The normal uterine cavity, however, is generally conceded to be sterile,[7] but there has been a long controversy over the bacterial flora of the vagina. Bacterial examinations of the vaginæ of a large number of pregnant women have led to contradictory results. Döderlein,[8] Winter, and others found pathogenic bacteria in a varying percentage of cases; while Krönig,[9] Menge, and others, found none, with the exception of the gonococcus. Döderlein,[10] made further studies and divided his cases into two classes: (*a*) Those with "normal" acid vaginal secretion in which he found no pathogenic bacteria; and (*b*) those with an "abnormal" weakly acid, neutral, or alkaline secretion, in ten per cent. of which he found streptococci. Later Krönig,[11] with improved technique by which he avoided contamination from the vulva, found no streptococci in either normal or abnormal cases. These results have been confirmed recently by Williams.[12]

The bulk of the evidence is now in favor of the view that infection comes from without in practically all cases. Experiments have shown that the normal vaginal secretion has distinct bactericidal power. Cultures of streptococci and other pathogenic bacteria, introduced into the vagina of a pregnant woman, have been destroyed, and disappear in from twenty-four to forty-eight hours. The gonococcus forms an exception; as far as known, it is the only pyogenic coccus which can live and thrive in the vaginal secretion.

Morbid Anatomy.—Any part of the genital tract may be infected, and accordingly we may have, primarily, puerperal vulvitis, vaginitis, endometritis, metritis, metro-lymphangitis, metro-phlebitis, or salpingitis. Extension of the infection to adjacent structures may give rise to parametritis, peritonitis, oöphoritis, or phlegmasia alba dolens. Further, with any of these conditions varying degrees of toxæmia and bacteriæmia may occur.

Puerperal vulvitis and vaginitis present no characteristics differing materially from those of ordinary infections of lacerated wounds. The so-called diphtheritic forms are usually due to mixed streptococcus infection, although true diphtheritic inflammation has been reported in a few rare cases (Bumm, Nisot, Williams).

Endometritis, or an inflammation of the uterine mucosa, is the most common form of puerperal infection.

It is a help in the study of the lesions to divide the cases into those which are due to the streptococcus, the septic cases, and those which are due to putrefactive bacteria, the putrid cases.

In the pure streptococcus cases the walls of the uterus are comparatively smooth, there is little or no accumulation of necrotic material, and the discharge is correspondingly small in amount and devoid of offensive odor.

In the cases in which putrefactive bacteria (colon and anaërobic bacilli) are present at the same time with the streptococci, and in the simple putrefactive cases the walls are rough, the cavity of the uterus is filled with masses of foul-smelling necrotic material, and the discharge is profuse, offensive, and frequently contains gas bubbles.

Microscopically there is in general a typical inflammatory reaction in the endometrium. The cavity of the uterus is lined by a surface layer of necrotic tissue which is filled with bacteria; beneath this is a layer of leucocytes, the so-called "protective wall" of leucocytes. In the virulent streptococcus cases the necrotic layer is slight or absent, and the protective wall of leucocytes is poorly developed; the streptococci invade the wall of the uterus along the lymphatics or veins, and can be traced to the peritoneum, the parametrium, and the ovary, and, in many cases of peritonitis, parametritis, oöphoritis, and phlegmasia alba dolens, to the veins of the pelvis and of the leg.

Infected emboli from thrombosed veins may be carried to distant organs and there set up secondary septic inflammations, or they may cause a general systemic infection.

In the milder streptococcus and staphylococcus infections the inflammation may be limited to the endometrium, with little or no invasion of the protective wall of leucocytes, and the general symptoms may be due largely, as in the simple putrefactive cases, to absorption of toxins.

In the simple putrefactive infections the necrotic layer and the protective wall of leucocytes are well developed, and the bacteria are confined to the necrotic layer.

In the mixed infections of streptococcus with putrefactive bacteria we may have a more or less composite picture of the conditions above described.

Since the discovery of the gas bacillus (aërogenes capsulatus) by Welch, in 1891, it has been found in a number of puerperal infections. These include cases of emphysema of the fœtus, puerperal endometritis, physometra, emphysema of the uterine wall, and puerperal gas sepsis. Many of the patients recovered. The fatal cases were characterized by an extraordinarily rapid development, post mortem, of gas in the tissues and blood channels of the fœtus and mother. It seems probable that

Digitized by Microsoft®

most of the fatal cases of air embolism previously reported were cases of gas-bacillus infection.

Symptoms.—Cases differ greatly in their character according to the variety and virulence of the micro-organisms, the site of the primary infection, and the degree of extension of the disease. As has been noted, the infection usually takes the form of an endometritis.

www.libtool.com.cn

In general, the symptoms are those of a wound infection with more or less toxæmia. A chill, fever, general malaise, rapid weak pulse, restlessness, and headache are most frequent.

The patient will have done well during the first few days of the puerperium, and then on the third or fourth day she will have headache and malaise, followed by a chill and a rapid rise of temperature to 103° F. or higher. In the simple cases there is but one chill, while the fever remains high for some days and then subsides. The lower abdomen is tender on pressure. The uterus also manifests increased tenderness, and is larger and more "doughy" in consistency than normal. The character of the lochia is changed. There is apt to be constipation and the urine is scanty and highly colored.

Clinically, the cases may be divided into the septic and the putrid forms. The well-known variation in the virulence of cultures of the streptococcus explains the not infrequent mild cases due to streptococcus infection.

The severer streptococcus cases are characterized by rapid onset, often with early delirium, or great mental prostration and apathy, although some show a remarkable absence of mental symptoms. With the invasion of the lymphatics and blood-vessels come the symptoms of general septicæmia, recurring chills, and high, irregular temperature; in such cases death usually follows within a week.

In the milder septic cases, if the infection is limited to the endometrium, the initial chill and rise of temperature are followed by a gradual decrease of the fever. The lochia are purulent but not profuse, and they are devoid of marked odor. The general symptoms subside after the uterus is washed out, and recovery usually follows, but a condition of subacute or chronic endometritis may persist for a long time.

If the infection is not limited to the endometrium, but extends along the lymphatics, it may give rise to abscess formation in the walls of the uterus, in the broad ligament, in the retroperitoneal tissues, or in the inguinal region; or it may extend to the peritoneum and set up a local or a general peritonitis. The latter is usually fatal. Again, there may be a direct extension of the infection to the Fallopian tubes with development of salpingitis or an abscess. Such extensions are accompanied by chills and a fresh access of fever. The abscess may rupture into the bladder, the rectum, through the skin in the inguinal region, or into the peritoneal cavity. If the abscess is drained satisfactorily the symptoms rapidly subside and recovery follows. Rarely an abscess may undergo gradual resorption.

Extension of the infection along the thrombosed veins of the uterus may give rise to pyæmia. In such cases the initial chill may be delayed, the temperature does not remain constantly high, but instead there is a typical hectic fever with alternating chill, fever, and remissions. The symptoms vary according to the number and size of the infected emboli, the organs to which they are carried, and the virulence of the micro-organisms. These emboli frequently give rise to an often fatal bronchopneumonia, or less frequently to destructive inflammations in various joints. In a few cases the thrombosis extends to the femoral veins and causes phlegmasia alba dolens. This usually occurs in the second week and is characterized by severe pain and swelling of the leg, with fever. The pain and swelling may persist for a long time, but uncomplicated cases end in recovery. The symptoms of thrombosis of the femoral vein may be the first evidence of an infection, the primary inflammation in the uterus having been so slight as to escape notice.

Putrid endometritis differs somewhat in its symptoms and course from the septic forms. The onset is usually on the third or fourth day, and the initial chill and rise of temperature may be as marked or even higher than in the septic cases, but the general condition is not so serious. The main difference is in the character of the lochia, which in the putrid form are profuse, offensive, and frequently have a frothy appearance owing to the presence of large numbers of gas bubbles. The cases improve rapidly after the masses of necrotic material have been removed and the uterus has been washed out. Nearly all of the putrid cases terminate in recovery.

Diagnosis.—Typical cases give no difficulty in diagnosis. In distinguishing between the septic and the putrid forms of endometritis the changes in the lochia are important. The profuse malodorous discharge and the roughened surface of the uterine mucosa are very distinctive in the putrid types; while a smooth uterine surface with scanty purulent discharge and high fever suggests a streptococcus infection.

In the mixed streptococcus cases, however, the uterine wall may be rough and the discharge profuse and offensive. Here the value of a bacteriological examination of the uterine lochia is particularly evident.

Fever, during the puerperium, may be due to diseases other than puerperal infection. Angina, acute pulmonary affections, influenza, acute inflammatory conditions of the breasts, typhoid fever, and malaria occasionally occur.

Some cases of puerperal infection are undoubtedly diagnosed as malaria. But we are not justified in attributing the fever to malaria unless we find the plasmodium in the blood, and even then we cannot exclude puerperal infection until we have proved that the uterine lochia are sterile.

"We might say that every rise in temperature in the puerperium should be regarded as due to puerperal infection, unless we can clearly demonstrate some other infection to be its cause" (Williams).

Fever due to auto-infection from the intestinal tract is promptly reduced by the effective action of a strong laxative. Certain mental disturbances, such as emotional excitement, fright, or grief, may be attended with a sudden rise of temperature, which falls to normal in a few hours.

The absorption of sterile exudates and blood clots is usually associated with a rise of temperature often to 100°, but rarely above 101° F., and this rise occurs in the first thirty-six hours.

Prophylaxis.—Puerperal infection is wound infection. Therefore in order to avoid infection scrupulous care, according to the principles of surgical technique, must be taken from the beginning of labor to the end of the puerperium.

Vaginal examinations in the last days of pregnancy should be made with antiseptic precautions. During and after labor they should be reduced to a minimum. Preliminary antiseptic douches in normal cases are to be avoided, since they decidedly decrease the bactericidal power and resistance of the vagina and its secretion. The use of the ordinary douche and the making of a vaginal examination by the nurse should be prohibited. If the vagina is known to contain pathogenic bacteria, the obstetrician himself should cleanse it with the utmost care; but such conditions should be corrected, if possible, long before the onset of labor.

Since the hands are the chief carriers of infection, they should receive careful attention. The following is one of the most satisfactory methods of hand disinfection:

1. Scrub the hands and forearms up to the elbows with a sterile brush, green soap, and hot water for three minutes, paying especial attention to the finger nails and palmar surfaces of the fingers—change the water at least once.
2. Trim the finger nails with a sterile knife or scissors, and clean the finger nails with a nail cleaner.
3. Repeat the washing for five minutes by the clock, using a fresh brush.
4. Rinse in fresh water.

Digitized by Microsoft®

5. Soak hands in a hot saturated solution of potassium permanganate until they are of a deep mahogany color.

6. Decolorize completely in a hot saturated solution of oxalic acid.

7. Soak forearms and hands in a 1 to 1,000 solution of bichloride of mercury for three minutes by the clock, or until the patient is ready for operation.

www.libtool.com.cn

It should not be forgotten that sterile hands may be contaminated readily at the bedside.

The patient also should be carefully prepared. At the onset of labor she should be bathed and given a rectal enema. The external genitals frequently harbor streptococci and various pathogenic and putrefactive bacteria. They should be carefully washed, before each vaginal examination, first with soap and hot water, and then with a 1 to 2,000 solution of bichloride of mercury; afterward they should be protected, with a towel soaked in the bichloride, until the physician is ready to make his examination.

During the second stage an antiseptic towel should be kept over the vulva and sterile sheets and towels should be arranged in such a manner as to prevent contamination.

In operative procedures rubber gloves may be worn to give added protection. They should be thoroughly boiled and then drawn over the sterilized hands.

Perineal tears offer ready entrance to bacteria and should be repaired. The sutures may be placed during the third stage and tied after the expulsion of the placenta.

Operations for the repair of lacerations of the cervix greatly increase the chance for infection, and should not be done unless imperatively demanded for the control of hemorrhage.

After the birth of the placenta the patient should be cleaned and the vulva covered with an ample sterile dressing, which is held in place by a T-bandage.

Ergot may be used to secure better contraction of the uterus, but should not be given until the placenta has been expelled.

During the puerperium the external genitals should be kept clean by frequent irrigation with a 1 to 4,000 solution of bichloride, and the vulval pads frequently renewed. Vaginal douches should be used only in exceptional cases, and then with the utmost regard for surgical cleanliness. Infections have been caused by the careless use of the vaginal douche, even in the later stages of the puerperium.

Treatment.—General treatment alone often gives the best results in the severe streptococcus cases. Strychnine, gr. $\frac{1}{30}$, may be given every two hours with half an ounce of whiskey every hour, but the quantity should be reduced promptly when the pulse shows improvement. The patient should be kept on the verge of strychnine poisoning and a state of drunkenness, if necessary. Mild cases require little medicine. The bowels should be kept open and good food given in all cases.

Antistreptococcus serum has given very unsatisfactory results. Laboratory experiments have shown that serum prepared from a given culture is protective for that particular culture and no other. Recent reports by Labusquière,[13] Savor, Blumberg, and Scharfe show results of doubtful or no value.

The cases of true diphtheritic infection reported by Bumm, Nisot, and Williams showed rapid improvement and recovery following the use of diphtheria antitoxin.

Salt solution enemata every six hours, given through the long rectal tube, are often of value in relieving symptoms and promoting diuresis. The subcutaneous injection of sterile decinormal salt solution has been of apparent benefit in some cases. Tincture of ferric chloride in large doses is of value.

Local treatment in the streptococcus cases should be limited to douches, preferably of hot sterile decinormal salt solution. These may be repeated every six hours if necessary. Dilute bichloride douches, 1 to 10,000, immediately followed by the salt solution, may be used. But antiseptic douches are dangerous and should be used with great care. Forty cases of death from bichloride poisoning have been reported.

Clots and fragments of the placenta may be removed with the finger or the dull curette. Curetting on the whole is dangerous, especially if streptococci are present, for by it we may break down the protective wall of leucocytes and expose fresh areas to infection, the very thing we wish to avoid.

Hysterectomy has been advocated for severe cases, but the results reported by Rochard, Bazy, Terrier, and Tuffier, with a mortality of from thirty-three to one hundred per cent., hardly justify a resort to the operation. Leopold[14] and Fehling do not favor it. As they show, to be of value it must be done early, before the infection has extended through the uterine wall. But at present we have no means of determining in which cases the infection will extend, and in which it will remain limited to the uterus. Ricard has collected eight hundred and fifty-one cases with fever at 102.2° F. and higher, showing a mortality of thirteen per cent. under general treatment.

Abscesses and dense areas of cellulitis in the parametrium should be opened through the vagina or through the abdominal wall.

Putrefactive cases with abundant foul discharge are greatly helped by cleaning out the masses of necrotic material with the finger or curette, and following this by a large douche of salt solution, the douche to be repeated every six hours. *Otto G. Ramsay.*

PULLER SPRINGS. — Madison County, Montana. Post-Office.—Puller Springs. Hotel.

This resort is reached by a good wagon-road, and has semi-weekly mails. The location is in a beautiful valley, having an elevation of 5,530 feet above the sea-level. The springs are two in number, the temperature of the water being 95° F. for the larger and 105° F. for the smaller spring. No analysis. The waters have been found beneficial in rheumatism and allied disorders. The beautiful location of these springs, coupled with the potential therapeutic properties of the water, will undoubtedly bring them into extensive use as the State becomes more thickly settled. *James K. Crook.*

PULSATILLA.—U. S. *Pasque Flowers.* The dried herb of *Anemone Pulsatilla* L. and *A. pratensis* L. (fam. *Ranunculaceæ*), collected soon after flowering, carefully preserved and kept not longer than one year. Both are low, hairy herbs and among the earliest and most beloved of spring flowers. For medicinal purposes the plant should be dried in the shade and stored in a cool and dry place. The drug is thus described: Silky-villous; leaves radical, long-petioled, the petioles usually purplish, the blades twice or thrice deeply three-parted or pinnately cleft, the lobes linear and acute; flowers long-peduncled, subtended by an involucre of three pinnately parted sessile leaves; calyx of (usually six) large, dull purple, hairy sepals; petals obsolete; stamens numerous; pistils several, be-

Digitized by Microsoft®

coming in fruit long, plumose-tailed akenes; inodorous and very acrid.

CONSTITUENTS.—Pulsatilla yields upon distillation with water a very pungent, volatile, oil-like principle, from which ether or chloroform extracts a peculiar camphor, which has been called *Anemone camphor*, and which possesses the acridity of the oil to such a degree that it is capable of blistering the skin. This camphor is divisible into anemonin and iso-anemonic acid. The former is a colorless, crystalline, neutral substance, of but little taste when cold, but intensely pungent when melted. It is but slightly soluble in cold alcohol, ether, or water, more so in those liquids when hot, and is readily soluble in chloroform. *Iso-anemonic acid* is a white, amorphous, insoluble substance, without odor, taste, or medicinal property.

ACTION AND USE.—The clinical investigation of pulsatilla has been greatly neglected by physicians, apparently with little better reason than that it is a favorite medicine with homœopaths and eclectics. That it possesses powerfully active properties is sufficiently proven by its action upon the skin and the mucous membrane. Its action is fairly well described in a general way by saying that it resembles that of aconite, but its special field of usefulness is well worthy of careful determination. It is a fairly active counter-irritant, and is frequently so employed. Although capable of blistering, if applied with friction, such a use of it is not wise, since the blister is rather uncontrollable. Applied to the mucous membrane, it produces a burning and tingling, followed by numbness, much as does aconite. In the stomach it acts as a stimulant, or in larger amount as an irritant emetic. Systemically, it reduces both the rate and the force of the heart and of the respiration. It is therefore an antiphlogistic, and is somewhat used as a respiratory sedative. Among the homœopaths and eclectics its sedative action is largely utilized in the treatment of inflammatory conditions of the genitals, although it is also a favorite emmenagogue.

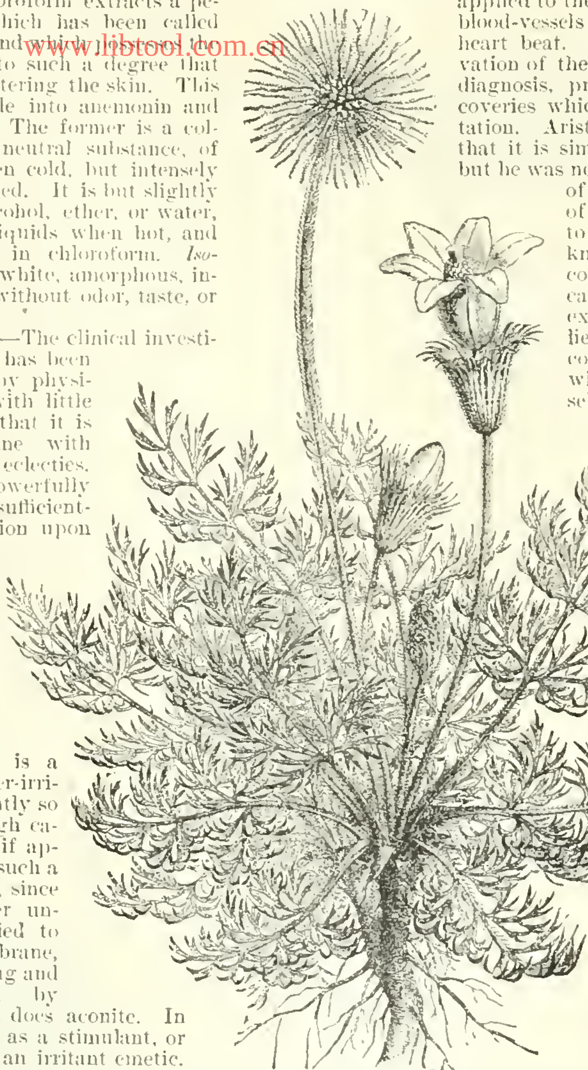

FIG. 3896.—Anemone Pulsatilla. (Baillon.)

There is no official preparation. The powdered drug may be given in doses of 0.06–0.3 gm. (gr. i.–v.) or the fluid extract in an equal number of minims. The tincture is probably more used than all other of its preparations combined. It is commonly made of twenty-per-cent. strength, and the dose is 0.5–1 c.c. (♏viij.–xv.). The extract is used in doses of one-half to two grains and anemonin in doses of one-fifth to one-half a grain.

ALLIED DRUGS.—*Anemone nemorosa* L., the common wind-flower, and various other anemones, have a similar composition to that of pulsatilla, and are similarly used. Various species of *Ranunculus* or buttercup, and of *Clematis* or virgin's bower, also exhibit resemblances in the same direction, as does Hepatica or liver-leaf. All these pertain to the family *Ranunculaceæ*. *Henry H. Rusby.*

PULSE, THE.—INTRODUCTORY AND HISTORICAL.—The pulse, literally a beating or throbbing, may be broadly defined as periodic movements caused by the rhythmic action of the heart. The term is commonly applied to the changes in size and tension of the blood-vessels which may be seen or felt at each heart beat. In the history of medicine the observation of the pulse, and also its employment in diagnosis, preceded by many centuries the discoveries which opened the way for its interpretation. Aristotle refers to the pulse, and states that it is simultaneous in all parts of the body; but he was not aware of its relation to the activity of the heart. Galen, equally ignorant of its origin, devoted much attention to it, but his lack of physiological knowledge led him to form many false conceptions, and he attached a significance to minor variations which later experience has not justified. He believed that the arteries expanded and contracted actively by some force which they possessed within themselves. In China medical science, like other things, has changed little in thousands of years. The native physicians there have very crude ideas of both anatomy and physiology, and yet they describe and even graphically depict the pulse in great detail. They imagine they find indications in it of the exact seat no less than the nature of nearly every disease.

A more reasonable claim, where the indications given are better supported by other symptoms, is ascribed by the poet Browning to Paracelsus, that erring Moses who in the sixteenth century began to lead the profession out of the Egypt of tradition.

"When we would thoroughly know the sick man's state
We feel awhile the fluttering pulse, press soft
The hot brow, look upon the languid eyes
And thence divine the rest."

The foundation for the scientific study of the pulse was laid by William Harvey, who discovered and described the circulation early in the seventeenth century. Among his conclusions we find that "the heart is the organ of propulsion for the blood" and that "the pulsation of the arteries is nothing else than the impulse of the blood within them." In 1707 Sir John Floyer states a little more definitely: "The pulse is that sensible motion which is given to the artery by the blood which the heart injects into it." Still fuller is the account given in Haller's "Elements of Physiology," published in 1760: "The arteries are, in a living person, always full of blood, since the jet or stream that starts from an artery is not interrupted by alternate stops, while the heart rests or relaxes itself, but it flows on in a continued thread. . . . Since, therefore, a new wave or column of blood is sent into the arteries already full, although it bears but a small proportion to the whole mass contained in the arterial system throughout the body, . . . yet by its immediate contact with the precedent wave or column, which

www.libtool.com.cn
Digitized by Microsoft®

moves slower as it gets farther from the heart, it consequently drives the same forward, lengthens the artery, and makes it assume a cylindrical form, augments its diameter, etc. This dilatation of the artery, whereby its light or capacity is changed from a less to a greater circle, is called the pulse." In 1767 Henri Fouquet described in

www.libtool.com.cn

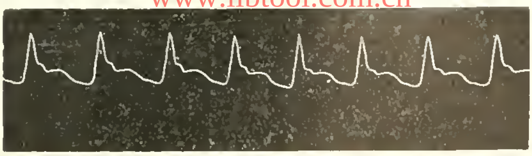

FIG. 3897.—Normal Pulse Tracing.

detail the sensations imparted to his finger by the pulse and was the first in Europe (the Chinese were before him) to represent the pulse by drawings. In 1855 K. Vierordt describes a rough means of recording the movements of the arteries automatically, thus laying the foundation of modern sphygmography. On this foundation a host of modern investigators, both laboratory and clinical, have raised a substantial structure of useful knowledge.

ARTERIAL PULSE. — *Description and Explanation.* — The arterial pulse comprises a succession of waves initiated in and near the heart and propagated through the arteries. As the contents of the left ventricle are forced through the semilunar valves, room is made for the blood, partly by the distention of the aorta, and partly by a pushing on of what is already there into the smaller arteries, causing the latter to be distended in turn. This distention slightly increases the calibre of the arteries; but what we recognize as the pulse, when we lay our finger on the wrist, is rather the increase of tension or pressure within the vessel which occurs at the same time. In some cases an artery may become more tortuous as the wave of increased tension is passing over it. With the finger on the pulse, it is sometimes possible to recognize more than one impact or wave. It is difficult, however, and often impossible to be sure of these so-called secondary waves by the sensation imparted to the finger, and we should know very little about them were it not for the assistance furnished by the sphygmograph. By means of this instrument it is possible to communicate the movements of the artery to a lever supplied with a writing point. This is brought to bear upon a piece of smoked paper moved by clockwork. The result is a graphic representation of the variations in pressure occurring within the artery. Some of the many forms of instrument and the method of employing them will be described in the article on *Sphygmography.* Fig. 3897 represents the tracing obtained by one of these instruments (Dudgeon's sphygmograph) from the radial pulse of a healthy man.

If it be examined it will be seen that each pulse beat is represented by a sudden rise followed by a more gradual fall. The sudden rise is known as the *primary or percussion wave* and can be traced to the contraction of the ventricle. The descent is broken by two secondary waves, of which the second, known as the *dicrotic wave*, is in this case the largest and most distinct. This wave is very constant, being found in almost all pulse tracings. It is preceded by a depression known as the *dicrotic notch*. There has been much controversy as to the cause of the dicrotic wave, one view being that it is due to a rebound of the blood from the aortic valves at the moment when they close, and the other that it is a wave reflected back from the small peripheral vessels. While a very few still hold the latter view, it has been discarded by most physiologists as a result of overwhelming evidence that has been advanced in favor of the rebound theory. If the wave were due to a reflection of the percussion wave from the periphery, it would occur earlier in the peripheral than in the central vessels, which is not the case. Moreover, a number of physiologists, notably Karl Hürthle, have shown that the dicrotic notch which marks the beginning of this wave follows immediately the closure of the aortic valves. He has invented the so-called differential manometer to record the time of closure of the valves. This instrument records the relation of the pressure in any two cavities. If connected with the aorta and left ventricle through a Hürthle's heart catheter, it indicates the moment when the pressure in the ventricle falls below that in the aorta. This moment corresponds of necessity with the beginning of a back flow into the ventricle, and must be directly followed by closure of the valves. In Fig. 3898 from Hürthle's "Beiträge zur Hæmodynamik" *A* is the curve of pressure at the root of the aorta, that of the left ventricle, and *D* the curve of the differential manometer showing the relation between the pressure in the ventricle and that in the aorta. When the curve *D* rises above the base line the pressure is higher in the ventricle, and blood begins to flow into the arteries; when it falls below the line, there is a tendency for a back flow to take place and the semilunar valves close. The vertical lines 1, 2, 3, 4, 5 show corresponding points of time in the three tracings. The aortic valves close directly after the line 3, which marks the beginning of a backward flow into the ventricle. This corresponds in time very closely with vertical line 4, indicating the commencement of the dicrotic wave. The close agreement in time between these two events is strongly suggestive of a causal relation. The correspondence between the closure of the aortic valves and the dicrotic wave has also been successfully demonstrated by Martius, Karl Schmid, Jr., and others by marking the time of the second sound of the heart as heard with a stethoscope upon the pulse curve.

The rebound from the semilunar valves may be explained as follows: The blood is thrown out of the ventricle at a certain speed and with a certain momentum. When the ventricle has emptied itself the momentum of the blood in the aorta tends to carry it forward away from the ventricle. This cannot actually take place, or a vacuum would be left at the root of the aorta, but the tendency in that direction causes a low pressure and consequent suction action at the aortic orifice. This lower pressure or suction leads to a wave in a backward direction, completing the closure of the semilunar valves. This is reflected forward again as the dicrotic wave. The dicrotic wave is most pronounced when the smaller arteries are dilated and the peripheral resistance is low. In this case the column of blood, meeting with little opposition, is thrown out of the ventricle with greater speed and momentum, and the recoil against the semilunar valves consequently occurs with greater force.

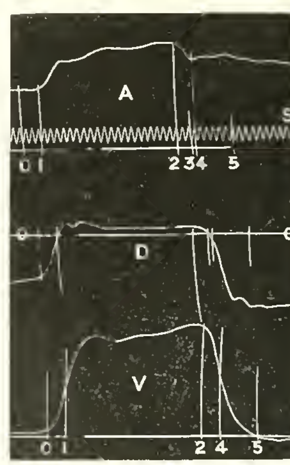

FIG. 3898.—Shows Relationship between the Pressure in the Ventricle and that in the Aorta. (From Hürthle.)

Immediately preceding the dicrotic wave another, and in this case (Fig. 3897) smaller, wave may be seen which is known as the *predicrotic* or *tidal wave*. The cause of this is more doubtful than that of the dicrotic wave. It is found in the curve of intraventricular pressure, and may even be present under certain conditions in the tracing of the transverse diameter of the frog's ventricle (Marey), so that it is frequently ascribed to a peculiarity in the contraction of the ventricular walls, "the systole not being equally sustained" (Foster) or "the outflow remainder wave" (Roy and Adami). There are those who ascribe this wave entirely to inertia and recoil of the instrument

Digitized by Microsoft®

used. The instrument may, and often does, exaggerate it, but there is little doubt of another factor being present. The most plausible explanation is perhaps something like this: both the percussion wave and the predicrotic originate within the ventricle during its systole; the reason of there being a depression or notch dividing them into two is that a slight fall of pressure occurs when the semilunar valves open and afford a passage for the blood into the aorta; the physical laws here exemplified may be studied in the mechanism of the hydraulic ram as has been pointed out by Karl Schmid, father and son. If the pressure in the arteries is low, the ventricle nearly empties itself with one effort, and the predicrotic wave is scarcely seen; but if the pressure is high, only part of the blood is forced out at first, and after a slight fall in pressure at the opening of the semilunar valves, the continued contraction of the ventricle raises it again up to or beyond its original height, forming the predicrotic wave. It is certainly a practical rule that where the predicrotic wave is pronounced and reaches a high level the blood pressure is high relatively to the strength of the ventricle.

Other secondary waves are sometimes seen upon pulse tracings and are probably due to oscillations taking place within the vessels, or in some cases they may be instrumental in origin. A multiplicity of secondary waves points to high blood pressure and consequent tension of the arterial walls. Elevations or depressions occurring upon the descending limb of a tracing are called katacrotic, those more rarely seen upon the ascending limb are called anacrotic. A tracing with interruptions upon the ascent is called an anacrotic tracing, and we may also speak of an *anacrotic pulse*. Similarly, where there are interruptions on the descent we speak of a katacrotic tracing and *katacrotic pulse*. A pulse may be both anacrotic and katacrotic. The normal tracing in Fig. 3897 is katacrotic only. The tracing shown in Fig. 3899, taken from a case of aortic stenosis, could be classed as both anacrotic and katacrotic. The predicrotic wave forms the summit of the tracing and indicates resistance to the outflow of blood from the ventricle; the primary or percussion wave forms an anacrotic crest or angle on the ascent, and the dicrotic wave is seen as an elevation on the descent (katacrotic).

Factors Contributing to the Character of the Pulse.—The exact character of the pulse depends on three principal factors: the force of the ventricular contraction, the degree of elasticity of the arteries, and the resistance offered to the outflow of blood from the arteries into the capillaries and veins. The quantity of blood in the body naturally occurs to one as a modifying factor, but its influence is difficult to trace, and in any case it probably acts chiefly by modifying the ventricular contraction. An additional factor that does, without doubt, however, exert a modifying influence in special cases is the condition of the aortic and to a much less extent of the mitral valves. Of the three principal factors mentioned *the ventricular contraction* determines the rate and combines with the other two factors to give the pulse its other qualities. *The elasticity of the arteries* modifies the pulse in the direction of less abruptness. The more elastic the larger arteries are, the less sudden is the increase of tension in the smaller ones. The diminished elasticity of age tends to make the rise of the pulse wave steeper. In cases of low blood pressure the same effect is noted, because the elasticity of the arteries is not fully brought into play. *The peripheral resistance* depends largely upon the degree of activity of the muscular coats of the arterioles. When these are relaxed the blood pressure falls, the ventricle empties itself easily, and the pulse is large and soft. When the arterioles are contracted the blood pressure rises, the work of the ventricle is increased, and this is indicated in the pulse by hardness and a prominent predicrotic wave. Advancing age tends to raise the peripheral resistance by the withering of many of the capillaries and consequent narrowing of the channel by which the blood must flow from the arteries into the veins. Age also affects the force of the ventricles and the elasticity of the arteries so that the pulse in old people varies according to the part of their vascular system where degenerative changes have been most active. As the thoughtful observer notes in the pulse the modifications brought about by ventricular activity and peripheral resistance, he will find there suggestions of many possible influences acting through the cardiac and vasomotor nerves.

Rate of Propagation.—It takes a certain measurable time for the effect of the ventricular contraction to make itself felt in increased tension of the peripheral arteries. In other words, the pulse waves travel at a certain rate. This "rate of propagation" varies somewhat, but is usually given as between three and ten metres a second. It is considerably influenced by variations in blood pressure and by the degree of rigidity or elasticity of the arteries; the more rigid the vessels the more rapid the propagation of the pulse.

Fig. 3899.—Anacrotic Pulse (aortic stenosis).

