occurrence into several groups. Of these the most important are: (1) *Occasional* parthenogenesis, of which the only authentic example appears to be the silk-moth. It has been known for a long time that once in a while a female silk-moth may be found capable of laying eggs, some of which will develop without fertilization. Geddes and Thompson include in this group a form of parthenogenesis that they also call *partial* and that Delage distinguishes as (2) *facultative*. This form is characteristic of the bees, ants, and wasps. The queen bee, for example, as was first shown by Dzierzon, appears to be able at will either to fertilize the eggs as they are laid by means of spermatozoa stored in the sperm sac or else to withhold fertilization. The eggs develop equally well in either case, but fertilized eggs always develop into workers or queens, while the unfertilized eggs invariably give rise to drones. This is proved partially by the fact, noted by Hensen, that when a queen bee has been impregnated by a drone of another variety, the female offspring, workers and queens, will all be hybrids, while the young drones will show purely the characters of the maternal race. Moreover, queens that have been prevented from receiving the male, old queens whose sperm sacs have become exhausted, and the workers that occasionally can produce eggs but have no copulatory organs, all produce male offspring only. Finally, von Siebold was unable to find any spermatozoa in eggs from drone cells.

(3) *Seasonal* parthenogensis accompanied by an alternation of generations is common with the Entomostraca and Aphidæ. In the Aphidæ the parthenogenic young are born alive as already described. That this process is dependent upon seasonal conditions is shown by the experiment of Réaumur and Kyber, who, by maintaining artificially summer conditions in a glass case, were able to obtain fifty continuous parthenogenic generations extending through four years. In the Entomostraca the summer eggs which develop parthenogenetically are smaller, have less yolk, and thinner shells than the fertilized winter eggs, which are well provided with food yolk and covering to withstand drying and cold. This form of parthenogenesis is also characteristic of the gall flies, but in most of these there is but a single parthenogenetic generation between two sexual ones.

(4) *Juvenile* parthenogenesis has been taken to include the summer reproduction of the aphids. But that view no longer prevails, for the parthenogenetic females appear to differ from the perfect forms chiefly in the absence of certain accessory reproductive organs. So the only real case seems to be that of a species of the gnat, Chironomus, in which the pupa produces parthenogenetic eggs. In a closely related group, the gall-midges, Cicidomya, there is a form of pædogenesis that appears to be distinct from parthenogenesis. While the larvæ may contain rudimentary ovaries or testes, the offspring are produced from clumps of cells formed in connection with the fat body. This appears to be a sort of internal budding.

Finally, we have (5) total, or *exclusive*, parthenogenesis. That is, in many rotifers, some of the Entomostraca, and a few insects, no males have ever been found, and it is inferred that in these cases there is perpetual reproduction by unfertilized eggs only.

(6) *Artificial* parthenogenesis, which may be quite a different thing from the normal process, will be discussed in another paragraph below.

Another classification of the phenomena of parthenogenesis is that of Taschenberg, who distinguishes three divisions: (1) *Thelyotoky*, when the unfertilized eggs give rise to females only, as in the summer generations of the aphids; (2) *Arrhenotoky*, when males only are produced, as in the case of the queen bee; and (3) *Deuterotoky*, when the offspring are of both sexes, as with the gall-flies.

Cytology.—It was first suggested in 1877 by Minot on theoretical grounds that parthenogenesis might be due to a failure of the egg to produce polar bodies (see articles *Ovum* and *Reduction Division*). Balfour in 1880 and later Van Beneden maintained that the extrusion of the polar bodies in eggs destined for fertilization is a special provision to prevent parthenogenesis. Theory also led Weismann to investigate the question of parthenogenesis, and he observed in 1885 that in the parthenogenetic eggs of Polyphemus, one of the Daphnidæ, but one polar body is formed. In 1888 Blochmann made the important discovery that in the plant-lice, aphids, parthenogenetic eggs produce but one polar body, while the fertilized eggs produce two. Weismann subsequently found this to be true of the eggs of ostracodes and rotifers, and was led to infer that the differences observed in these forms is one that distinguishes all parthenogenetic eggs from those destined for fertilization. But doubt was thrown upon this view by the observations of Blochmann (1888–89) and Platner (1889), who discovered that in the honey-bee and in the moth Psilura (Liparis) the parthenogenetic eggs produce two polar bodies. The difficulty has been met by Brauer's brilliant research, in which he discovered that there are two types of parthenogenesis. Both

Digitized by Microsoft®

types occur in the eggs of Artemia. In each case the first maturation spindle contains eighty-four chromosomes in the form of typical tetrads (Fig. 3742), which divide so that eighty-four dyads are removed in the first polar body and eighty-four remain in the egg (Fig. 3743). There are indications of an attempt to form a second polar spindle, but no division takes place, and the eighty-four dyads give rise to a reticular cleavage nucleus (Fig. 3744).

www.libtool.com.cn

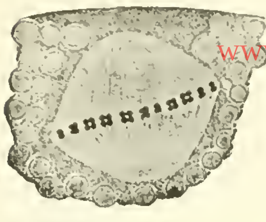

FIG. 3742.—First Maturation Spindle in Parthenogenetic Egg of *Artemia salina*. × 1060. (After Brauer.)

In the second type, which is less frequent, a second polar spindle is formed and the eighty-four dyads divide, producing two groups each containing eighty-four single chromosomes (Fig. 3747). Ordinarily these remain in the egg, producing two small reticular nuclei (Fig. 3748). Preparatory to division two centrosomes appear, whether by the division of a single one or not is not known. But, at any rate, they form a single spindle in which the one hundred and sixty-eight chromosomes arrange themselves in two distinct equatorial plates (Figs. 3749 and 3750). In rare cases, however, Brauer observed that the second polar body is actually extruded, and then its nucleus returns into the egg and presumably undergoes the changes just described. This furnishes an explanation of the appearances observed in the bee and Psilura, suggesting that further investigation will show that the nucleus of the second polar body reunites with the egg nucleus to form the cleavage nucleus in a manner similar to the union of the sperm nucleus with the egg nucleus (see *Impregnation*). If this be true, it will be established as a general fact that the parthenogenetic egg contains the same amount of chromatin as the ordinary egg does after union with the spermatozoon. The formation of the second polar body appears to reduce the amount of chromatin to a point where under ordinary conditions the egg is unable to undergo further division. But if the amount of chromatin be restored by the entrance of the spermatozoon or by the return of the second polar nucleus, then the egg may start upon its new cycle of development.

FIG. 3743.—Extrusion of the First Polar Body of the Same. × 1060. (After Brauer.)

FIG. 3744.—Egg Nucleus Derived from Half of the First Spindle Remaining in the Egg. The centrosome has divided. × 490. (After Brauer.)

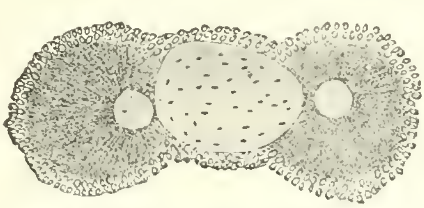

FIG. 3745.—Egg Nucleus of the First Type at the Beginning of the Formation of the Cleavage Spindle. × 490. (After Brauer.)

Brauer made the further observation, which is of considerable importance for the theory of the individuality of the chromosomes (see *Chromosomes*), that so far as he was able to trace them through the first few cleavages, the chromosomes reappear in subsequent cell divisions in the same number that was present in the first cleavage nucleus. That is, he found eighty-four when no second polar nucleus had been formed and one hundred and sixty-eight of half size when a second polar nucleus had been formed (*cf.* Figs. 3745 and 3749).

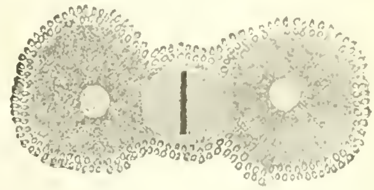

FIG. 3746.—Cleavage Spindle of the First Type. × 490. (After Brauer.)

Very recently (1902) Petrunkewitsch has studied the maturation of the winter eggs of Artemia, and he failed to find Brauer's second type, but further investigation is necessary to throw serious doubt on the positive results of Brauer's very careful work.

Heredity.—We are indebted to Dr. Ernest Warren for the only observations made so far upon heredity in parthenogenesis. The forms that he studied are Daphnia (1900) and an aphid, *Hyalopterus trirhodus* (1902). From 23 individuals of Daphnia he obtained 96 young, and from 60 aphids he reared 455 offspring. Measurements were made of parents and offspring of both species, and the coefficients of heredity were calculated by the methods described in another place (see article *Heredity*).

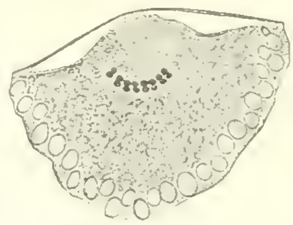

FIG. 3747.—Second Maturation Spindle of the Same. × 1060. (After Brauer.)

The results of direct inheritance were found not to differ very much from those obtained in sexual reproduction; taking the mean of Daphnia and the aphid, the coefficient for parental inheritance was found to be 0.41, and for grand-parental 0.24. But in collateral inheritance there seems to be considerable difference. The mean fraternal correlation for the two species is 0.66, considerably higher than the average for sexual reproduction, which Pearson places at 0.49 or 0.50. It is generally supposed that sexual reproduction tends to increase the variability of the race, but Warren found no significant difference in that particular between these species and sexual forms. But the whole subject of heredity and variation of asexual forms needs much more investigation before generalizations of importance can be made in regard to the different effects of sexual and asexual reproduction.