Further information on some of the subjects treated of above will be found in the article on *Circulation*.

The Examination of the Pulse and What it Shows.—One should not make any direct examination of the radial pulse until he has obtained what information he can by inspection of the visible parts of the body. A glance is often sufficient. In the face one can find indications of the condition of the capillary circulation in the glow of health or in pallor or lividity. In the neck there may be violent throbbing of the arteries or distention and pulsation of the veins. In the fingers one may find lividity and clubbing or a capillary pulse. The pulsation of the temporal and radial arteries may be visible.

It is important to choose for the examination of the pulse a time when the patient is as little excited as possible. It is well to distract his attention by conversation. To obtain the best results the patient should lie or sit in a comfortable position. The observer should be in front of the patient or to his right side. The patient's right arm should be supported with the elbow flexed and the forearm half pronated. Two or three fingers of the observer's right hand should be laid upon the radial artery where it passes over the lower end of the radius between the styloid process and the flexor tendons. The fingers are to be moved up and down the artery and across it, first with light pressure and then with sufficient to flatten out the vessel so as to bring out *the condition of the arterial wall*. If the artery can be felt and rolled beneath the fingers when flattened out it indicates the thickening of arteriosclerosis or the rigidity of atheromatous or calcareous degeneration. If the latter change has taken place to a marked degree, one can often feel the arterial wall to be uneven and ribbed. If the artery can be felt to be tortuous, one is justified in inferring that the patient has been the subject of relatively high blood pressure extending over a long period. In examining the wall, as described above, an impression will often be received of *the calibre or fulness of the artery*. One is very apt to be misled on this point, according to Leonard Hill, by the fact that the venæ comites accompany the artery and contribute to the sensation of size given to the finger.

The arterial pressure may be roughly estimated by the amount of pressure which must be exerted by the finger to obliterate the pulse in the portion below. The artery should be pressed directly backward against the radial bone, and it is well to compress it below as well as above the examining finger so as to exclude any "anastomotic pulse" from a communicating vessel. A correct judg-

Digitized by Microsoft®

ment as to arterial pressure can be acquired only by much practice. One is very liable to confuse the sensation given by high arterial pressure with that of a thickened or calcareous artery.

Low arterial pressure is found in fevers, especially the later stages, in most wasting diseases, and in many forms of heart disease. High pressure occurs especially in nephritis, lithæmia, and lead poisoning.

www.libtool.com.cn

The pulse proper should be examined with reference to its rate, regularity, size, and quickness. The so-called *hardness or softness of the pulse* is practically identical with the arterial pressure which has just been discussed. *The rate of the pulse*, whether frequent or infrequent, is to be determined by counting the pulse beats by a watch for not less than half a minute. It is well to note the number of beats in each period of five seconds so as to determine whether or not the rate is variable.

When the pulse is too frequent to be successfully counted in the ordinary way it is sometimes possible to calculate its rate by counting every second beat and doubling the result. When some or all of the beats are too feeble to be distinguished, the rate can be obtained by auscultation of the heart. A record of the variations in the pulse rate from day to day is often valuable. Before drawing conclusions from the rate of the pulse, due weight must be given to the fact that it may be modified by very slight influences such as the position of the patient or slight mental excitement. If the rate be abnormally high it should be counted again when any excitement has had time to subside. The rate of the pulse varies much within the limits of health. *Age* has a very great influence. The average rate is something over 130 in the first year of life, about 90 in the tenth year, 70 in adult life, and 75 or 80 in those who have passed the allotted span. *Sex* has little influence, the average in females being only a few beats per minute more than in males of the same age. What little difference there is in the two sexes may with reason be attributed to *size*, for, as a rule, the larger the body the less frequent the pulse. Tables showing in more detail the effects of age, sex, and size on the rate are given in the article on *Circulation*. *The time of day* has a slight influence on the pulse rate, which is usually five or ten beats higher in the afternoon and evening than in the morning. *Meals*, especially if hot, may increase the rate for one or two hours. *Change of position* from lying to sitting raises the rate from two to five beats per minute. On standing a further increase of four to eight beats may result. *Exercise* has a still greater influence, very slight exertion sending the pulse up twenty or thirty beats, and violent exercise may more than double the rate. An increased frequency out of all proportion to the effort made is commonly seen in the debilitated and the diseased.

Pathological frequency of the pulse may be conveniently divided into three groups (Mackenzie). First, those in which the heart responds to an extra call upon it by an excessive increase of rate; second, those in which the pulse rate is continuously increased; third, those in which periods of increased rapidity take place in irregular paroxysmal attacks.

To the first group of *abnormal excitability* belong all cases in which the reserve power of the heart is impaired. This may be the result of some general disease or of valvular or other heart affection. When no other sufficient cause can be found, one may suspect a neurotic temperament or the abuse of some stimulant or narcotic (alcohol, tea, or tobacco).

In the second group of *continued frequency* we may place (*a*) most febrile diseases. In fever the pulse usually bears some relation to the temperature. It is commonly increased about ten beats per minute for each degree Fahrenheit of pyrexia. Marked exceptions to this rule are found in typhoid fever where the increase in the pulse rate is usually small for the amount of pyrexia, and in meningitis where the rate is very variable, but may be lower than normal in spite of considerable fever. (*b*) Diseases of the heart. Increased frequency of the pulse is a common but by no means an invariable symptom of valvular disease. In disease of the aortic valves, especially aortic stenosis, the pulse rate is less likely to be increased than in mitral disease. In degeneration of the heart muscle the pulse rate is very variable, and may be either higher or lower than normal. The rate is usually increased in pericarditis and in overstrain from excessive work. (*c*) Exophthalmic goitre. (*d*) Numerous other conditions such as incipient tuberculosis, exhausting diseases, neuroses, pregnancy, hemorrhage, alcoholism, great anxiety, severe pain.

The third group of *paroxysmal attacks* embraces palpitation and paroxysmal tachycardia. In *palpitation* we have a sudden onset of rapid, violent heart action accompanied by throbbing of the larger arteries. This excessive throbbing does not extend to the smaller arteries, "the radial pulse, for instance, being rapid but having no excess of force" (Balfour). True palpitation occurs in weakly anæmic individuals, and is induced by psychical and gastric reflexes of various origins, "never by exercise." The patient is usually painfully conscious of the violent action of his heart.

In *paroxysmal tachycardia* the subjective symptoms are less pronounced. The heart may be beating even more frequently than in palpitation, and yet the patient be unconscious of the fact. The attacks are variable in duration, but may last several days. During the attack the heart frequently dilates as a result of incomplete emptying by the rapid feeble beats. Mackenzie looks upon the disease as caused by some local heart stimulation giving rise to a prolonged series of premature systoles.

Diminished frequency of the pulse must always be carefully distinguished from those cases of missed beat in which only every second pulse is strong enough to be felt at the wrist. It is a safe rule to count the heart sounds before diagnosing an abnormally slow pulse. An infrequent pulse is sometimes present in individuals who show no other signs of disease. It is said that the pulse of Napoleon Bonaparte was never over forty. An infrequent pulse is most common in the latter half of life. It may sometimes be a symptom of degeneration of the myocardium. It is often seen in diseases accompanied by high blood pressure, such as chronic nephritis, and as a result of poisons produced within the body, as in jaundice, or introduced from without, as digitalis. The most marked instances of infrequent pulse, or *bradycardia*, as it is called, are those following injury to the spinal accessory nerve. This nerve arises from the spinal cord as far down as the fifth or sixth cervical vertebra, and may be implicated in fracture of the spine or inflammatory compression of the cord in this region. In such cases the pulse may fall to thirty, twenty, or even lower. A pulse rate of eight per minute has been recorded. In such cases syncopal attacks and epileptiform seizures are common.

Regularity of the Pulse.—In healthy people who are not suffering from any disturbing influences, the pulse beats are usually regular in rhythm and volume. This may be recognized by the examining finger. In some cases, however, we find variation in the intervals between the beats or in their volume or both. Such departures from the normal present themselves in a great variety of types which are often referred to by different names in the various books on the subject, so that considerable confusion of terms exists. The following table is suggested as a classification of the different kinds of irregularity, although I am quite aware of its imperfections and recognize the fact that there is some overlapping so that the same pulse might be put under more than one heading:

- Allorrhythmia (Greek, another rhythm).
  - P. alternans.
  - P. bigeminus.
  - P. trigeminus.
  - P. paradoxus.
- Arrhythmia (without rhythm).
  - P. intermittens (dropped beat).
    - P. deficiens.
    - P. pseudo intermittens (hemisystole).
  - P. intercidiens (premature systole).

Digitized by Microsoft®

P. irregularis.
Diastolic.
Systolic.

In *allorrhythmia* the variations in rhythm are themselves rhythmical. Thus in the first subdivision, *pulsus alternans*, we have alternately a strong pulse beat and a weak one. This is sometimes ascribed to a strong beat of the left ventricle and a weak beat of the right ventricle alternating with a weak beat of the left side and a strong beat of the right side. In *P. bigeminus* the beats are in pairs, two beats with a short interval between and then a pause. P. bigeminus must be carefully distinguished from *P. bisferiens* which is a pulse where the predicrotic wave is well marked so that each single pulse has a double crest. In *P. trigeminus* there are three beats and then a pause. Cases are reported in which there are two beats and a pause followed by three beats and a pause. *P. paradoxus* is where the pulse becomes extremely feeble or fails altogether at the end of each inspiration. When pronounced this form of pulse usually indicates adhesive pericarditis or great obstruction of the respiratory passages. A slight variation in the pulse at different stages of respiration may be present in healthy people.

Arrhythmia includes those forms of pulse irregularity which have no rhythm of their own. *P. intermittens* is where from time to time the finger misses a beat. It is sometimes spoken of as dropped beat. Where the ventricle misses a contraction altogether we speak of a *P. deficiens*. Where there is a beat of the ventricle which, while it can be heard over the heart, is too weak to propagate a pulse to the wrist, we speak of a *hemisystole*, causing a false intermission. In *P. intercidiens* instead of a beat being dropped out we have one occurring before its proper time. We may refer to this event as a *premature* systole. Such a premature systole is often too feeble to be felt at the wrist, and is then a hemisystole also. At other times it is distinctly felt, and when it occurs at regular intervals may give rise to a pulsus alternans or pulsus bigeminus. Where there are one full beat and two premature systoles regularly repeated we get a pulsus trigeminus. Under the heading simply of *pulsus irregularis* we may put any irregular pulse that cannot be classified in any other group. This and pulses of the other groups as well, may be separated into two divisions of some practical importance. In the first of these the irregularity is due to a variation in the length of the pause (*diastolic*). Such irregularity is frequently found in the healthy, and is of little importance. In the other division the irregularity is due to variation in the force and duration of the ventricular contraction (*systolic*), and the pulse beats are felt to vary in strength. Pulses of this kind are more apt to indicate danger and should be carefully considered after thorough examination of the heart. Diastolic irregularity is frequently seen in children, and Mackenzie proposes to call it *the youthful type* of irregularity, although it is often seen in adults too, especially as the pulse is slowing down during convalescence from a fever. For systolic irregularity Mackenzie proposes the term *adult type* of irregularity. The terms systolic and diastolic seem to the present writer less open to objection.

In looking for the *cause of pulse irregularity* we first turn to the heart and find that sometimes the lack of normal rhythm is due to independent action of the ventricle and sometimes may be traced back to the auricle. To determine which chamber is primarily at fault may best be complished by taking simultaneous tracings from the radial and jugular, as will be further explained shortly in connection with the venous pulse and also in the article on *Sphygmography*. Irregularity is frequently a result of the strain put upon the heart by valvular disease, but is not often seen in pure aortic cases. It is especially in cases of advanced mitral disease in which the auricles are overworked and distended, perhaps paralyzed, that we get the most pronounced forms. Among other causes of irregularity are myocarditis and fatty degeneration, anæmia, strain, and digitalis poisoning. The latter is said to be often characterized by a pulsus trigeminus.

One cause of pulse irregularity that requires special discussion is vagus inhibition. Some writers go so far as to make influences reaching the heart through this nerve almost the sole cause. Such a statement is doubtless an exaggeration, and yet many influences act reflexly through the vagus in such a way as to cause irregularity. Among these we may include emotional shocks, such as sudden joy, sorrow or fear, mental strain and worry, gastro-intestinal disturbance, pain, injury, cold, either external or internal.

Fig. 3900 is a tracing from a patient in whom the heart appeared quite normal. She had suffered much from domestic trouble for several months and it is possible that that was the cause of the irregularity.

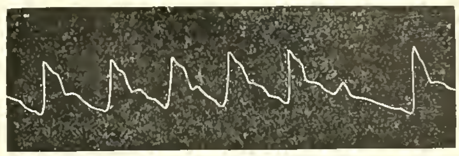

Fig. 3900.—Pulse showing Premature Systole.

To the finger on the wrist it seemed as though there were an occasional intermission. The pulse tracing shows that this was not a pulsus deficiens but merely a weak beat (hemisystole). If careful measurements be made it will be seen that the weak pulse beat comes a little before it is expected (premature systole). One frequently finds irregularities of this kind in people without any other symptoms of disease. An instance which came under my notice recently would suggest that it may sometimes be an hereditary peculiarity. I had the opportunity of examining a father and son, both of whose pulses were irregular. In the father's pulse there was a weak premature systole at intervals varying from a few beats up to thirty or more. In the son they occurred every four or five beats if he kept very quiet, but slight exertion caused the entire disappearance of the irregularity. Both of these men have hearts rather below than above the average size, and neither of them has any symptoms of disease.

As to *prognosis in cases of irregularity*, such cases as those just mentioned in which the heart appears quite sound need not excite any alarm, especially if the irregularity be known to be of long standing. If the heart is dilated the case should receive more consideration. Cases of diastolic irregularity in the young or convalescent need not excite any alarm. It is a totally different thing when an irregularity develops in a case of old heart disease or in the course of a fever. In both of these cases it suggests overloading or paralysis of the auricles, and is a symptom of danger. Cases of pneumonia in which the pulse becomes intermittent before the crisis are usually fatal. As a rule, where people have an intermittent pulse during health the onset of fever causes the intermission to disappear. When this does not occur, it may be taken as a danger signal. Generally speaking, the more rapid the pulse the more serious is the occurrence of intermission or other irregularity. Irregularity can be given its proper importance only when considered with other symptoms. If there are no other serious symptoms and the heart can respond well to extra calls upon it, then irregularity is of little importance. When, on the contrary, there are other symptoms that the heart is laboring under stress of work, then irregularity may be taken as an additional bad sign, and the more so the higher the temperature and the more frequent the pulse.

Size or Excursion of the Pulse.—Pulsus magnus or parvus, large or small pulse. These terms are used to describe the sensation that the finger has of being lifted as the pulse wave passes. When the sensation is very considerable we speak of a large pulse, when it is slight of a small pulse. One naturally explains this sensation by supposing that the artery expands as the result of increased tension. Many writers, however, among whom

Digitized by Microsoft®

Sir William Broadbent is prominent, minimize the effect of arterial expansion or deny its occurrence. According to them the finger pressing upon the wrist pushes in or flattens the artery between the beats, but feels a tendency of the vessel to resume its cylindrical shape under the increased tension of the pulse wave. This latter view seems very reasonable, but some slight expansion must certainly take place.

www.libtool.com.cn

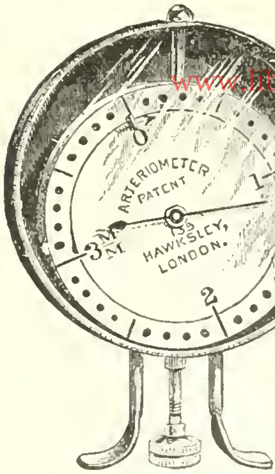

FIG. 3901.—Oliver's Arteriometer.

A large pulse means that a large quantity of blood is being forced into the arterial system at each heart beat and points to a powerfully acting ventricle and unobstructed vessels.

A small pulse may be present in a variety of conditions. It may be from the presence of some disease of the valves of the heart putting the ventricle at a disadvantage. It may be from some obstruction between the ventricle and the wrist, such as aortic stenosis, aneurism, or tumor. Or the artery being examined may be abnormally small on account of some other artery like the ulnar being larger than usual. The most obvious cause of all is a heart beating feebly.

If we get a small pulse in a contracted artery we call it a wiry pulse, if the arterial tension is still considerable; if the tension is low and the pulse very small, we speak of a thready pulse, which is seen in cases of severe shock or where a patient is in extremis. A small pulse in a relaxed vessel is sometimes spoken of as a trembling or a running pulse.

Quickness of the Pulse.—Pulsus celer or tardus, quick or slow pulse. These terms are properly applied not to the rate of the pulse, but to the suddenness with which the expansion of the vessel takes place. In the quick pulse the sensation imparted to the finger is that of a sudden tap. In the slow pulse there is a sensation of more gradual lifting or heaving, and the feeling of pressure lasts for an appreciable time. A quick pulse is seen when the ventricle empties itself easily. It is usually present when the blood pressure is low, but not in aortic stenosis, for then there is obstruction to the work of the ventricle. The most characteristic form of quick pulse is the Corrigan's or water-hammer pulse of aortic regurgitation. The character of a slow pulse differs according to the position where the obstruction to the outflow of blood from the ventricle may be. If the obstruction is at the aortic valves the pulse is slow and of low tension, as in aortic stenosis. If the obstruction be in contracted peripheral vessels, then the pulse is slow and of high tension, as in chronic nephritis.

A dicrotic pulse is one where the dicrotic wave can be felt as well as the primary wave It is characteristic of relaxed vessels with a fairly strong heart action. It is most common in fever where the arterial tension is usually rather low. When the blood pressure falls very low, as in a failing heart, the dicrotic wave tends to disappear. It will be more fully discussed in connection with pulse tracings.

Symmetry of the Pulse.—An examination of the pulse is not complete without comparing the corresponding arteries on the two sides of the body. When there is a difference on the two sides, it is necessary to trace up the course of the vessel on the side where the pulse is weakest. Somewhere in its course from the heart to the wrist one may find a tumor or aneurism or deformity causing pressure and partial obstruction. Dr. Allison, of Edinburgh, made the claim in a clinical lecture some seventy years ago that he had observed in a severe case of fever that the pulse had a fuller character on the side on which the patient was lying. He ascribed this to the influence of gravity acting on weakened relaxed vessels much as it would do after death. I do not think there is anything in Oliver's recent experiments to render this unlikely.

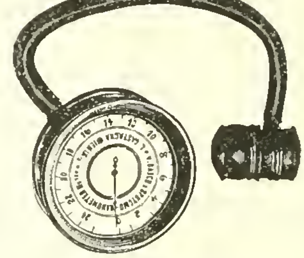

FIG. 3902.—Von Basch's Sphygmomanometer.

Field of Response.—This is a term suggested by Mackenzie for the ability of the heart to rise to occasions. We may also speak figuratively of the heart's "bank account." This may be investigated by noting the effect upon the pulse of various degrees of exertion. Sometimes a pulse which seems good when the patient is resting changes its rate and character to such an extent on slight exertion as to indicate serious weakness. The breathing should be noted and may furnish confirmation of the opinion formed from the pulse. This is a method of considerable value in estimating the seriousness of an irregular pulse. The less dangerous forms of irregularity tend to disappear on slight exertion, whereas cases due to a failing heart may be expected to show increase of irregularity and breathlessness.

INSTRUMENTAL AIDS in the examination of the pulse. *The calibre of the vessel* may be approximately measured by *Oliver's arteriometer* of which an illustration is given in Fig. 3901. The principle is that a pointer on the graduated dial marks the distance which the central foot has to be pushed down from the time it begins to press on the artery till it quite obliterates it. The readings of this instrument may not be absolutely reliable, but it is sufficiently accurate for comparing the size of the same artery under different circumstances. In this way it has been used by the in-

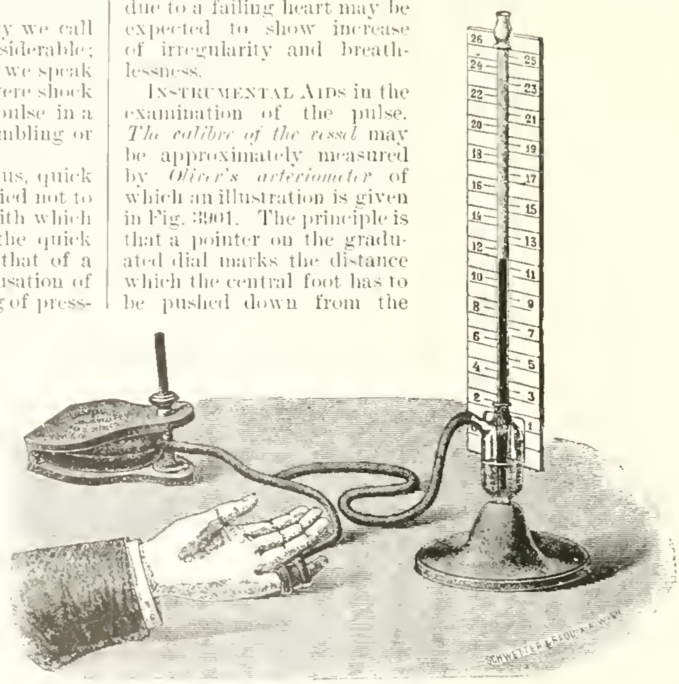

FIG. 3903.—Gaertner's Tonometer.

Digitized by Microsoft®

ventor for working out the effect of various influences on the vaso-motor tone and the distribution of the blood in the body.

Arterial Pressure.—A number of instruments are on the market for measuring the arterial pressure in man and several different principles are represented. The best known instrument for this purpose is perhaps the *sphygmomanometer of von Basch.* This is shown in Fig. 3902. It consists of a capsule which is pressed upon the radial artery until the pulse is obliterated below, and a dial and pointer which indicate how much pressure has been exerted. It is only moderately accurate. Leonard Hill claims that errors as great as from 30–70 mm. of mercury are made with it. Much would doubtless depend upon the man using it. *The tonometer of Gaertner* (Fig. 3903) seems to be a very good instrument. Dr. Orr, of Montreal, reported at a recent meeting of the Canadian Medical Association an exhaustive study of the pressure in different diseases in which this instrument was used. The most striking results were the high pressures obtained in many cases of nephritis, and the fact that in cases of valvular disease of the heart the pressure average was not very different from that found with sound hearts. With this instrument we measure the amount of pressure which must be exerted around a finger to prevent the blood flowing through its vessels. The instrument as shown is well adapted for the office, and a more portable modification may be obtained for carrying about.

www.libtool.com.cn

Other instruments for measuring blood pressure depend upon the principle that the excursion of the pulse is greatest when the pressures inside and outside the artery are equal. The *sphygmometers of Hill and Barnard*, the *sphygmomanometer of Riva Rocci*, and the modification of it used in the Johns Hopkins Hospital, and the *hæmodynamometer of Oliver* are all of this type. Of all these the simplest is one of the two forms invented by Hill and Barnard (Fig. 3904). It consists of a vertical glass tube five inches in length which expands above into a small bulb and is closed at the top by a glass top. A small india-rubber bag partly protected by a metal cup is fixed to the tube below. The bag is filled with colored fluid, and on pressing it down upon an artery the fluid rises in the tube and compresses the air in the bulb. The more one presses the more the fluid rises; at a certain height the meniscus of the fluid exhibits more pulsation than at any other height. At this point the top of the meniscus indicates the arterial pressure. This instrument has been described at length because it is cheap, simple, and fairly accurate if carefully used.

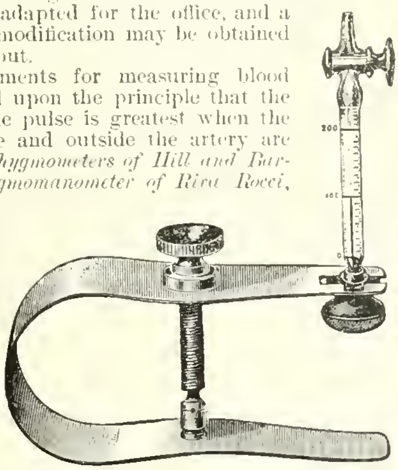

FIG. 3904.—Sphygmometer of Hill and Barnard.

The pulse waves may be made to record themselves automatically by one of the various forms of *sphygmographs.* These instruments, as already said, are contrivances by which movements of a blood-vessel are transmitted to a lever, which records them on smoked paper. For the various forms of instrument and the method of using them the reader is referred to the article on *Sphygmography.* The product is a tracing, of which a normal example has already been given in Fig. 3897.

Criticism and Appreciation of the Sphygmograph.—It was thought for a time that the sphygmograph would indicate, so that he who ran might read, the pressure, size, and quickness of the pulse, as well as the peculiarities incident to various diseases; these hopes have proved vain, and we now know that the sphygmograph is inferior to the finger in most of these points. One great difficulty in the interpretation of the sphygmogram is that a great variety of tracings may be obtained from the same pulse by simply varying the pressure of the

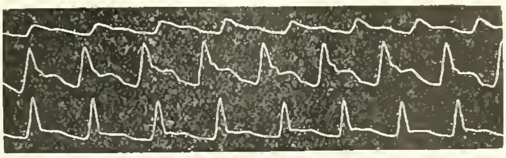

FIG. 3905.—Pulse Tracings which show Effect of Varying Pressure.

instrument or by employing different makes. Fig. 3905 shows three pulse tracings taken within a few seconds of each other from the radial artery of the writer. The differences are due to the pad being pressed down upon the artery with varying force. Fig. 3906 shows tracings taken, the upper from the carotid, and the lower from the radial of the same subject, within a few minutes of one another. In this case the carotid was recorded by air transmission and the radial by transmission through a spring. Features are sometimes found in pulse tracings which do not represent anything in the pulse at all, but are dependent on inertia or rebound of the instrument.

In spite of all these pitfalls that beset us, however, it is possible to take sphygmograms that will afford us much information about the pulse and the conditions which determine its character. In tracings we can see the principal events of the pulse in their proper time relations. They show us what to feel for, and corroborate or controvert the opinions we have formed of the pulse from our tactile examination. The sphygmograph is very useful as a guide to those who are learning to feel the pulse and in whose finger tips the tactile sense is not fully educated. There are points about the pulse, too, that even the most highly trained "thumb and finger fail to plumb" which are shown with ease by this instrument. The dicrotic wave and the predicrotic wave usually belong to this category. In irregular pulses we often have premature systoles or other weak heart beats causing pulse waves too weak to be felt by the finger, but not too weak to be shown by the instrument. Then tracings enable us to compare the time relations of the waves in different arteries or to compare the time of the arterial pulse with the heart beat or with the venous pulse. Such tracings are of value in working out the rate of propagation of the pulse and the direction in which the waves travel. The venous pulse very often can only be safely interpreted in the light of such simultaneous tracings.

It is doubtful whether sphygmography will ever be a routine method in general practice, but for the specialist, the teacher, and the investigator it is very valuable, and, when the elements are mastered, becomes an interesting and instructive practice.

Normal Pulse Tracings—High and Low Pressure.—The four tracings shown in Fig. 3907 are all taken from people in good health without any circulatory or general disease.

As far as tracings can do so, the first of these four sphygmograms indicates rather high blood pressure and

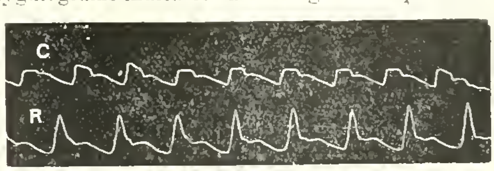

FIG. 3906.—Pulse Tracings Taken from the Carotid (*C*) and the Radial (*R*).

the last one low pressure, while the two between represent intermediate conditions. One is safer in trusting the finger for indications of the arterial pressure than in

Digitized by Microsoft®

trying to read it from a tracing, but attention to the following points usually enables one to form a fairly correct opinion from a tracing. In the first place the tracing must be taken by a person of experience. A poorly

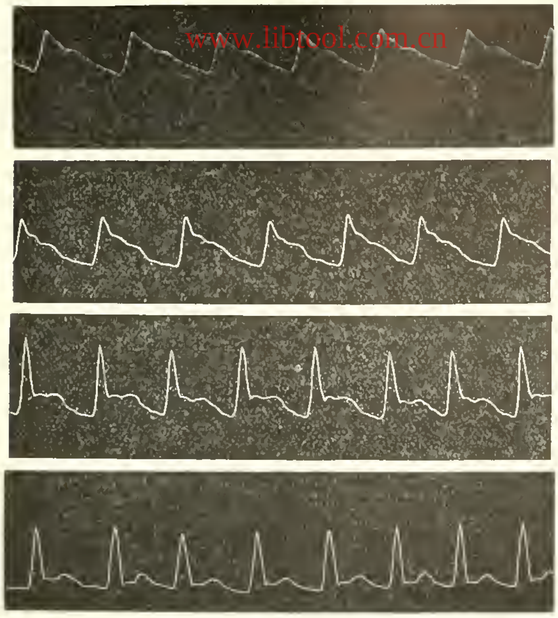

FIG. 3907.—Normal Pulse Tracings, Indicating Different Arterial Pressures.

taken tracing is very misleading. Where the blood pressure is high the rise and fall of the waves are more gradual, in low blood pressure quick or steep. In high blood pressure the dicrotic wave is small and high up on the descent. As the blood pressure becomes lower this wave becomes more distinct and approaches nearer to the base line, and may appear as a wave rivalling the primary wave in size and separated from it by a distinct interval. If the blood pressure becomes very low indeed, as in cardiac failure, then the dicrotic wave becomes smaller again and may quite disappear. A well-marked dicrotic wave is a sign of relaxed peripheral vessels and not of a weakly beating heart. It is seen best developed at the beginning of fevers when the skin is hot and the blood distributed to the surface, but the heart still beating strongly.

The predicrotic wave is most pronounced in cases in which there is most resistance to the outflow from the ventricle, and therefore usually indicates high blood pressure. It is also seen, however, in aortic stenosis (see Fig. 3899). A practical rule for judging of the predicrotic wave is given by Gibson: "Draw a line from the top of the primary wave to the lowest point of the dicrotic notch." If the predicrotic wave fails to reach this line the pulse is of low or medium pressure. If the predicrotic wave rises higher and crosses this line the pulse is of high pressure (better, the resistance to outflow of blood from the ventricle is great). Another peculiarity often

FIG. 3908.—High-Tension Pulse. (Hutchison and Rainey.)

seen in high-pressure pulse tracings is the presence of several oscillation waves on the descent such as those seen in parts of Fig. 3908.

When interpreting tracings it is well to bear in mind that the part from the beginning of the primary wave to the bottom of the dicrotic notch corresponds to the time when the blood is being driven out of the ventricle into the arterial system. This almost corresponds with the ventricular systole, and may conveniently be called *the systolic portion* of the tracing. From the bottom of the dicrotic notch to the beginning of the next primary wave the aortic valves are closed and no blood is leaving the ventricle. This may be called the *diastolic portion* of the tracing.

Any peculiarities in the systolic portion may usually be traced to the ventricle; but the diastolic portion cannot depend directly upon the ventricle, as during this time the aortic valves shut off the arteries from the heart. Variation in the rate of the pulse is brought about principally by shortening or lengthening of the diastolic por-

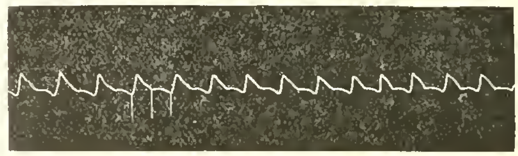

FIG. 3909.—Frequent Pulse.

tion. Thus in an infrequent pulse like that in Fig. 3908 the diastolic portion which I have marked *D* is about twice as long as the systolic portion *S*, whereas in Fig. 3909 where the pulse was 130 as the result of a fever, the two portions are of about equal duration.

In some cases the shortening of the diastolic portion takes place to such an extent that the next percussion wave commences before the dicrotic wave is complete and cuts into the descending limb of the latter. The result is a tracing like that shown in Fig. 3910. *S* is the percussion and *D* the dicrotic wave. It will be noticed that the dicrotic notch *N* is the lowest part of the tracing. Such a tracing is called *hyperdicrotic* or *superdicrotic*.

THE PULSE IN VARIOUS PATHOLOGICAL CONDITIONS.—*Affections of the Aortic Valve.*—The pulse of aortic regurgitation is one of the most typical, and is known as *Corrigan's pulse*, from Sir Dominic Corrigan, who was one of the first to describe it, or as the *water-hammer pulse* from a toy of that name that gives a sudden shock to the

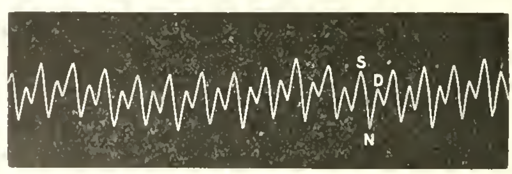

FIG. 3910.—Hyperdicrotic Pulse. (Mackenzie.)

fingers. Corrigan's pulse may be described as large and quick, usually infrequent and regular. It is sometimes described as collapsing because the vessel seems to become empty between the pulse beats. The impression given to the finger is that of a momentary tap.

The peculiarities of Corrigan's pulse are best made out by raising the patient's arm high above his head while feeling his radial.

The statement made by Henderson, Balfour, and others that the rate of propagation is slower in aortic regurgitation than where the heart and vessels are normal has been shown by François Frank, Keyt, and Mackenzie to be without foundation. A prominent feature of aortic regurgitation is the violent throbbing of the vessels of the neck. A capillary pulse may also usually be seen. In some cases the pulse wave passes right through the capillaries into the veins and may be observed in the veins of the back of the hand, and, sometimes, a tracing may be obtained of this rare form of venous pulse. Such a tracing is figured in Gibson's book on the heart.

Digitized by Microsoft®

Tracings from the radial in aortic regurgitation are characterized by a steep rise and fall of the percussion wave and by the fact that the predicrotic wave is usually more pronounced than the dicrotic. The tracing shown

www.libtool.com.cn

FIG. 3911.—Aortic Regurgitation.

in Fig. 3911 is from a case of moderate severity and illustrates these points. In a more pronounced case the dicrotic wave would be still less marked or even absent altogether, and the percussion wave might be even steeper in its rise and fall. The presence of a fairly pronounced dicrotic wave does not, be it noted, exclude a moderate degree of aortic regurgitation.

The pulse of *aortic stenosis* is not so characteristic as that of regurgitation. It usually feels slow and sustained to the examining finger, is of normal or diminished frequency, and, like that of aortic regurgitation, regular in rhythm and volume. The tracing is usually anacrotic (see Fig. 3899). The predicrotic wave rises higher than the primary, indicating the difficulty the ventricle has in emptying itself. The details vary in different cases. Sometimes the primary and predicrotic waves form two well-marked crests separated by a distinct depression, forming the so-called *pulsus bisferiens.* In other cases instead of the tracing being anacrotic we may simply have a primary wave with a gradual rise and a rounded crest, followed by a poorly marked dicrotic wave.

In *mitral regurgitation* and *mitral stenosis* the pulse may be quite indistinguishable from the normal. As one or other of these diseases progresses, however, dilatation of the ventricle, and especially of the auricle, takes place; then the pulse tends to become weak, rapid, and markedly irregular in both rhythm and volume, constituting the so-called "*mitral pulse.*" This pulse varies so much in its details in different cases that it is useless to figure any one form as typical.

Affections of the Heart Muscle.—There is nothing uniform or typical about the pulse in these conditions. It may be abnormally slow or fast or irregular. The cardiac field of response is diminished. Any departure of the pulse from the normal rate or rhythm should lead one among other things to consider the probability of the heart muscle being diseased, but other considerations besides the pulse will have to be depended on for the solution of the question.

The presence of the pulsus paradoxus in certain cases of *adhesive pericarditis* has already been referred to.

In *aneurism* of the transverse part of the aorta the left radial pulse is often smaller and slower than the right. It sometimes feels delayed too, but this is questioned by some writers. The exact character of the radial pulse varies greatly in cases of aneurism according to the situation of the disease, the degree of degeneration of the vessels generally, and the condition of the aortic valves. Fig. 3912 shows simultaneous tracings from the aneurism and the right radial in a case in which a large pulsating aneurism extended from the chest up the right side of the neck. The exaggeration of the predicrotic wave seen in this tracing seems to be very common in aneurism, as it is in both forms of aortic valvular disease.

In fever we have to distinguish between the effect of the pyrexia as such upon the pulse and the effect of the disease causing the pyrexia. Moderate pyrexia tends to modify the pulse through both the heart and the peripheral resistance. The heart is made to beat more rapidly, partly by a direct action of the increased temperature on the heart tissue itself, and partly indirectly through the cardiac centres in the medulla. The superficial arteries are dilated and an increased amount of blood is carried to the skin. The effect of these changes is to cause a pulse of increased frequency and diminished pressure with exaggeration of the dicrotic wave. To the finger such a pulse feels frequent, large, and soft. It is often referred to as bounding. A tracing would more or less approach the type shown in Fig. 3913.

If the pyrexia runs high or lasts long the heart suffers and becomes feeble and often irregular. In such cases the pulse is very frequent and is small, soft, and compressible. Tracings taken at intervals, when the heart is failing, show gradual disappearance of the dicrotic wave, the absence of which in a case of fever is usually a very bad sign. Irregularity of the pulse in the early stages of a fever or increase of rate in an adult beyond 140 per minute are symptoms which usually indicate great danger. During convalescence slight irregularity is common and of little significance. The character of the pulse in fever may be much modified by other influences, such as specific poisons or mechanical interference.

SUMMARY OF THE DIAGNOSTIC VALUE OF THE PULSE.—The pulse furnishes the best single indication of the state of efficiency of the circulation. In it we find indications both of the condition of the vessel walls and of the strength of the heart beat.

Very important information may be obtained by observing the changes in the pulse during bodily activity.

The discovery of high tension may direct our attention to the presence of nephritis or lithæmia.

In aortic valvular disease a quick collapsing pulse or a

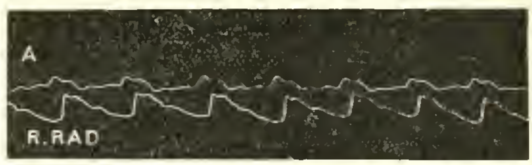

FIG. 3912.—Simultaneous Tracings from a Thoracic Aneurism and from the Right Radial Artery.

slow, small pulse will indicate the predominance of regurgitation or stenosis.

In mitral valvular disease a rapid irregular pulse is suggestive of loss of compensation and dilated or paralyzed auricles.

In pericarditis with effusion, where the heart sounds are faint, the pulse is of especial value in indicating the degree of cardiac failure.

In fever the rate, the tension, and the presence or absence of irregularity are of great prognostic value. A sudden change in the pulse may be the first indication of a crisis or a fresh complication. In many diseases the pulse is of value in furnishing indications for treatment (stimulants) and in exhibiting the effect of the remedies used.

In the search for all these indications the finger is the best means to employ. In special cases some of the more elaborate instruments may furnish additional or confirmatory information.

THE VENOUS PULSE.—*Introductory.*—The term venous pulse is applied to changes in size and tension occurring in the veins as the result of the action of the heart. The

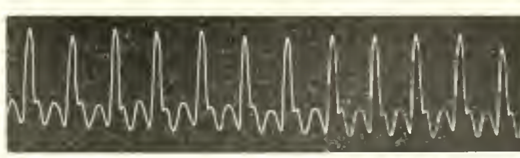

FIG. 3913.—Pulse in Sthenic Fever. (Mackenzie.)

distention and collapse of the veins caused by the alternate phases of respiration are not included. A true venous pulse in a healthy animal seems to have been first described by Wedemeyer of Hamburg, in 1828. He made his observations on a horse. Since that time numerous physiologists have seen and recorded the venous

Digitized by Microsoft®

pulse in healthy dogs, cats, rabbits, and other animals. It has been noted in the veins of the thorax, neck, abdomen, and limbs. Mosso obtained the first venous pulse tracing from a human subject in 1879. Since then those who have looked for it in man have found it to be very common. In the writer's experience it may be seen and recorded in the majority of people by those who make the examination under suitable conditions. It is most frequently seen in the jugular veins, external and internal. In the case of the external jugular one can usually see the blue vein through the skin; in the case of the internal jugular one can see the movements imparted to the skin over it. Sometimes one vein can be seen best, sometimes the other. For the observation of the venous pulse two conditions are usually necessary, viz., that the veins be reasonably distended with blood, and that the neck be not too fat. Probably in the majority of people the recumbent position is necessary for it to be recognizable. For the method of taking tracings of the venous pulse see *Sphygmography*.

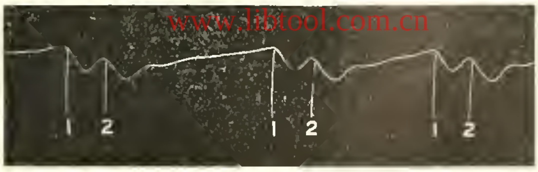

FIG. 3914.—Negative Venous Pulse (dog).

VARIOUS FORMS OF VENOUS PULSE. — The venous pulse is seen in many different forms. This renders its study more difficult than that of the arterial and has discouraged many from undertaking it. Its modifications, however, may be traced with considerable confidence to their respective causes, and are replete with indications of the condition of the heart for those who will take the trouble to familiarize themselves with them. James Mackenzie, who has written more exhaustively on the venous pulse than any other English writer, claims that it "gives us far more information of what is actually going on within the chambers of the heart" than the arterial pulse.

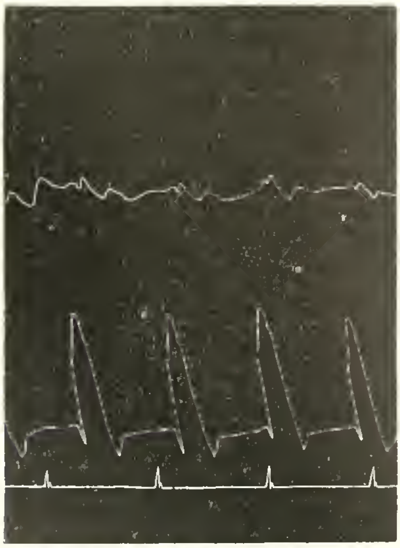

FIG. 3915.—Curves of Auricular (above) and Ventricular Pressures, from a Dog. Time in seconds.

The principal forms met with may be designated according to their place of origin as:

1. Auricular, negative, or normal.
2. Ventricular, positive, or pathological.
3. Arterial.
4. The modified negative of auricular paralysis.

The auricular or *negative* venous pulse follows very closely the curve of pressure in the right auricle. It is obtained in its most complete form when the pulse is not too frequent. Fig. 3914 is taken from the internal jugular of a dog under the influence of morphine with a pulse rate of 45 per minute.

It will be observed that the down strokes in the tracing which denote the collapse of the vein (negative pulse) are far steeper than the rises which indicate refilling. The fall beginning at 1 is called the *systolic collapse*, and is due to the diastole of the auricle drawing in blood from the veins during the ventricular systole. The fall beginning at 2 is the *diastolic collapse* due to the diastole of the ventricle. The ascending portions of the tracing, which indicate filling of the veins, are caused principally by the blood flowing in from the capillaries faster than the heart can receive it. Just before the systolic collapse (1), however, we may in some cases observe two small elevations, the *presystolic* and the *systolic rise*. These may be traced back to their origin in the systole of the auricle and of the ventricle. We speak of the long ascent leading up to these waves as the *diastolic rise*. The irregularities at the beginning and in the middle of this diastolic rise are unexplained. The interpretation given above of the systolic rise as due to an impact propagated backward through the auricle and veins by the ventricular systole is disputed by some writers (Mackenzie), who ascribe it entirely to a shock imparted to the vein by the pulse in the carotid. This view is doubtless partly true, as there is often a wave in the venous pulse due to the carotid impact; but it is equally true that there is quite frequently a wave at the top of the diastolic rise that can be found both in the venous pulse and in the curve of auricular pressure, and that may be shown to be synchronous with the ventricular systole. In Fig. 3915 simultaneous tracings are shown of the pressures in the right auricle and ventricle of a dog taken with Hürthle's catheter. Corresponding points of time are marked by the vertical lines. It will be noted that there is a very distinct wave in the auricle synchronous with the ventricular systole. This is no doubt due to the rise of pressure in the ventricle pushing the tricuspid valves back and thus imparting a shock to the auricle.

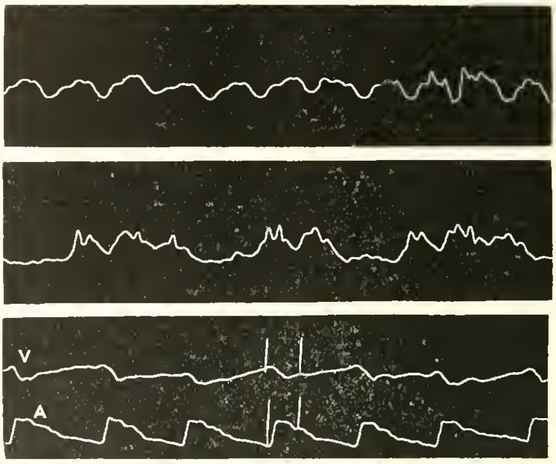

FIG. 3916.—Three Types of Negative or Auricular Venous Pulse (human).

For the rise in the tracing (Fig. 3914), leading up to 2 there is, so far as I know, no satisfactory name. Some writers call it the first diastolic rise, but it is systolic in time. Others call it the ventricular rise, but it is not caused by the ventricle but by the blood flowing in from the periphery. A rational term to apply to it would be the *prediastolic rise*, for it leads up to and is interrupted by the ventricular diastole.

When the pulse is frequent the waves are crowded together, and some of those described are not seen at all or cannot be identified. Take, for instance, Fig. 3916 where three examples are given of venous pulse tracings from human subjects. It is very difficult to distinguish the different waves described above in these three tracings. In the last of the three a method is shown by which the difficulty may be partially solved. In this, simultaneous

Digitized by Microsoft®

records are taken from the external jugular vein (above) and the radial artery (below). Corresponding points of time are marked on the two tracings, and by these it can be seen that synchronous with the rise of the radial pulse tracing there is a fall in the venous, the systolic collapse.

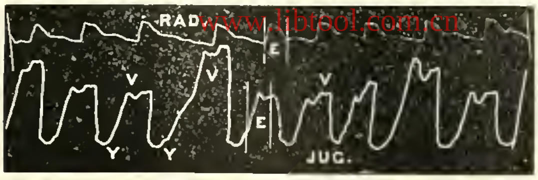

FIG. 3917.—Ventricular Venous Pulse (below); Radial Pulse (above). (Mackenzie.)

This systolic collapse alone is sufficient to prove the venous pulse to be of the auricular or negative variety. Using the radial pulse as a guide, it is possible to find traces of the other waves described as typical, although they are not very distinct. Be it noted here that the systolic and diastolic portions of the jugular pulse correspond very closely in time with the systolic and diastolic portions of the radial pulse, because, as has been pointed out by the writer, the greater distance of the radial from the heart is compensated for by the fact that the rate of propagation of the venous pulse is only about one-third that of the arterial.

As a rule, the auricular venous pulse can be readily recognized without taking a tracing. It is characterized by a sudden collapse of the veins of the neck followed by a more gradual filling. Where the pulse is infrequent the collapse is double, corresponding to the systolic and diastolic collapse seen in a tracing (Fig. 3914). The proper organ for the examination of the venous pulse is the eye, and it is best seen with the patient reclining with the head on a level with the body (no pillow). The finger is of little use as the changes in tension are too slight to be appreciated by it. It is a good plan to have the finger on the radial as a guide to the time relations. In cases of doubt, as when the pulse is frequent, simultaneous tracings must be taken of the jugular pulse, and either the apex beat, or the carotid, or the radial.

The presence of the auricular venous pulse has little significance. I have seen it at all ages from infancy to old age, and have recognized and recorded it in healthy and athletic young men as well as in a variety of diseased conditions. It is practically never absent from healthy dogs, and I believe that when it cannot be observed in a human subject, who is in a proper position for observation, it is because the tissues of the neck are too thick for it to show through rather than because it is not there. It is more marked than usual when the tissues of the neck are specially thin or when the veins of the neck are distended. For it to be seen at its best the heart must still be beating with fair vigor. Among the conditions in which the auricular venous pulse is pronounced are nearly all forms of emaciation and general debility, diseases in which the entrance of blood into the chest is interfered with, such as rickets and chronic coughs, conditions in which there is slight dilatation of the heart as at the end of long continued fevers or in the various forms of anæmia.

The ventricular or positive venous pulse is seen where the high pressure existing in the ventricle during systole is transmitted to the veins so as to prevent the usual systolic collapse. In a typical ventricular venous pulse the only collapse we have in the veins is the diastolic collapse caused by the blood being sucked in by the diastole of the ventricle. In these cases the veins of the neck can usually be seen to be distended, and the pulse can be seen in them even with the patient standing or sitting up. Moreover, the filling or distention of the veins is seen to take place, or, at least, to be completed suddenly, and the finger can detect a positive impact corresponding in time with the carotid pulse. Simultaneous tracings from the jugular vein and the radial artery show absence of the usual systolic collapse. Instead, we see a continued rise or a sustained elevation of the tracing during the ventricular systole, succeeded by a sudden diastolic fall. These points may be very well seen in Fig. 3917. In this figure simultaneous points of time in the radial and jugular pulses are marked by vertical lines including between them the systolic period *E*. It will be noted that the venous pulse consists of a single large wave with a divided crest, and that the only pronounced collapse is after the systole is over. A somewhat less typical case observed by the writer is shown in Fig. 3918. This was taken from a case of tricuspid regurgitation in which compensation had been partly restored by digitalis.

The ventricular venous pulse is found in three conditions. By far the most usual cause of it is *tricuspid regurgitation*, but it cannot quite be called pathognomonic of this lesion, as there are two other rare conditions in which it is found. One of these is mitral regurgitation with patent foramen ovale, of which a case was recently reported in "The Johns Hopkins' Hospital Bulletin" by W. S. MacCallum. The other is adhesive pericarditis, in which the contraction of the ventricle draws in the thoracic wall and causes compression of the thoracic viscera; sufficient pressure is thus exerted on the great veins to initiate a positive wave which is propagated into the veins of the neck.

The ventricular pulse may in some cases be confounded with the pulse of auricular paralysis which will be described shortly.

The arterial venous pulse includes four different forms of pulsation in the veins, of which none call for more than a mention.

1. A pulse may be transmitted from the arteries through the capillaries in aortic regurgitation or where there is great dilatation of the peripheral vessels.

2. Cases are on record in which there has been an anastomosis between a peripheral artery and vein with consequent transmission of a pulse.

3. Pulsations which are arterial in origin are sometimes seen in the veins of closed cavities like the eyeball.

4. Veins may have a pulsation transmitted to them from arteries as a result of mere juxtaposition. This last fact must be remembered in interpreting the tracings obtained from the veins of the neck, especially the internal jugular, as frequently one of the waves seen is due to the impact of the carotid upon the vein. Such waves are best identified by comparing the tracing with a simultaneous one from an artery.

The Venous Pulse of Auricular Paralysis.—When the auricle is paralyzed the presystolic (auricular) wave is absent and so is the systolic collapse (auricular diastole). The tracings obtained are very similar in form to those of tricuspid regurgitation, as the tracing continues to rise until the ventricular systole is complete, and then a fall due to the ventricular diastole occurs. The venous pulse of auricular paralysis with competent tricuspid valves can be distinguished from the systolic pulse of tricuspid regurgitation better by the finger than from a tracing. In a tracing, it is true, the rise is more uniform and gradual in auricular paralysis than in the ventricular pulse where a systolic elevation may be made out; but in some

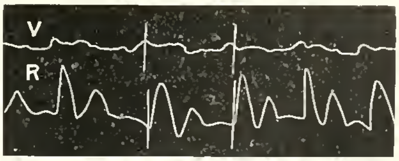

FIG. 3918.—Venous Pulse from External Jugular (above); Arterial Pulse from Radial (below).

cases it is difficult to decide from a tracing which we have to deal with. The finger, on the contrary, can recognize a distinct positive impact in the veins in the case of a ventricular venous pulse, whereas in the pulse of auricular paralysis no such positive impact is felt. Fig. 3919

Digitized by Microsoft®

shows a tracing such as we sometimes meet with. This is from an old woman with a dilated and irregular heart, but no murmurs. The venous tracing shows, as a rule,

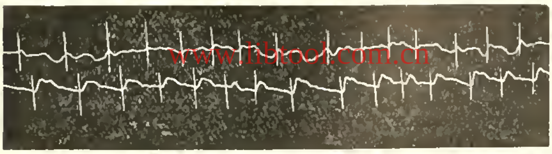

FIG. 3919.—Jugular Pulse (above), Radial (below). Corresponding points are marked.

the most pronounced collapse during diastole and resembles somewhat the ventricular pulse shown in Fig. 3918. There was no positive beat in the veins of the neck, however, and there were no heart murmurs, so I ascribed the condition to dilatation and threatening paralysis of the auricles without any serious amount of regurgitation. In this tracing a presystolic rise and systolic collapse are occasionally seen, so that the paralysis of the auricles was not absolute.

THE VENOUS PULSE IN IRREGULAR HEART ACTION.—A number of observers have recently been making use of the venous pulse as a means of deciding the primary seat of irregularity in the rhythm of the heart. One example will have to suffice. Fig. 3920 is a tracing taken from one of the cases referred to, in discussing the arterial pulse, of a father and son, both in good health and both with irregular pulses. This tracing is taken from the son. The venous pulse is small, as is usually the case

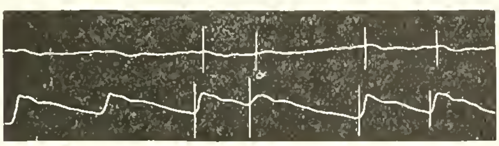

FIG. 3920.—Jugular Pulse (above); Radial (below). Corresponding points are marked.

in a healthy adult, but suffices for the purpose. An irregularity may be seen in both the arterial and the venous pulse of the nature of a premature beat. In the ordinary beats preceding and following the premature one, a faint wave may be detected in the venous pulse synchronous with the primary wave in the radial. This is the systolic wave. Just preceding the systolic wave a fainter one which is presystolic and due to the auricular systole may be seen. In the venous beat corresponding to the premature wave in the radial a systolic wave may also be seen, but the auricular wave follows it instead of preceding it, showing that the auricle in this case contracts after the ventricle, and therefore the anomalous stimulus causing the premature beat must have acted on the ventricle. If measurements be made it will be found that the pulse intervals on either side of the premature beat are together equal to the preceding and succeeding ones, or to two average pulses. This, according to Hering, Cushny, and

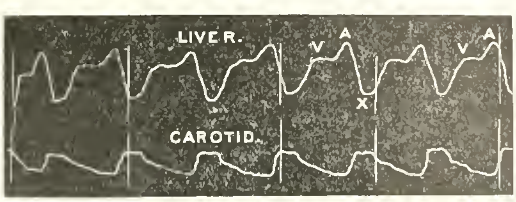

FIG. 3921.—Auricular Liver Pulse.

others, points to the auricle not being implicated in the irregularity. When the auricle is the primary seat of the disturbed rhythm, such a correspondence is not usually found. This rule is said by Gerhardt, however, to be not without exceptions. The full importance of thus differentiating the seat of the irregularity is not fully worked out, but on the whole those cases in which the irregularity is confined to the ventricle are less serious than those in which the auricle is also irregular in its rhythm.

THE LIVER PULSE.—A pulsation can be felt and recorded in the liver in certain cases in which the right side of the heart and the veins are much distended. In some cases the tracing has the form corresponding to the auricular venous pulse. In these cases, according to Mackenzie, there are usually tricuspid stenosis and auricular hypertrophy, as the normally weak auricular waves have not force enough to make themselves felt in the liver.

In other cases the liver pulse has the characters of the ventricular venous pulse, and then we may be reasonably

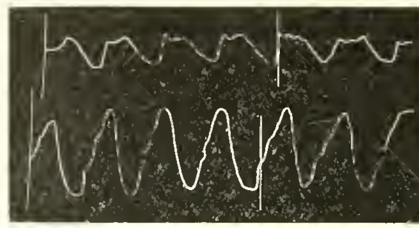

FIG. 3922.—Ventricular Liver Pulse. (Carotid above; liver below.)

certain of the existence of tricuspid regurgitation. Tracings of these two forms of liver pulse taken from Mackenzie's book are shown in Fig. 3921 and Fig. 3922.

CAPILLARY PULSE.—This consists in alternate reddening and paling of an area of the skin with each heart beat. It is most frequently looked for in the bed of the finger nails, and may be brought out most distinctly by raising the arm. Quincke, who first described the capillary pulse, recommends rubbing gently a spot upon the forehead and looking for it there. The capillary pulse may be taken as an indication of aortic regurgitation with a strongly acting ventricle (hypertrophied).

William S. Morrow.

PUMPKIN SEEDS.—*Pepo,* U. S. P. *Semen Peponis.* The dried ripe seed of *Cucurbita pepo* L. (fam. *Cucurbitaceæ*).

The nativity of the pumpkin is not certainly known, though it was probably North American. It presents numerous varieties, and the squashes, at least some of them, have been regarded by some botanists as pertaining to the same species. Although squash seeds appear to possess similar properties, they are not included, as a drug, under the above title.

Pumpkin seeds are about 2 cm. (⅘ in.) long, broadly ovate, flat, white, or whitish, nearly smooth, having a shallow groove near to and parallel with the edge; containing a short conical radicle and two flat cotyledons; inodorous; taste, bland and oily.

The active constituent is supposed to be a small amount of a soft, green, acrid, and bitter resin, which possesses the same properties as the entire drug. With this there

Digitized by Microsoft®

exists a yellow or somewhat reddish-yellow, bland fixed oil, to the extent of about thirty-five per cent., a little sugar, crystallizable albumin, and other unimportant constituents. The oil, which consists of glycerides of palmitic, myristic, and oleic acid, portions of which acids also exist in a free state, has been credited with the properties of the drug, but possibly, if pure, does not possess them.

Pumpkin seeds are markedly diuretic, but their medicinal use is as a pleasant and moderately certain tænicide. Only the kernel should be used, and it is commonly given in the form of an electuary or emulsion, the dose amounting to from 25 to 50 gm. (℥⅞ to ℥iss.). Fifteen grains of the resin is an equally efficient dose, though not so pleasant.

Throughout the West Indies, Mexico, Central America, and many other countries, pumpkin seeds, as well as squash seeds, are largely consumed as food.

Henry H. Rusby.

PURGATIN.—Purgatol, anthrapurpurin diacetyl ester, is an odorless, tasteless, yellowish-brown powder recommended by von Hösslin as an agreeable laxative. It acts slowly, requiring thirteen to twenty-four hours, and produces a copious, non-liquid stool. The urine is colored red. Dose, 0.5–2 gm. (gr. viij.–xxx.).

W. A. Bastedo.

PURGATIVES, OR CATHARTICS, are medicines which are used to produce alvine evacuations. According to their activity and power, they are divided into laxatives and mild and drastic purgatives.

Purgatives which act very gently, producing soft, feculent stools without notable irritation, are called *laxatives*. This term is also applied to more powerful purgatives when they are given in small doses, so as to act mildly. (See *Laxatives* in Vol. V.)

Purgatives which operate briskly, usually producing more or less fluid evacuations, sometimes with griping and tenesmus, but without serious irritation, are called *mild* or *simple purgatives*. To this group belong some of the salts of magnesium, sodium, and potassium, which, from their resemblance in chemical and physical properties, and in physiological action, are termed *saline* purgatives.

The term *drastic* is applied to those purgatives which operate energetically, producing numerous evacuations, and, in excessive doses, more or less gastro-intestinal irritation.

Purgatives which produce watery stools, especially the salines and some of the drastics, are called *hydragogues*, and those which cause the evacuation of large quantities of bile, *cholagogues*.

Mode of Action.—All purgatives accelerate the peristaltic movements of the intestines. Radziejewsky carefully observed the rapidity of peristalsis in dogs, both before and after the administration of purgatives. In the normal state the movements of the small intestine were rapid, those of the large intestine very slow. After the administration of purgatives, the movements of both became much accelerated, but most markedly those of the large intestine.

It was assumed that purgatives, especially the hydragogues, also induce a discharge of fluid from the intestinal mucous membrane. Experiments on animals at first seemed to show that this was an error. Thiry completely separated a portion of the small intestine from the rest of the bowel, without dividing its vessels and nerves, sewed up one end, which was returned into the abdominal cavity, and attached the open end to the wound in the abdominal wall. Into the cul-de-sac thus formed he introduced croton oil, senna, and Epsom salt. No accumulation of fluid took place. Schiff experimented in a similar manner with aloes, jalap, and sulphate of sodium, and Radziejewsky with croton oil and sulphate of magnesium, both with the same negative result. Radziejewsky also analyzed the fæces before and after the administration of purgatives. The evacuations produced by purgatives contained more water and sodium salts than normal fæces, and sometimes products of pancreatic digestion, but never as much albumin as should have been present if transudation of fluid from the intestinal blood-vessels had taken place. It was therefore concluded by these investigators, and is still maintained by some recent authors, that purgatives do not induce either transudation or increased secretion, and that the watery character of the stools results only from the greatly accelerated peristalsis, which interferes with the absorption of the fluid normally secreted.

But subsequent investigations yielded different results. Moreau introduced sulphate of magnesium into a portion of intestine isolated by means of two ligatures, and after some hours found a decided accumulation of fluid. Brunton, experimenting in a similar manner, found that croton oil, gamboge, elaterin, and Epsom salt caused a decided accumulation of fluid. That the accumulated fluid was not a transudation was evident from the fact that it contained very little albumin. Brieger injected into an isolated portion of intestine very small quantities of colocynth. No accumulation of fluid took place, but the bowel was contracted and slightly reddened. Larger quantities of colocynth, as well as croton oil, caused an accumulation of bloody fluid, with decided inflammation of the mucous membrane. After injecting calomel, senna, rhubarb, aloes, and castor oil, Brieger found the bowel empty and firmly contracted. Sulphate of magnesium in very dilute solution caused no accumulation of fluid, but concentrated solutions of this salt, so also Glauber salt, caused very decided accumulation. That the fluid was a secretion, and not a transudation, was evident from the fact that it readily converted starch into sugar and dissolved raw fibrin.

Thus it has been found in experiments that sulphate of magnesium, sulphate of sodium, croton oil, gamboge, colocynth, and elaterin, not only accelerate the peristaltic movements of the intestines, but also induce a secretion of watery fluid from the intestinal mucous membrane; and that castor oil, rhubarb, aloes, senna, calomel, and minute quantities of colocynth accelerate peristalsis, but do not notably increase secretion.

Hess, in experiments on dogs, endeavored to determine the manner in which purgatives increase the peristaltic contractions. He made gastric fistulæ a short distance from the pylorus, so that he could easily introduce purgatives into the duodenum. After having determined the quantity of the purgative (sulphate of sodium, castor oil, croton oil, senna, colocynth, gamboge, and calomel) which would act briskly, he introduced into the duodenum a small, empty india-rubber ball, to which was attached a long, fine india-rubber tube. After this had been carried by the normal peristaltic contractions a certain distance, which varied in the different experiments, he filled it with water to such a degree as to obstruct the bowel. The purgatives which previously had acted briskly then completely failed. Hess therefore concluded that the peristaltic movements excited by purgatives are probably not propagated through long distances by means of nervous apparatus, or, according to Engelmann, from muscle to muscle, but that they are reflexly excited in each part of the intestine by direct stimulation of its mucous membrane.

Mild Purgatives.—Of the purgatives which act vigorously, without causing severe irritation of the intestines, the following are commonly employed: aloes, rhubarb, senna, castor oil, salines, and mercurials.

Aloes.—In large doses, from five to twenty grains, aloes produces semi-liquid or liquid stools. The first evacuation rarely occurs before six hours, and often not before ten or twelve hours. Some griping usually precedes the evacuations, and they are often attended by a feeling of heat in the anus, and by straining, especially if the medicine be repeatedly taken. From the slow action and the tenesmus, it is supposed that aloes influences the rectum more than other parts of the intestines.

In experiments on rabbits, Kohn found that aloes caused moderate hyperæmia of the stomach, intestines,

www.libtool.com.cn
Digitized by Microsoft®

and kidneys. In various animals large doses of aloin, injected into the subcutaneous tissue, were followed by gastritis, sometimes with hemorrhage and ulceration, and in rabbits by degeneration of the epithelium of the kidneys.

According to the experiments of Rutherford, aloes increases the secretion of bile and renders it more watery. Various observers have found that it does not act when bile is absent from the intestines.

www.libtool.com.cn

Aloes was formerly employed in large doses to produce brisk purgation, when acute disorder of any organ of the body supervened soon after the cessation of an habitual hemorrhoidal discharge. It was sometimes given to produce a revulsive effect in cases of congestion of the brain, apoplexy, hemiplegia, and insanity. At the present time it is rarely used, except in small doses as a laxative. According to G. B. Wood, it sometimes quickly cures jaundice when other remedies have failed.

Aloes is contraindicated in inflammatory affections of the intestines and kidneys, in irritable and bleeding piles, in uterine hemorrhage, and during menstruation.

It is generally administered in pillular form, and the official *pills of aloes* are preferable to other preparations. Each pill contains two grains of aloes.

Rheum.—In dose of thirty to forty grains, taken at one time, or ten to twenty grains, repeated several times at short intervals, rhubarb produces semi-liquid stools in from five to ten hours, usually with griping, but without severe irritation. Some constipation generally follows. Recent experiments have confirmed the ancient opinion that rhubarb increases the secretion of bile.

Rhubarb is a suitable purgative when the bowels require thorough evacuation in patients who are occasionally subject to diarrhœa. Sometimes it is preferred to other purgatives in catarrhal jaundice.

It may be given in the form of powder, fluid extract, tincture, or wine. Aromatics are generally associated with it to prevent its griping effect. ℞ Pulv. rhei, ℈ij.; pulv. aromatici, ℈i. M. Div. in pulv. iv. Sig.: One powder every two hours. They may be conveniently taken in syrup or molasses, or in wafers. The fluid extract is given in doses of fifteen to thirty minims, mixed with syrup and an aromatic water. ℞ Extr. rhei fluid., ℥ iss.; syr. zingiberis, ℥ ss.; aq. cinnam., ℥ iss. M. Sig.: One tablespoonful every two hours till the bowels move. The tincture and wine are suitable for feeble patients, especially if they are accustomed to alcoholic beverages, and may be given in doses of half an ounce, repeated, if necessary, at convenient intervals.