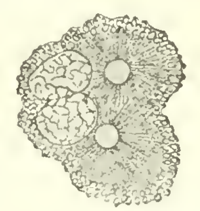

FIG. 3748.—Two Egg Nuclei Derived from Halves of the First and Second Spindles. × 490. (After Brauer.)

Artificial Parthenogenesis.—It has been known for a long time that the ova of animals that reproduce by the sexual method only will sometimes undergo an irregular segmentation. R. Bomet (1900) has given an exhaustive review of these phenomena as observed in vertebrates, and concludes they are pathological in character. The seg-

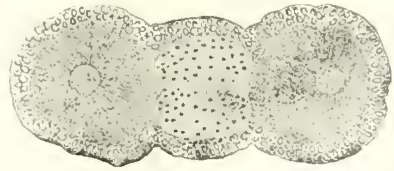

FIG. 3749.—Egg Nucleus of the Second Type at the Beginning of the Formation of the Cleavage Spindle. × 490. (After Brauer.)

Digitized by Microsoft®

mentation observed is a fragmentation of the cell leading to dissolution. He places in this category the early experiments of Dewitz (1887), who found that frogs' eggs treated with corrosive sublimate would undergo segmentation. Similarly Tichomiroff (1886) was able to induce the development of unfertilized eggs of the silk-moth by treating them for a few minutes with sulphuric acid, but this is a species in which occasional parthenogenesis is known to occur.

www.libtool.com.cn

Fig. 3750.—Cleavage Spindle of the Second Type. × 490. (After Brauer.)

In 1899, however, Loeb made the remarkable discovery that by the use of a solution of magnesium chloride of a certain strength (a mixture of $\frac{20}{8}$n $MgCl_2$ and sea-water in equal parts for two hours) he could induce development in the unfertilized eggs of a sea-urchin (Arbacea), a group in which normal parthenogenesis is unknown, so that the egg not only divided but continued through the blastula and gastrula stages, and eventually formed normal pluteus larvæ (Fig. 3751). At first he attributed this result to the specific effect of the magnesium ions. But later researches showed (1900) that other salts and such organic substances as urea and cane-sugar could produce the same result. Loeb then concluded that the cause of development was not the specific effect of certain ions, but that it was due to an increase of osmotic pressure. Especially he noted that the reagents used seemed to cause a liquefaction of the nuclear membrane, and he regarded that as a prerequisite for cell division.

This idea was taken up by Mathews (1900), and he found that various agents that caused the liquefaction of protoplasm, such as lack of oxygen, slight increase of temperature (from 32° to 33° C. for two to four minutes), ether, chloroform, and alcohol would all induce segmentation in sea-urchin eggs. Later Mathews (1901) found that the eggs of a starfish, *Asterias forbesii*, could be caused to develop by shaking or by simple removal from one dish to another by means of a pipette, provided the eggs are taken at the right time, namely, from two to four hours after they have been shed, when "both polar globules have been extruded and the female pronucleus has re-formed and reached a considerable size." From eggs treated in this way he was able to rear some larvæ to the late gastrula and early bipinnarian stages. Loeb (1901) has been able to obtain artificial parthenogenesis also in an annelid, Chætopterus. By treating the unfertilized eggs with solutions of sodium, magnesium, and calcium chlorides and with cane sugar he obtained development into swimming trochophore larvæ. Fischer (1902) has obtained swimming larvæ from unfertilized eggs of two other annelids, Amphitrite and Nereis. From the former by treatment with calcium nitrate, and from the latter by using solutions of potassium chloride having considerably higher osmotic pressure than the sea-water.

By extracting the spermatozoa of sea-urchins Gies (1901) tried to obtain an enzyme that would cause the eggs to develop. But his results were negative. And he was led to criticise the positive results previously obtained by Piéri, which he attributes to carelessness in the non-removal of spermatozoa; and the results of Winkler, which he regards as due to osmosis.

After all, the physiologists have done little more than to establish the fact of artificial parthenogenesis. So far they have been unable to formulate any clear general statement as to the cause of the phenomenon, and they have told us next to nothing in regard to the internal conditions of the egg during this process.

The first one to approach this problem from the inside, as it were, was R. Hertwig (1896), who found that in unfertilized eggs of sea-urchins, Echinus and Sphærechinus, treated with dilute solutions of strychnine, the nucleus might give rise to a bipolar mitotic figure. Sometimes the chromosomes would divide, and sometimes two complete nuclei would be formed, and in a few cases irregular or incomplete cleavage stages were observed. Using mainly unfertilized eggs of Arbacea, T. H. Morgan has made a series of studies (1896, 1899, 1900) upon the effects of solutions of sodium and magnesium chlorides and also dilute strychnine upon the cytoplasm, his "principal discovery being that the eggs become filled with 'artificial astrospheres' (asters) containing deeply staining centrosome-like bodies, which may become connected with the nucleus and 'seem to act as anchors for the chromosomes and move out into the egg with the chromosomes attached to them.'"

Our principal knowledge of the internal phenomena of artificial parthenogenesis is due to the beautiful work of E. B. Wilson (1901), begun soon after the publication of Loeb's first paper. He completely confirmed Loeb's general result, finding that "unfertilized eggs of Toxopneustes (a sea-urchin), when treated with a mixture of equal volumes of sea-water and twelve per cent. $MgCl_2$ and then replaced in pure sea-water, may segment, give rise to actively swimming blastulæ and gastrulæ, and in many cases to plutei." The different stages, however, showed a large number of abnormalities and monstrous forms, and even the most perfect specimens were not exactly like those produced from fertilized eggs.

As to the internal changes observed in these eggs, we have space here for only the briefest possible summary of the most important results. The first change noticed in the eggs was the appearance of a vague primary radiation centring in the nucleus. In many eggs a varying number of secondary centres of radiation (cytasters) were formed at various points in the cytoplasm. Then after a reduction of the rays almost to the vanishing point and their reappearance nuclear division proceeds as in fertilized eggs; but the division of the cytoplasm may be delayed until several nuclei are formed. Serial sections showed that no sperm nuclei were present. The internal changes, while showing an interesting parallel to those occurring in fertilized eggs, were unmistakably different from the latter. During cleavage many of these eggs show but *one-half* the normal number of chromosomes, namely, eighteen instead of thirty-six, and most of the

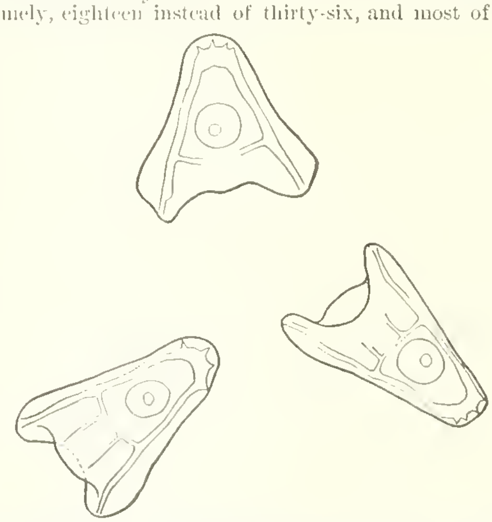

Fig. 3751.—Normal Plutei Reared from Unfertilized Eggs; treated with equal parts of a $\frac{20}{8}$n $MgCl_2$ solution and sea water. Magnified. (After Loeb.)

eggs failed to form any trace of a vitelline membrane, which in fertilized eggs is formed after the entrance of the spermatozoon. Both the primary and secondary asters are formed *de novo* and subsequently multiply by division; and both may act as centres of cytoplasmic division. But, as a rule, complete division does not take

Digitized by Microsoft®

place except when the asters are connected with chromosomes. Even in enucleated fragments of eggs, produced by shaking, asters may be formed in the magnesium solution, and these, like the others, may contain at their centres deeply staining bodies resembling centrosomes.

Delage (1901) has also investigated the internal phenomena of artificial parthenogenesis, using eggs of species of sea-urchins and starfish. He obtained development in the former after both polar bodies had been formed, and in the latter after only one polar body had been formed as is the case in normal parthenogenesis. He claims also that the number of chromosomes present is the same as in fertilized eggs. But Boveri (1902) has shown this to be an error, the number of chromosomes found by Delage in the sea-urchin being really half the normal number, thus confirming Wilson.

PARTURITION. See *Labor and Gestation.*

PASSION FLOWER.—*Passsiflora.* The rhizome of *Passiflora incarnata* L. or of *P. lutea* L. (fam. *Passifloraceæ*).

The herbage is also sometimes employed.

These are soft woody vines, climbing high over shrubbery and trees in the Southeastern United States, where the edible fruit of the first-named is considerably used under the name May-pop.

The elongated rhizome, usually known commercially as "Passion flower root," quite closely resembles menispermum in appearance, being elongated and cylindrical. It rarely reaches a fourth of an inch in thickness and the nodes are rather obscure. It is yellowish or light brown, often with a greenish tinge, and finely striated. It has a small hollow centre surrounded by a greenish or yellowish, finely radiated wood zone, and a moderately thick, purplish bark section. Both odor and taste are slight and indefinite, the latter somewhat fatty and disagreeable. The constituents have not been examined with any care. A trace of alkaloid has been reported.

Passion flower has been exploited by commercial interests, and most of its literature has been compiled with a view of creating a demand for it. *P. incarnata* has been considerably employed in eclectic and homœopathic practice. These authorities attribute to it mild sedative and even hypnotic powers, while larger doses are said to be emetic. Its use by these practitioners in numerous grave conditions, as well as their minute doses, involve obvious absurdities. Whatever benefit may be derived from its use may result from the administration of from 2 to 4 c.c. (fl. ʒ ss.–i.) of the fluid extract. *Henry H. Rusby.*

PATCHOULI, OIL OF.—*Oleum Foliorum Patchouli.*—A volatile oil distilled from either the fresh or the dried leaves of *Pogostemon Heyneanus* Benth. (*P. Patchouli* Pell.; *P. suavis* Tenore. Fam. *Labiatæ*).

The Patchouli plant is native and cultivated in the East Indies, especially in the Straits Settlements, and the drug or the oil distilled from it is mostly exported from Singapore. The oil ranges from pale yellow to brownish, usually with a greenish tinge, and is occasionally of a deep brown color. Its specific gravity varies from 0.97 to 0.99, even when pure. With ninety-per-cent. alcohol, it yields a clear solution which usually remains clear upon the addition of more alcohol (Gildemeister and Hoffman). The oil has a characteristic and very intense and persistent odor. Its composition is not well known, though it yields a peculiar camphor known as Patchouli camphor. This oil is little, if at all, used medicinally, though it has the ordinary aromatic stimulant properties of its class. It has very important uses in perfumery.

Henry H. Rusby.

PATELLA, AFFECTIONS AND INJURIES OF.—The patella is a sesamoid bone developed in the quadriceps tendon, and is therefore a part of the extensor apparatus of the knee. Some anatomists have considered the patella homologous with the olecranon process of the ulna; but there are serious objections to this view, and it is not indorsed by Poirier and Charpy in their recent work.

The first rudiments of the patella appear about the tenth week of fœtal life, and ossification usually begins from one centre about three years after birth; but the *x*-ray often fails to cast a shadow until the sixth year. The principal functions of the patella are to increase the leverage of the quadriceps muscle and to protect the knee-joint anteriorly. It seems to be, however, a luxury rather than a necessity, since its congenital absence may produce little or no disturbance of function. The kangaroo, which has no bony patella, is noted for its powerful posterior limbs.

Fractures and traumatic dislocations of the patella, and prepatellar bursitis are discussed in other sections of this work; there remain the congenital and developmental anomalies, and certain diseases, deformities, and painful affections which follow.

Absence and Retarded Development of the Patella is a not unfrequent accompaniment of congenital deformities involving the knee, especially of absence or imperfect development of one or more bones of the leg, and of congenital flexion, hyperextension, and ankylosis of the knee. Of these conditions the one which has attracted most attention is the so-called congenital dislocation of the knee, where the child is born with one or both knees in hyperextension, and the tibia luxated forward. In a large proportion of these cases no patella is discoverable in infancy; but in many, if not most, it develops later, and may reach normal proportions. Such a case, observed by the writer,[1] had no patellæ at seven months of age; but they could be felt as very small nodules six months later, and at three years of age were well developed. At thirteen years this boy was active, and had good functional use of the knees and perfectly developed patellæ.

Many of the cases in the literature are reported too young to determine the fact of permanent absence. Rectification of the deformity and orthopedic treatment seem to exert a favorable effect on the development of the patella in these young cases. Potel[2] has collected 78 cases of congenital knee luxation, of which about half were bilateral; in 50 of these cases the condition of the

Digitized by Microsoft®

patella is noted, of which 18 were normal; in 16 the patella was absent, in 10 atrophied, and in 2 anomalous. Potel reports in addition 20 cases of absent or rudimentary patella accompanying other deformities of the knee. Little[3] reports 42 cases of absent or rudimentary patella, not including a remarkable group of 18 cases in four generations of one family who had no patellæ and no thumb nails. Other family groups have been reported by Wirth[4] and Wolf. Many of Little's cases are on Potel's list and on the later list of Thorndike.[5] Some of the individuals in whom the patella never develops are nevertheless active and even athletic, and unconscious of any defect. While extremely rare, cases of complete absence of the patellæ, due to developmental defect, and uncomplicated by other anomalies, do exist. Joachimsthal[6] proved by *x*-ray examination that Wirth's case was indisputable. As absence of the patella is usually a syndrome rather than a pathological entity, the treatment is that of the primary affection, and in the case of congenital luxation and some other deformities it is usually effectual. The following advice, given in a recent work of reference,[7] is erroneous: "When the patella is absent it is usually necessary to produce an artificial ankylosis between the femur and tibia." On the contrary, it is rarely if ever necessary to have recourse to this operation for this reason.

Split Patella.—Very rare are the cases of congenital split patella. Grüber[8] reports a case in which both patellæ were divided into a small superior external and a large inferior internal segment separated by a groove. Joachimsthal[5] reports a case of horizontal and another of vertical fissure in which fracture was excluded.

Congenital Dislocations of the Patella.—While this condition is uncommon there is a considerable literature on the subject. Steindler[9] reports sixty-one cases of outward and two of upward dislocation. This deformity is frequently combined with genu valgum, but such combinations are not always congenital; moreover, there are many cases of congenital dislocation in which no genu valgum is present. The affection seems to be usually due to imperfect development of the anterior part of the external condyle. Alsberg[10] reports three cases in one family, father, son, and daughter, in which the displacement was outward and bilateral. In two of these cases there was practically no disability.

Cases of congenital dislocation are also reported by Potel,[2] Bergmann,[11] Elliott,[12] Drehmann,[13] Gallet,[14] Cayre,[15] and McLaren.[16] The so-called congenital dislocation upward is rather an elevation than a luxation of the patella, as has been pointed out by Blencke.[17]

Pathological Displacements of the Patella.—The commonest of these is displacement upward from elongation of the ligamentum patellæ; this is rarely congenital, though a certain congenital laxity of the ligaments may predispose to this affection. Shaffer[18] has pointed out that elongation of the patellar ligament and displacement of the patella upward may be an important factor in the production of certain knee disabilities, and has recently[19] indicated its connection with slipping patella and displacement of the semilunar cartilages. Shaffer states that with the knee flexed at ninety degrees and the quadriceps tense, the distance from the apex of the tibial tubercle to the lower edge of the patella in an adult is normally not over two inches, and is often less. In his cases of upward displacement the patellar ligament was often three inches or more long.

In rupture of the ligament the patella is drawn upward by the quadriceps, and in rupture of the quadriceps at its insertion the patella drops downward. Schulthess[20] has shown that in congenital spastic paraplegia the ligamentum patellæ is elongated, and the patella displaced upward, probably from the continued traction of the spastic quadriceps. With the knee flexed at ninety degrees, the inferior border of the patella makes a sharp projection in front of the knee in these cases.

According to a recent investigation of Peltesohn[21] the patella was elevated in eleven out of fourteen congenital spastic cases.

The posterior surface of the patella is concave owing to its abnormal relation to the end of the femur.

Slipping Patella; Intermittent Dislocation of the Patella.—In this affection, either from congenital defect, laxity of the ligaments, trauma or genu valgum, the patella becomes displaced outward, and the malposition tends to recur more and more frequently in spite of reduction; it finally may become permanent. Shaffer believes that this condition is often associated with elongation of the ligamentum patellæ, and that this is an important factor in the affection. In several cases he found an exostosis in the intercondylar groove, due, as he supposes, to the absence of the patella from its normal position. Wiemuth[22] reports 66 cases, of which 32 were of congenital origin, 14 traumatic, and 20 pathological. Schanz,[23] Friedländer,[24] and others report cases.

In the milder cases various knee-caps and appliances may be used to hold the patella in place, or to prevent abnormal movement at the knee, but in inveterate cases one or more of the following operative procedures may be necessary:

1. Genu valgum, if present, should be corrected, though this will not always prevent the displacement.
2. The tibial tubercle with the ligamentum patellæ may be detached with a chisel, and sutured or nailed at a point farther inward on the tibia.
3. The intercondylar groove may be deepened, and an exostosis, if present, removed.
4. The capsular ligament on the inner side of the patella may be folded and sutured (Le Dentu).
5. Artificial bow leg may be produced after a supracondylar osteotomy (Chiene).
6. The patella may be excised (R. Fowler).

Ankylosis of the Patella.—After inflammation of the knee-joint involving the contiguous articular surfaces of the patella and femur, the patella may become adherent. This of course prevents voluntary motion at the knee. Where the joint surfaces between the femur and tibia are good, or where it is necessary to do so in order to correct the position of the knee, the patella may be separated by the fingers, mallet, or chisel (see papers by Hübscher[25] and Cramer[26]).

Atrophy of the Patella.—The patella follows the usual law of bone growth, increasing in size and density according to the work put upon it; active muscular individuals have large and strong patellæ. The patella also adjusts itself to the shape and pressure of adjacent structures; hence its size and shape are altered in various pathological conditions. If the function of the leg is interfered with, the development of the patella is retarded or checked, and later atrophy may set in. Individuals with clubfoot, congenital dislocation of the hip, and other affections which limit the use of the limb, show less development of bone as well as of muscle on the affected side. In infantile paralysis the effect on function and on bone growth is much more marked, and has been thought to be largely due to interference with trophic centres in the cord. It is well known that chronic joint disease has a profound effect on bone growth. In osteitis of the knee and hip all the bones of the affected limb are shortened, thinned, and narrowed, and this is due to atrophy as well as to retardation of growth. In a series of hip and knee cases measured by the writer,[27, 28] the patella was found to be from one-eighth to one-half inch narrower on the affected side within two years of the onset of the affection. The bone was markedly diminished in bulk, in many instances being less than half the size of its mate.

Riders' Painful Patella.—Rosenberger[29] has recently described a painful affection of the patella observed in cavalry and mounted officers, who have worn tight, stiff breeches and have been continuously in the saddle. The inner border of the patella, which has little adipose padding, and which is most exposed to pressure in riding, is the most painful part. There is at first more or less disability, which together with the pain soon passes off on rest and relief of the pressure. No other symptoms were observed by him, but according to Düms[30] there

Digitized by Microsoft®

may be inflammatory swelling of the quadriceps tendon with crepitus.