Senna.—Senna operates gently and slowly in doses of fifteen to thirty grains, producing one or two pultaceous stools in from five to ten hours. Large doses act more briskly. Two or three drachms usually produce semi-fluid discharges in three or four hours. The evacuations are preceded by pretty severe tormina, and sometimes by nausea and eructations. Borborygmi and occasional small fluid stools often continue for from twelve to twenty-four hours.

Though it acts vigorously, and produces quite liquid stools, containing about eighty-five per cent. of water, senna never causes severe irritation or inflammation of the intestines. It is supposed, however, that large doses may influence the uterus, and, given during pregnancy, induce hemorrhage and abortion.

The watery character of senna stools is generally regarded as evidence of increased intestinal secretion; but in careful experiments Brieger found no accumulation of fluid in an isolated loop of intestine with which senna had been in contact some hours. That it greatly accelerates the peristaltic contractions of the small intestine appears from Radziejewsky's experiments. This investigator found that in dogs, normally from seven to nine discharges took place from a fistula in the ascending colon in three or four hours after a feeding; but when senna was administered the discharges began in ten or fifteen minutes, and numbered about thirty in four hours.

Cathartin, the active principle of senna, in doses of gr. iss.–iiss., produces thin stools with colicky pains in from three to fourteen hours. An amount equal to two grains, injected into the subcutaneous tissue, was followed by copious evacuations in from eight to twelve hours.

As senna acts rapidly and efficiently, it is suitable when the contents of the intestines require speedy removal. Combined with Epsom salt, as in the official compound infusion of senna, it is frequently employed in the early stage of inflammatory diseases, except those of the alimentary canal. It is better adapted than rhubarb and some other mild purgatives for patients disposed to costiveness.

Senna, in large doses, is contraindicated in inflammation of the intestines, hemorrhoids, menorrhagia, threatening abortion, and prolapse of the uterus or rectum.

It is generally given in the form of the *infusum sennæ compositum*, which, in quantities of about two ounces, repeated several times at intervals of one or two hours, soon produces copious watery discharges. The fluid extract of senna may be given in doses of half a drachm to two drachms with syrup and an aromatic water. ℞ Extr. sennæ fluid., ℥ ss.; syr. zingiber., ℥ ss.; aq. cinnam., ℥ iij. M. Sig.: A tablespoonful every hour until the bowels act. The syrup of senna is a convenient preparation for children in doses of from one to four drachms.

Oleum Ricini.—Castor oil, in doses of half an ounce to an ounce, usually produces semi-fluid evacuations in from three to six hours, generally with little or no griping or other symptoms indicating irritation of the intestines. Nausea and vomiting may occur in very susceptible persons, especially if the oil is rancid or the stomach disordered.

From its efficient and speedy operation, castor oil is well adapted to all cases requiring a thorough cleansing of the alimentary canal, as when the presence of poisons, undigested food, or products of decomposition in the intestines indicates the use of a brisk purgative. Its gentle, unirritating action renders it suitable when a purgative is required in inflammation of the intestines, inflamed hemorrhoids, fissure of the anus, metrorrhagia, and after parturition. For methods of disguising its taste, see article on *Laxatives.*

Saline Purgatives.—The following saline purgatives are commonly employed: Sulphate of magnesium, sulphate of sodium, citrate of magnesium, tartrate of potassium and sodium, and bitartrate of potassium.

Large doses of saline purgatives produce copious watery stools. This peculiar action was explained by chemists as resulting from osmosis, the dense saline solutions within the intestines causing the less dense fluid of the blood to pass through the walls of the blood-vessels. But the fact that large doses of salines, when given in very dilute solution, so as to be less dense than the fluid of the blood, act as efficiently and often more speedily than concentrated solutions proved that this theory was untenable. Subsequently it was shown, by Buchheim and others, that only salts of low diffusibility are efficient purgatives, and that this property impedes their absorption in the intestines, causing them to pass nearly entire into the lower part of the large bowel and to excite purgation.

For a time it was supposed that the accelerated peristalsis resulting from the presence of saline solutions was sufficient to explain their rapid and peculiar action. But the investigations of Moreau, Brunton, Brieger, Hay, and others, have conclusively shown that dense saline solutions produce an active secretion of watery fluid from the intestinal mucous membrane. Brieger and Hay found that very dilute solutions, although they may purge rapidly, do not cause an increase of secretion; and Hay observed that when concentrated solutions are given, the quantity of fluid secreted depends upon the degree of concentration. Solutions containing less than five per cent. of a salt, produce little or no secretion, but stronger solutions always have this effect. Under ordinary circumstances, the amount of fluid secreted corresponds very nearly to the quantity required to form a five-per-cent. solution of the amount of salt administered. In consequence of the secretion of a large quantity of fluid,

Digitized by Microsoft®

when concentrated saline solutions are given, the fluid of the blood becomes proprotionately diminished. This continues only a short time, as the blood absorbs fluid from the tissues until it has nearly regained the quantity lost by increased secretion.

Thus the mode of action of saline purgatives depends upon the quantity and the degree of dilution. Very dilute solutions excite no intestinal secretion, but rapidly produce watery stools; while concentrated solutions cause a decided increase of secretion, diminish the fluid of the blood, excite absorption of fluid from the tissues, and in a short time produce watery evacuations.

www.libtool.com.cn

Saline purgatives are preferred to other mild cathartics for evacuating inspissated fæcal masses. As a rule, they should be given in very dilute solution. In the early stage of inflammatory diseases, salines are often employed for the purpose of lowering temperature and blood pressure, and thus diminishing the inflammation. They are of little use in such cases unless given in concentrated solution, so as to excite a decided increase of the intestinal secretion. The utility of salines is most conspicuous in cases of ascites and general dropsy. Administered in very concentrated solution, they often in a short time produce a very notable effect, especially if the patient have entirely abstained from food and drink for some hours before taking the saline.

Magnesii Sulphas.—Epsom salt is generally preferred to other saline purgatives. In doses of half an ounce to an ounce it usually produces watery stools in several hours, the first discharge sometimes taking place in one hour. This rapid action is rarely attended by severe griping. As it is readily soluble in water, it may be given in very concentrated solution, a method strongly recommended by Hay in cases of dropsy. It is frequently associated with senna, as in the compound infusion of senna.

Its taste is somewhat improved and its activity increased by sulphuric acid. ℞ Magnesii sulph., ℥ i.; aq. destill., ℥ ij.; acid. sulph. arom., ʒ ss.; syrupi, ℥ i. M. Sig.: One or two tablespoonfuls every hour. The bitterness of Epsom salt may be disguised by strong coffee and aromatics, especially cinnamon water. ℞ Magn. sulph., ℥ i.; aq. cinnam., ℥ iij.; syr. aurant., ℥ i. M. Sig.: A tablespoonful every hour.

Sodii Sulphas.—Glauber's salt has a still more repulsive taste than Epsom salt. It is therefore rarely employed when saline purgatives are indicated. According to recent researches, it causes a decided increase of the secretion of bile and renders it more watery. In all other respects its action closely resembles that of Epsom salt. The following substances have been employed to correct its disagreeable taste: Lemon juice, aromatic sulphuric acid, carbonated water flavored with syrup, and extract or fluid extract of licorice.

Sodii Phosphas.—This salt, although an effective purgative in doses of ʒ ss.–i., is rarely employed in the diseases of adults. It is sometimes used in laxative doses, ʒ ss.–ij., several times daily in catarrhal jaundice and other diseases supposed to indicate a cholagogue. On account of its not unpleasant taste, it is frequently used as a purgative in the diseases of children. The following is an agreeable mixture: ℞ Sodii phosphatis, ʒ ij.; syr. rubi idæi, ℥ ss.; aq. destill. q.s. ad ℥ iij. M. Sig.: One teaspoonful every hour.

Liquor Magnesii Citratis.—The solution of citrate of magnesium has an agreeable taste, and is therefore often preferred to other saline purgatives for unloading the bowels in simple constipation. It is, however, less efficient than the sulphates of magnesium and sodium, sometimes operating briskly, sometimes producing no purgative effect. Usually a whole bottle, containing twelve ounces, taken in several portions at short intervals, is required. In cases of dropsy and inflammatory diseases other saline purgatives are preferable.

Potassii et Sodii Tartras.—In doses of half an ounce to an ounce, Rochelle salt usually produces liquid stools in a few hours. As it has a less disagreeable taste than Epsom salt, generally agrees well with the stomach, and acts gently, it is often employed when a mild purgative is indicated in the diseases of children, females, and delicate persons. It somewhat increases the secretion of bile. From two to four drachms, dissolved in sweetened water, may be taken at intervals of two hours till the bowels respond.

Potassii Bitartras.—Large doses of cream of tartar, half an ounce to an ounce, are followed by watery stools, which are often preceded by flatulence and griping. It is rarely used alone, but frequently in combination with jalap. When given in large doses, it should be suspended in an aromatic water to prevent griping.

MERCURIAL PURGATIVES.—Of the preparations of mercury which produce catharsis, calomel and blue mass are frequently used. Metallic mercury is sometimes employed in obstruction of the bowels.

Hydrargyri Chloridum Mite.—Calomel, in doses of from five to ten grains, usually acts in about six or eight hours, producing copious semi-liquid, dark brown or green evacuations. As a rule, no marked incidental effects are observed; but sometimes, especially after the larger quantity, the evacuations are preceded by griping, nausea, and depression. Smaller doses, one to three grains, act more slowly and very gently. Accurate chemical analyses have discovered in calomel stools bile pigments, leucin, tyrosin, peptones, sulphide of mercury, and unchanged calomel, but no skatol and indol.

The presence of bile in the stools was formerly regarded as a certain evidence of an increased secretion of bile. But in numerous careful experiments on dogs, and in some observations made on patients having accidental biliary fistulæ, it was found that purgative doses of calomel notably lessen the secretion of bile. To explain the presence of bile in the stools notwithstanding diminished secretion, it was then assumed that calomel greatly increases the peristaltic contractions of the small intestine, especially of the duodenum, and thus hurries the bile already secreted downward so rapidly that reabsorption cannot take place. The presence of leucin and tyrosin in calomel stools rendered this view very plausible. But the fact that some purgatives, which act more rapidly than calomel, and doubtless strongly accelerate the peristaltic contractions of all parts of the intestines, do not produce markedly bilious discharges seemed to show that this assumption was incorrect.

The recent experiments of Wassilieff show conclusively that calomel produces bilious stools, by arresting decomposition in the intestines. He divided fresh oxgall into three portions, each weighing 200 gm.; to one portion was added 3 gm. of calomel, to another 2 gm., and to the third none. They were kept in a warm room, and occasionally agitated. The portions containing calomel at once became green, and retained this color as long as the experiment was continued, which was six days. They readily responded to Gmelin's test for bile pigment, and showed no trace of decomposition. The portion not containing calomel had become brownish-yellow in one day, did not exhibit the reaction of bile pigment, and was soon putrid. Doubtless calomel exerts the same antiseptic influence in the intestines. Under ordinary circumstances the bile pigments, bilirubin and biliverdin, become converted into hydrobilirubin, and hence cannot be detected in the fæces. Calomel prevents this decomposition, and by increasing peristalsis causes the unchanged bile pigments to be evacuated. In the same manner it prevents further changes of leucin and tyrosin, and the formation of skatol and indol.

Calomel is a very effectual purgative in the morbid state called biliousness—marked by a sallow complexion, yellowness of the white of the eyes, a bitter taste, defective appetite, and sometimes nausea; by headache, mental dulness, and depression; and sometimes by light-colored stools and sedimentary urine. By arresting decomposition and removing bile and other substances before they can be absorbed, it thoroughly relieves both the intestines and the liver.

In small doses calomel has been found useful in the

Digitized by Microsoft®

gastro-enteritis of children. Its utility is probably due chiefly to its antiseptic action.

Administered in doses of from five to seven grains, for one or two days, in the first week of typhoid fever, calomel somewhat lowers the febrile temperature and renders the disease milder. As other purgatives are less useful, it probably exerts a destructive influence upon the micro-organisms which cause the disease.

www.libtool.com.cn

As a rule, calomel is indicated as a purgative in all acute affections of the intestines resulting from fermentation and putrefaction.

Together with jalap or rhubarb, calomel is sometimes administered in the early stage of inflammatory disorders of the internal organs. Though not useless, it produces very much less effect on the quantity of fluid in the blood-vessels and on the blood pressure than large doses of the saline purgatives.

Calomel should not be used in habitual constipation.

It is usually ordered in powder with sugar, or with jalap, rhubarb, or bicarbonate of sodium. ℞ Hydrarg. chlor. mitis, gr. v.; sacch. albi, gr. x. M. Sig.: Take at once. ℞ Hydrarg. chlor. mitis, gr. iij.; pulv. jalapæ, gr. x. M. Sig.: Take at once in syrup or molasses. ℞ Hydrarg. chlor. mitis, gr. v.; sodii bicarbon., gr. xv. M. Sig.: Take in molasses or syrup. In all cases, if calomel have failed to act after eight or ten hours, a saline purgative or castor oil should be given.

Massa Hydrargyri.—Blue mass is a somewhat uncertain purgative when given in doses of from five to ten grains. It is, therefore, usually combined with rhubarb, aloes, podophyllin, or compound extract of colocynth, or, if given alone, a dose of castor oil, Rochelle salt, Epsom salt, a senna draught, or a seidlitz powder, is administered after eight or ten hours. It is held to be efficient in biliousness, and is usually given in the evening.

Hydrargyrum.—Metallic mercury in large doses quickly passes through the alimentary canal in consequence of its great weight. Probably the dragging and stretching of the mucous membrane, resulting from the presence of large quantities, excite very powerful peristaltic contractions, which rapidly carry the metal through the intestines.

Metallic mercury has been employed in intestinal obstruction when all other ordinary means had failed to give relief. Bettelheim (*Deutsches Archiv f. kl. Med.*, Bd. 32, p. 53) carefully studied seventy cases of obstruction, reported during the last fifty years, in which mercury was used. In fifty-seven cases a cure resulted, that is, the obstruction was relieved either temporarily or permanently. In no case did it cause rupture, inflammation, or gangrene of the bowel, while in some instances it saved life. Bettelheim therefore considers it proper to administer mercury in cases of obstruction due to fæces, ascarides, and even to intussusception or torsion, if other ordinary means have failed to give relief.

The dose of metallic mercury varies from one to ten ounces.

Drastic Purgatives.—Of the cathartics which operate violently and produce serious irritation of the intestines, when given in excessive doses, only the following are commonly employed: jalap, scammony, colocynth, podophyllum, gamboge, croton oil, and elaterin.

Jalapa.—Jalap is the mildest drastic, and resembles senna in its action. In doses of fifteen to thirty grains it usually soon causes a feeling of discomfort in the epigastrium, and sometimes nausea. After two or three hours tormina and several liquid stools occur. Smaller doses, five to ten grains, act gently, producing one or two pultaceous evacuations. In very excessive doses jalap causes vomiting and profuse rice-water discharges, with great depression.

The resin of jalap, in doses of from one to three grains, acts as a laxative, but in larger doses, from five to fifteen grains, it produces watery stools in a few hours.

According to recent investigations, jalap does not act well when bile is absent from the intestines. In experiments on dogs it was found to increase moderately the secretion of bile.

On account of its rapid, safe, efficient, and hydragogue action, jalap is frequently employed when a brisk cathartic is indicated. In cases of acute constipation, and in inflammatory diseases, it is usually associated with calomel, and in ascites and anasarca with bitartrate of potassium. The official *pulvis jalapæ compositus*, consisting of thirty-five parts of jalap and sixty-five parts of cream of tartar, is generally preferred to other hydragogues in dropsy. In doses of half a drachm to one drachm, it usually produces watery discharges in a few hours.

The resin of jalap may be given in doses of from one to eight grains in powder or emulsion. ℞ Resin. jalapæ, pulv. acaciæ, āā gr. viij.; sacch. albi, ʒ ss. M. Div. in part. æqual. iv. Sig.: One powder every two hours till the bowels move. ℞ Resin. jalapæ, gr. viij.; pulv. acaciæ, sacch. albi, āā ʒ i.; aq. menth. pip., ℥ ij. M. Sig.: One tablespoonful every two hours. Sometimes resin of jalap is given in combination with calomel. ℞ Resin. jalapæ, hydrarg. chlor. mitis, āā gr. iv.; sacch. albi, ℈ i. M. Div. in part. æqual. iv. Sig.: One powder every two hours.

Jalap is contraindicated in inflammatory affections of the alimentary canal.

Scammonium.—Scammony resembles jalap in action, but is less certain, sometimes producing little or no effect, at other times acting harshly, with griping and tenesmus. Usually it is followed by watery stools in a few hours. The presence of bile in the intestines is necessary for its action. It is rarely used except in combination with other purgatives, as in the official *compound cathartic pills*. The dose of scammony, to act briskly, is from ten to twenty grains, and of its resin, from five to ten grains.

Colocynthis.—Large doses of colocynth produce numerous fluid evacuations, with griping and tenesmus. Excessive doses cause sanguinolent stools, great abdominal pain, intense depression, and sometimes death.

Small doses, one to three grains, act gently, producing loose stools without notable griping. But if frequently repeated, such doses soon cause tormina and tenesmus, and slimy stools.

According to Brieger, small quantities of extract of colocynth, 0.02 gm. dissolved in 2 gm. of water, injected into isolated portions of intestine, produce slight hyperæmia and peristaltic contraction, but no accumulation of fluid. But larger quantities produce decided inflammation and an effusion of bloody fluid.

In experiments on dogs Rutherford found colocynth to cause an increased flow of watery bile.

On account of its harsh operation, colocynth is rarely employed alone to produce brisk purgation; but in small doses, in combination with other laxatives, it is frequently given in habitual constipation.

The dose of the extract of colocynth, as a laxative, is one-sixth to two-thirds of a grain, and of the compound extract, from one to five grains. The latter preparation is sometimes given in doses of five to fifteen grains, to purge briskly. Usually the extract of hyoscyamus, or the extract of belladonna, is combined with it, to prevent griping. ℞ Extr. colocynth., gr. i.; aloes, gr. vi.; extr. hyoscyami, gr. vi. M. Ft. pil. vi. Sig.: One pill at bedtime. ℞ Extract. colocynth. comp., gr. xij.; extr. bellad., gr. ij. M. Ft. pil. vi. Sig.: One pill at bedtime.

Cambogia.—Gamboge is held to be still more irritant than colocynth. In experiments Rutherford found, after large doses, violent irritation of the duodenum and small intestine generally, with profuse catharsis, but no increase of the bile flow.

It is, perhaps, never given alone, but is sometimes added to other purgatives to increase their action, as in the compound cathartic pills. Very small doses, one-sixth to one-half grain, are said to produce pultaceous stools without much griping. Generally, doses of three to four grains cause some nausea and colicky pain, and several watery stools. Excessively large doses, one drachm, have caused fatal gastro-enteritis.

Formerly gamboge was frequently employed in obsti-

Digitized by Microsoft ®

nate constipation, ascites, anasarca, paralysis, insanity, gout, and skin diseases. Generally it was given together with aloes, jalap, bitartrate of potassium, and calomel. ℞ Cambogiæ, gr. iv.; pulv. jalapæ comp., ʒ ij. M. Div. in pulv. iv. Sig.: One powder every two hours till the bowels act, in cases of dropsy.

Pilulæ Catharticæ Compositæ.—The compound cathartic pills contain small quantities of aloes, scammony, colocynth, jalap, gamboge, and calomel. On account of their complex composition they are supposed to affect all parts of the intestines, and to increase the secretion of bile. One pill usually acts as a laxative, while three or four produce free purgation. They are suitable to acute constipation not complicated with inflammation of the intestines, but should not be employed in habitual constipation.

Podophyllum.—This purgative, even in large doses, usually acts slowly, from six to ten hours elapsing before the bowels move. Doses of ten grains rarely cause marked incidental effects, but twenty or thirty grains are usually followed by nausea, and sometimes vomiting and depression, and severe colicky pain. The evacuations sometimes have a dark color, from which it was assumed that they contain a large quantity of bile. In experiments on dogs Rutherford found that moderate doses of podophyllin cause an increased flow of bile.

The resin of podophyllum, commonly called podophyllin, is used as a laxative. Doses of one-eighth to one-half grain usually produce a gentle movement in eight or ten hours. Large doses, from two to four grains, cause nausea, sometimes vomiting, severe griping, and numerous stools, which may be slimy and bloody and followed by intense depression.

Podophyllin is not suitable in cases requiring brisk purgation. But in chronic constipation it is much used, because it continues to act for a long time without necessitating an increase of dose. It is frequently employed when symptoms are present which show that the secretion of bile is abnormal. Usually it is given in pillular form, with extract of hyoscyamus or extract of belladonna. ℞ Podophyllini, gr. ij.; extr. hyoscyami, gr. viij. M. Ft. pil. No. viij. Sig.: One pill at bedtime. It has also been given in solution as follows: ℞ Podophyllini, gr. ij.; alcohol. dil., ℥ ij.; tinct. zingiberis, ʒ ij. M. Sig.: A teaspoonful in a wineglassful of water.

Podophyllotoxin is said to act more regularly than the official resin. It has been given to adults in doses of one-sixth to one-fourth of a grain, and to children in doses of one-sixtieth to one-twelfth of a grain. Brun employed it in alcoholic solution as follows: ℞ Podophyllotoxini, 0.5 gm.; spir. vini rectif., 7.5 gm. M. Sig.: From five to fifteen drops in sweetened water.

Oleum Tiglii.—Croton oil is a very energetic drastic, a drop sometimes producing from five to fifteen watery evacuations. Often the first evacuation occurs in one or two hours.

The susceptibility of different persons to its action varies, in some one drop acting intensely, while in others it produces only a few semi-liquid stools. In rare instances purgation does not result from the dose mentioned, but there takes place general disorder, marked by palpitation of the heart, pain in the extremities, severe headache, giddiness, and prostration.

Frequently the action of croton oil is attended by symptoms indicating irritation of the stomach and intestines—a sensation of heat in the epigastrium, more or less nausea, sometimes vomiting, borborygmi, colicky pain, and tenesmus.

Excessive doses quickly induce vomiting and purging, and great prostration. Twenty drops have proved fatal.

Croton oil is used when a powerful purgative is indicated, and milder medicines have failed to act or cannot be administered. Sometimes this is the case in obstinate constipation, lead colic, and diseases of the brain and spinal cord. When brisk purgation is necessary, and swallowing is very difficult, the oil is preferred to more bulky cathartics, a drop being mixed with a little sugar, or a little bread crumb, and placed on the back of the tongue.

The oil has been strongly recommended for the removal of tapeworm—one drop mixed with one drachm of chloroform and one ounce of glycerin, to be given early in the morning.

Croton oil is usually given in pillular form. ℞ Ol. tiglii, gtt. i.; micæ panis, q. s. M. Ft. pil. iv. Sig.: One pill every hour. It is said that the oil acts more gently when combined with compound extract of colocynth and extract of belladonna. ℞ Ol. tiglii, gtt. i.; extract. colocynth. comp., gr. viij.; extr. bellad., gr. i. M. Ft. pil. iv. Sig.: One pill every two hours. Sometimes it is given mixed with sugar. ℞ Ol. tiglii, gtt. i.; sacch. lactis, ʒ i. M. Div. in part. æq. iv. Sig.: One powder every hour. It may also be mixed with castor oil, or made into an emulsion, as follows: ℞ Ol. tiglii, gtt. i.; pulv. acaciæ, ʒ ij.; syr. amygdalæ, ℥ ss.; aq. destill., ℥ iiiss. M. Ft. emuls. Sig.: One tablespoonful every hour.

Elaterinum.—Elaterin is the most powerful and drastic of all purgative medicines. The twentieth of a grain, given to an adult, will generally produce watery stools in one or two hours. Sometimes this speedy action is not attended by marked incidental effects; but often, especially if it is given alone, nausea, severe griping, borborygmi, and some prostration are produced. Excessive doses may cause intense gastro-enteritis and fatal collapse.

Elaterin is employed in ascites and anasarca, when gentler hydragogues have failed to act efficiently. As a rule, it is given only every other day, and not continued longer than a week or ten days, lest it excite serious intestinal inflammation. After an interval of a week its use, if necessary, may be resumed. It is contraindicated in dropsies complicated with intestinal irritation, and must be used with extreme caution in very young, aged, and feeble patients.

It may be ordered in solution, pill, or powder. ℞ Elaterin, gr. ss.; alcohol., ℥ ss.; acidi nitrici, gtt. ij. M. Sig.: From twenty to forty drops in an aromatic water. ℞ Elaterini, gr. ½; extr. hyoscyami, gr. vi. M. Ft. pil. vi. Sig.: One pill every hour till stools take place. ℞ Elaterini, gr. ¼; sacch. albi, ʒ i.; ol. menth. pip., gtt. ij. M. Div. in part. æqual. vi. Sig.: One powder every hour until the bowels act.

General Indications.—Purgatives are used (1) to evacuate the intestines; (2) to diminish hyperæmia of remote parts or organs; (3) to promote the absorption of exudations and transudations; and (4) to eliminate noxious substances.

1. *All purgatives evacuate the contents* of the intestines; but when this is the sole indication for their use, only laxatives and mild purgatives should be given. In chronic or habitual constipation those laxatives are most suitable which act slowly, producing normal or nearly normal fæcal evacuations, without losing their activity in small doses after frequent repetition, and without interfering with general nutrition. Experience has shown that aloes possesses these properties in the most eminent degree. Podophyllin, cascara sagrada, rhubarb, and compound extract of colocynth are also eligible. The saline laxatives are sometimes used in habitual constipation; but as their prolonged use is followed by impairment of nutrition, they should not be given to feeble patients unless required by other indications.

In occasional or acute constipation any laxative or mild purgative may be employed. If hardened fæcal masses are present in the intestines, the saline laxatives and castor oil are most suitable. Sometimes all the mild purgatives fail to act in acute constipation, especially when the cause of the constipation is still present, as in lead poisoning. Drastics, if carefully used, are then appropriate, and croton oil is usually preferred. Metallic mercury has been successfully used after all ordinary purgatives had proved ineffectual.

To remove poisons and irritating substances from the intestines, those purgatives which act speedily and gently

Digitized by Microsoft®

should be preferred, especially castor oil and salines. When irritation of the intestines results from decomposition or fermentation, calomel is the best purgative.

2. *To diminish hyperæmia* of remote parts or organs, purgatives which act rapidly and produce semi-liquid or watery discharges are required. Mild purgatives deplete indirectly by sweeping the intestinal secretions and partially digested food downward so rapidly that absorption is impeded. Saline purgatives, in strong solution, excite a copious secretion of watery fluid, and thus directly deplete the blood. Drastics act in a threefold manner, accelerating peristalsis, increasing secretion, and exciting intestinal hyperæmia. The choice of a purgative will, therefore, depend upon the intensity and duration of the disease to be influenced, the organ affected, and the character of the general symptoms. In congestion of the liver, calomel, followed by a saline laxative, is the most suitable purgative. In congestion or inflammation of most organs, saline cathartics and compound infusion of senna are usually employed; but in very severe congestion or inflammation of very important organs—such as the brain and spinal cord—drastics are preferred, especially croton oil.

3. *To promote absorption of exudations* and transudations, the hydragogues are most suitable. Generally the saline hydragogues, given so as to produce copious watery stools, soon cause rapid absorption. In cardiac dropsy they often diminish the dropsical swelling very notably in a few hours. Of the drastic hydragogues the compound powder of jalap and elaterin are the most useful. Generally the former is preferred on account of its mild action. But when it fails to act efficiently, or when an effusion of serum occurs rapidly, and in such large quantity as to produce extreme distress, such as alarming dyspnœa in pleuritis, elaterin is usually given. Sometimes it so rapidly induces absorption of the effusion as to give decided relief in a few hours.

4. *To eliminate noxious substances*, calomel, salines, and drastics are used. The utility of calomel in biliousness and congestion of the liver is in part due to the rapid removal of irritating and decomposing substances from the alimentary canal. Saline laxatives, especially sulphate of magnesium, are indicated in chronic lead poisoning, to remove the poison from the intestines as fast as it is eliminated by the liver. They are also suitable in cases of uræmia, especially if at the same time it is necessary to induce absorption. In uræmic coma, croton oil is sometimes preferred to milder purgatives.

Contraindications.—All purgatives are contraindicated in peritonitis, intestinal hemorrhage, perforation of the bowels, strangulated hernia, and extreme debility. Brisk purgatives are generally inappropriate during pregnancy, especially if previous abortions have occurred, and during menstruation. They should not be used if there exist severe rectal lesions, or a tendency to looseness of the bowels. Even laxatives are contraindicated in habitual constipation, until all other known means have failed to establish a normal habit of defecation.

Samuel Nickles.

PURPURA.—(Synonyms: *Hæmorrhæa petechialis*; Fr., *Purpura*; Ger., *Blutflecken*.) Purpura is a disease characterized by the extravasation of blood into the skin. In many instances, however, it is not limited to this organ and may be encountered in almost any structure of the body. The parts coming most readily under visual inspection are naturally the skin and mucous membranes, although in severe and fatal cases the autopsy shows that the internal viscera are likewise involved. It may be asked whether purpura is not rather a symptom complex than a well-defined affection *per se*. It occurs under so many apparently varied conditions that one is at a loss to ascribe to it definite limitations. In this connection, however, it will be considered from a dermatological standpoint, the skin being the organ most extensively involved. The clinical manifestations of purpura vary; hence several varieties have been described, although the essential feature is the occurrence of hemorrhage into the structures surrounding the blood-vessels. In severity purpura likewise varies greatly, being in some instances an exceedingly mild affection with extravasation only in dependent parts, as the legs; or it may be an extremely severe and rapidly fatal disease. Between these extremes numerous grades, both in appearance and in severity, occur. Usually purpura is accompanied by constitutional symptoms which to a great extent depend upon the amount of cutaneous hemorrhage.

For convenience of description the various lesions have received distinct names. Thus we speak of *vibices* when the extravasation of blood into the skin assumes a streaked or elongated form. *Ecchymoses* are irregular extravasations of blood involving considerable areas, and giving

Fig. 3923.—Purpura Simplex. (Case of Dr. William T. Corlett.)

the appearance of bruises. *Ecchymomata* or *hæmatomata* are terms used to designate tumors formed by the extravasation of blood, usually occurring when a large vessel wall has given way. The term *purpura papulosa* is employed to designate pinhead-sized extravasations which are usually situated in the upper part of the derma. *Hæmorrhagic bullæ* are extravasations underneath or between the layers of the epidermis, while *hæmatidrosis* is a rare condition in which the sweat glands give forth a bloody exudate. *Petechiæ* are cutaneous areas of extravasation of various shapes and sizes.

The cutaneous lesions of purpura are characteristic in that they are symmetrically arranged, are of a dark bluish color, and do not disappear on pressure. At first they may be of a bright red or claret color, although at an early stage they take on a purplish hue; as absorption goes on the color undergoes various changes from a brown to a greenish-yellow tint, such as may be observed in an ordinary bruise. The cutaneous manifestations occur in successive crops; hence various shades of color may be seen at the same time. Most cases of cutaneous hemorrhage may be grouped under three heads, which will be treated as varieties of the disease.

Purpura Simplex represents the mildest form of the disease. This is commonly observed in the skin, and is frequently limited to this structure. As a rule, it is unaccompanied by constitutional symptoms. It usually makes its appearance suddenly, and is first seen on the dependent parts, as the legs (see Fig. 3923), although in children the arms, neck, and other parts of the body may be involved. The most usual sites are the inner aspect of the legs, the dorsum of the feet, and the posterior surface of the forearms. In this form the mucous membranes may be involved to a slight extent, that most frequently implicated being the mucous membrane of the mouth, although we have reason to believe that the hemorrhagic process is not limited to these structures, but that, on account of the mildness of the symptoms, it escapes notice when occurring in parts not easily inspected. In this variety the lesions consist of variously sized and shaped petechiæ

Digitized by Microsoft®

which are at first roundish or oval, and which sometimes extend at the periphery; at other times they remain stationary until absorption takes place. A more infrequent form, in which the lesions are punctate (*lichen lividus* of Willan) and surround the exit of a hair shaft, is also encountered. The lesions in purpura usually continue to appear for several days or weeks, although the disease is self-limited and as a rule terminates in recovery within one or two months. The cutaneous lesions soon undergo resorption and deposition of hæmatin which leaves an indelible stain in the tissue.

www.libtool.com.cn

Purpura Rheumatica, Peliosis Rheumatica, Toxic Purpura (*Purpura exanthématique* of the French) is a more severe form of the disease, so called because of its association with vague pains which are usually referred to the joints or muscles, and are supposed by some to be closely related to acute articular rheumatism. In this variety constitutional symptoms are more marked. In some cases distinct swellings occur about the joints, there is a slight elevation of temperature, the tongue is frequently coated, and usually there is anorexia, sometimes with nausea and vomiting. Extravasation of serum alone may likewise take place, giving rise to urticarial lesions in the skin (*purpura urticaria*). In very rare instances the serous exudate occurs in the epidermis, giving rise to bullæ and œdematous plaques. Stelwagon ("Diseases of the Skin," 1902, p. 466) has observed swelling of the lips and throat which he describes as a *febrile purpuric œdema*. Sometimes the eruption becomes associated with symptoms of a multiform erythema, the lesions varying in appearance, although always associated with cutaneous hemorrhage. From the foregoing it may be seen that this form of purpura is closely allied to the exudative erythemata.