Diseases of the Patella: Primary Tuberculosis.—Fibrous, fatty, sarcomatous, and other tumors of the patella or of parts adjacent to it have been reported, and syphilitic and staphylococcic infections may occur, but the most common and important disease of the patella is tuberculosis. Secondary infections, especially of the articular surface proceeding from tuberculous or other inflammation of the knee-joint, are not infrequent, and are a common cause of adherent or ankylosed patella. Infection may also occur from disease of the prepatellar bursa. Primary tuberculosis of the patella has been described by Volkmann and others, and has lately attracted considerable attention. Gross[31] in an excellent paper reports 36 cases, including 4 of his own. In 33 the age was known, of which 13 were under and 20 over the age of twenty. There is spontaneous pain in the patella in the daytime and often at night, with extreme tenderness on pressure; the subcutaneous surface of the patella may be uneven to the touch; during the early stages the functions of the knee are but little interfered with. The knee is usually held in extension or nearly so. The most significant symptom is cold, prepatellar abscess of slow formation. Such an abscess is much less movable than a bursal swelling, and puncture or exploration should clear up doubtful cases. Later on, sinuses may form, leading to cavities in the cancellous tissue. Volkmann[32] depicts (Fig. 3752) such a case in section. If it is overlooked or neglected extensive disease of the knee-joint usually results. The treatment consists in the removal of diseased tissue, by *évidement* of the focus, and when necessary by excision of diseased synovial membrane. In the late cases, in which the joint is seriously infected, the latter will require appropriate treatment.

www.libtool.com.cn

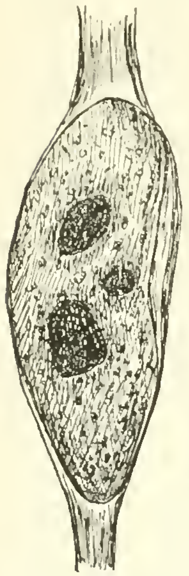

FIG. 3752.—Tuberculous Cavities in Patella. (From Volkmann.)

Gross' conclusions are that primary tuberculosis of the patella is more frequent than is usually supposed; that treatment is usually too long postponed; that it is a serious affection rapidly perforating into the joint; that with an early diagnosis a relatively simple operation will cure it; the procedures ordinarily employed are *évidement* of the focus, and in the later cases subperiosteal or total ablation of the patella, with synovectomy or arthrectomy when necessary. Absence of the patella interferes but little with function, and it may be reproduced after total subperiosteal ablation. He remarks that: "If one bears the possibility of tuberculosis of the patella in mind many knees will be saved."

Other papers on primary tuberculosis of the patella by François,[33] Forget,[34] Ménard,[35] Ribas,[36] Schlüter,[37] Kummer,[38] and Kocher[39] may be consulted.

PAU.—The city of Pau, chief town of the Department of the Basses-Pyrénées, France, stands upon the north or right bank of the river called the Gave de Pau, at the height of 130 feet above the river-bed, and 620 feet above sea level. The latitude of Pau is 43° 17' N.; its longitude is 0° 23' W. The population of the town is about thirty-three thousand. Its situation, on the edge of a plateau immediately above the river-bed, and the location, at the brink, as it were, of this plateau, of the old castle with its terrace, of the Place Royale, the Boulevard du Midi, and the Parc (containing thirty acres of ground and beautifully planted with shade trees) render the town a decidedly picturesque place in appearance, while the view of the Pyrenees Mountains, which may be had from all the points just mentioned, is remarkably fine, and is said by Murray to be similar to, although inferior to, the famous distant view of the Alps which is obtained from the platform at Berne.

The reputation of Pau as a winter health resort is notoriously great, and its hotels are excellent, especially such as lie in that part of the city which is nearest the edge of the plateau, and from which the view just mentioned is obtained. This portion of the city, at least, is well drained; of the rest I cannot speak positively. The soil at Pau is sandy.

The mean temperature of each of the five months, November to March, is given by Dr. Julius Hann as follows: November, 47.84° F.; December, 43.34° F.; January, 42.26° F.; February, 44.42° F.; March, 48.20° F. I have no data at hand to illustrate either the extreme or the average daily maximum and minimum temperatures; but the average monthly range during the season in question is 36.5° F. (Hann's "Handbuch der Klimatologie.")

Dr. Yeo tells us that "frost and snow and cold nights are not uncommon in winter"; and it is evident that the climate of Pau at this season cannot be pronounced a very warm one. In "Murray's Guide-book" we read that "though the climate is mild the variations in temperature are often sudden." On the other hand, Dr. A. Rotureau (in the "Dictionnaire Encyclopédique des Sciences Médicales"), although giving for the monthly means of November, December, and January figures which are lower than those of Dr. Hann, and although admitting that the temperature quite frequently falls below the freezing point, nevertheless appears to regard the winter climate of Pau as one characterized rather by equability than by variability of temperature, and Dr. Weber tells us that the nycthemeral range of temperature seldom exceeds 16° F.

The mean annual rainfall is 42.7 inches, of which 11.3 inches falls in winter (Rotureau), and during the six months from November to April the average number of

Digitized by Microsoft®

www.libtool.com.cn

days on which rain falls is between eighty and ninety (Weber). As to the manner in which rain habitually falls, we are told by Dr. Rotureau that, although falls of rain are frequent, they are not usually of long duration, and commonly occur in the early part or toward the close of the day. The relative humidity of the atmosphere at Pau is considerable; according to Dr. Weber, it is on the average from 80 to 85 per cent. Dr. Hann's figures for the five months, November to March, derived from observations taken only twice a day (viz., at 7 A.M. and at 2 P.M.), are as follows: November, 75 per cent.; December, 76 per cent.; January, 74 per cent.; February, 72 per cent.; March, 70 per cent.

The leading characteristic in the climate of Pau, and the feature to which it largely, and no doubt deservedly, owes its popularity as a winter resort, is the prevailing stillness of the atmosphere. The great chain of the Pyrenees Mountains, distant only fifteen or twenty miles, acts as a barrier to protect the region about Pau against southerly winds; while we are told by Dr. Yeo that "a series of plateaux rising behind the town" afford a good degree of protection from northerly winds. The west and the east are the quarters in which least protection against wind is afforded; but Dr. Rotureau claims that the hills known as the Coteaux de Jurançon and the trees of the Parc serve in some degree to break the force of the westerly winds, and that the easterly winds are modified in character by being obliged to pass over a district of relatively considerable elevation before reaching the town (sont mitigés par les hauteurs du terrain sur lesquelles ils doivent passer avant d'atteindre la ville). He also tells us that the east wind at Pau is a fair-weather wind and a dry one. The "mistral" of Provence and the Riviera does not exist at Pau, although the northwest wind is a bringer of cold and dry weather. The westerly wind is damp and warm. In Dr. Rotureau's article will be found other interesting facts concerning the winds of Pau, and concerning the comparative windlessness of its climate. Suffice it to say, in this place, that, while occasional wind-storms of considerable severity are there experienced, the climate is nevertheless one properly to be regarded as exceptionally free from winds.

Huntington Richards.

[The diseases for which the climate of Pau is regarded as beneficial are the various catarrhal conditions of the respiratory passages: dry bronchitis with irritable cough, emphysema, and nervous complaints of an erethistic nature. Formerly Pau enjoyed a wide reputation as a winter resort for cases of pulmonary tuberculosis, but at the present time it is considered too moist for the successful climatic treatment of this disease. There is, however, in the neighborhood of Pau a small sanatorium (The Trespoey Sanatorium) six hundred and ninety-five feet high, for the treatment of pulmonary tuberculosis; it is open from the middle of October to the middle of May. One can find at Pau good facilities for golf, polo, tennis, and cross-country racing. There are four English churches and a Scotch one. There has recently been opened a winter palace of much magnificence, where operas, etc., are given. English physicians are also to be found here.—*E. O. O.*]

PAVILION SPRING.—Berks County, Pennsylvania.
POST-OFFICE.—Wernersville. Sanatorium.

ACCESS.—Via Bound Brook route, Central Railroad of New Jersey, Lebanon Valley Railroad, or Philadelphia and Reading Railroad to Wernersville; thence one and three-quarter miles by private conveyance to spring.

The Pavilion Spring is not itself a resort, but its waters are used commercially, and locally it is used to supply the Grand View Sanatorium. It is located on the grounds of the sanatorium, near Wernersville, and nine miles from the city of Reading. The situation of the sanatorium is on the South Mountains, about one thousand feet above tide water, in the midst of charming and picturesque surroundings. This institution is an old and well known health resort, having been established in 1847. The buildings have been greatly enlarged and improved recently, and the resort is now fitted up with all kinds of appliances and conveniences for combating morbid conditions. The Pavilion Spring was analyzed in 1885 by Prof. Otto Luthy, analytical chemist, of Philadelphia, with the following results:

Reaction neutral. One United States gallon contains: Potassium sulphate, gr. 0.18; sodium sulphate, gr. 0.02; sodium chloride, gr. 0.06; sodium carbonate, gr. 0.33; calcium carbonate, gr. 0.23; magnesium carbonate, gr. 0.12; iron oxide and alumina, a trace; silica, gr. 0.94; organic and volatile matter, gr. 0.10. Total, gr. 1.98.

This water is very lightly mineralized, containing, indeed, fewer solid ingredients than that supplied to many of our larger cities. It is remarkably pure, however, and well adapted for table purposes. The water contains a considerable amount of carbonic acid gas and atmospheric air.