This toxic form of purpura is sometimes associated with complications of a grave nature. Thus endocarditis and pericarditis, together with necrosis and sloughing of the mucous membrane of the mouth, have been observed by Osler.[1] It is sometimes recurrent and may appear annually throughout a period of several years. Henoch[2] has called attention to gastro-intestinal symptoms occasioned by hemorrhages into the intestinal mucosa; this has been accompanied by vomiting and diarrhœa, the stools not infrequently being tinged with blood. Hemorrhage may likewise take place to a slight extent into the bladder. This has been most frequently observed in children. In severe cases the kidneys are affected, giving rise to the symptoms of acute hemorrhagic nephritis. In these cases albumin is usually present in the urine. The spleen is sometimes easily palpable.

Purpura Hæmorrhagica, sometimes known as morbus maculosus Werlhofii (which see), and also as land scurvy. This is a more grave affection than the two preceding varieties. The severity of the disease, however, largely depends upon the cause as well as on the extent of the cutaneous hemorrhage. The onset of this variety varies; it may be insidious, appearing as a mild attack with few or no constitutional symptoms; soon gradual impairment of the health becomes manifest, and the patient becomes weak from loss of blood. The appetite disappears, assimilation is interfered with on account of intestinal hemorrhage, and diarrhœa with bloody stools finally occurs. The gums bleed easily, and there is not infrequently hæmaturia, epistaxis, or hæmoptysis. The lesions usually assume the form of large ecchymoses or ecchymomata, and the mucous membranes are apparently involved to an equal, if not greater, extent than the skin. In the latter the disease may appear on the more dependent parts, although the whole body soon becomes involved. In severe cases symptoms of collapse occur, and the disease may soon terminate in death (*purpura fulminans*). At other times the disease pursues an uninterrupted course for several months, when finally resolution takes place and the patient recovers. At other times extravasation of blood takes place into the brain or spinal cord, giving rise to symptoms referable to a tumor in these parts. There is usually but slight elevation of temperature in this form, although the disease is sometimes noted to be ushered in with a slight fever, the temperature rising one or two degrees.

Cutaneous hemorrhage may also occur as a symptom of other well-recognized diseases, such as variola, the plague, and cerebro-spinal fever, and in cases of poisoning from the bite of poisonous reptiles.

Etiology.—The disease occurs in both sexes, and is met with at all ages. It is a fairly common disease in my experience, and has been most frequently encountered between the ages of sixteen and forty-five. The general health of the cases that have come under my observation, previous to the advent of the cutaneous hemorrhages, has been good, although, as has been stated, there is sometimes a tendency for the disease to recur from time to time during a period of several years. In a series of cases which I had the opportunity of observing a number of years ago, bad hygienic conditions with a defective food supply were undoubtedly the chief etiological factors in the disease. Of these the chief rôle must be given to the withdrawal of green vegetables from the dietary, most notably potatoes, cabbage, and greens; at any rate, on supplying these articles in moderation the disease disappeared from various families in which it had been observed to occur for a long time. Further, in my experience the disease has been met with more frequently in women than in men, the nationality most frequently affected being the Bohemian. It has occurred usually in people in the lower walks of life. Various drugs have been known to produce cutaneous hemorrhage, notably potassium iodide, chloral, belladonna, ergot, phosphorus, iodine, quinine, copaiba. These drugs do not produce the same effect in all people, there being in some individuals an idiosyncrasy by which the ingestion of certain substances, innocuous to others, gives rise to toxic effects. Again, toxic substances or their ptomaïns, by acting on the nerve centres, are thought to be potent factors in the causation of purpura, notably in the erythematous or toxic form.

As malaria undermines the general health, it is thought by some to contribute to this condition. Other diseases contribute in like manner to purpura, most notably those which tend to profound anæmia, such as scorbutus, hæmophilia, pyæmia, sarcoma, nephritis, scarlatina, typhus fever, cerebro-spinal fever, variola, and rubeola, as well as various diseases of the nerve centres, such as locomotor ataxia and hysteria. The venom of serpents must likewise be mentioned in this connection. In new-born infants the sudden change to which the circulation is subjected may give rise to cutaneous hemorrhage, which should be looked upon as purely mechanical. Various micro-organisms have likewise been described as associated with purpura. Martin de Gimard,[3] Letzerich,[4] and Kolb[5] have succeeded in producing the disease in animals by inoculating with pure cultures, and doubtless this accounts for some cases, especially among the severe forms. From the foregoing it will appear that the cause of purpura varies in different cases, and no one condition can be assigned as invariably producing the disease.

Stelwagon, in summarizing the various causes of purpura, believes that the etiological factors may be divided into classes, most conspicuous of which are the vasomotor, toxic, and infectious; and that some of the latter arise from auto-intoxications, which have their origin in the intestinal tract. This latter seems especially true in those cases which are marked by a multiform erythema and urticarial lesions. It is evident, therefore, that we have in purpura a condition of variable appearance and widespread distribution, affecting almost every organ and structure of the body and producing symptoms which vary according to the part attacked. What we know, therefore, is this: purpura is a symptom, in the broad sense of the term, of many conditions, many of which at the present time are wholly unknown.

Pathology.—The most constant findings in purpura are circumscribed areas of blood extravasation, which are usually found in the papillary layer of the derma. Less frequently the epidermis may be invaded, the latter occurring only when the blood extravasation has been

Digitized by Microsoft®

excessive, as from rupture of an arteriole, or when the disease assumes a toxic form (*peliosis rheumatica*). When the disease is not limited to the skin, the deeper part of the derma or even the subcutaneous structures (purpura hæmorrhagica) may be involved. Again, there may be only a few red blood cells surrounding the vessel (diapedesis), in which case the lesions are usually limited to the superficial stratum of the derma. If the disease has existed for some days the characteristic retrogressive changes are found, namely, the presence of coloring matter from the blood giving rise to a rust-like stain, which gradually fades away, leaving only a slight pigmentation. Frequently these are the only changes found. At other times the vessels in the area involved are markedly dilated (*purpura ectasique* of the French), and red blood cells are found outside the vessel wall. This Leredde regards as due to paralysis of the vaso-motor filaments distributed to the vessel. This form is supposed to be of toxic origin involving primarily the nerve centres. Aside from these changes there have been noted dilatation of the vessels with proliferation of the endothelium, together with an accumulation of blood cells, fibrinous thrombi, and microbic emboli. Furthermore, amyloid degeneration of the vessels has been noted, together with proliferation of the connective-tissue cells and necrosis of the vessel wall. The study of the blood has of late attracted close attention, and Lenoble[6] holds that true purpura (*P. myéloïde*) or the toxic form is invariably due to alterations in the blood. The following, according to this observer, are always present and may be regarded as characteristic:

1. Absence of contraction of the clot and consequent expression of the serum. This is constant, and it is only after recovery that the expression of serum becomes normal. In light cases one can see a certain degree of contraction of the clot, although occurring a little later than usual.

2. The appearance of bone-marrow cells which are always present, sometimes abundant, and are characterized (*a*) by the apparition of nucleated red blood cells, few in the chronic, but more abundant in the acute form; in the latter case, however, they are not permanent. These red cells are in the group of Ehrlich's normoblasts, more rarely megaloblasts or even microblasts (one case); (*b*) by the appearance in the circulation of myelocytes which are usually neutrophilic, more rarely eosinophilic. This reaction is always slight or feeble, and varies from a fraction of one per cent. in the chronic type to six or seven per cent. in the acute form.

3. Marked changes in the blood platelets, which are diminished in number and increased in volume, but whose chief alteration is in the more or less complete loss of their characteristic grouping. This loss of the power of clumping explains the lack of contraction of the clot, the special anæmia, and the profuse hemorrhages which are characteristic of the disease.

These changes, which are constant, may persist indefinitely in the chronic form. In the subacute form the duration is variable, and normoblasts may be found long after recovery is apparently complete.

The following are given as accessory and inconstant blood changes:

1. Leucocytosis with increase of the polynuclear eosinophiles and especially of the lymphocytes. These last are always increased, and were omitted from the primary changes mentioned because they are found in all forms of purpura. Their presence is as important as is that of the myelocytes, whose office it is to repair the constant loss of the large mononuclears which undoubtedly act as macrophages. According to the Dominici these cells also give rise to parent cells of the elements which are destroyed by the circulating toxins.

2. Frequent but inconstant is the appearance in the pure blood of a reticulum either with a coarse or with a fine network.

3. Contrast between the number of red corpuscles, which may be much increased, and the amount of hæmoglobin per cell, which may remain small.

This disease is thus controlled by a double cause, viz., an infection and an anæmia. The intensity of the symptoms varies with the intensity of the infection. The blood shows few changes in chronic, subacute, and transient types, but in the acute form the blood appears disorganized and shows the presence of bone-marrow cells, while the red blood cells have become very vulnerable. This is shown by the large number of pseudoparasites whose importance has been dwelt on by Hayem.[7]

Diagnosis.—Little difficulty need be experienced in recognizing a well-marked case of purpura. In purpura simplex the lesions sometimes resemble flea-bites or the bites produced by other insects (*purpura pulicosa*). In the latter, however, there may be seen a characteristic inflammatory halo surrounding a deep red punctate centre, which is never present in purpura. Erythema nodosum might, late in its course, be mistaken for purpura, especially when the dark-red inflammatory nodules of the erythema have receded, leaving bruise-like areas. The location and history of the affection should enable one to differentiate between them. It should be borne in mind that erythema is an acute affection of two or three weeks' duration, with large, elevated, slightly inflamed and painful nodules, usually limited to the anterior surface of the legs and to the forearms; while the lesions of purpura appear in successive crops lasting from four to twelve weeks, are of a dark color, usually not elevated except in the form of bullæ, and are not inflammatory nor painful. In erythema the redness disappears on pressure, while this does not take place in purpura. Pain has been experienced on pressure in erythema, but pressure does not cause pain in purpura. From trauma purpura may be distinguished by the multiform character and distribution of the lesions, and by the absence of any history of injury.

The late manifestations of syphilis likewise give rise to pigmentation, but they are also preceded by inflammation, and are always chronic, which offers a sharp contrast to the lesions of purpura. Even in the necrotic form of purpura the lesions are smaller, are multiform, and are of comparatively shorter duration than those of syphilis. From the various drug eruptions, noticeably that of cubebs and copaiba, the erythema is of a brighter red and disappears on pressure. In the acute infectious exanthemata cutaneous hemorrhages are not uncommon, notably in variola and rubeola; but in the former we have a grave affection which, as a rule, rapidly advances to a fatal termination, and in measles the coryza and other characteristic features of the rash would enable one to exclude purpura which has a slower evolution and less often terminates fatally.[8]

Prognosis.—This depends on the extent of the cutaneous hemorrhage, the cause of the disease, and the complications present. In simple purpura the prognosis may be considered favorable, whereas in toxic cases, or in those accompanied by marked involvement of the viscera, the prognosis must be guarded. In purpura simplex the majority of patients recover in from four to twelve weeks. In purpura rheumatica the disease is liable to return, although it is seldom from the primary affection that a fatal issue ensues. In severe forms the disease is always grave, if not fatal.

Treatment.—The first consideration is rest in a horizontal position. Except in very mild cases this should be maintained very strictly throughout the whole course of he disease. Many cases are reported in which fresh crops of eruption have appeared after the patient assumed the erect posture. When the lower extremities are mainly involved, it is well to elevate the feet above the horizontal plane by means of pillows. When the extremities are the chief seats of predilection, flannel bandages may be applied so as to give support by gentle pressure. The room should be well ventilated and an abundance of direct sunlight admitted The diet should be simple, nutritious, and easy to digest. In toxic cases diffusible stimulants may be indicated. The drugs which have given the best results are: turpentine, in doses of five drops three times a day, or by inhalation; ergot, or the

www.libtool.com.cn
Digitized by Microsoft®

subcutaneous injection of ergotin, which is highly spoken of by Crocker; silver nitrate, gr. ¼ to gr. ½ in pill form; aromatic sulphuric acid; and chloride of lime in doses of from fifteen to thirty grains three times a day. The latter remedy should not be given for a longer period than two or three days, as it acts directly on the coagulation of the blood. Astringents in the form of iron or a four-per-cent. solution of hydrochlorate of cocaine have been resorted to in severe cases. Ice in the mouth, or elsewhere, may be indicated as a local application. Boulloche[9] recommends the injection of artificial serum, and relates a case of fulminating purpura in which death seemed imminent, but which, under this treatment, made a complete recovery. In this case 120 c.c. were given. Absolute cleanliness should be insisted upon, and some mild astringent and antiseptic gargle may be applied to the mouth and fauces. Further than this the treatment depends largely on the cause of the disease and the complications which are encountered.

PYKNOSIS (also spelled *Pycnosis*) is the term applied to that condition of the nucleus in which, in the early stages of necrosis or just preceding necrosis, it stains more intensely with nuclear stains. At the same time there is usually a contraction of the nucleus; but the nucleus may remain of normal size or even swell. *Karyorrhexis* may follow pyknosis, or there may occur a gradual *karyolysis* without a disintegration of the chromatin elements. In sections stained with hæmatoxylin the pyknotic nuclei may appear almost black. This phenomenon is usually explained as due to a condensation of the chromatin. Pyknosis may be observed in necrosing cells of all organs and tissues; it is seen particularly in necrosing syncytial cells, bone-marrow giant cells, muscle cells, sarcoma cells, etc. Pyknotic cells are sometimes mistaken for newly formed cells; and in some cases the differential diagnosis is difficult. This is particularly the case in striped muscle. Undoubtedly many of the cells regarded as evidences of muscle regeneration have been cells in a condition of pyknosis.

PYOKTANIN.—(*Methyl violet.*) An aniline dye introduced in 1890, by Prof. J. Stilling, as a powerful antiseptic for surgical purposes.

Dr. Stilling summarized its qualities as follows: (1) Pyoktanin is an antiseptic surpassing all others. The bacteriological researches have shown blue pyoktanin to be about three times as strongly antiseptic against anthrax bacilli as sublimate is, and to be quite as efficacious as sublimate toward the staphylococcus aureus. (2) It is an absolutely non-toxic substance. (3) In consequence of this non-toxicity it is a matter of indifference in many cases of wounds, etc., whether somewhat weaker or stronger solutions, or even the pure drug, be used. (4) It does not coagulate albumin—a negative quality of high value physiologically, which pertains to no one of the antiseptics heretofore known. (5) It possesses an extremely high degree of diffusibility, permeates the interior of the eye like atropine, and acts similarly in other tissues.

It was recommended to be used in all inflammatory affections accompanied by the formation of pus. Conjunctivitis, urethritis, and inflammation of mucous surfaces were especially benefited, but it was also used with success in the treatment of ulcers and other suppurating wounds. Methyl violet failed to prove itself of particular value, and has fallen into disuse. In many instances favorable results were not obtained, and it frequently produced marked irritation. Its intense coloring properties also proved particularly objectionable. Probably its most important use has been in the treatment of inoperable malignant disease.

In 1891, Professor von Mosetig reported a number of cases treated by injections of pyoktanin, with very favorable results. For some time he had used the different forms of aniline as an injection, with the purpose of staining the nuclei of the cells and thus checking their growth, but the constitutional symptoms produced had always been a hindrance to the treatment. When Professor Stilling introduced methyl violet he at once began to use it for this purpose. The germ-destroying power of the agent, in connection with its diffusibility in healthy and diseased tissues, made it a very promising agent, especially as it was also harmless and devoid of any injurious effect on the human economy. The first case was in a woman, sixty-six years of age, with a large tumor of the lower jaw which prevented her from swallowing and caused great suffering. After thirty-five injections of 6 gm. of a 1 to 500, and afterward of a 1 to 300, solution, the tumor was so much reduced without ulceration that the patient could eat without discomfort. In the case of a man, fifty-eight years of age, with a cystosarcoma of the chest wall, measuring 13 cm. in width by 18 in length, after twelve injections of 6 gm. of a 1 to 300 solution, the measurements were reduced to 10 by 12 cm. In two cases of adenocarcinoma of the neck, the same treatment proved so effectual that the patients considered themselves cured. Another case was that of a woman, sixty years of age, with papilloma of the bladder; for which 20 gm. of a 1 to 1,000 solution was injected into the bladder every second day. After the injections there was notable improvement, the hæmaturia had ceased, and there was little or no pain. Professor Mosetig also cited a case of a man, sixty years of age, with an enormous sarcoma of the pelvis; colotomy had been performed. After sixteen injections of 6 gm. of a 1 to 500 solution into different parts of the mass, it had shrunk to one-half its former size, and the patient was greatly relieved and able to walk about for a few hours daily.

Since Professor Mosetig's announcement numerous cases have been treated and reported. The results have varied greatly, some surgeons claiming very remarkable cures, while others have failed to observe any signs of benefit, and look upon it as a perfectly useless procedure. The greater number of those who look with favor upon the treatment, including its author, do not claim that it is a curative agent for cancerous diseases, but simply that during its use the progress of the growth is checked, the local condition improved, and a temporary relief obtained. The following directions are given for its employment: Under proper antiseptic precautions the part is to be carefully curetted until all the diseased tissue that is accessible is removed. When there is no ulceration of the surface, the curetting is omitted. After the curetting, a tampon of iodoform gauze is placed in the wound and allowed to remain for forty-eight hours. The surface is then washed and carefully dried and the injections are made into the tissue, to the depth of the needle if necessary, according to the extent of the tissue involved. Other injections are made into the surrounding tissues, as many

Digitized by Microsoft®

www.libtool.com.cn

as fifteen punctures being made at one sitting. It is advised to begin with the deeper injections, in order to avoid a discoloration of the tissues on the surface in the early stages. After the injections have all been made, pure pyoktanin powder is introduced into the cavity, or gauze or cotton, medicated with it. The tampon is left in position until the second day, when it is removed and the parts are thoroughly washed and the injections repeated. The introduction of the solution exerts an analgesic action, and also checks the profuse hemorrhage that is frequently present.

Intrapulmonary injections have also been used for the treatment of pulmonary tuberculosis. The liquid employed was a 1 to 500 solution, of which eight to sixteen minims were injected. The injections are reported to have been well borne, but when the liquid penetrated to the bronchi, a violent attack of coughing was provoked. Therapeutically, it is said to have produced a lessening of the hectic condition and reduced the number of bacilli in the sputa. *Beaumont Small.*

PYRAMIDON—dimethyl-amido dimethyl phenyl-pyrazolon, dimethyl-amido-antipyrin, $C_6H_5N.N(CH_3)_2.CO.CH.NCH_3.CCH_3$—is a yellowish-white, tasteless crystalline powder, which is soluble in ten parts of water. With ferric chloride it gives an evanescent deep bluish-violet color, a distinction from antipyrin which gives a red color.

Employed in smaller dosage than antipyrin it has an antipyretic action like that body and a more sedative action on the nerves. Robin et Bardet found prompt relief in trigeminal neuralgia. Laudenheimer praises it in the pains of tabes, alcoholism, chorea, neurasthenia, and hysterical conditions. Pollak notes sweating and some flushing of the face, but reports the drug specially applicable in the hectic fever of pulmonary tuberculosis. Horneffer found it effective in facial neuralgia but not in sciatica. Bertherand ascertained that doses of 0.3 gm. (gr. v.) increased the coefficient of nitrogen elimination ten per cent. in eight days. In a diabetic who was excreting 2–3 gm. (gr. xxx.–xlv.) of sugar a day, pyramidon sent the sugar up to 15–20 gm. (gr. ccxxv.–ccc.); so it is contraindicated in this disease. This investigator found the profuse sweating an objection, especially in tuberculous patients. In sciatica he obtained good results from hypodermic injection. Albrecht was able to shorten and modify severe asthmatic attacks in emphysema by doses of 0.3 gm. (gr. v.) two or three times a day for several days. In pneumonia, typhoid, scarlet and other fevers the drug has been used with asserted good results. The dose is 0.06–0.65 gm. (gr. i–x.), and 3 gm. have been given in one day without ill effects.

The pyramidon camphorates, both the acid and the neutral salts, are preferred by some therapists in tuberculosis. Bertherand recommends these compounds for preventing the excessive sweating of pyramidon. The dose of the neutral salt is 0.5–0.75 gm. (gr. viij.–xij.), the larger dose representing 0.5 gm. (gr. viij.) of pyramidon; the dose of the acid salt is 0.75–1 gm. (gr. xij.–xv.).

Pyramidon salicylate is claimed to be especially valuable in neuralgia and rheumatism in dose of 0.75–1 gm. (gr. xij.–xv.). *W. A. Bastedo.*

PYRANTIN. See *Phenosuccin.*

PYRIDINE (C_5H_5N)—a liquid base present in coal tar and separated by fractional distillation. It is also obtained from bone oil, or Dippel's oil. It is a decomposition product of various alkaloids, and is present in tobacco smoke.

It is a colorless liquid, with a peculiar empyreumatic odor and pungent taste. It is very hygroscopic and mixes freely with water, alcohol, and oils. Its specific gravity at 32° F. is 0.9858. Pyridine resembles alkaloids in its property of forming salts with acids. In toxic doses pyridine is a powerful depressant, causing paralysis and death from failure of respiration. The blood is also altered and destroyed. Germain Sée has studied its action in various forms of asthma and recommends it when the disease is of a nervous origin. One drachm is placed in a saucer in a closed room, at a temperature of 68° to 77° F. In about an hour evaporation will have taken place, and the patient should then inhale the impregnated atmosphere for fifteen or twenty minutes, which may be repeated two or three times a day. The drug may also be inhaled by placing ten or fifteen drops on a handkerchief.

The drug has not, however, established itself as a remedy of much value, and is rarely employed in this country. It must not be confounded with pyrodine, which is a preparation of hydracetine. *Beaumont Small.*

PYROGALLOL: PYROGALLIC ACID.—Pyrogallol is a triatomic phenol, $C_6H_3(OH)_3$, producible by the action of heat on gallic acid, whence the common name "pyrogallic acid." It is official in the United States Pharmacopœia under the title *Pyrogallol*, Pyrogallol. It occurs in long flattened prisms, or in needles; colorless, odorless, but with a bitter taste. It dissolves in 1.7 parts of cold water, and very readily in boiling water and in alcohol. In solution, exposed, it oxidizes, turning brown. Pyrogallol possesses the poisonous property, more or less common to the group of phenols, of affecting the blood and bringing about hæmoglobinuria. Administered by injection to rabbits, this medicine has speedily caused chill, dyspnœa, tremor of the extremities coming on in paroxysms, and death. The urine in such cases has shown the characteristic features of hæmoglobinuria, and the blood has exhibited discoloration and destruction of the red blood corpuscles. In rapidly produced death by large doses, the blood has turned black or, in some cases, of a chocolate color and jelly-like consistence. In the human subject death has resulted, in one instance, from the application, to one-half the body at once, of a ten-per-cent. pyrogallol ointment. In this case a violent chill, with vomiting and collapse, set in six hours after making the application of the salve. The patient rallied, but forty hours later a second attack ensued, ending in coma, with great reduction of temperature. Death occurred on the fourth day. During the illness the urine was much diminished in quantity, and showed, in highest degree, the condition of hæmoglobinuria, being dark brown in color and, upon standing, depositing a thick sediment of amorphous, blackish material. The blood was found, post mortem, disintegrated, and the kidneys bluish-black and stuffed with the same material as the urinary sediment. Pyrogallol has been used in medicine almost exclusively as a local application for the relief of certain skin diseases, notably *psoriasis*—an application often successful when other remedies may have failed. Applied in solution or in ointment, pyrogallol stains the skin somewhat, but the stain speedily disappears. Linen clothing, however, may be permanently injured by the action of the medicine. To avoid this latter effect, a solution of pyrogallol in flexible collodion has been proposed (Elliot). Such preparation, when dried to a film upon the skin, seems still to exert the therapeutic action of the medicine, but, being dried, is without action upon the clothing. Pyrogallol may be applied in ointment or in solution, and strengths are used ranging from five to fifteen per cent. of the remedy. The higher percentages, in ointment certainly, may irritate severely, and should be used with caution. Applications should never be extensive at any one sitting, for fear of enough absorption to bring about constitutional poisoning. *Edward Curtis.*

PYROSAL—antipyrin salicyl-acetate—occurs in colorless crystals of acidulous taste and difficult solubility in water. It contains fifty per cent. of antipyrin and thirty seven per cent. of salicylic acid. Introduced by Riedel, this compound has been used as an antipyretic and analgesic in rheumatism, influenza, migraine, sciatica, etc. The action is prompt, and no untoward effects have been noted. The dose is 0.3–0.7 gm. (gr. v.–x.), repeated frequently. *W. A. Bastedo.*

QUARANTINE.—The term "quarantine" has its origin from the Italian "quaranta," meaning forty, this being the number of days for which vessels were, in the fifteenth century, held under observation on account of epidemic disease. It is now applied to what should more properly be known as maritime sanitation. In addition to this, it is also applied to restrictions against the advance of epidemic disease on land.

www.libtool.com.cn

While it may be fairly assumed that all who are in anywise interested in the subject of quarantine are already fully conversant with the history of such measures as have been taken in the past for preventing the spread of epidemic disease, nevertheless, for the sake of comparison with what is now considered proper, and to set forth more clearly the great strides which have been taken in sanitary science and in the methods employed in the exclusion of exotic disease, a short *résumé* will not be amiss.

It is generally understood that the quarantine which was established by Venice in 1403 for the exclusion of plague was the first systematic attempt to exercise any kind of surveillance over commerce for the conservation of public health. It may be remarked, however, that a species of land quarantine, namely, the isolation of lepers, was certainly existent fourteen centuries before that time, possibly at a much earlier period.

The general idea in the fifteenth century seems to have been that no measures of purification were indicated, but that detentions for a period of forty days would suffice to allow the disease to die out; and in truth this was what frequently happened. The unfortunate individuals comprising the *personnel* of a vessel in quarantine had to take their chances, and these were admittedly slight, of escaping the scourge while they were huddled together with its already stricken victims, the authorities believing that the lives of a few were well sacrificed in the interest of the many, and that their duty ended with providing food for these unfortunates and keeping them within fixed bounds.

The foregoing statement may be said to sum up the maritime quarantine system as it existed five hundred years ago. Of land quarantine there seems to have been none, or, if it existed at all, it was of the same brutal character as that applied to the shipping.

When the bubonic plague swept over Europe with such appalling results in this same fifteenth century, the people fled unrestrictedly from any stricken community and scattered death in their wake. Abject cowardice and sublime courage shone out in vivid contrast to one another.

Coming down to more recent times, we find that as late as 1850 a very nebulous idea held sway in the minds of men as to proper methods for preventing the ingress of pestiferous diseases, and the forty-days detention period which was instituted by Venice four hundred and fifty years before, and which Spain adopted against yellow fever from the West Indies a century later, was still in vogue and constituted practically the sole maritime guard of most states against disease; while, on the other hand, some few advanced communities, in sheer disgust at measures which, while destroying their commerce, gave no adequate protection against the ravages of yellow fever, smallpox, and cholera, the preventable diseases then uppermost in men's minds, had thrown off all restraints and were willing to risk the disasters incident to an epidemic, rather than the ills of ruined commerce. And this indeed was a rational decision; for, however we may view the matter from a theoretical standpoint, the question practically put is this: Can a community better afford to take a slight or even a pronounced risk of disease which will destroy a certain percentage of its population, than to take the risk of commercial death which will annihilate it as a community? The former risk is the more rational, and especially when we bear in mind that all quarantine must of necessity involve a certain feature of necessary risk; for, even were it possible to evolve an absolutely safe system, no community would allow such a system to stand, involving as it would most serious hindrances to commerce.

One of the most talented editors of the American press, some years ago, denounced the then existent system as "sanitary savagery," and we must admit that there is some justification for this appellation.

The sole aim, the very *raison d'être*, of a quarantine is the exclusion of exotic disease. If it does much less than this it fails to fulfil its obligations to the community; and, by doing more than this, it retards commerce, interferes with legitimate vested right, and becomes an object of well-merited aversion.

Quarantine is the sanitary vidette and skirmish line, and it may, and often does, fail to keep out exotic disease even though carefully and scientifically conducted. Nothing short of correct laboratory methods (absolutely inapplicable to practical quarantine) could under all conditions exclude disease. Such being the case, we must view a proper quarantine, to express the matter in homely parlance, very much as a sieve, which will exclude the major part of the solids from a given volume of water passing through. Now, if we apply such a sieve to a river, so long as the water can pass by, leaving behind most of the detritus carried in suspension, all will be well; but substitute for that sieve an impervious dam, and so surely as you do, that dam will be swept away. So, likewise, if we place a quarantine of scientific accuracy at the gateway of any of our large commercial cities, we shall have built practically a sanitary dam, and we shall soon find that commerce, having submitted to what it considers a reasonable amount of obstruction, will refuse to accept further restriction, and our sanitary dam will be swept away by the overwhelming outflow of public opinion, which will, rightly or wrongly, tell us, and tell us in unmistakable terms, that the public is willing to take some slight risks for the sake of commerce, and does take these risks, and will not submit to any system which seriously interferes with the community's means of obtaining a livelihood.

We must bear in mind that while the sanitary aspect of a quarantine is undoubtedly of primary importance, commercial interests demand and should be granted consideration in such matters, and while commercial interests are secondary, they are entitled to careful thought; for we must not forget that the condition brought about by a stoppage or even a slowing of business in any large community means suffering and privation to thousands. When you stop the wages of the breadwinner, you inevitably, though indirectly, produce sickness, the very thing we propose to prevent, and it matters little to the victim whether that sickness be of an epidemic or a non-epidemic character.

When, in the early eighties, the Marine Hospital Service assumed the small quarantine functions previously assigned to the National Board of Health, and with these functions took over the quarantine stations which had been established by the National Board of Health at Ship Island, Mississippi, and Blackbeard Island, Georgia, the system of long-drawn-out detention, plus a fumigation with sulphur dioxide and some spraying with solution of bichloride of mercury, was still in vogue; but there was no clearly defined idea as to how, or why, or when things should be done.

Dr. A. N. Bell, who was at the time an officer in the United States Navy, had indeed in the fifties made a most valuable contribution to sanitary science in the shape of a report of the disinfection done by steam on board a United States man-of-war, which had become infected by yellow fever during a cruise in the West Indies, but no one seems to have taken any particular interest in the matter, and it had been practically forgotten until about 1883, when Dr. Joseph Holt, of New Orleans, the president of the Louisiana State Board of Health, inaugurated a system of disinfection near the mouth of the Mississippi River, the mainstay of which was the application of steam. It is probable, however, that the first really scientific application of live steam to the disinfection of textiles, etc., was made by Dr. H. R. Carter, Surgeon of the United States Marine Hospital Service, at the Gulf Quarantine, Chandeleur Island, Mississippi, in 1888.

Digitized by Microsoft®

He there demonstrated the principle that steam, to be practically effective, must be diffused through the matter to be treated (must circulate), or else that a vacuum must first be provided to insure the penetration of the steam, as otherwise there would be dead air spaces in which only dry heat of not more than 90° C. would be secured; in other words, these areas would not really be disinfected.

www.libtool.com.cn

Dr. Carter, at the Gulf Quarantine, and the writer, at Blackbeard Island, Georgia, were during that year simultaneously working toward the same end, and endeavoring to bring about improvements which establish the following basic principles that are now, it is believed, universally acknowledged:

1. That a suspected ship must—if we wish to make sure that she shall do no harm—be considered to all intents and purposes as an infected ship.

2. That members of the *personnel* must be removed from possible infection as soon as practicable after the ship arrives in quarantine.

3. That so far as the ship itself is concerned, it is as free from danger five minutes after the completion of a proper disinfection as it would be in five years.

4. That the longer the ship lies without disinfection, the more infected, other things being equal, will she become.

5. That the period of incubation of the given disease having elapsed since the person was removed from possible exposure, such person can safely go at large.

These hypotheses all seem very plain and simple. Doubtless they are at the present time, but prior to the time mentioned, as a survey of the then exising state of municipal quarantine regulations will show, it had been at many places the custom to detain a vessel from a yellow-fever port for anywhere from fourteen to forty days, and to disinfect her at some time during this detention, no particular time being stated.

To Dr. Joseph Holt, of New Orleans, belongs the credit for the first real awakening to the fact that quarantine should mean sanitation and not punishment of the unfortunate victims of epidemic disease.

To Dr. H. R. Carter belongs the credit for the enunciation of the principle that detention of persons under observation must be rational, and must of necessity follow their complete disinfection or, to state the matter more clearly, their complete removal from sources of infection; that, scientifically speaking, detention applies alone to *personnel*, and not to inanimate things; that such detention need be only for the period of incubation, and must be for the *full period* of incubation. He worked assiduously to inculcate these ideas, and succeeded.