PELLAGRA.—(Synonyms: Lombardian leprosy; erythema endemicum; Maidismus; *Mal de misère* [French]; *Mailändische Rose* [German]; *Mal roxo* [Spanish]; *Mal rosso; Scorbuto Alpino* [Italian]).

DEFINITION.—An affection, limited to certain countries of the temperate zone, which has been most prevalent where maize or Indian corn is the principal article of diet. It is thought to be a trophoneurotic disease of toxic origin, affecting mainly the digestive tract, cerebrospinal centres, and the skin.

The disease was first observed in Spain in 1735, and it still exists to a limited extent in that country, although it is mainly encountered in Northern Italy, in the country about Rome, in Southern Austria, in the Tyrol, and in Roumania, while Manson reports the disease as prevalent in Egypt. No cases have appeared in this country, although it is sometimes imported with immigrants coming from countries where the disease prevails.[1]

SYMPTOMS.—The disease occurs in both men and women, and it has usually been observed in adults, although children are by no means exempt. It first makes its appearance in the spring or early summer; continues during the summer months, and then subsides as winter approaches. The first symptoms refer to the digestive tract and consist mainly of loss of appetite, thirst, vomiting, together with intestinal disturbances which give rise to diarrhœa; or, more rarely, constipation may be at first complained of, but this is usually followed by obstinate diarrhœa. As might be expected in this condition the tongue is furred, and epigastric pain is not infrequently complained of. In addition, there are lassitude, sometimes dizziness, noises in the ears, headache, and sleeplessness. These symptoms are soon followed by anæmia, palpitation on slight exertion, and sometimes œdema. Pains occurring either in the joints or in the lower part of the spine may likewise be complained of. In the course of a few months, or it may be not until the summer following, the skin shows signs of being implicated in the disease. At first there may be a general pallor, or even jaundice, which is soon followed by an erythema. The erythema often develops somewhat suddenly, although less abruptly than is usually the case with simple erythema, and its duration is more prolonged. The parts exposed to the sun's rays are at first, and throughout the whole course of the disease, the regions mainly involved. The changes consist of an erythematous blush which may be uniformly distributed over the area involved, or the eruption may appear in the form of patches of various shapes and sizes. These are generally first noticed on the backs of the hands, the face, neck, and forearms in laborers who are accustomed to go in the sun bare-armed. The same may be observed on the feet and legs of children who are wont to go barefooted; and it has been observed by Raymond[2] to recur in parts once af-

Digitized by Microsoft®

fected, although subsequently protected from the direct rays of the sun. The eruption at first bears some resemblance to an ordinary sunburn. In unusually severe cases the cutaneous eruption is often of a livid red color which disappears on pressure, and in some instances hemorrhagic petechiæ are encountered; bullæ have likewise been observed, and marked œdema of the parts affected is not an uncommon symptom. The subjective symptoms complained of in the skin are slight burning or itching, although the latter symptom is usually described by the patient as merely prickling or tingling, rather than the well-defined itching experienced in eczema. These constitute what may be called the first stage in the cutaneous manifestations.

www.libtool.com.cn

Toward the last of the summer, however, the skin assumes a dark, sometimes muddy, color; it becomes rough, the epidermis being thickened and slightly scaly, and not infrequently excoriated patches are encountered. These are occasioned by the rubbing and scratching indulged in by the patient. The duration of the eruption is variable.

Usually the active cutaneous symptoms begin to subside within a few weeks, or soon after midsummer, when the patient apparently recovers, and as cold weather approaches no vestige of the disease may be apparent. In this case the patient remains free from the disease until the following spring when the symptoms return usually with greater severity than characterized those of the preceding year. More frequently, however, the symptoms do not wholly subside upon the approach of winter. With the recurrence in the severity of the eruption the skin soon becomes thickened and fissures occur about the small joints; this is accompanied by marked exfoliation and constitutes the second stage of the eruption. The severity of the disease varies in different seasons and in different individuals, but it is usually commensurate with the privations to which the patient is exposed. Year after year the erythema returns and finally there takes place marked atrophy of the derma, the skin becomes shrivelled, and the fingers assume a semiflexed position, constituting the third stage of the cutaneous lesions.

During the second year the nervous system shows more unmistakable signs of implication. At this time changes in the reflexes are seldom wholly absent. In 165 cases examined by Sandwith,[3] the knee jerk was found to be normal in only 3, in 45 it was slightly exaggerated, in 70 very brisk, in 15 feeble, and absent in 23. In addition to this the patient complains of pain and tenderness in the dorsal region, the pain sometimes radiating to the extremities. According to Crocker[4] the third nerve is frequently paralyzed, and changes have been observed in the fundus oculi. These symptoms are followed by delirium, and after many years by melancholia, mania, and a tendency to suicide, while insanity is not infrequently the final sequence. It is estimated that about ten per cent. of the patients finally drift into the lunatic asylums of Italy (Billod). In young people bodily defects are sometimes attributed to this disease, especially defective development of the organs of generation, while it is said that the mental powers may be unnaturally precocious. Other symptoms noted late in the course of the disease are paralyses of various parts of the body, those most frequently reported involving the legs and arms; while atrophy of various internal organs is often observed post mortem.

Pathology.—According to Lombroso[5] the principal factor in the causation of pellagra is undoubtedly some toxic effect on the sympathetic system and the vagus nerve. The first change observed in the skin is hyperæmia, which goes on to exudation and consequent hypertrophy. Similar changes have been best observed in the meninges of the brain, as well as in the liver, spleen, kidneys, and lungs. When, as is usually the case, death occurs late in the course of the disease, atrophic changes have been for the most part observed. The most constant post-mortem changes are, therefore, general emaciation, atrophy of the skin, which presents a shrivelled, sometimes furrowed appearance, together with marked atrophy of the liver and spleen. In some instances these changes have been noted in the kidneys. Symmetrical sclerosis has been observed by Tuczek in the posterior columns of the cord and in the pyramidal tract; while in some cases fatty degeneration of various internal viscera is the most conspicuous feature. In one hundred and thirteen autopsies Lombroso found exudation into the liver, kidneys, spleen, and the meninges of the cord. He likewise found atrophy of viscera supplied by the vagus, fatty degeneration of the liver and kidneys, and pigment changes in the cells of the brain and cord.

Etiology.—It was formerly supposed that the exclusive use of unwholesome maize as an article of diet was the cause of pellagra. There can be no question, however, that bad hygienic surroundings together with exposure to the sun are the most important factors in the etiology of the disease. According to Lombroso (*loc. cit.*), the immediate cause of pellagra is a toxic influence analogous to ergotism, and further that maize when decomposed gives rise to a fatty oil or extractive which has been denominated pellagrozein. In experiments made with this oil on both men and animals it has been shown that symptoms somewhat analogous to pellagra have followed its administration. On the other hand, many cases of pellagra are reported in which the ingestion of maize has played no part. Thus Hardy,[6] Schreiber,[7] and others have reported cases of pellagra in which maize had not entered into the dietary. Alcohol and syphilis have likewise been looked upon as etiological factors. While it must be acknowledged that they may be contributory in producing the debilitated state essential in its causation, there is no positive ground for believing that they ever give rise to the disease *per se*. It is well known that maize as an article of diet is perfectly wholesome when sound and properly cured; but, like rye, maize may become affected, giving rise to a potent toxic poison analogous to ergot. Dr. Zampa,[8] medical officer of health in the province of Rome, claims to have traced a direct connection between the disease and certain topographical conditions, although malaria seems to have no part in its causation. The disease is most commonly met with among the agricultural class, although in rural districts it does not spare the artisan or those engaged in other pursuits. According to Zampa, damp, dirty, ill-ventilated habitations, scarcity of pure drinking-water, and a large consumption of "polenta" (a porridge made of maize seasoned with a little salt) as the chief article of diet, are the chief causes of pellagra. Crocker very aptly summarizes the cause of pellagra into "peasant life, poverty, and polenta." The disease is not contagious nor is it inherited. The age at which the disease is most commonly met with ranges between thirty and fifty years.

Diagnosis.—Like many infectious diseases the diagnosis of pellagra is not difficult when it is encountered in connection with other cases of the same nature, in communities where pellagra is known to be endemic, or in those known to have suffered from previous attacks of the disease. On the other hand, in sporadic cases or in countries where the disease is seldom encountered, its recognition may be somewhat difficult. The first point to be considered is the nutrition of the patient, for malnutrition is essential to the development of the affection. Gastro-intestinal disturbances, together with erythema appearing on the backs of the hands, on the face, more rarely on the forearms and dorsal surfaces of the feet as warm weather comes on, might be mistaken for ordinary sunburn. The association of gastro-intestinal disturbances, however, should put one on guard, while the persistence of the eruption would soon lead to a more thorough investigation, when the association of other symptoms or the history of previous attacks would enable the physician to make a positive diagnosis. Later in the course of the disease the occurrence of nervous symptoms would be conclusive to one familiar with the salient features of pellagra. Finally, with the continuation of the eruption year after year, together with great debility,

Digitized by Microsoft ®

despondency, an inclination to melancholia, and aberration of reflexes, an error in diagnosis need not occur.

Prognosis.—The prognosis will depend upon the severity of the disease and the extent to which it has advanced. During the first attack the prognosis may be said to be favorable, provided the patient can obtain suitable nourishment, and provided the impairment of the digestive functions be not sufficiently grave to interfere with normal nutrition. On the other hand, after the disease has existed one or more years and general impairment of nutrition becomes more marked, together with involvement of the nerve centres, the prognosis is always extremely grave. When the disease goes unchecked the final fatal termination may be expected in from three to twelve years, the average being about five. In all cases the prognosis will depend upon the ability of the patient to place himself under the most favorable conditions for recovery.

Treatment.—There are no drug specifics in the treatment of pellagra, and regulation of the diet should be the first consideration. In conjunction with this, proper attention should be paid to the digestive tract, which may require sedatives or soothing medicines, such as olive oil or albolene, together with opium, bismuth, etc. The food selected should be light and easy of digestion, and it should be given in small quantities at frequent intervals according to the strength and general condition of the patient. Milk, eggs, and meat broth are usually indicated in severe cases, and as the strength increases a meat diet with vegetables and bread obtained from well-ripened grain should be given. Next in importance to the diet are the hygienic surroundings of the patient. As has been shown, most cases occur among those who have been subjected to the vilest hygienic conditions; therefore it should be seen that the room occupied by the patient be sufficiently large to insure pure air together with free ventilation; dampness should be avoided by selecting a room to which the sun gains access at least during some portion of the day. Massage and rubbing with salt may be of benefit. By way of further medication, after the more pressing symptoms have been allayed, tonics and vegetable bitters, such as quinine and iron, together with cod-liver oil, should be prescribed. In some cases the administration of arsenic is followed by marked improvement. The cases in which this remedy is most liable to prove beneficial are those which have extended over several years and in which the disease has assumed a chronic stage. To quiet the apprehension of the patient, especially when the nervous manifestations assume a serious aspect, opium may be given.

William Thomas Corlett.

PELLITORY.—*Pyrethrum*, U. S. P.; *Pyrethri radix*, Br. P.; *Spanish Pellitory; Spanish Chamomile.* The dried root of *Anacyclus Pyrethrum* (L.) DC. (*Anthemis P.* [L.] fam. *Compositæ.*)

The pellitory plant is a pretty little perennial herb, which somewhat resembles the chamomile, whence one of its common names. It is a native of the Mediterranean basin, where it is cultivated not only as a drug, but also as a garden flower.

From 5 to 12 cm. (2 to 5 in.) long and 1 to 2 cm. ($\frac{2}{5}$–$\frac{4}{5}$ in.) thick, nearly straight and unbranched, cylindraceous, tapering or slightly fusiform, bearing a few tough, hair-like, yellowish rootlets and in the centre of the crown usually a tuft of cottony or silky, whitish, fibrous tissue; externally deep brown, or slightly grayish brown, inconspicuously annular near the crown, very roughly wrinkled and pitted, harsh to the touch; fracture short and sharp; bark thick, the inner layer brown, containing about three circles of dark red resin cells, the outer layer dark brown; wood yellow-brown, finely radiate, containing four or more circles of resin cells; inodorous, pungent, and acrid, producing a prompt and strong sialagogue effect.

The acridity of pellitory is due to a number of constituents, or possibly to some one which is carried in the former. These are a resin and two fixed oils, all present in large amount, as well as the alkaloid *pyrethrine*. The latter is readily decomposed into a derivative alkaloid, believed to be piperidine, and piperic acid. The resin contains a small amount of the alcohol-soluble body, *pellitorin*. The substance which has been sold as "pyrethrin" is merely a fatty and resinous extract. Tannin and volatile oil are present in small, and inulin in large amount.

Action and Use.—These have been but little investigated, notwithstanding that the powerfully active properties of the drug warrant a thorough experimental study. It is one of the most powerful of sialagogues, a property which we have not yet learned to utilize, in spite of the important digestive functions of the saliva. It is at least possible that so powerful an action upon the salivary glands is associated with a similar action upon the pancreas, but no observations are recorded upon this point. The most general application of the drug is as a dental anæsthetic and counter-irritant, and it enters into numerous "toothache drops" which have themselves largely gone out of use. There is a twenty-per-cent. official tincture, made with alcohol, the dose of which is a fluidrachm.

Allied Drug.—*German pellitory* or *pyrethrum* is the root of *A. officinarum* Hayne, the nativity of which is not certainly known, but which is a product of cultivation. The root is very much more slender and elongated than the other, and usually comes to market with long portions of the stem attached. It has a circle of large resin cells in the bark, but there are none in the medullary rays. Its constituents and action are practically identical with those of the official variety.

Henry H. Rusby.

PELVES, DEFORMED.—Any marked deviation in size or symmetry from the normal pelvis may be regarded as constituting a deformity of the pelvis, whether the effect on the course of labor be serious or not.

A deformed pelvis may be due to an error in development, to local disease, injury, or new growth, or indirectly to injury, disease, or maldevelopment of the adjoining skeleton. Thus from errors in development there are the abnormally large pelves, called justo-major; the justo-minor, or disproportionally small, sometimes of a persisting infantile type; and the pelves of the masculine type, large and thick-boned, but with a narrowed pubic arch and pelvic outlet.

From local errors in development there are the rare varieties, where one or both of the sacral alæ are lacking, giving the Naegele (oblique) or Robert (transversely contracted) pelves. The split pelvis is one in which there is failure of meeting of the pubic bones at the symphysis.

From constitutional disease or errors of nutrition causing softening of the bones, there result the pelves deformed by rachitis and osteomalacia. From local disease there may be caries of some of the pelvic joints, with arrest of development and later ankylosis. The sacro-iliac joints, if diseased in early life, may cause extreme deformity. Following injuries there may be pelvic fracture with formation of callus. New growths may limit or obliterate the pelvic cavity—a primary sarcoma or secondary carcinoma, or some form of enchondroma or exostosis.

Any injury or maldevelopment of parts of the skeleton adjoining the pelvis, especially during early life, may have an important bearing upon the subsequent developments of the pelvis, and leave indirectly its stamp on the general contour of the latter. Thus, for example, poliomyelitis, causing a paralysis and subsequent atrophy of one limb, leaves the pelvis on that side comparatively

www.libtool.com.cn
Digitized by Microsoft®

undeveloped. As a further result of the shortening of the limb there must be compensatory scoliosis, with its effect upon pelvic growth.

Other forms of paralysis of the lower extremities, or joint diseases of hip, knee, or ankle, may affect the pelvis in the same way. A congenital hip-joint dislocation may seriously affect the normal growth of the pelvis. Other results of skeletal deformity upon the pelvis are not infrequently seen from defects in the spinal column, such as simple, compensatory, or rachitic scoliosis, caries of the vertebræ, and, rarely, the anterior dislocation of the bodies of the lumbar vertebræ, known as spondylolisthesis. Senile changes in the pelvis before the end of the child-bearing period sometimes cause obstruction by ankylosis of the coccyx with the sacrum.

www.libtool.com.cn

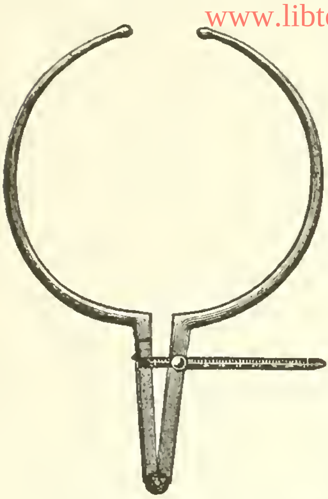

FIG. 3753.—Baudelocque's Pelvimeter.

Habits of living must always be counted upon as etiological factors. The poorly nourished and poorly housed are the ones who present pelves deformed from rachitis and tuberculosis. For this reason the percentage of deformities is small among our native country classes, large among the dwellers in cities, especially of the slums, and greatest among the immigrant population. Abroad, where the sanitary conditions of life are worse, still higher proportions of deformity are found, and osteomalacia is occasionally met with.

There are racial peculiarities in the shapes of the pelvic brim. The Caucasian normal type is one which is wide transversely; the outline of the Australian pelvic brim is almost circular; while the African pelvic brim is one which is relatively constricted transversely, and has a long antero-posterior diameter. This type of pelvis, if affected by the unsanitary conditions in which the negroes commonly live in this country in cities, supplies a large proportion of bad pelvic deformities. Thus one author has reported seven per cent. of deformed pelves in whites in a city hospital service, as against twenty-one per cent. in blacks.

The recognition of the deformity is important. One "must learn pelvimetry if he is to do intelligent obstetrics." Much can be ascertained by inspection of the patient. The facial appearance, form, carriage, height, gait, or obvious deformities of spine or lower extremities may lead to suspicions and put one on the track of a pelvic defect. A careful questioning may elicit a history of diseases such as rachitis or tuberculous bone disease, or bring out information concerning previous difficult labors.

But the history may be lacking, and all external appearance of deformity absent. Moreover, in all cases, no matter how obvious the deformity, its true extent and its obstetric significance can be ascertained only by careful pelvimetry, through palpation, vaginal examination, and instrumental pelvic measurements. External measurements, except in some cases of great obesity, are of a certain value in determining the types of deviation from the normal. Of greater importance is the exploration by vaginal examination of the pelvic cavity.

For external measurements there have been chosen certain easily recognized bony landmarks. The distance between these points is taken by a form of caliper called the pelvimeter. Of the commoner types perhaps those of Baudelocque and Breisky are best known. The essentials of a good pelvimeter are compact size and an accurate and legible scale, preferably in centimetres.

The first measurement usually taken is the distance between the anterior superior spines. For this measurement the patient should be flat on the back, with all but the thinnest clothing removed from about the hips and lower abdomen. The thumb and forefinger should steady each tip of the pelvimeter. The thumb should now be allowed to rest in the notch below the spines and the tips of the pelvimeter be lightly pressed against their outer side and the reading made. Taken in this way the measurements will be fairly constant when made by different individuals. The average interspinal diameter is 24 cm.

The next measurement should be the distance between the crests of the ilia, this measurement being made between the points which are most widely separated. The patient lying in the same position, the tips of the pelvimeter are slipped back along the outside edge of the crests, and the widest points of divergence noted and measured. This is called the intercristal measurement. It should average about 28 cm. These two distances furnish an indication of the transverse diameter of the pelvic brim, especially if taken in consideration with the so-called external oblique measurements.