Another point of interest in quarantine, as it existed in the eighties, is the absolute inadequacy of the appliances for disinfection and for the general handling of vessels. It is true, as above stated, that Dr. Bell had, in the fifties, proved the adequacy of steam disinfection extemporaneously applied, and that Dr. Joseph Holt, president of the Louisiana State Board of Health, had announced and proved his idea of steam disinfection.

These ideas, however, were slow in taking root; and, as late as 1890, there were only three quarantines equipped with steam disinfecting apparatus. It was about 1890 that Dr. Oliphant, of New Orleans, the then president of the Louisiana State Board of Health, and Dr. Kinyoun, of the Marine Hospital Service, promulgated the idea of generating sulphur dioxide by a furnace and obtaining a higher percentage than the 4.5 per cent. (by volume) of the gas obtainable by the pot plan.

The foregoing is an amply sufficient summary of what quarantine was.

The system now in practice under the administration of the United States Public Health and Marine Hospital Service and of the most advanced State authorities is, like almost all institutions which have arisen under the ægis of our race, a conservatively constructed plan, arrived at by slow, steady advances, by careful trial of methods, by rejection of unfit and acceptance of well-proven methods, and with the end constantly in view that every protection must be given to the people, but that nothing should be done which will unnecessarily hamper the commerce of the nation or of any local community.

All methods of disinfection are thoroughly tried in the Hygienic Laboratory, and, if proven acceptable there, are then given what may be termed a field trial, *i.e.*, a test under very practical conditions, but under the eye of scientists who are able to determine their exact value. Careful investigations are made into the nature of the various infectious diseases, and the findings of all scientists regarding their causative agencies and methods of propagation receive thoughtful consideration by those who are working out the problem of how to deal with each upon the arrival of a ship in quarantine infected therewith. These investigations are going on day by day without ceasing, to the end that nothing shall be done that ought not to be done, and nothing left undone that ought to be done.

No other of the great powers has such strong reasons as the United States for the establishment and maintenance of a strict system of maritime sanitation, for the reason that no other nation of prime importance has at its very doors an endemic disease (yellow fever) constantly demanding admission. It is true that cholera and plague do on occasion threaten the nations of Europe, but this is at long intervals. One result of this necessity for vigilance has been a largely increased interest in such matters, and, as the outcome of this interest, there has been established by the United States a system (not as yet perfect or general, but widely distributed) of foreign inspection of vessels and *personnel* bound for the United States. That this foreign service is valuable there can be no denial; but equally certain is it that it can only be an outpost, and must be strongly backed up by a thoroughly efficient service at our own ports.

The United States Public Health and Marine Hospital Service has, at the present writing, inspectors stationed at the principal ports of China, Japan, the Island of Cuba, Mexico, and Central America, and it has also in the past, as occasion demanded, placed inspectors at various other ports. It is the policy of the service to meet, by detailing inspectors to that point, any exigency which arises in the shape of epidemic disease at any given point, and which threatens the sanitary integrity of the United States. As illustrative of the latter statement, it may be said that during the major part of 1893 the service had twelve medical officers stationed at those European ports from which the passenger traffic to this country was heaviest. In addition, the State of Louisiana has inspectors at West Indian and at several Central American ports, which they deem it advisable to watch on account of the large commerce between those ports and their own. As the writer has had no accurate knowledge of State inspection and the work of State inspectors, he will limit this discussion to the subject of national foreign inspection.

At Havana, Cuba, the Marine Hospital Service, for several years before the Spanish War, maintained an inspection service which was of great value to commercial and sanitary interests in that it gave data to the consul-general upon which to issue bills of health, which data, as a whole, formed an abstract of the sanitary condition of the port and vessel, and enabled quarantine officers to decide more promptly than they otherwise could, what treatment should be accorded each vessel upon her arrival in this country. It is well known that the Southern ports and New York placed great reliance upon this Havana bill of health.

At the beginning of the Spanish War this inspection service was, of course, discontinued, but at the close of that war there was established in the whole island of Cuba a regular system of maritime quarantine, providing for the inspection and disinfection of both incoming and outgoing vessels, which system was as near perfect as circumstances would permit; and this was continued until the spring of 1902, when, the Cuban Government assuming charge of its own functions, the quarantine was turned over to them, and the system of inspection which had hitherto existed was resumed.

Digitized by Microsoft ®

The same class of work is now done at other Cuban ports as at Havana, and while the Havana inspection is the most important one in the inland, others are none the less valuable as giving a clean-cut idea of the status of the port and ship on the day of sailing.

The inspectors in Europe in 1893 had the difficult task of endeavoring to prevent, by strict surveillance of ports, ships, and passengers, the introduction of cholera into the United States. Whether or not this effort was worthy of being made may be judged by the facts. Two ships brought each from Europe with them cases of cholera to the United States. While this was all that came to our shores, the non-inspected ships from Europe for South America, Africa, and other continents at times had many victims of cholera, and it is doubtful if there be any sanitarian who has been interested in such matters who does not remember the dreadful state of affairs aboard the unfortunate Neapolitan steamers bound to Rio in 1893. The facts are quoted from a report written at the time from Naples:

"The four for South America, with the result in each case, were as follows: The figures are not official, but are practically accurate in every respect. All were turned back by the South American authorities: *Vencinzio Florio*, about 50 deaths; *Andrea Dorio*, 90 on way out, total not ascertained; *El Remo*, 84 deaths; *Carlo R.*, about 230 deaths.

"To summarize, then, eight ships left Naples. The water supply was the same and the food about the same; the class of passengers identical, and their places of origin similar, in many cases identical. All four leaving [for South America] without precautions became floating pest-houses. Of the four for the United States, the one leaving before cholera appeared in Naples had three deaths; the other three were made to conform to the regulations, and all escaped."

The benefits to be derived from foreign inspection, however, are not by any means comprised in the present statement of what has thus far been accomplished by this agency. An honest and well-trained sanitarian at each port, which by virtue of its unsanitary surroundings menaces our health, if he be provided with the necessary authority, can and will do a great amount of good; possibly, nay probably, not what the general public may expect, certainly not an absolute sanitation of departing ships, obviating all necessity of quarantine at home, but work of great practical value none the less. Under no condition should we accept a bill of health from these inspectors as pratique; such bills should only be construed as information, and, when properly made, as extremely valuable information.

Inspectors should have the several duties of, first, keeping themselves posted, not only as to the health of the city where each is located, but of all the country commercially tributary to that city; second, reporting at stated intervals to the home office any facts bearing on the possibility of the introduction of disease from their ports, and in extra emergencies they should make cable reports of such facts; third, supervising all vessels, cargoes, and passengers for the United States in times of actual epidemic; fourth, collating and submitting for the benefit of the health authorities at home new facts on the subject of State and municipal sanitation independent of epidemic disease; that is to say, new ideas as to drainage, sewerage, irrigation, and ventilation, and all such other matters as may bear upon the public health in any way whatever. In a word, these inspectors should develop, for sanitary purposes, as has already been done for business purposes, a full-fledged system, a medical consular system, if you choose to designate it, which may gather unto itself all matters which may in any way help us to attain to the end we have in view, and let that end be the conservation of the health of this nation. To accomplish this there is only one path open. It is assumed, in the first place, that to enable an inspector to enforce his demands and be something more than a mere spy upon commerce, much authority is needed. This authority can be conferred only by the national Government, and by it only through treaty with the nation whose ports we should inspect, unless we evade this by having our inspectors appointed deputy consuls, or by having them serve in the office of the consuls as, under the law of 1893, was done in Europe, and is now done in the tropics. Inspectors, then, to have authority, must be national inspectors, because even though their reports and their work are public property and would be for the public weal, their work is not intended alone to benefit Louisiana or New York, Massachusetts or Georgia, but every State in the Union. Ohio and Kansas have as much interest in the health of the nation as any seaboard State, and only by national service can the whole nation be fully and equally served at an equal cost to all. It is not certainly known to whom belongs the credit of first using this very valuable adjuvant to an efficient quarantine service, but it is reasonably sure that it was inaugurated by the State of Louisiana, and when we have come to learn the full value of a rightly applied foreign inspection, it is fair to say that the whole nation will owe a vote of thanks to that State.

Let us practically illustrate some of the workings of an inspector abroad, from both a sanitary and a commercial standpoint. In September, 1893, becoming cognizant of the presence of the cholera spirilla in the Elbe River at Hamburg, and consequently expecting an outbreak of cholera, the inspector began to put all emigrants for the United States under observation, and confiscated all foodstuffs whose history was not clearly known. After taking away about twenty-five bushels of such food from a lot of five hundred and seventy-five people bound for New York he permitted the vessel to sail. A case of cholera developed on the second day out. It was afterward clearly shown that this case developed from the eating of a piece of sausage which an emigrant had concealed in his shirt bosom. Now let us suppose that nothing had been done with these people; that they had not been kept under observation; that they had been allowed to take their twenty-five bushels of possibly infected foodstuff along with them, and then let us conjecture how many cases might have developed, if one developed from one joint of sausage. This is cited to show what it is believed any fair-minded man will concede, viz., that even though there are occasional errors of omission (and such will occur in all inspections), an inspection is of immense value. With the exception of the instance just narrated, and one other of a similar character, infection occurred only on one ship out of the hundreds which were given bills of health in Hamburg in 1893, and all ships sailed on time. This result forms a striking contrast with the cases of the vessels bound from Naples to South America.

Now, as to the commercial aspect of the matter. Upon the beginning of the inspection work on April 1st, 1893, it was found that a majority of articles were being subjected to a so-called disinfection—one that was absurd, uncalled for, and in some instances fraudulent, not a true disinfection in any sense; that other articles were being shipped which it was impossible to disinfect and which should not have been allowed shipment. The report of the Chamber of Commerce was promptly obtained, and from that was drawn a full list of all articles ever shipped from Hamburg to the United States. From this list the following classification was made: "A," articles to be shipped free from any inspection; "B," articles requiring a permit from the inspector and possible disinfection; "C," articles which must be disinfected; "D," articles forbidden shipment on account of the impossibility of disinfecting them. Disinfection establishments which did a reliable disinfection were then sought out and specified, and their certificates accepted. At the hour of sailing the ship was boarded and her custom's manifest presented for inspection. This enabled the inspector to see at once of what her cargo consisted. One ship only was held, and compelled to discharge her forbidden cargo; but during the remainder of the year 1893 no other such trouble occurred. The shippers expressed themselves as gratified at the facilitation of their business by, first, an exact knowledge of what they were to do or not to do; second, by the removal of an embargo on

Digitized by Microsoft®

many articles; third, by a lessening of expenses incurred through unnecessary disinfection. Although the system has been discontinued since December, 1893, the good results of this European inspection have not altogether ceased up to the present moment. One of those results was the establishment, by German authority,—at Spandau and subsequently at Tilsit and Illowa, the latter two on the Russian frontier—of stations for the cleansing of persons and baggage of the hunted and hated Russian Jew. These stations handle nearly all of that class, and, in the event of another outbreak of cholera in Russia, they will be of untold advantage both to the emigrant and to the public. It is not unfair to claim that these stations would not have been established except for the example of American inspection abroad. A system almost identical with that at Hamburg was pursued in Bremen, Antwerp, Rotterdam, Havre, Naples, and in the chief ports of Great Britain, and it is a matter of history that only two very slight infections developed aboard ships, although three hundred thousand people were inspected, kept under observation, and embarked during the period alluded to.

We are compelled to admit that we cannot remedy the sanitary condition of any foreign port except in so far as criticism may serve to arouse a sense of shame in a municipality, just as the same weapon might compel a dirty boy to wash his face.

Of course, after the actual outbreak of disease, we can, by delaying the commerce of the infected town, compel the authorities to remedy, in some measure, the defects; but it is doubtful if we could accomplish this except at such a time, and then it would be too late.

Finally, it is probable that our strongest protection lies in stationing the best available men as inspectors at all such ports, and by this means obtaining timely warning of approaching danger. Then, when the disease arrives, we should be ready to fight it with the most approved appliances known to modern science, operated by the most skilled physicians the Government can assign to this work.

We now come to the discussion of what a maritime quarantine under the best modern conditions actually is, how it should be equipped, and how operated.

The Quarantine Itself.

In the selection of a site for a quarantine station, the following points should be borne in mind: The station should be accessible to incoming vessels, and should deflect them from their regular course, in coming into port, only to the minimum extent. There should be as great a depth of water at the quarantine station as the maximum draft of vessels entering at that port. It should be so far away from the port as not to be in the way of the further growth of the city, thus preventing any necessity for the future removal of the station, and also avoiding antagonism of public sentiment. A quarantine plant, to be complete in all repects, should comprise:

1. Boarding Facilities.—The necessities vary from a small rowboat at some stations to an able seagoing tug at others. It may be stated as a general rule that for a land-locked station, south of the territory in which harbors become icebound, a good, stanch naphtha launch, not only will suffice for boarding purposes, but will be preferable to almost any other type of vessel, because of the ease with which it can be handled.

2. Anchorages.—At a complete quarantine station two anchorages should be provided, one for infected and one for non infected vessels, and they should be sufficiently removed from one another to prevent vessels undergoing inspection at the non-infected anchorage being infected from the other, or infected anchorage.

3. Disinfecting Plant.—The disinfecting plant may be either on a wharf or on a floating platform. It is believed that, other things being equal, a wharf is superior to the floating platform, and that the latter should be resorted to only where natural conditions interfere with the erection of a proper wharf or make such construction too expensive. The disinfecting plant itself should consist of: (1) Steam disinfecting chambers; (2) means for generating sulphur dioxide; (3) machines for generating formaldehyde gas; (4) vats for holding disinfection solutions; (5) large, air-tight wooden chambers for the application of gaseous disinfection to large quantities of material; (6) force pumps for applying disinfecting fluids.

Steam Disinfecting Chambers.—The probably most effective and mechanically as well as scientifically most perfect steam disinfecting chamber in use to-day is what is known as the Kinyoun-Francis steam chamber, devised by Dr. J. J. Kinyoun, with the assistance of Mr. Francis, of the Kensington Engine Works, of Philadelphia. When, as is now generally done, there is attached to this chamber a formaldehyde retort, it becomes a doubly useful appliance. The chamber is provided with an ejector which will produce a vacuum of fifteen inches in the largest-sized chamber—a chamber, for example, approximately five feet in diameter and sixteen feet long—in one minute. This is, according to the observation of the writer, about five times as rapid work as can possibly be accomplished in the production of a vacuum by the ordinary air pump. The chamber is double-jacketed, and by a system of pipes and valves the steam may be forced through the chamber in various directions, causing a circulation of steam, and resulting in increased efficiency in disinfection. When it is desired to use formaldehyde from the retort attached to the side of the chamber, a vacuum is produced, the pressure raised in the formaldehyde retort to about sixty pounds, and the valve leading into the vacuum barely opened. It should not be forgotten that if the valve is opened wide, the fluid contents of the formaldehyde retort will be carried over into the chamber, thus spoiling the articles to be disinfected. Lack of space forbids a more thorough description of this apparatus, which has been exhaustively described by Dr. M. J. Rosenau ("Disinfection and Disinfectants," p. 57, *et seq.*).

Means for Generating Sulphur Dioxide.—The sulphur furnace mentioned above, which was invented by Dr. J. J. Kinyoun, then a medical officer of the Marine Hospital Service, was designed to meet the existing demand for a greater percentage of sulphur than could be produced by the pot method, and in careful hands it is capable of generating a much larger percentage of sulphur dioxide than the pot method does. It has now, however, been very definitely ascertained that such large percentages of sulphur dioxide are not only unnecessary, but are so destructive in their action as to render it inadvisable to use them; consequently, the much simpler method of placing the required amount of sulphur in an ordinary pot, which in its turn is placed in a vessel of water, and the sulphur then lighted by the use of a few ounces of alcohol, has largely superseded the furnace and answers every purpose.

Machines for Generating Formaldehyde Gas.—(1) Autoclave under pressure. (2) Retort without pressure. (3) Generator, or lamp.

The above-mentioned three methods are given, and all of them, within their proper limitations and properly used, are effective. It may be well to say that, as a general rule, formaldehyde disinfection should be confined to small spaces, and not undertaken in such large compartments as the hold of a vessel, something like two thousand cubic feet of air space being the maximum limit wherein efficiency can be attained. In addition to the three appliances mentioned above there is a means, which has previously been mentioned, of applying formaldehyde and dry heat in partial vacuum in a steam chamber.

Tanks should be provided for holding solutions of carbolic acid, bichloride of mercury, permanganate of potash, or other solutions which may be desirable for use at the station.

Air-tight wooden chambers for the application of gaseous disinfectants to large quantities of material consist simply of an ordinary room having but one door, which is adjusted to fit as tightly as possible. The room itself should have a triple lining; it should be ceiled first with wood; then upon this should be placed a lining of tarred

Digitized by Microsoft®

paper, and finally over this should be fastened a tightly fitting wooden ceiling. In this are arranged racks and hooks for spreading out or hanging up the articles to be disinfected.

Force pumps are simply ordinary Worthington or other pumps of equal force, made to resist, so far as possible, the action of bichloride of mercury.

www.libtool.com.cn

Detention Barracks.—There should be provided at every quarantine station adequate quarters for the comfortable housing, without crowding, and for the segregation, if necessary, of such a number of people as may ordinarily be expected to be held in detention at any given time. These quarters should be, as elsewhere stated, very thoroughly screened to prevent the ingress and egress of mosquitoes, flies, and other insects. The plumbing should be of the best and the sewers should be so arranged as to make it possible entirely to disinfect the dejecta. The kitchen, which is to provide food for the occupants of these quarters, should be far enough away to prevent any possible risk of contamination of food; and at the same time arrangements should be provided for the disinfection—before they are returned to the kitchen—of any food carriers which may be used in the barracks or hospital.

A steam laundry is a very useful adjunct to this portion of the station.

Crematory.—The station should be provided with a crematory capable of handling a human body in a decent and proper manner, or of disposing of any contaminated material which is deemed to be beyond the reach of mere disinfection.

Inspection of Vessels.—Experience has demonstrated that, prompted by anxiety to avoid delays and to save expense to owners, the average ship master has no compunctions of conscience regarding deception, and will often deceive the boarding officer if he is not very acute. In view of this fact, many of the ablest officers in the national service make it a custom to indulge in cursory inquiries and to stroll about the ship for a few moments, asking apparently careless questions of subalterns and crew, before beginning the regular inspection. The writer on one occasion found a man in his bunk (convalescent from yellow fever), who subsequently stood in line for inspection and declared himself well.

After such a cursory glance at ship and personnel, it is customary to call for the ship's papers, including the bill of health which, under the law of February 15th, 1893, all vessels entering a port of the United States must bring from the United States consul at the port whence they sailed. The captain, and the ship's surgeon, if one be carried, are then carefully interrogated as to the minutest details of the voyage, and as to the health of the crew and passengers, if the ship has within recent date come from a suspected port. All hands are then mustered and compared with the ship's papers.

This muster is one of the choice occasions for deception by the master. He may report any missing man as being on duty with the engines, and, if told to send a substitute to duty and bring the man, will even endeavor to pass off upon the inspecting officer a man already before him. In dealing with the fire-room force of an Atlantic liner (often one hundred and fifty or more) the inspecting officer must remember that this is a trick easily accomplished.

When the inspection of the *personnel* has been completed, it is then necessary to go through the whole ship, and especially those compartments devoted to the occupancy of crew or passengers. Every hole and corner in every compartment is to be searchingly investigated. If any inspection is needed, an absolutely complete one is an imperative demand. Firemen have been known to put their belongings in the firebox of a boiler which was temporarily disused, and cover them with cinders. In view of the known occurrences of this kind, it is absolutely necessary to use the most stringent care in searching every possible hiding place, and to bear in mind another fact which, while well recognized by most quarantine officers, seems beyond belief, viz., that the article most likely to be so hidden is *always that which with greatest certainty is infected*.

The clothing of a man dead of communicable disease was secreted by his comrades in the furled sails of a bark at the South Atlantic quarantine, and only the large and badly distributed bulk opened the way for its discovery.

Fortunately, cargo is, as a rule, composed of new goods, and it is therefore hardly probable that it contains any infection. Indeed, while I am not as yet willing to subscribe absolutely to the innocuousness of cargo, I must admit that it is likely to come up for serious consideration only as regards one particular; I refer to the question of food-stuffs coming from some cholera centre. These food-stuffs, however, are not, as a rule, of such a character that they would be likely to transport the comma bacillus in a living state across the Atlantic Ocean. An examination of the ship's manifest will, therefore, show fairly well whether there is a necessity for taking any measures regarding cargo, and such measures belong to the disinfection rather than the inspection of the vessel.

Food and water supply should be investigated if such a disease as cholera is aboard, and water supply alone for mosquitoes if yellow fever is found. In the absence of either, no attention need be paid to these supplies.

Ballast has long been a bugaboo at Southern quarantine stations, and the writer confesses to having been at one time a strong believer in the transmission of yellow fever through *infected* ballast, but he is now fully convinced (through the findings of the Army Yellow-Fever Commission) that yellow fever cannot be conveyed through the medium of clean, *dry* ballast, of the character ordinarily used, be it either rock or sand. Nor would there be any danger in sea-water ballast in tanks.

There is probably no doubt that dirty and damp rubbish might convey plague or cholera, and even yellow fever by serving as a brooding place for mosquitoes; but clean, dry rock or sand would almost certainly convey nothing of an infectious nature. Dirty rubbish ballast should be debarred at all ports, and ships which insist on bringing such stuff should pay the penalty of disinfection.

The inspection of ballast and the determination of its character are, as a rule, easy of accomplishment. If the inspection satisfies the quarantine officer that the vessel can be admitted to entry without jeopardy to public health, she is given pratique and concerns him no further. If, however, it is decided that she is infected, measures appropriate for the eradication of the disease with which she is known to be infected must be taken.

In order that we may properly consider what measures are necessary for the correct treatment of a vessel infected with any given quarantinable disease, a brief *résumé* of the salient points of each of these diseases will be in order, such *résumé* to include, so far as is possible in each case, the period of incubation, the actual cause of the disease, the characteristics and viability of the causative micro-organism, when known, and its manner of spread. Symptoms of diseases will not be considered, such being out of place in an article of this character.

Yellow Fever.—Considerable space will be given to the discussion of this disease because, as above stated, it is the one perennial threat against the Southern borders of the United States. Its period of incubation varies from a few hours to five days, and in a few rare instances slightly more than five days. Its cause is as yet undetermined. Its method of transmission has, fortunately, been determined to be through the medium of the mosquito, and that it is most probably not conveyed in any other way. It is now known, therefore, that yellow fever is not a contagious disease in the same sense as scarlet fever or smallpox is contagious. Consequently there is no danger to be apprehended from a yellow-fever patient, provided the presence of the mosquito can be entirely excluded. It is evident, therefore, that our whole effort in prophylaxis against yellow fever must be devoted to the exclusion, and, wherever possible, to the extinction, of this insect.

In view of the recent findings of the Army Yellow-Fever Commission, to the effect that yellow fever is con-

Digitized by Microsoft®

veyed from man to man solely through the agency of an intermediary host (the Stegomyia fasciata), it becomes at once necessary to inquire what bearing the acceptance of these findings in their entirety will have upon the question of precautions to be taken against the admission of yellow fever into our ports.

www.libtool.com.cn

Vessels should be inspected now before they leave the yellow-fever port and all mosquitoes destroyed.

The Public Health and Marine Hospital Service, fully alive to the importance of the facts above stated, has stationed officers at foreign ports to do this work wherever it can be done without conflict with the laws and regulations of the place. It will not do to assume that vessels cannot carry mosquitoes, as some have asserted; as a matter of fact, they do carry them. Thus, for example, one vessel, the *Maria Blanquier*, arrived at Sapelo Sound, Georgia, after a voyage of about forty days from Rio, with myriads of Stegomyia fasciata aboard, and it only needed that she should have had one case of yellow fever in Rio to have had every soul on board stricken en route, and the vessel (short-handed) be perhaps a castaway.

To sum up, then, we find that the disinfection of vessels from a yellow-fever port, and only a few days out from such port, is still necessary, and that such disinfection should compass the *entire* destruction of all mosquitoes on board the ship. The best means to this end will be a gaseous disinfection by SO_2 of not less than four per cent. volume strength for a period of at least six hours, and better twelve. This disinfection should be carried out simultaneously in all parts of the vessel, and scrupulous care should be taken to see that the fumes reach *all* dead air spaces, and particularly all parts of the living apartments.

If a vessel has been away from a yellow-fever port for more than ten days,—*i.e.*, several days beyond the incubative period of yellow fever,—and if at the same time a well-authenticated history of no sickness en route has been obtained, it would be very natural to assume, especially if the Stegomyia had not been found in the vessel, that she was not infected and that consequently she might safely be allowed to pass on without subjecting her to a process of disinfection. The records, however, show plainly that it is not always safe to reason in this manner. Thus, for example, Surgeon H. R. Carter, of the Public Health and Marine Hospital Service, has published in Bulletin IX. of the Yellow-Fever Institute, July, 1902, a report of a number of instances in which yellow fever was apparently contracted on board an infected ship. Owing to the lack of space I shall be able to quote only one of the instances mentioned in this report.

"III. British ship *Avon*, in rock ballast: twenty-two in crew, four immune to yellow fever. Sailed from Rio de Janeiro April 20th. All well in port and en route until thirty-eight days out, when a boy in port watch sickened with yellow fever. Taken to hospital, Gulf Quarantine, on third day, and died on sixth day. Another case developed two weeks later in a quarantine attendant who helped me clean up the room, sail locker, in which the boy was sick aboard ship.

"It is remarkable that there should have been only one case of yellow fever among the crew aboard this vessel. At the time, it was ascribed to the fact that this boy, the only one on the port watch, helped a man, shipped in Rio de Janeiro and immune to yellow fever, overhaul his chest a few days before the boy was taken sick. Whether there was an infected mosquito in the chest which had survived this length of time, or whether there was any relation between the chest and the fever, may be a question. It in no wise affects the present question that the disease was contracted aboard. It was the first case seen at this station that year."

Cholera.—The period of incubation of this disease is from a few hours to five days; more often it is about three days. The cause is the comma bacillus of Koch, now generally known as the Spirillum choleræ asiaticæ. (For details in regard to this disease see the article on *Asiatic Cholera* in The Appendix.)

The manner of spread of this disease, the introduction of which into the human system is by the alimentary canal, is through the medium of dirty hands, polluted food, polluted water. Both food and water may be polluted, and probably are, by flies, which, having come into contact with cholera dejecta, subsequently make their way to the food supply. These insects probably played an important part in the great epidemic of cholera in Hamburg in 1892, after the disease became general in the city, though in the beginning it undoubtedly arose from the presence of the spirillum in the main water supply of the city, the Elbe River, and it was the ultimate correction of this water supply which had more to do, than any other one factor, with the wiping out of the disease. In fact, it appears doubtful whether more than occasional cases of cholera would occur in any community where the water supply is guarded with great care. It is not simply through drinking it, however, that individuals may contract cholera from infected water; they may also acquire the disease by eating fruits and vegetables which have been washed in such infected water.

Bubonic Plague.—The period of incubation of this disease rarely exceeds seven days, and is more generally from three to five days. The cause is the Bacillus pestis, a short rod which is capable of bipolar staining with aniline dyes, and whose viability and general characteristics have been well stated by Dr. M. J. Rosenau in his work on "Disinfection and Disinfectants." It will suffice here to state that it survives in moist and albuminous surroundings for quite a long time, and in test tubes in laboratory work for months and even years. It dies quickly when dried, but retains life longer when dried upon textiles and other similar fomites than in any other form of dryness, especially if the temperature is under 19° C. It is, therefore, to be borne in mind that the colder the climate the greater is the danger to be feared from infected fomites, and the more thorough should be the procedures adopted for effecting disinfection. A dry atmosphere and sunlight kill the bacillus quickly, and inversely, darkness and damp atmospheres promote its vitality. It is not a water-borne infection, though it may live for a time in water. It is largely spread to man through the agency of rats, fleas, flies, and other small animal life. It therefore follows that, to disinfect for plague, it is necessary to use such agents as will destroy this small animal life, as well as the plague organism itself.

The past history of this disease, although it has been written in a very unsatisfactory manner, is nevertheless sufficiently full to indicate that it has probably obtained a foothold in communities, in almost every instance, for a relatively long time before it has been recognized. It may be that it has existed among the rats and other animals for many months before any human being has become infected thereby, and a study of all the great epidemics of plague will indicate that it has existed among men for a very considerable period of time before it has been recognized as plague, and before measures have been taken to prevent its spread. There is little doubt that the great plague in London did not occur within one month or one year after the disease first gained a foothold in that city. It appears very probable that it had already been there for several years, slowly and steadily gaining a foothold for the great outbreak. Again, it is apparent that in the beginning of an outbreak this disease is more mild in character than later on in the epidemic. This characteristic has been observed in the case of yellow fever also. There are apt to be mild, so called ambulatory cases, which would not be recognized as plague under any other condition than that of an active epidemic, and these may spread the disease just as surely as a virulent case; and it is these which doubtless do spread the disease from person to person and from place to place long before there is any general recognition of its existence.

Smallpox.—The incubative period of this disease has been variously stated as being from five to thirty days. These wide limits, however, are exceptional, and most authors agree upon an incubative period of from ten to twelve days in a majority of cases. An experience extending over many hundreds of cases justifies the state-

Digitized by Microsoft®

ment that in at least ninety per cent. of all cases, the initial fever of the disease will begin in approximately ten days from the time of exposure, and will hardly vary twenty-four hours from this time. The causative agency of this disease is not known. Its mode of transmission is generally through actual contact with a person who has the disease in the eruptive stage. It is not denied that intermediate contact, such as the carrying of the disease by a careless doctor from a smallpox patient to a healthy family at a distance, may be possible, but such occurrences are so rare as to be hardly worthy of consideration in actual practice. In other words, while such carelessness might result in carrying some of the contagium upon the clothing of the person, and thus the question of intermediate fomites be brought into play, it is very much more generally true that when the disease is carried by fomites, it is carried by clothing actually worn and used by a person infected with smallpox, and subsequently taken to a healthy person. There has been much discussion as to the period when smallpox becomes contagious. While, generally speaking, it may be safe to take precautions with regard to an exposure to a smallpox patient in the febrile stage, it has been found that almost without exception—and, so far as the writer is aware, absolutely without exception—no infection has ever resulted from exposure to either the febrile or the papular stage of smallpox. It is only after desquamation has begun that the patient is liable to communicate the disease to others; and this contagiousness will continue until desquamation has thoroughly ceased. Consequently, it is important, before discharging a convalescent from smallpox, to ascertain if every single scale has been cast off from the scalp and from the palmar surfaces of the hands and feet; for it should be borne in mind that the desquamation from the scalp is retarded by the hair, and that this is particularly so with regard to the negro, while the thick epidermis of the palmar surfaces makes them the last to desquamate.

Typhus Fever.—The incubative period of typhus fever is ordinarily stated at about two weeks; it is probably a little less than this, some authors giving it as twelve days. The exact cause of the disease is unknown. It is exceedingly contagious, probably the most pronouncedly contagious of all the quarantinable diseases.

To quote Dr. Rosenau: "Typhus fever is believed to be 'contagious' in the sense that it is communicated by contact between the sick and the well. When the disease exists in epidemic form it is the most highly contagious of all the diseases of man. The nurses, physicians, and those who come in contact with the patient are the first to take the disease. Few escape.

"It is evident that sanitation is much more needed to prevent the spread of this disease than disinfection; in fact, while disinfection is practised for typhus fever, there is nothing to indicate that it is efficacious in preventing the spread of the disease."

Disinfection of Vessels for Various Diseases.

Yellow Fever.—As stated in the discussion of yellow fever, the disinfection of a vessel infected with this disease necessarily involves the destruction of all the mosquitoes aboard such a vessel; and while this is probably all that should be done, it is nevertheless still the custom—and one which probably will continue until all health authorities are fully convinced that there is no other means of transmission than that afforded by the mosquito—to carry this disinfection somewhat further. To compass the destruction of the mosquito, it is simply necessary to introduce simultaneously into each and every part of the vessel—cabin, forecastle, between-decks, hold, and any other compartments in the vessel—sulphur dioxide gas of a minimum strength of four per cent. per volume for each thousand cubic feet of air space of the vessel. In an empty vessel it is desirable to continue introducing the gas for from six to twelve hours; in a vessel containing cargo it will be necessary to provide channels through the cargo, in order that the gas may permeate as far as possible, and to continue the introduction of the gas for twenty-four hours, in order to insure the destruction of all the insects. If the disinfection of baggage and textiles of other kinds is to be undertaken, this is done for the different articles, according to their class, in the manner described in detail in the article on *Disinfection.*

From a sanitary standpoint the vessel and its inanimate contents may now, after such a thorough disinfection, be considered no longer a source of danger, and the owner may be permitted to remove his ship from quarantine.

As regards those who were on board the vessel at the time of her arrival, it will be necessary, before carrying out the measures for disinfection described above, to dispose of them on shore, at the station. The sooner any infected persons are isolated or segregated, in order to prevent a further spread of infection, the better it will be for all parties concerned. The sick should be taken to a hospital so thoroughly provided with screens as to prevent the ingress or egress of mosquitoes; the healthy persons should be placed in barracks similarly provided, in order to prevent the spread, to the remaining healthy patients, of infection from any one of them who may subsequently be taken sick. This screening must be so absolutely perfect in character that it shall not only exclude the most of the mosquitoes, but all of them; and in the event that some solitary mosquito should find access to any of the rooms, steps should be taken to insure its destruction. To prevent the harm which might result from the accidental contamination, by one or two of these insects, of any ward or barrack building, it will be necessary every day to burn a certain quantity of the so-called Persian insect powder in every apartment, and then afterward to sweep up and kill the stupefied insects which will fall to the floor upon the inhalation of the fumes.