The ratio of the interspinal measurements to the intercristal has a distinct value in the study of certain types of deformity, especially the rachitic.

The external oblique measurements are those taken from one posterior superior spine to the opposite anterior superior spine. To take the left oblique measurement the doctor stands on the right of the patient, who lies on her left side. The distance from the left posterior superior spine to the tip of the right anterior superior spine is measured. The posterior spines are not very prominent, but are usually indicated by the presence of a dimple on either side of the sacrum from one and one-half to two inches from the median line. The patient now lies on the right side, and the right oblique measurement is taken. The average length of these measurements is 22 cm. The right oblique is commonly 0.5 cm. larger than the left. The obliques furnish a fair idea of the oblique diameters of the pelvic brim. Any marked deviation of their normal relation to each other is a good index to oblique pelvic contraction.

For estimation of the antero-posterior diameter, or so-called conjugate of the pelvic brim, a measurement is taken which is called the external conjugate. This is the distance from the tip of the last lumbar spine to a point about one-quarter of an inch below the upper edge of the pubic symphysis in the median line. Some authorities give the depression just below the last lumbar spine as the posterior landmark, but this gives less constant and exact measurements. The last lumbar spine is usually the most prominent spine in that region. It is found about 2 cm. above the level of a line drawn through the two posterior superior spines. This measurement calls attention to contractions in the antero-posterior diameter of the pelvis. In the normal pelvis it measures from 20 to 21 cm. Any pelvis measuring less than 18 cm., even if justo minor, should be regarded as flat. There are, however, possibilities of error in this measurement. Occasionally a

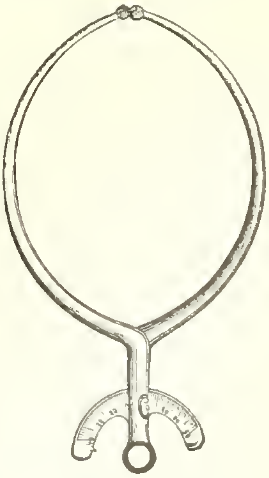

FIG. 3754.—Breisky's Pelvimeter.

Digitized by Microsoft®

pelvis which has an external conjugate of large size will show flattening upon internal pelvimetry.

One other external measurement is sometimes of importance; that is, in the type of pelvis where there is obstruction at the pelvic outlet due to a narrowing of the pubic arch and an approximation of the tuberosities of the ischia. This is called the bi-ischial diameter. It is easily taken, while the patient is in the lithotomy position. The tuberosities may be readily felt, and the distance between them taken by tape measure or pelvimeter. If the distance be below 9 cm. the narrowing is dangerous.

The most valuable information is furnished the physician by vaginal examination. After he has acquired some experience he will be able to make out variations in the size of the cavity of the pelvis. If he can readily with the finger touch the sacral promontory, flattening is certain. Fairly accurately to estimate the internal conjugate, the first and second fingers of the right hand are introduced until the middle finger rests against the promontory. At the point where the index finger intersects the symphysis a mark is made by the finger nail of the left forefinger. The internal oblique conjugate is the distance between this mark and the tip of the middle finger. Subject to slight variations the true internal conjugate may be estimated by the subtraction of 1.5 cm. from these figures. The normal internal conjugate is 11 cm. Any conjugate below 10 cm. indicates a dangerously flattened pelvis.

Of the various types of deformities which are perhaps most commonly seen are the pelves of normal symmetry but of extremes of size. The justo-major pelves are those of exaggerated size. They occur usually in women of robust type, who have an otherwise large frame. These women are often tall, but they may be of normal stature. The effect of such a pelvis upon labor is slight. Certain authors suggest that from the lack of bony resistance there is a tendency to precipitate labors and resulting lacerations. There may be an increased proportion of uterine displacements from lack of bony support. The practical obstetrician may disregard this deformity. The diagnosis of this condition may be made in those cases in which the oblique diameters measure 24 cm. or more.

The justo-minor or equally contracted pelvis is of more serious moment. It is usually found in smaller women, but may occur in women of otherwise normal development. It may be classified as one of symmetrical shape, but with external obliques measuring 20 cm. or less. The etiology of this condition cannot always be explained. It is of great frequency in the African race. In this class, however, the deeper conjugate acts somewhat in compensation. In some cases the justo-minor pelvis is only a part of a dwarfed general system. In some cases it seems to go with under-developed pelvic organs, a retention of the juvenile type. Unfavorable surroundings in childhood or during intra-uterine life may have affected development unfavorably. The effect upon labor depends necessarily upon the degree of the deformity and the size of the child's head. In those patients who are naturally small the child will be in proportion, except where the father is of large size or where pregnancy has been prolonged beyond the normal time. In these cases the only safety for the child depends on strong uterine contractions and a capacity for extreme moulding of the fœtal head. In the African race, as the fœtal cranial bones are notably soft, and the uterine pains usually very effective, the head moulds extremely well. The justo-minor pelvis, therefore, in the negress has little significance except in those cases in which some other kind of deformity is added to the general contraction. In the Caucasian the larger and firmer head of the fœtus causes trouble, and may necessitate very active interference.

The mechanism of the labor in the justo-minor pelves is as follows: The head, unable to engage by moderate flexion, becomes more and more flexed until the occipital bone presents. The external occipital protuberance may be felt. Engaging in one oblique the head gradually descends, under the influence of strong pains. The overlapping of bone at the lambdoidal sutures is an index of the amount of moulding accomplished. If the obstruction is so moderate that the pains can accomplish the delivery, after a rather protracted second stage the head reaches the pelvic outlet. Obstruction occurs until the head is well past the mid-pelvis. During this time the suffering from the pressure against the pelvic bones may be very severe. At the time of the uterine contraction the patient cries out as if suffering intensely. Between the pains there is aching discomfort from the continued pressure of the impacted head. Rarely, after the head has safely passed the pelvic brim, the shoulders may furnish some obstruction.

If the pains are not effectual in advancing the head, and artificial assistance be not forthcoming, the muscular force may diminish. Weaker and infrequent contractions may cause labor to linger along until the patient suffers from extreme prostration; or the pains may be so severe as soon to develop a tonic uterus, with retraction and migration of the muscular fibres to the fundus and a thinning of the lower uterine segment. The end result of such a case may be spontaneous rupture of the uterus. Should the breech present in a patient with a justo-minor pelvis, the complication for the child is apt to be fatal; for while the body moulds easily into the pelvis, the descent of the head can be accomplished only by moulding, which is impossible in the short space of time that safety permits for the extraction of the after-coming head. There are cases on record in which the force necessary to deliver the head through a justo-minor pelvis has caused a diastasis of one or more of the pelvic joints.

The *masculine type of pelvis* is most often found in women with large muscular frames. The external measurements may be even justo-major. The bones are unusually thick. The peculiar deformity in this type of case is in the narrowing of the pubic arch. The pelvis may be shallow or deep. In the latter case it is best described as funnel-shaped. The true funnel pelves, however, are more extreme cases than those of the masculine type, and usually occur in connection with some spinal deformity, especially kyphosis.

The diagnosis is an easy one to be overlooked, because of the otherwise large development of the patient. Indeed, in many instances the case is allowed to go on until the obstruction during the second stage of labor calls attention to the deformity. It is upon the vaginal examination that the diagnosis must be based. The pelvic walls are felt to be drawing nearer together as the outlet is approached. At the outlet the approximation of the ischial spines and tuberosities to each other should be recognized, and also the sharper angle of the pubic arch.

In the masculine pelvis labor progresses normally, even to the time of the appearance of the caput in some cases. And then as the head encounters the bony obstruction all progress ceases, or very slowly and by increased expulsive effort the head is moulded past the outlet. The narrowed arch forces the head posteriorly, and, thus increasing the tension upon the perineum, causes a liability to extensive lacerations. These lacerations may involve not only the perineum, but sometimes run up on either side of the vulva, along the line of the pubic rami. Where they extend into the venous plexuses of the vestibule, hemorrhage may be very persistent. From the prolonged pressure various necroses of the vagina or the cervix, or a trauma to the bladder, may be caused.

The pelvic narrowing sometimes causes faulty flexion of the head. The occiput may be forced to rotate posteriorly. Sometimes rotation is so interfered with that the head is born obliquely or even transversely.

The treatment is usually by assistance with low forceps. If this is not sufficient, symphyseotomy may be of especial value in this deformity. But the fact that the prolonged pressure in the second stage may have injured the child beyond hope of recovery must be taken into consideration before any major surgical operation on the mother is undertaken.

The *simple flat pelvis* is a fairly common type of de-

formity, and one which may have a serious effect on labor. It occurs usually in pelves with measurements otherwise normal. If this deformity be engrafted on a justo-minor pelvis, the consequences are most serious. The cause of this condition is not always plain. A slight degree of rachitis, the carrying of heavy burdens, excessive standing on the feet, prolonged illness in bed in early life may all have some effect. This flattening is most often met with in the lower classes and the foreign born.

www.tlbtool.com.cn

The deformity may be anything from a simple jutting forward of the promontory to a marked approximation of sacrum to symphysis, changing the cordiform outline of the brim to a shape more reniform. There is a compensatory slight widening of the pelvic brim transversely.

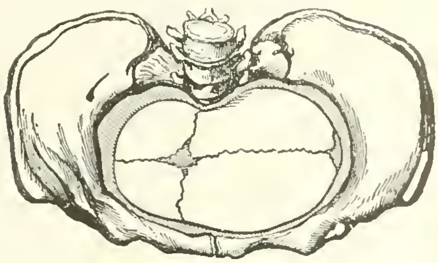

FIG. 3755.—Position Assumed by the Head in a Flat Pelvis. (After Simpson.)