Finally, any person effectually isolated from infection, and remaining healthy more than five days, may be released.

Cholera.—Upon the arrival of a vessel at a quarantine station with cholera on board, or having had cholera on board at a recent period during the voyage, it is advisable, when possible, to remove from the vessel all of her *personnel* (both crew and passengers), isolating and segregating these people ashore very much after the method prescribed in dealing with a yellow-fever ship. In addition to the precautions to be taken against insects in the case of yellow fever, it is necessary to provide, in the case of the cholera suspects, recently cooked food which shall not have been contaminated by an insect, and a water supply of undoubted purity. It will also be necessary to make arrangements for either the disinfection or destruction by fire of all the dejecta of all persons kept under observation; for it should not be forgotten that the apparently healthy person may carry within his alimentary canal the cholera spirillum, and may infect sewage, which in its turn may ultimately infect a water supply.

For the ship itself, the measures to be taken are as follows: 1st. A thorough mechanical cleansing, such as is very admirably done by the Hamburg-American and North German steamship companies on their passenger steamers when they arrive at the home port. This consists in washing the vessel with what they know as Seifenlager, a very strong solution of soap and water, plus a certain amount of caustic potash. When every part of the vessel, which may properly be so treated, has been cleansed in this manner, and when the ornamental wood and bright work finish, which cannot be so treated, has been washed with a solution of carbolic acid or other agent which will not damage it, thorough dryness, so far as practicable, should be obtained, and the gaseous disinfection applied simultaneously to every part of the vessel. This gaseous disinfection should be preferably of sulphur dioxide, four per cent. twelve hours' exposure, as elsewhere stated; but, in certain compartments on the finer class of vessels, this style of disinfection would result in damage, which can be obviated by using instead, in such apartments, a six-per-cent. volume of formaldehyde gas for a period of from six to twelve hours. All

Digitized by Microsoft®

textiles which will not be damaged thereby should be subjected to live steam for a period of thirty minutes; and such as will not bear this treatment should be disinfected by the conjoint use of a vacuum and formaldehyde gas, six per cent. volume, for an exposure of one hour's duration. All textiles which have been polluted by cholera dejecta should without exception be burned, and no attempt should be made to disinfect and re-use such articles. The detained *personnel* may be released when five days have elapsed since their last possible exposure to infection.

www.libtool.com.cn

Plague.—Measures to be taken in the treatment of a vessel infected with plague are identical with those used in the case of a cholera-infected ship, except that on account of the peculiar methods of transmission of this disease (partly through small animals), it is necessary to use a germicidal agent which will destroy animal life as well as bacteria; and for this purpose formaldehyde is not strictly reliable; consequently, all gaseous disinfection done on a plague-infected vessel must and should be done with sulphur dioxide. The segregation and careful attention to the individuals, including the adoption of stringent measures capable of preventing the pollution of either dejecta or sewage, apply to this disease as strongly as to cholera; and for the reason that small insect life has a bearing in the transmission of the disease, the screening provided for cholera and yellow fever, while not so absolutely essential, is nevertheless advisable, and, wherever possible, should be used. Manifestly the persons under detention may be released at the expiration of from seven to eight days since their last possible exposure to infection.

Smallpox.—Here we have to deal with a disease which does not require such rigid measures as have been applied to any of the other quarantinable diseases. If a person in any given apartment of a vessel has been afflicted with smallpox, it does not necessarily follow that all the persons on the vessel are to be detained in quarantine, nor that the whole ship is to be disinfected. It will be sufficient if we disinfect with scrupulous care all possibly infected personal belongings, and, in the same manner as is applied for yellow fever, all portions of the vessel which have been invaded by the disease. At the same time it is important to keep under observation those persons who have been in direct contact with the afflicted party, or who have not been vaccinated. The usual custom is to vaccinate immediately all exposed persons and hold them under observation for fourteen days; to release at once all those who have not been exposed and who are vaccinated; and to disinfect such parts of the vessel as have been in touch with the actual case, releasing the vessel at once, and holding only the suspects. Should the infection on the smallpox vessel be so general as to justify the opinion that all on the vessel have been more or less exposed, then it becomes necessary to disinfect the vessel in the same manner in which it would be done for yellow fever, and to disinfect it throughout, holding under observation for fourteen days all of its *personnel*.

Typhus Fever.—In view of the little that is known of typhus fever, *i.e.*, as to its manner of transmission, period of incubation, etc., it is exceedingly fortunate that we seldom or never find a general infection of typhus fever aboard ship. Should such a calamity supervene, all the *personnel* should be immediately segregated ashore, and the groups placed far enough apart, if sufficient ground is obtainable, to prevent the infection of one by the other, it having been claimed that aerial infection plays a part in this disease. The vessel should be disinfected in the same manner as for cholera, and the *personnel* kept under observation for a period of fourteen days from their last exposure to possible infection.

Leprosy.—The quarantine regulations of the United States demand the retention at quarantine of any alien leper, and his replacement upon the vessel when outward bound.

Minor Communicable Diseases.—There are, in addition to the diseases above discussed, several others which at times call for treatment, but which are not generally classed as quarantinable diseases. These diseases—scarlet fever, measles, diphtheria, and even some others—are as a rule passed up to the local board of health for proper handling.

When treated at quarantine, they call for the same measures as are applied to smallpox (except of course vaccination).

Land Quarantine.

Because of lack of space only brief notice can be given this subject, which after all is simply a common-sense application of maritime rules to exactly the same diseases on land. The people are to be handled in precisely the same manner as at a maritime station, and if we simply transfer our disinfecting agents from a ship to a house, the methods remain the same. The difficulties of administration are greater because, while at a maritime station the quarantine officer is practically supreme, in land quarantine he has to meet the whims and foibles of local lay authority, or even of individuals.

Joseph H. White.

QUASSIA.—*Quassiæ lignum* or *Lignum Quassiæ. Jamaica Quassia. Bitter-wood. Bitter-ash.* The dried wood of *Picrasma excelsa* (Swz.) Planch (*Quassia e.* Swz.; *Picræna e.* Lindl.; *Simaruba e.* DeC.—Fam., *Simarubaceæ*), U. S. P.

The Jamaica quassia tree is said closely to resemble a small or medium-sized ash tree. It occurs chiefly in Jamaica, but to some extent in other parts of the West Indies. Quassia was originally derived from a different plant, considered below, but was later replaced by this one. The wood occurs in billets of various sizes, dense, tough, of medium hardness, and of a nearly uniform yellowish-white color; internally porous, with a minute pith, indistinct rings, and medullary rays which, on tangential section, exhibit from two to five vertical rows of cells; inodorous and intensely bitter.

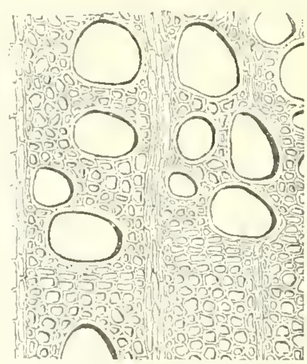

Fig. 3924.- Section of Quassia Wood. (Baillon.)

It is usually met with in the form of chips or raspings.

The powdered wood is devoid of stone cells, contains crystals of calcium oxalate, and exhibits the tangential appearance of the medullary rays described above.

Quassia contains neither tannin nor starch, and, if pure, yields not more than four per cent. of ash. Its bitter principle is the crystalline substance *quassiin*, freely soluble in alcohol and chlorofom. Although it requires 1,200 parts of water for solution, the dose is so very small that water constitutes a satisfactory menstruum. Quassiin is further resolvable into two crystalline bodies, called respectively *α-picrasmin* and *β-picrasmin*. A minute amount of alkaloid has been reported, but is probably of no medicinal importance.

Action and Uses.—Quassia is generally regarded as a pure or simple bitter tonic, like gentian, and is mostly used as such, being given, either alone or in combination with aromatics and stimulants, as a stomachic and appetizer. In debility, in convalescence from fevers, in dyspepsia, it has been, and is still, in considerable use. Its taste is, however, more bitter and disagreeable than that of gentian or quinine.

Quassiin is a powerful irritant and convulsive poison when concentrated or used in overdoses, and is apt after long administration to set up a gastric irritation. Its use is therefore better alternated with that of other medicines.

Digitized by Microsoft®

It is particularly poisonous to the lower animals, on account of which it is much used as a rectal injection for the destruction of ascarides. For the latter purpose, from a half-pint to a pint of the ten-per-cent. infusion is employed. The death of an infant has followed such use. The freedom of quassia from tannin renders it a desirable bitter for mixing in prescription with the iron preparations. The Pharmacopœia provides an extract (*Extractum Quassiæ*), the dose of which is 0.03–0.2 gm. (gr. ss.–iij.), but this is the least desirable preparation for use, since the patient fails to receive the beneficial effect of the bitter taste. The dose of the official fluid extract is 1–4 c.c. (fl. ʒ ¼–i.) and of the tincture, which is by far the most efficient of all preparations, 2–8 c.c. (fl. ʒ ss.–ij.). The infusion is a popular form of administration, and should be of five-per-cent. strength. Another excellent method is to introduce cold water into cups made of quassia wood. The water becomes almost at once intensely bitter, the patient receiving the full benefit of the bitter taste, with little systemic effect.

www.libtool.com.cn

Surinam Quassia.—This, the original quassia, is still the one chiefly employed in Southern Europe, and is official in nearly all pharmacopœias. It is the product of *Quassia amara* L., of the same family, a shrub or small tree of Northern South America, whence it extends up into Central America and into the West Indies. The billets are much smaller, usually from one to three inches in diameter, crooked, and still bearing the bark, which is of an ashy gray color and nearly smooth. The wood is somewhat heavier than that of the Jamaica variety, and exhibits medullary rays only one row of cells wide on tangential section. The bark is full of large stone cells, which are seen in the powder, since bark and wood are usually ground together. The active principle of this variety is practically identical with that of the other, and the properties, uses, and doses are the same.

The same statements may be made concerning East Indian quassia and Japanese quassia, derived from other species of *Picrasma*. *Henry H. Rusby.*

QUEBRACHINOFORM. See *Formaldehyde.*

QUEENS ROOT. See *Stillingia.*

QUERCIFORM. See *Formaldehyde.*

QUINAMINE. See *Cinchona.*

QUINCE SEED.—*Cydonium* (U. S. P., 1880).—The dried ripe seeds of the common quince, *Cydonia Cydonia* (L.) Lyons (*Pyrus Cydonia* L.; *Cydonia vulgaris* Pers. fam. *Rosaceæ*) together with the gum in which they are naturally embedded.

The quince is a native of Southwestern Asia and adjacent Europe, but the seeds are wholly the product of cultivated plants. They occur agglutinated in masses of eight to ten or more, being embedded in a colorless, transparent gum, of which about twenty per cent. is obtainable, and for which they are valued. One part of this gum makes about 100 parts of mucilage. This has little adhesive power, but is excellent for the ordinary medicinal uses of mucilage, such as the making of collyria, demulcent drinks, etc. When the drug was official, it was directed that the official mucilage be made by taking 2 parts of the seeds with 98 parts of water.

Henry H. Rusby.

QUINETUM. See *Cinchona.*

QUINIDINE. See *Cinchona.*

QUININE. See *Cinchona.*

QUININE, NEW COMPOUNDS OF.—In the following preparations, the dose, unless specified, is that of quinine sulphate.

Acetyl-salicylate—for rheumatism.

Arsenite—sixty-nine per cent. quinine. Dose 0.005–0.03 gm. (gr. $\frac{1}{12}$ to gr. ss.).

Bichloride—very soluble. Improvement in recurrent cancer followed daily injections of 0.5–1 gm. (gr. viij.–xv.) by Jaboulay in France and Trible in America.

Borate—a yellow insoluble powder, antiseptic.

Caseinate.

Chloro-carbonate—freely soluble, almost free from bitter taste.

Chloro-phosphate—fifty per cent. quinine; soluble in two parts of water.

Chloro-sulphate—seventy-four per cent. quinine; soluble in one part of water.

Dibromguaiacolate—guaiaquinol.

Dihydrobromate, dihydrochloride, dihydroiodate—all readily soluble and used by hypodermic injection for whooping-cough. Dose, 0.06–0.2 gm. (gr. i.–iij.).

Dihydrochloride-carbamate—muriate of quinine and urea. Seventy per cent. quinine; very soluble.

Ethyl carbonic ester—Euquinine (see Vol. IV.).

Ferri-chlorid—dark reddish-brown crystals used in two-per-cent. solution as a hæmostatic in internal hemorrhage and in uterine hemorrhage.

Glycerophosphate — kinewin, especially employed in neuralgia. Dose, 0.1 gm. (gr. iss.).

Guaiacol bisulfonate—guaiaquin, an odorless, non-caustic substitute for guaiacol.

Hydroquinone-hydrochloride—antipyretic.

Ichthyol-sulfonate—sulpho-ichthyolate, employed in tuberculosis.

Iodo-hydroiodate—insoluble in water. Used as substitute for iodides in syphilis, and in the same dosage.

Lactate—readily soluble.

Lygosinate—antiseptic compound of di-ortho-cumarketone (lygosin).

Methyl-di-hydrazin-perchlorate—compound of quinine hydrochlorate, caffeine, and antipyrin.

Phospho-hydrochloride—soluble.

Phosphoric acid ester—phosphorylquinine.

Salicylic acid ester—salicyl quinine or saloquinine (see *Saloquinine*).

Salicyl-salicylate—(see *Rheumatin*).

Silico-fluoride—soluble in water.

Sulpho-creosotate—used in tuberculosis.

Urethane—very soluble, made by mixing 3 parts of quinine hydrochloride, 1.5 parts of urethane, and 3 parts of water. *W. A. Bastedo.*

QUININE. (TOXICOLOGICAL.)—Any high degree of toxicity can hardly be said to exist in the ordinary use of cinchona and its alkaloids or their salts. There are certainly symptoms very commonly associated with their therapeutic uses, even in most moderate doses, which are characteristic and indicate some functional disturbance of various organs. Such are the sense of constriction about the forehead, the ringing of the ears, and occasionally nausea. In many persons these are not sufficiently marked to attract attention unless the doses given are very large or long continued. Of these the sense of fulness and the deafness are the commonest, and are looked upon as necessary accompaniments of the administration of the drug, not giving rise to uneasiness either in the patient's or in the physician's mind, and expected to disappear promptly when the medication is stopped. They are the physiological evidence of mild cinchonism. The susceptibility of individuals varies greatly as to the amount of the drug which will produce such manifestations. Some persons are occasionally met with who suffer so promptly and acutely from these troubles that treatment to counteract them has to be instituted in order that enough of the required drug may be taken into the system to produce the desired effect upon the primary disease. Many, on the other hand, show so little susceptibility that astonishingly large and rapidly repeated doses may be given with only beneficial results.

Liebermeister (quoted by Kunkel) says: "I have up to this time employed quinine in large doses in more than fifteen hundred patients with abdominal typhus, and also in hundreds of pneumonias and other diseases. The number of single doses, of from 1 to 2, up to 3 gm.,

Digitized by Microsoft®

which I have prescribed, may run up to ten thousand, and not once have I seen any essential or lasting injury which one might seem warranted in ascribing to quinine." The cause of the disturbances produced by quinine has not yet found a satisfactory explanation.

www.libtool.com.cn

Notwithstanding the infrequency of toxic manifestations from the use of quinine, a large number of cases can be found in the periodical literature of the last half-century, some of an acute character after minimum doses, and some in which the most inordinate quantities have been taken. It is these latter which present the most serious symptoms, and are even followed by death. The former must be regarded as due to an idiosyncrasy, which also is not infrequently hereditary, while the latter may properly be classified as cases of poisoning, whatever the action of the drug or whatever organs are specially involved. There is still another class of cases, viz., those in which quinine, given in very moderate doses, especially in certain tropical districts of Africa, to persons who are already the subjects of malarial dyscrasia, quite promptly causes a sharp advance in temperature accompanied by hæmoglobinuria—the Schwarzwasserfieber of German writers. The following may serve as illustrations:

Hare reports the case of a man of fifty-three for whom two grains of quinine, three times a day, was prescribed. It produced an intense erythematous rash, which was subsequently followed by desquamation, including the palms of the hands and soles of the feet. On learning that quinine was contained in the medicine prescribed for him, he said that he had once before had the same experience, an eruption having developed after he had taken a cocktail containing a few drops of elixir of calisaya. This man's daughter, twenty years of age, also suffered from a rose rash followed by desquamation after taking a small dose of quinine.

Husemann reports the case of a soldier in good health who took 12 gm. of sulphate of quinine in a five-per-cent. solution. He died in four hours in an access of heart weakness. A third report is by Guersant. A French physician in a rural district was in the midst of an outbreak of malarial fever. When his wife was taken ill he gave her 240 grains of quinine in the course of a short time, and she fell into a state of stupor with amaurosis, deafness, and difficulty of moving, whereupon he gave her 375 grains more, and the serious symptoms increased. Fortunately for her he was about this time taken ill with the fever himself, and she finally recovered. He administered to himself, however, 900 grains by mouth and rectum, which brought him to a condition resembling that of a man affected with pneumonia terminating in hepatization; but he managed to take in the course of eight or nine days five ounces more of quinine. When at last he came under the observation of another physician he was in a cold sweat, deaf, blind, his respiration difficult and rattling, and in a profound stupor, looking like a drunken man. Delirium and death soon closed the scene.

I. B. Yeo reports his own experience as follows: Fearing that he had taken cold, he administered to himself two doses of two or three grains each of quinine. The next morning he found upon his legs an erythema with much itching, which faded in three or four days. He repeated this experience twice at intervals of two months, the last time taking three grains and the rash appearing in a few hours. Five months later, imagining that the former doses might have contained some impurity, he took pains to get the sulphate of quinine from a druggist of the best repute, and the usual eruption in three and a half hours followed the taking of three grains. Six weeks later, a dose of one fourth of a grain, directly after breakfast, was followed by the rash in five hours.

Not to burden this paper with the details of the action of quinine in disturbance of all the various organs, it will suffice to mention those of special interest and importance, whether such toxic effect is manifested after the introduction into the system of such quantities as would everywhere be considered large if not excessive, or of such minute doses that their poisonous activity is the evidence of an individual idiosyncrasy. Of these the most prominent are the effects upon the skin, upon the eyesight and hearing, upon the kidneys, and upon the pregnant uterus. Some reference should also be made to effects upon the general nervous system.

Cutaneous disorders may arise from the local irritating action of quinine when the skin is denuded, according to Hugounenq, and it has frequently been observed that the operatives in quinine factories suffer from similar local troubles, with also a certain amount of constitutional disturbance, even when the skin is sound.

Authorities differ in their views of the pathogenesis of these eruptions, Lewin saying that no absorption of quinine takes place through the sound skin, and that the eruption occurring in quinine workers is not to be regarded as an occupation disease, but as an idiosyncrasy against quinine, which seems not a very tenable theory in view of the frequency with which such cases occur. He says also on the next page that it is the direct contact of the quinine with the skin, its excretion through the medium of the sweat glands, among other like possibilities, which chiefly furnishes the explanation of this irritation rather than a disturbance of the stomach or bowels producing a reflex irritation of the skin or any action of the drug in solution in the blood acting upon trophic or vaso-motor nerve tissues.

Morrow considers that the theory of the stimulation of the sensory nerves of the gastric mucous membrane, producing reflex dilatation of the cutaneous vessels, is applicable to only the milder and superficial forms of eruption. He also refers to the theory of an elective affinity of the sweat glands for the drug, its attempted elimination through this channel causing local irritation. He says that the toxic action of quinine upon the skin may result from electrolytic action, from its use in pomades or lotions, and from subcutaneous injection as well as from ingestion of the drug.

Writers report many forms of quinine eruption, although that resembling scarlatina is the commonest and most important from the point of view of diagnosis. It is most apt to follow the taking of sulphate of quinine rather than other preparations.

Thus there is pruritus, which is often limited to certain regions, such as the glans penis, the hands, or the legs. Erysipelatous and gangrenous forms are reported, although the latter is very rare. The urticarial form is wont to be accompanied with much constitutional disturbance. Hyde and Montgomery remark that it is hardly to be distinguished from an *urticaria ab ingestis*. The mucous membrane of the throat and fauces may be involved in this form. Eczematous and bullous forms are mentioned, and finally the petechial, which may be accompanied by bleeding from the buccal mucous membrane or by sanguinolent stools, sometimes following very small doses of the drug. Desquamation of greater or less extent is a not infrequent sequela of these various forms of eruption. In the matter of differential diagnosis the greatest interest attaches to the exanthematous form from its likeness to scarlatina. The eruption is of a vivid hue and disappears under pressure. The history of the case, as to whether quinine has been given or not, is of the utmost importance, and Morrow points out that there is usually no fever, and that the eruption subsides when the drug is discontinued. Quinine can also be easily detected in the urine.

With reference to the effects of quinine upon the sight and hearing it is observed that they are wont to be more persistent than other toxic effects of the drug, lasting often for years or permanently, while the others disappear on its discontinuance. The symptoms of its injurious action on the eye are increased lachrymation, itching and œdema of the lids, photophobia (which may be only transient, but may persist), diminished or lost pupillary reaction, and sometimes complete but usually temporary loss of sight, either in one or in both eyes. But the most typical and persistent lesion is concentric limitation of the visual field, which may exist even though the acuity of vision is little impaired, and which may be demon-

Digitized by Microsoft®

strable even when the acuity of vision is completely restored. At the same time there may be a diminished sense of light, as if a veil were interposed. There may also be color blindness, which but slowly disappears. The changes appreciable by the ophthalmoscope are in the papilla of the optic nerve and the vessels of the retina, the media remaining clear. There is a high degree of constriction of all the vessels, tending to atrophy, and the optic nerve is pale (Lewin and Kunkel).

www.fibool.com.cn

Quinine given in even very moderate doses generally causes some hardness of hearing with tinnitus or roaring in the ears. There may even be complete deafness lasting for twelve or twenty-four hours. Existing middle-ear disease may be exacerbated or an otitis externa may develop. Under these conditions may be observed a slight injection of the vessels of the handle of the malleus and some degree of opacity and retraction of the membrana tympani.

It has been observed that what has been called quinine fever sometimes supervenes upon the administration of small doses of the drug in persons who are the subjects of malarial infection, the symptoms consisting in the rather prompt appearance of chill, fever, and sweating, with sometimes disorders of the alimentary canal and bloody urine. No satisfactory explanation has been offered for these manifestations. When it is added that to quinine is attributed an occasional irritation of the urinary passages leading to albuminuria, and that sometimes the urine also contains blood, hæmoglobin, and methæmoglobin, we are very near to the condition known under the German name of Schwarzwasserfieber (black-water fever), which Kunkel describes as follows: "This is a disease of the African tropics, and is so far directly associated with malarial infection that it occurs only in men who have been infected with malarial virus. They are apt to be only apparently in good health, or have a malarial dyscrasia. There is always a chill, followed by nausea, intractable vomiting, and other signs of severe constitutional disturbance, such as diarrhœa, dulness of mind, restlessness, dyspnœa, and irregular febrile movement, as in cases of septic infection. There are indications of serious blood decomposition. The urine is of a dark reddish-black color, and contains pigment granules, renal epithelium, and casts, but no erythrocytes. The symptoms of acute nephritis are always present. The prognosis is bad and death follows with signs of heart failure or of uræmia. In cases that do not succumb kidney lesions remain, and after the seizure the blood corpuscles and hæmoglobin are enormously diminished."

Kunkel enters quite extensively into the discussion of this subject, and cites many authorities who furnish good evidence that in the course of malarial disease, when quinine has not been given, attacks of hæmoglobinuria occur, and that they seem to occur most often in regions where the local perniciousness of the disease is greatest. Thus they occur in Greece more than in Germany, and in Africa more than in India.

Again, in cases in which small doses of quinine are given to the subjects of malarial infection, but who are not seriously ill at the time, bloody urine will quite promptly appear. Thus good authorities agree that in certain persons saturated with malaria the blood corpuscles become very sensitive to the action of quinine and readily break down. The question also comes up, in this connection, regarding the similar action of chlorate of potash, of carbolic acid, and of arseniuretted hydrogen as blood poisons. There seems good evidence also that not only are small doses of quinine not curative in these conditions, but that they excite the disease, which can be cured by large doses only, 4 gm. for example. Welsford, however, is of the opinion that black-water fever is a localized disease, and that some malarious districts in Africa are free from it; also that quinine certainly does cause hæmoglobinuria, but only rarely. He reports a case in which two ten-grain doses on two occasions induced black urine.

The action of quinine as an ecbolic is based on the occasional occurrence of abortion in malarial districts after this drug has been given. It is also reported that in China it is depended on to produce abortion, and that female operatives in quinine factories frequently abort. There is by no means an agreement of good authorities on this subject, however, and the best opinion favors the belief that this action is occasional rather than regular, and should be regarded as an incidental or by-effect rather than an evidence of toxicity.

It remains to consider the poisonous action of quinine upon the central nervous system. It is by no means easy to discriminate between the effects of quinine itself and those due to the disease for which it is given, especially as in severe cases, like pneumonia, intermittent and continued fevers, where large doses might probably be used, the disease itself might present such symptoms as headache, sleeplessness, and a state of collapse with loss of consciousness, delirium, or even tetanic or convulsive manifestations, such as are said to be due to the action of the drug upon the nervous system. Therefore cases illustrative of these effects are the unusual ones in which great quantities of quinine have been rapidly taken into the system when not called for by the existing disease, or far beyond its requirements, such as some already cited in this article, or the following, reported by A. E. Roberts:

"A woman, aged thirty-five, took about 20 gm. of quinine, became insensible in an hour, and this state lasted until the next day. She was cold and cyanotic, with slow and feeble respiration, pulse 45 and very weak, pupils widely dilated and insensible. Still she recovered. Her hearing became normal in a week, but it was two weeks before she had even a slight perception of light, and this was not wholly regained for months."

Such histories are the basis for the opinions of Briquet, A. B. Palmer, and Kunkel, the former of whom says: "If 2 gm. or more are taken and continued for several days, we observe an overwhelming, an exhaustion, stupor, somnolence, weakness of sight, dilatation of the pupils, and tremblings of the limbs. Very large doses lead to complete loss of consciousness, loss of sight and hearing, and complete immobility of the limbs. The delirium or intoxication of quinine is usually gay. He concludes that quinine produces a slight and temporary excitation of the encephalon, then soon a sedative action, which gradually increases, and which may go on to the destruction of nervous power."

Palmer describes as quininism ("cinchonism," Foster's "Medical Dictionary") those disorders of the cerebrospinal functions indicated by headache, giddiness, contraction or sometimes dilatation of the pupil, ringing or roaring in the ears, deafness, partial blindness, abnormal touch and smell, difficulty of controlling muscular acts, somnolency, sometimes delirium, at other times stupor, sometimes a severe sense of stricture about the chest. These effects are for the most part temporary, but sometimes more permanent. Kunkel concludes that with poisonous doses of quinine the central nervous system is progressively paralyzed in all parts. In case of severe acute poisoning death occurs from paralysis of respiration, artificial respiration prolonging life until paralysis of the heart occurs.

When we come to look for the lessons to be drawn in the way of prophylaxis against the possibly toxic action of quinine it is clear that the dangers due to idiosyncrasy are not serious, for its results are so soon in evidence from such small doses, and so very uncomfortable to the subject, that he will be quite apt to remember them, and to avoid the drug in the future. The injurious effects of quinine, Lewin tells us, are more apt to be observed in women and aged people than in others, while persons with delicate skins and those subject to eczema are particularly liable to quinine exanthemata. To these classes then, and especially to persons suffering from eye and ear diseases, quinine should be given most cautiously or not at all.

There is little likelihood that any impurities in the drug are responsible for the toxic effects attributed to quinine. In fact, Lewin declares that there are no dangerous adul-

Digitized by Microsoft®

terations of it unless salicylic acid is the adulterant. He also warns against prescribing sulphate of quinine and iodide of potassium together, lest iodine should be set free in the intestinal canal.

There is not much to be said about the treatment of the toxic effects of quinine. Usually stopping the administration of the drug is soon followed by relief of the symptoms. When it is esteemed necessary to give the medicine, although unpleasant effects are already present or may be anticipated, several means of counteracting them are recommended. The bromides, and particularly hydrobromic acid, have quite a reputation, while Lewin and others have found ergotin, given in about equal doses with the quinine, efficient. Morrow and others recommend tincture of hyoscyamus. In dangerous cases in which there is collapse, the usual measures for stimulating the circulation by external applications and friction are in order, as well as the internal use of hot tea and coffee, and perhaps the subcutaneous injection of tincture of musk.

MacGregor favors subcutaneous saline injections in treating black-water fever. *J. Haven Emerson.*

RABIES OR HYDROPHOBIA.—Rabies or hydrophobia is an acute infectious disease of the central nervous system which occurs in man as well as in other warm-blooded animals. As a spontaneous disease, as distinguished from that due to intentional inoculation, it is met with in the dog and allied species, the wolf, the fox, the jackal, the hyena. Cats are also more or less often affected. Osler states that the disease is said to prevail among the skunks of the Western States of North America. So far, no species of animal except pigeons has been found to be refractory to intentional inoculation with the rabies virus. In these birds the older individuals are not normally susceptible, but they become so on the deprivation of food, and the young birds are normally susceptible.

From the many points of analogy which exists between rabies and other acute infectious diseases, the conclusion would seem unavoidable that rabies is caused by a specific micro-organism; but all efforts to establish this by experiment and observation have so far proven futile, though several unsubstantiated claims to this effect have been made, it is true. Although the specific infectious agent is not known, it can be propagated in the central nervous system of living animals, not of dead animals. By inoculation of animals it has been shown that the poison is always present, sooner or later after infection, in the brain, spinal cord, nerve trunks, and saliva of infected animals. It is present in these situations even before any symptoms have developed, during the incubation period, while the animal is apparently well. It is usually not present at any time in the milk, lachrymal secretion, pancreas, testicle or semen, aqueous humor of the eye, cerebrospinal fluid, or in the fœtus, though it has been found occasionally in one or other of these situations.

Accidental infection usually results from the bite of a mad dog, and therefore is due to the introduction of the saliva of the rabid animal into the wounds made by the teeth. Sometimes infection results from the licking of an abrasion by a pet dog that is going through the incubation period and before any symptoms of the disease have manifested themselves in the animal. For this reason mad dogs are specially dangerous while they are going through this stage. They are not suspected of being mad, and are not avoided as they are after the symptoms appear. Novi states that midges and flies are also capable of carrying the contagium. Artificially, as already stated, the disease may be produced by inoculating animals with tissues from an infected animal. Injection under the dura mater of suspensions of the spinal cord from an animal dead of rabies in neutral beef broth, is the method very commonly resorted to, and this produces the disease very uniformly. The point of the hypodermic needle is inserted beneath the dura mater through a small trephined opening at the summit of the cranium a little to one side of the median line. With aseptic precautions and with ordinary care in manipulation, there is no immediate danger to the animal from the operation itself, either as regards the effect of the trauma or from infection with pyogenic organisms. Occasional failures to produce the disease by the method just described have been reported, it is true, but the failure was probably due, at least in most of these cases, to the use of too small an amount of material for the injection. To insure success, the amount used must not be less than one-thirtieth of a gram by weight of the cord, according to Kruse, although even smaller amounts are usually effectual. Johne, Dawson, Oshida, and others recommend injecting suspensions of the cord through the optic foramen. If this method is resorted to it is recommended to anæsthetize the animal, or to keep it perfectly still by any method, otherwise there may result a fatal trauma of the brain. Oshida has successfully inoculated rabbits by using a long needle and passing this through the optic foramen, through the brain, up to the dura mater. Similar injections into the sciatic nerve or other large nerve trunks, or into the anterior chamber of the eye, are also usually successful. Intravenous injections are also usually successful in small animals, but not in large. The same is true of intraperitoneal injections. Subcutaneous injection is very uncertain. The reason that has been suggested for the frequent failure of subcutaneous injection is that by this method the virus is not brought in contact with an injured nerve, an essential condition for successful inoculation, according to this view. Those offering this explanation cite in support of their position the facts that the disease is more apt to follow from the bite of a mad dog if the injury is situated on the hands or face where the nerve supply is specially abundant; also that injections into nerve trunks, the brain, or the spinal cord, are uniformly successful, and less so in other situations, as has been said; and, finally, that deep lacerated wounds are particularly dangerous.