Nothing about the general appearance of the individual in most cases would lead one to suspect the difficulty. The external conjugate in some cases shows no shortening. The internal measurement is therefore of greatest importance. The flattening, if of much significance, will allow the promontory to be easily reached by the examining finger. The extent of the deformity may be readily ascertained by the method suggested above.

If the narrowing be of slight extent, normal spontaneous delivery is possible, but there is a tendency to dry labors and a slight modification of the mechanism. The head engages transversely, poorly flexed, but slightly inclined laterally, so that the anterior parietal bone presents. Occupying the direction of least resistance the occiput slips to one side, thereby causing the bitemporal diameter to engage the conjugate rather than the biparietal. During the time of moulding the woman suffers severely from the pressure of the head against the sacrum.

As soon as the widest part of the head has passed the constriction advance may be rapid. Because of the poor flexion of the head rotation of the occiput to the front occurs late if at all. The head is often born obliquely, sometimes even transversely, or with the occiput still posterior. The shoulders and hips are apt to be born transversely. If much moulding has been necessary, the posterior parietal bone may show a grooving parallel with the coronal suture, caused by the pressure of the head against the promontory. The posterior parietal bone is overlapped by the anterior.

The effects of the flat pelvis upon labor may be only those mentioned above. If the child be small, attention may not be drawn to the deformity. The well-known tendency of women to have larger children in succeeding pregnancies, however, often brings the first manifestation of a flat pelvis in a later pregnancy in a woman who has already had several normal deliveries.

If the deformity be more serious the head engages, but cannot mould sufficiently to pass the brim. After a reasonable length of time artificial assistance must be employed. In the cases of greater flattening no engagement occurs and exhaustion soon supervenes from the futile efforts of the uterus at expulsion. The head rides high above the pelvic brim. The uterus tends to fall forward, causing a pendulous abdomen, which makes the efforts at engagement of the head still more ineffectual.

The flattening, preventing the fitting of the head in the pelvic basin, may cause malpresentations. The lack of adjustment between head and pelvic brim may cause a prolapse of the cord. In the earlier months of pregnancy the projecting promontory may force the uterus into retroflexion and ultimate incarceration in the hollow of the sacrum. Where the head cannot engage or descend into the pelvis the dilatation of the cervix is incomplete because the presenting part does not reach it to cause pressure against it. Instead of the usual meniscus-shaped bag of membranes a cylindrical-shaped bag forms which is ineffectual as a dilator and very prone to early rupture.

The flat pelvis may be the cause of a breech presentation, and when this condition occurs in a pelvis which by measurements other than the conjugate is shown to be ample, the breech labor seems to be the safest. The reason for this is that the after-coming head enters the pelvic canal, with the smallest part of the wedge first. The larger part adjusts itself to the most roomy part of the pelvis. The occiput slips toward one side of the pelvis, and in so doing causes the bitemporal diameter to engage the conjugate, instead of the biparietal, as is usual in vertex cases. The bitemporal diameter has the advantage of being at least 1 cm. smaller than the biparietal. The force which must now be applied from below, by traction on the child, will complete the necessary moulding in the safest possible way.

It is for this reason that the method of delivery by version and breech extraction is often considered and safely employed in a labor case with a flat pelvis.

A kind of pelvis which always shows flattening and yet is quite distinctive in type occurs in those women who have suffered from rachitis in infancy or childhood. The rachitic pelvis shows the effect of various pulling and pressure forces upon the different bones.

The extent of the deformity varies with the severity of the disease and depends somewhat upon the position occupied by the patient during the course of the disease, *i.e.*, whether lying in bed, sitting up, or walking about. One other factor is the arrested general development which occurs at that time.

The weight of the pelvic viscera combined with muscular traction tends to flatten the ilia and to prevent the inward curvature of the crests to the anterior superior spines. In this way the spines are thrown outward. In severe cases the ilia flare to the spines. The intercristal diameter is thus smaller than, or of the same width as, the interspinal. About two-thirds of the way to the posterior spines on the crests there is frequently a sharp angle where the crests turn in toward the spines.

The brim of the pelvis is diminished in the conjugate by the pressure of the weight of the trunk transmitted along the spine to the sacrum, and forcing it down and forward on its transverse diameter. The lower half of the sacrum tends to be thrown backward, but the tip is pulled forward in compensation, in sharp flexion, by the sacro-sciatic ligaments. The sacrum is further changed, so that its anterior surface instead of presenting a concavity from side to side is convex or flat. Sometimes there is a sharp bending backward of the lower part of the sacrum at the juncture of the first and second sacral vertebræ, causing the second vertebra to form a false promontory, which in estimating the internal conjugate must be accepted as the working promontory.

There is a widening of the pubic arch from muscular traction on the ischial tuberosities. If the patient be allowed to walk during the disease, there may be some constriction of the pelvis transversely by pressure over the acetabula. In general the size of the pelvis is restricted. The flattening is the worst feature. The pelvic brim presents a reniform outline, with a slightly increased transverse diameter. The pelvic cavity is usually ample and the outlet wide. The symphysis forms a wider angle with the plane of the sacrum. All degrees of deformity are met with.

The diagnosis of the extreme cases is easy. In slighter deformities the history of the patient is of some help—

late walking, late dentition, unhygienic surroundings. There may be evident the square forehead, rickety chest, bowlegs, or any of the rachitic skeletal changes apart from the pelvis. Locally, there is found the changed ratio of the interspinal to the intercristal measurements; the easily felt promontory, with perhaps a false promontory at the junction of the first and second lumbar vertebræ; the sacrum convex from side to side; and the wide pubic arch.

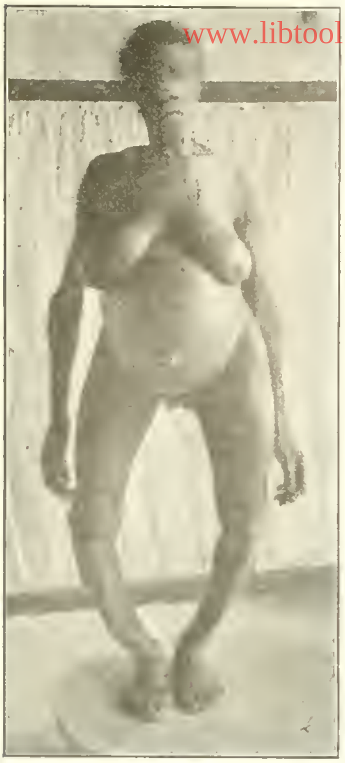

FIG. 3756.—Rachitic Negress Delivered by Cæsarean Section at the Sloane Maternity Hospital, New York City. (Service of Dr. Edwin B. Cragin.)

The effect of *rachitis* on labor depends on the extent of the deformity. Even in cases of slight deformity the effective working space of the bony passages is circumscribed. In lesser cases the mechanism may resemble that of a simple flat pelvis. In worse cases a spontaneous delivery or even engagement of the head is impossible.

Osteomalacia, or *malacosteon*, is a disease which causes a softening of the pelvic bones by the absorption of the lime salts. It develops during pregnancy or lactation; more usually the latter. The condition is rarely met with in this country. Nothing is known of its etiology other than that it is a disease of nutrition. The softening of the bones, however, is the occasion for an extreme collapse of the pelvic basin. The sacrum and the regions of the acetabula are crowded in so that the pelvic brim is triradiate in shape. This collapse leaves the symphysis projecting like a beak, giving the pelvis the name of the "rostrate pelvis." The pubic arch is much narrowed. Severe cases of rachitis show a similar deformity. For differentiation, in the cases of osteomalacia the ilia are curved like scoops and the crests are more sharply curved, while in rachitis the ilia flare and the spines are widely separated.

The history of cases of osteomalacia is characteristic. The trouble develops during the child-bearing period. There are dull aching pains in the extremities and lumbar region, with difficulty in walking and rotation of the body as one foot is advanced in front of the other. The stature is appreciably diminished during the course of the disease. There may be tenderness over the anterior pelvic wall. Examination reveals the beaked pelvis, the narrow pubic arch, and, if the finger can reach so high, the triradiate pelvic brim. Such a pelvis, unless in the earlier stages and quite soft, will not allow any form of conservative operative delivery *per vias naturales*. The Cæsarean operation with extirpation of the uterus furnishes the best solution of the difficulty.

Kyphosis developing in early life from caries of the vertebræ, possibly from rachitis, leaves its stamp upon the pelvis, producing the type known as the *kyphotic pelvis*. This was first described by Breisky in 1865. The difference in the direction of the pressure, transmitted through the spinal column on the sacrum, is dependent upon the location of the kyphos. The deformity is most marked when the kyphos is low down. In the upper dorsal region spinal deformity will affect but slightly pelvic development.

The characteristic kyphotic pelvis has a displacement of the upper end of the sacrum backward. This gives an unusually deep conjugate. The lower end of the sacrum is thrown forward. There is an approximation of the posterior superior spines and of the ischial tuberosities. There is a narrow pubic arch. The sacrum is long, narrow, and straight. This pelvis presents therefore the funnel type. The pelvic brim is deep and ample, but the outlet is much narrowed. Combined with kyphosis there is usually some scoliosis, causing some pelvic obliquity. Some of these individuals have smaller measurements in general, due to arrested development.

A kyphotic pelvis does not affect the course of the labor to the extent that would be anticipated from the examination and inspection of the patient. The successful outcome of labor in these dwarfed women is often a surprise to even the experienced.