Whether the abundant nerve supply renders a part specially liable to infection or no, the danger of infection from bites on the hands and face is at least enhanced independently of this by the fact that these are usually bare, whereas the clothing over the rest of the body may prevent the infectious saliva from coming in contact with the wounds. On the other hand, it has been shown that application of the infectious material to the uninjured

Digitized by Microsoft®

conjunctiva, the uninjured genital mucous membrane, or to the uninjured alimentary mucous membrane may be followed by the disease; so it does not seem necessary for the nerves of a part to be injured, in all cases at least, unless we assume that where infection follows applications of the virus to the mucous membrane there are minute abrasions too small to be detected with the naked eye. But whatever the portal of entry, the disease develops only where the poison invades the central nervous system, and all observation goes to show that the course of the poison from the seat of infection to the brain and spinal cord is not through the blood or lymph channels, which are the distributors of the micro-organisms and toxins usually in other infectious diseases, but that the virus travels for the most part, if not exclusively, by way of the nerves themselves.

www.libtool.com.cn

In rabies, as in other infectious diseases, there is always a period of incubation between infection and the appearance of the symptoms of the disease. This period of incubation varies in rabies not only in different species of animal, but also in different individuals of the same species. In dogs it lasts for from three to five weeks, seldom more, and seldom less. Bollinger states that in one case in a dog it lasted for eight months, and that is the maximum. In human beings the period of incubation varies greatly in length in different cases; from six weeks to two months is common, though cases have been reported in which the period of incubation is said to have lasted for one or even two years; but these long periods of incubation are certainly rare, if they occur at all. The disease usually shows itself in the course of the second month after the person has been bitten, rarely in less than fifteen days, more rarely still after three months or longer. In the rabbit the period of incubation is twelve to fourteen days when the animal is inoculated with cord from a mad dog, but it becomes shorter and shorter by successive inoculations of suspensions of the cord from one rabbit to another through a series—in other words, the virus becomes more and more virulent by successive passages through rabbits. This increase of virulence, however, cannot be carried on indefinitely, for there comes a time when further inoculations do not increase the virulence, and the virulence is then said to be fixed. Pasteur's "virus fixe" is obtained in this way, and consists of a portion of cord from a rabbit dead in nine or ten days of rabies. This explanation of what is meant by "virus fixe" should be carefully borne in mind in order to understand much of that which follows, for it will be necessary to use the term frequently. It may also be noted in passing that this "virus fixe" is made use of in the production of the "vaccines" for treating persons who have been bitten by a mad dog, as explained below. By the use of large rabbits the potency of the virus may be so increased by successive passages that the period of incubation finally will be six or seven days; and by the use of small Russian rabbits the period of incubation may be still further reduced to five or six days. Successive passages of the virus through apes, on the other hand, decreases the virulence, the period of incubation becomes longer. In ducks and geese the period of incubation is fourteen days. In chickens the disease has a period of incubation of forty days. Chickens, like pigeons, are partly refractory to rabies, as shown by Dr. Paul Gibier in 1884 (Thèse de Doctorat, Paris, 1884).

But the symptoms do not appear as soon as the rabies poison invades the brain and spinal cord, for these are infectious for other animals before any signs of the disease have shown themselves in an infected animal. Roux and his pupils, and others, have found that not only the medulla, but also the saliva of infected animals is infectious for other animals for from twenty-four to forty-eight hours—sometimes for three days—before any symptoms have developed. The different parts of the spinal cord become infectious for other animals at different times; the part nearest the seat of inoculation becomes infectious first, as a rule. Högyes found that the brains of rabbits inoculated under the dura mater are fully virulent in six days, as soon as the first characteristic symptoms appear, but that the medulla is fully virulent before this time, on the last part of the fourth or on the first part of the fifth day, at the beginning of the febrile symptoms. Vestea and Zigari and others found that after subdural inoculation the medulla becomes infectious for other animals several days before the lumbar cord. By inoculation into the sciatic nerve, on the other hand, the lumbar cord usually becomes infectious for other animals before the medulla. Nevertheless, this is not always the case, for Kraus, Clairmont, and Keller have shown that the medulla is sometimes infectious after inoculation into the sciatic nerve at a time when the lumbar cord is not infectious at all. This is not the rule, however, for usually the lumbar cord is infectious for other animals in six or seven days after inoculation of the "virus fixe" into the sciatic nerve, whereas the medulla does not usually become infectious by this time by similar inoculation. On the other hand, the medulla becomes infectious for other animals in one day after intracerebral inoculation with "virus fixe," and in three days, or even in a shorter time, after subdural inoculation with "virus fixe," less than half the time required by inoculation into the sciatic nerve for the poison to accumulate in the lumbar cord in sufficient amount to be infectious for other animals. Enough of the poison, however, gets into the lumbar cord in twenty-four hours after inoculation into the sciatic nerve finally to cause the disease in the infected animal, as explained more fully below.

Kraus, Keller, and Clairmont have furthermore shown that intracerebral injection of the "virus fixe" causes the development of the poison more quickly than the subdural injection. In intracerebral inoculation with "virus fixe" the poison is present in the medulla in twenty-four hours in sufficient amount to cause the disease on inoculation into other animals. In subdural inoculation, on the other hand, it is not certain that the medulla is ever infectious in as short a time as twenty-four hours after inoculation. It is true that rabbits inoculated with the medulla of rabbits taken out twenty-four hours after subdural inoculation usually die of gradual emaciation, a sort of marasmus, but they show no symptoms typical of rabies, and the medulla of these rabbits is not infectious.

Subdural inoculation, intra-orbital inoculation, and inoculation into a large nerve trunk, as into the sciatic nerve, all have about the same effect as regards the appearance of the poison in the spinal cord. In no case does the poison invade the entire nervous system all at once; on the contrary, there is always a more or less gradual extension along the course of the nerves or the spinal cord.

Kraus and his colleagues report one experiment in which the inoculation was made with "virus fixe" into the lumbar cord in a rabbit. The cord in this case was cut out twenty-four hours after inoculation, and different portions of it were inoculated under the dura of different rabbits. The results of these inoculations showed that the lumbar portion was typically virulent; the rabbit inoculated with this died of unmistakable rabies. The dorsal portion produced no symptoms. The medulla caused the death of the rabbit in fourteen days without any symptoms of rabies, it is true, but the medulla of this animal caused death in another rabbit in sixteen days with all the symptoms of rabies. The reason why the virus in its passage through the dorsal cord to the medulla from the seat of inoculation in the lumbar cord should not have found conditions for lodgment and development in the dorsal cord is not apparent. It would seem as if this observation shows that the medulla and lumbar cord have special affinity and attraction for the rabies virus. Some of the other observations mentioned above also seem to indicate that the most favorable situations for the development of the virus are, first, the medulla, and next to this the lumbar cord; and that the rest of the central nervous system becomes invaded only after these two locations have been fully impregnated.

The source of the rabies virus also affects the length of time of the development of the disease as well as the ac-

Digitized by Microsoft®

cumulation of the poison in the central nervous system. Tests upon animals show that the virus present in the cord of a dog suffering from an ordinary case of rabies, the "street rabies," takes longer to invade the nervous system and produce the disease than the "virus fixe," the virus obtained by successive passages through rabbits. This is shown not only in the difference between the period of incubation in the disease produced by inoculation with "virus fixe" on the one hand, and that produced by inoculation with the "street virus" on the other, but also by the fact that the cord of an animal inoculated with the "virus fixe" is infectious for other animals in a much shorter time after inoculation than is the cord of an animal inoculated with "street virus." It has been stated that the medulla of an animal inoculated under the dura with the "virus fixe" becomes virulent in two or three days after inoculation. The medulla of an animal inoculated under the dura with the "street virus," on the contrary, does not become virulent for other animals before the sixth day, and usually is not virulent before nine or ten days, and the lumbar cord is frequently not virulent at any time after inoculation with the "street virus." The reason for this difference between the "virus fixe" on the one hand, and the "street virus" on the other, is not apparent. The disease without proper treatment is just as surely fatal in the one case as in the other, and the symptoms in both seem to be of equal severity. The only difference seems to be that in the one case the poison is generated more quickly than in the other.

But, although, as has been stated, the lumbar cord does not contain enough of the rabies virus to be infectious for other animals for several days after inoculation into the sciatic nerve, enough of the poison gets to the cord in twenty-four hours by this method of inoculation to cause the disease in the animal itself; for Kraus and his co-workers inoculated a rabbit in the sciatic nerve with "virus fixe," and the animal died of typical rabies in spite of the fact that a portion of the sciatic nerve was excised at a point situated between the seat of inoculation and the cord. On the other hand, Bombicci prevented the disease from developing after intra-ocular inoculation by enucleation of the eye twenty-four hours after infection, and Babes and Talasescu also prevented the disease by cauterization of the seat of infection twenty-four hours after inoculation. But Babes has shown that even comparatively late cauterization or excision of the seat of infection delays the appearance of the symptoms, even if it does not prevent the disease, an important factor in the proper treatment of the disease, as will appear in the proper place.

The virulence of the virus may be destroyed, decreased, or increased in various ways. Light, temperatures of 50° to 60° C., drying, various antiseptics, and artificial digestion all weaken or destroy the virulence. Caterina found that formalin destroys the virus in fifteen minutes, but not in five or ten minutes. Putrefaction has but little or no effect on the virulence. The virulence is retained by preserving the infectious material in neutral glycerin and in the cold. Reference has already been made to the fact that successive inoculation through certain animals weakens the virulence for other animals, it even destroys the virulence in some cases, while similar inoculations through other animals increases the virulence. In other words, the rabies virus assumes a certain definite degree of virulence, which is different and characteristic for each species of animal; and the degree of virulence peculiar to a species of animal is attained by a sufficient number of successive passages through individuals of the species. If the virus used for the first inoculation in the series has a shorter period of incubation and kills more quickly than is normal for the species of animal under experiment, the subsequent inoculations of the series will take longer and longer to produce the symptoms and death till the normal degree of virulence for the species is reached. It does not appear from the literature at hand just how many passages are necessary to reduce the virulence in a given case, probably very few. On the other hand, if the virus used for the first inoculation has a period of incubation longer than is normal for the species under observation, it will have a shorter and shorter period of incubation after each passage till the norm is reached. The acquisition of a high degree of virulence is slow; starting with the virus from a mad dog, it takes a year or more to obtain virus of the highest degree of potency in the rabbit. The virulence of the virus is in inverse proportion to the length of the period of incubation. Thus, as has been already mentioned, the virus of rabbits is more virulent than that from dogs, because the period of incubation between the inoculation and the outbreak of the symptoms of the disease is shorter in the rabbit, after a series of inoculations in these animals, than it is in the dog under similar circumstances. The virus from the dog is more virulent than that from apes for the same reason, and while it is true that, starting with the virus from a dog, this becomes more and more virulent for rabbits by successive passages through these animals, a degree of virulence is finally reached beyond which it is impossible to increase the virulence. When the period of incubation is reduced to five or six days it is impossible to reduce this any further, the virulence becomes fixed. So that for each species of animal there appears to be a normal fixed period of incubation. And although increased virulence for the animal through which the virus is passed is usually accompanied by an increased virulence for other animals, it is not always so; for recent observations tend to show that the "virus fixe," the most virulent virus for rabbits, is decidedly less virulent for man. At least human beings inoculated with this virus do not develop rabies, in spite of the fact that they are not previously prepared by inoculations with attenuated virus. It is true that in the cases of this kind so far reported, the persons had been bitten by mad wolves, but it is not clear how this could diminish the action of the "virus fixe"; on the contrary, it would seem more probable that it would increase the action of the latter. After all, it would seem hardly correct to measure the virulence of rabies virus by its relation to the period of incubation on inoculation, for the virus from an ordinary case of spontaneous rabies in a dog causes the disease apparently with just the same certainty and with equal severity as the "virus fixe," only the period of incubation is longer with the former than with the latter. The disease, if not treated, is as surely fatal with the one kind of virus as with the other. Pigeons are not susceptible to rabies, but they become so by starvation, as already stated. In chickens the disease has a period of incubation of forty days, and it can be propagated by inoculation through a series of chickens. For these birds the period of incubation is just the same with the "virus of the street," from a case of spontaneous rabies in a dog, as it is with the "virus fixe." With either virus the disease progresses slowly after the appearance of the symptoms; the fowls usually live fourteen days after symptoms appear, and finally die of progressive paralysis. In ducks and geese the period of incubation is fourteen days. Inoculation of rabbits with the brain of birds dead of rabies is rarely followed by the disease; so while the virulence of the virus by successive passage through birds is preserved for these, it becomes weakened for rabbits.

Kraus and Maresch have studied the effect upon the rabies virus of blood serum of normal animals, and of blood serum of animals possessing artificial immunity. Their results show that the blood serum of ordinary non-immune dogs and rabbits has no effect upon the rabies virus; but the blood serum of dogs and rabbits that have been given artificial immunity destroys the virulence of the virus. Of this serum 0.01 c.c. destroys 0.5 c.c. of the "virus fixe" diluted in the proportion of one part of the virus to fifty of indifferent fluid. Pigeons' blood has no effect, neither the blood from normal pigeons, nor that from pigeons that have been previously inoculated with the virus. Chicken's blood serum, on the other hand, has the property of destroying the virulence of the virus. This property is possessed by the blood serum of ordinary, untreated chickens, and it does not seem to be in-

Digitized by Microsoft®

creased by previously producing immunity in the chickens. The serum from a normal chicken destroys the virulence of the virus in the proportion of 0.5 c.c. of the serum to 1 c.c. of "virus fixe" diluted in the proportion of 1 part of "virus fixe" to 100 of indifferent fluid. A smaller amount of the serum, 0.25 c.c., does not destroy the virulence of 1 c.c. of the virus.

www.libtool.com.cn

Högyes found by using dilutions of various concentration that all strengths above 1 to 200 of the usual thick suspension of the cord constituting "virus fixe" kill rabbits as promptly as the undiluted virus. Even 1 to 250 kills, but less promptly than the undiluted virus. A strength of only 1 to 5,000 occasionally produces death with prolonged incubation of the disease. Very feeble preparations, 1 to 10,000, fail to produce the disease.

During the period of incubation the individual suffers no special inconvenience, not more than would be caused by a wound of equal severity resulting from the bite of an animal that is not rabid. Indeed, it is stated by Tillmann that a wound inflicted by a rabid animal heals usually with exceptional rapidity in human beings; nor are there any other symptoms during the period of incubation to indicate whether the person has been bitten by a rabid animal or no. This lack of anything to characterize the period of incubation applies to rabies in beasts as well as in man.

In dogs the first symptoms of the disease consist of melancholia and moroseness, with restlessness and irritability, loss of appetite, dysphagia, and nausea. The dysphagia is specially noticeable in the case of liquids, and the name hydrophobia is given to the disease on this account. Abnormal appetite is also present; the animal endeavors to eat straw or dirt or anything lying around, no matter how unsuitable it may be as food. These symptoms may be insignificant at first, and for this reason the animal is more dangerous at this time than at a later period when the symptoms are more manifest. This stage lasts from a half day to two or three days, and is usually followed by the stage of raging madness. This, however, is not always the case, for sometimes the morose stage is followed by paralysis affecting the muscles of the jaws and later of the hindquarters. The lower jaw drops, the mouth remains wide open, the bark is peculiar and hoarse, there are also rapid emaciation, tottering, and final complete paralysis of the hindquarters, and the animal dies in two or three days. This form of the disease is spoken of as "dumb rabies," or as "quiet or melancholy rabies," and runs a more rapid course than the "raging madness." In the latter form of the disease the animal is sullen and morose as in the dumb form; there are also the same restlessness, loss of appetite, and emaciation, but in addition to this the animal has paroxysms of maniacal rage characterized by a desire to snap and bite at everything around. Bollinger states that the great aversion to water seen in the earlier stage of the disease is lacking in the maniacal stage, and in this stage there is only exceptionally spasm of the muscles of deglutition. The maniacal stage lasts for three or four days and then passes into the paralytic stage, which is the final stage as in dumb rabies, and lasts for from three to six days. In the paralytic stage the animal has a bristling coat, the voice is hoarse, dyspnœa increases, and there are local or general convulsions. The termination is always fatal.

In rabbits inoculated with unattenuated rabies virus, either "virus fixe" or virus from "street rabies," the disease always takes the form of "dumb rabies." But Genaro has described a peculiar form of the disease in rabbits inoculated with attenuated virus. In this form of the disease the animals die with progressive emaciation, without any of the ordinary symptoms of rabies, but the brain and spinal cord of these animals produce typical rabies when inoculated into other animals. An example of this form of the disease has been noted above in the citation from Kraus, Keller, and Clairmont's result with inoculation of a rabbit with the medulla of a rabbit taken out twenty-four hours after injection of "virus fixe" into the lumbar cord. It will be remembered also that these observers noticed that some of their rabbits died of a sort of marasmus after infection with attenuated cord, but that the cord in these cases was not infectious for other rabbits.

In the human subject the first symptoms to appear after the stage of incubation are psychical. The individual is depressed in spirits, excitable, irritable, and restless. He also suffers from sleeplessness and loss of appetite, and in some cases even at this stage there is antipathy toward liquids. He is also oppressed with a feeling of impending danger. The reflexes and sensibility are often greatly increased. A noise, even loud talking, and a bright light are distressing. The injection of the larynx and consequent difficulty of swallowing, which is the most distressing as well as the most characteristic symptom of the disease in man, is included in this stage by Osler. Tillmann regards this symptom as marking the onset of the second stage. Some authors note a rise of temperature and acceleration of pulse during this period, others not. Huskiness of the voice is also present, but this symptom depends upon the injection of the larynx, and is not always included in the prodromal stage. Although the wound is usually healed by this time, there is sometimes a return of inflammation in the cicatrix accompanied by pain, burning, and itching at this point. Pain in the bitten part is often the first manifestation of the disease and may be present several days before the onset of the other symptoms.

If the injection of the larynx with its accompanying manifestations is regarded as the beginning of the second stage, the prodromal stage seldom lasts more than twenty-four hours; for the injection of the larynx, with spasm of the muscles of deglutition and inability to swallow, appears rarely later than at this time. Along with these symptoms there appear severe spasms of the muscles of respiration. These occur in paroxysms along with the cramps of the pharynx, and are brought on by the slightest excitation of the nerves; even the sight of liquids is enough to cause them. The spasms are not confined to the larynx and respiration, but soon become general, and are usually clonic, sometimes tetanic. The nerves of special sense are also affected, not only the sight and hearing, as already noted, but also the sense of smell. The salivary secretion is also increased. The mind is for the most part clear, but there are apt to be maniacal seizures from time to time. The pulse becomes gradually weaker. After a paroxysm it is greatly accelerated. The temperature is somewhat elevated; it usually runs to 38° or 38.5° C. (100.4° to 101.3° F.). Dating from the laryngeal symptoms, the second stage lasts for from one to three days.

The third stage is marked by weakness, paralysis, and exhaustion. There is abatement of the spasms and of the difficulty in swallowing and breathing. This stage lasts for from six to eighteen hours, when death takes place, sometimes with recurrence of convulsions, but oftener quietly. By some authors consciousness is said to be preserved to the last, by others it is stated that unconsciousness supervenes.

The total duration of the disease in man, from the first appearance of the prodromal symptoms to death, is rarely less than two days or more than four days. The termination is always fatal if the symptoms once develop.

The macroscopic changes shown at autopsy are not characteristic either in man or in beasts. The blood shows insufficient aëration, is dark and thick. The mucous membranes show a catarrhal condition with hyperæmia and ecchymoses, specially pronounced in the mucous membranes of the respiratory and digestive tracts. There are general parenchymatous hyperæmia and cyanosis. In dogs the stomach usually contains various indigestible substances which the animal has swallowed to satisfy the abnormal appetite. Emaciation is also pronounced. But the most marked lesions are met with in the central nervous system. Besides extensive œdema of the brain, there are very considerable microscopic changes. These consist of diffuse myelitis of both white and gray matter, accompanied by degeneration of the nerve fibres and ganglia. The axis cylinders of the nerve fibres of the central ner-

Digitized by Microsoft®

vous system are hypertrophied. The nerve cells are atrophied and contain pigment. These changes are most marked in the motor centres. The most characteristic lesions, however, are seen in the cerebro-spinal ganglia, in which there is a proliferation of the endothelial capsule of the ganglion cells and a corresponding destruction of the latter cells (Van Gehuchten and Nelis).

www.libtool.com.cn

The diagnosis of rabies presents no difficulty. It is true that the disease is simulated by tetanus arising from an infected wound in the regions supplied by the cranial nerves; then, besides, pharyngeal spasms are also a marked symptom of this affection. But the history of the injury would suffice in most cases for a diagnosis; this would be misleading only in case the tetanus bacilli are introduced into a wound caused by a dog bite, a contingency which is not at all probable. The different lengths of the periods of incubation of the two diseases also afford a point of differentiation. But the surest method of diagnosis is the inoculation of a rabbit under the dura mater with a bit of the cord or brain (rubbed up in bouillon or glycerin) of the animal that has inflicted the bite. If this animal was really affected with rabies, this inoculation would produce the disease in the rabbit in from twelve to twenty-one days. Consequently, if this step be taken promptly after the bite has been inflicted, there will still be time enough to prevent the development of the disease by a resort to the Pasteur method, to be described later. However, in cases of bites on the head or face, the treatment must be begun as soon as possible after the accident, and it would be very unwise to wait for the result of such an experiment. A diagnosis may be reached in twenty-four hours, if the dog died of rabies or was at least in the paralytic stage, by the method of Van Gehuchten and Nelis, *i.e.*, by the microscopical examination of some of the cerebro-spinal ganglia, especially the vagus ganglia which are easily found.

If facilities for inoculating a rabbit are not at hand, material from the animal should be sent for diagnosis to some convenient laboratory. It suffices fully for all purposes to send the medulla in a small vessel containing glycerin, as recommended by Kempner. This method not only possesses the advantage of great convenience, but the material arrives at the laboratory in good condition for inoculation, which is not always the case with the other methods of shipment that are recommended.

The disease can be cured, or, rather, prevented from developing, only during the incubation period, before any symptoms have developed; after this, the treatment is only palliative, and consists in keeping the patient as quiet and undisturbed as possible in a darkened room, and in the administration of quieting drugs. Curare is strongly advised by some, while by others it is not even mentioned in the list of suitable drugs. Chloral hydrate, potassium bromide, and similar drugs are also advised by some. Osler advises resorting to morphine hypodermatically and to the use of chloroform at the start. Dr. Rambaud reports that he has obtained the best results (experience of about thirty cases) from the employment of hyoscine hydrobromate in doses of gr. $\frac{1}{100}$ injected hypodermatically. Cocaine applied locally may be used to diminish the sensibility of the pharynx so as to enable the patient to take liquid nourishment where swallowing is otherwise impossible. Nutrient enemata are also recommended.

The disease may be prevented from developing by speedy excision, or by thorough cauterization with the actual cautery or the strong mineral acids, not with nitrate of silver. These are usually of no avail when not resorted to within a short time after the bite. But cauterization or excision would seem advisable, nevertheless, even several hours after the bite, for, as stated above, the absorption of the virus into the nervous system from the seat of inoculation is sometimes delayed as long as twenty-four hours. Moreover, as already stated, Babes has shown that even when the disease is not prevented in this way, the period of incubation is lengthened by excision or cauterization, a most desirable result when the Pasteur treatment is resorted to, as it should be, and indeed now universally is.

Although the disease is altogether beyond treatment after symptoms develop, and although cauterization and excision are uncertain, the Pasteur method of inoculation affords a means of prevention that very rarely fails. The principle of this treatment, or, rather the object aimed at, is the rapid production of immunity in the patient during the period of incubation of the disease. If immunity can be established before the termination of the period of incubation, before any symptoms have developed, the progress of infection is arrested. The method consists in inoculation once a day, for from fifteen to twenty-one days, with virus of graded potency. The virus employed consists of bits of the spinal cord of rabbits possessing such potency, by repeated passages through the central nervous system of these animals, that it produces death from rabies in nine or ten days in rabbits by subdural inoculation. As indicated on more than one occasion above, this constitutes the "virus fixe" of Pasteur. The graded potency which is required if the virus is to be used upon human beings, is obtained in the following manner: The spinal cord of a rabbit that has died of rabies on the ninth or tenth day after inoculation is carefully removed and hung up in a flask, at the bottom of which are placed a few pieces of caustic potash. Protection against dust, etc., is secured by stuffing sterilized cotton into the neck of the flask which is kept in a dark room, at a constant temperature. In this way the cord is subjected to a slowly advancing process of desiccation, as a result of which the rabies virus is rendered progressively less virulent. On the day following that on which the cord was introduced into the flask, it is spoken of as cord of the second day, or No. 2. On the third day it becomes cord No. 3; and so on up to the fourteenth day. After the fourteenth day what remains of it, if not entirely used, is discarded. It is customary, at the Pasteur Institute in Paris, to use for the first injection an emulsion made from portions of the cord of both the fourteenth and the thirteenth days. In the New York Pasteur Institute, however, the first injection contains portions of the cord of the twelfth and eleventh days. An emulsion is made by rubbing up a segment of cord measuring 0.5 cm. in length in 6 c.c. of normal salt solution (sterilized) for one patient. Two separate injections are made simultaneously, one in the right and the other in the left hypochondriac region. Each succeeding couple of injections is made with a stronger emulsion, that is, with an emulsion made from a segment of the cord that has been subjected to one day less of drying than the preceding one. The most virulent cord used in Paris is that of the third day; in New York, that of the second day. The time for using this is reached somewhere between the seventh and the tenth days, and then a return is made to the cord of the sixth or fifth day, after which a gradual increase is again made until cord of the third or second day is reached. But if the treatment has been deferred, for any reason, so long that there is danger of the disease developing before the entire series of injections can be administered one day apart, the interval between the injections is shortened, and two or more injections of increasing strength are given daily instead of one each day for the first three or four days. Finally, when the case comes for treatment very late, and the necessity for such treatment is therefore urgent, it is maintained by some that all the twelve or thirteen injections should be administered in twenty-four hours, or that the preliminary injections should even be dispensed with entirely, and virus of full potency administered at the start. The procedure mentioned last, the use of unattenuated "virus fixe" without any preliminary inoculation with attenuated virus, has been practised with good results in cases of persons bitten by wolves, the most dangerous of all forms of infection. This procedure, however, is condemned by the Pasteur Institute in Paris as well as by the New York Institute, as it has caused several deaths.

Babes has advanced the theory that the reason why the

Digitized by Microsoft®

"virus fixe" does not itself produce the disease in man is that the injections are always made under the skin of the abdomen where it is not likely, owing to the presence of abundant adipose tissue, that any nerves are injured. But Marx is quoted by Babes as authority for the view that the virus becomes attenuated for human beings and for monkeys by being passed through rabbits, although enhanced in virulence for rabbits themselves.

The writer desires to acknowledge his indebtedness to Dr. George G. Rambaud, of the New York Pasteur Institute, for assistance kindly rendered in revising that portion of the text which relates to preventive treatment.

RACHISCHISIS. See *Spina Bifida.*

RACHITIS.—See *Rickets.*

RAG-WEED.—AMBROSIA. *Ambrosia* is a genus of the Compositæ, containing about a dozen species, mostly North American. The best-known species is *A. artemisiifolia* L., the common annual rag-weed, and one of the most abundant and troublesome of weeds. It is best known to medicine because the presence of the pollen in the nares is believed to be the principal cause or occasion of the disease hay fever. This and other species contain small amounts of amaroid and volatile oil, and have been employed, especially in domestic practice, as aromatic bitters. The idea that a preparation of rag-weed can act as a specific in hay fever is in the highest degree fanciful.

Henry H. Rusby.

RAILWAY MEDICINE AND SURGERY.—While, as a matter of course, passengers and employees have been killed and injured ever since the inception of railways, and railway surgeons have been known over fifty years (Dr. W. W. Apply was appointed surgeon for the Erie R. R. in 1849), the recognition of railway surgery as a special branch of the healing art is a matter of the last twenty years, and has reached its highest degree of development in the Western United States. It seems as fully entitled to recognition as military surgery, with which it has many features in common.

Prior to the War of the Rebellion, the mileage was mostly east of the Mississippi; skilled assistance being as a rule easily obtainable, there was little demand for systematic surgical service such as is now met with. Even at the present day in the Eastern States, where railways traverse thickly populated communities, the stations are almost in sight of each other, and cities and towns with well-appointed hospitals occur at frequent intervals. In the extreme Western States, however, perhaps several hundred miles of unsettled or sparsely inhabited territory may intervene between the locations of properly equipped hospitals. Hence during the building of the great transcontinental lines, provision had to be made for the care of employees injured during the construction of the road, all of them away from their homes and in uninhabited districts. In many instances this hospital department became a permanent feature after the roads commenced operation.

Except for the fact that it will have a larger proportion of emergency cases, the practice of the railway surgeon will not differ materially from that of his surgical brethren in general. The injuries with which he has to deal are very similar to the severe crushing injuries from machinery or heavy vulnerating bodies in ordinary surgical practice. They, however, present some special features. Thus, for example, owing to the fact that the extremities often become engaged between two unyielding surfaces—the rail and the flange of the car-wheel,—these railroad injuries are often extremely severe in character, with great destruction and laceration of the soft parts, and comminution of bones. Again, they are attended by a high degree of mortality, and their effect on the nervous system is overwhelming, shock being especially noticeable in this class of injuries. In addition to the crushing force, there should be taken into account the weight and velocity of the moving train. The weight varies from ten tons for empty flat cars to twelve or fifteen for box cars; from twenty to sixty for coaches; and it amounts to one hundred tons or more for locomotives. The railway surgeon often has to exert his skill under the most unfavorable circumstances and the most depressing surroundings, laboring at night with no light but the trainmen's lanterns, far from skilled assistance or even habitations, and amid rain, sleet, and snow.

The present mileage of steam roads in the United States is over 200,000, on which over 600,000,000 passengers were carried last year (1901–02). To operate this system required in 1895 an army of 785,000 men; in 1901 this number had grown to 1,071,000. In the Middle Atlantic States the number of employees per one hundred miles is 1,140; next come the New England States with 827; and so on, the lowest being the Middle Northwestern States with 303. For the year ending June 30th, 1902, the total number of casualties to passengers and employees reported was 42,619 (2,819 killed; 39,800 injured). Passengers killed, 303; injured, 6,089; employees killed, 2,516; injured, 33,711. (Report of Interstate Commerce Commission.)

As regards the different classes of employees, brakemen are injured most frequently, then come switchmen, firemen, and engineers in the order named. In former years the largest number of injuries resulted from coupling and uncoupling cars. In 1893 the "Safety Appliance" law was enacted, requiring the use of automatic couplers. This law went into full effect in August, 1900, and the results from this humane legislation are both surprising and gratifying. The number of employees killed in 1902 as compared with 1893 is sixty-eight per cent. less, and the diminution in the number of those injured is no less than eighty-one per cent., notwithstanding the much larger number of employees. Other frequent sources of accidents to trainmen are getting on or off trains in motion, falling from the cars, collisions, and derailment. The principal causes of accidents to passengers are collisions, derailment, and falls from the cars. According to Herrick, about fifty per cent. of injuries to employees involve the upper extremity, thirty-three per cent. the lower extremity, twelve per cent. the head and face, and eight per cent. the trunk.

To furnish relief for sick and injured employees there are four principal methods in operation at present: (1) the relief system; (2) the surgical service without a chief surgeon; (3) the surgical service with a chief surgeon; (4) the hospital system.

1. The relief system is in operation on a number of roads, among them the Baltimore & Ohio, Pennsylvania, Reading, Burlington, and Plant System. Membership may be either voluntary or compulsory. Under this plan the employee is assessed monthly according to the amount of his wages—usually from twenty-five cents to two dollars. When injured, he receives a certain sum monthly during this period of disability. Provision is also made for death, and for benefits in case of permanent disability. In some associations membership lapses if the employee quits the service of the company, in others the death benefits may be retained. In others again, additional features are found in the shape of savings, building and loan departments, and old-age pensions. The scope of such a system on a large trunk line may be gleaned from the last annual report of the one in operation on the Pennsylvania west of Pittsburg. The membership was 23,179, an increase of 2,122. The average number of members disabled per day was 778, or 35 for each 1,000. The death rate was 13 for each 1,000. Applications for membership were 11,010, while the cessations of membership were 8,868, of this number 8,090 having left the service. The total receipts for the year were $415,643, the disbursements $349,104.

2. The local surgeons are appointed by the superintendent or general manager. Local surgeons are generally located at divisional or terminal points, and along the remainder of the route,—as a rule, about fifty miles apart.

3. A chief surgeon is appointed who selects his own

Digitized by Microsoft®

assistants. It is asserted for this plan that it reduces the number of damage claims. There being more miles of railroad in the rural districts than in cities and towns, accidents frequently occur at remote points. Consequently it is often the practice to locate, at convenient points, division surgeons who are subordinate to the chief surgeon and who in their turn have charge of a division or branch of the line, and of the local surgeons in their territory.

4. The hospital plan is in operation among other roads—on the Missouri Pacific, Chesapeake & Ohio, Wabash, Southern Pacific, Santa Fé, St. Louis, and San Francisco. It embraces the care of the employee whether sick or injured, and whether his illness occurs on duty or not. The chief surgeon is in charge, and the executive board or board of governors is composed of representatives both from the employees and from the railroad company. As in the relief system there is a monthly assessment, and in addition the company either makes an annual donation or meets a deficiency should one arise. Minor ailments and injuries are attended to by the local surgeons, but if the illness proves to be serious or lasting, patients are sent to the main hospital, or on the longer systems to a branch hospital which is located at some accessible point. The Northern Pacific Beneficial Association, which was founded in 1882, may be selected as a type of this plan. This body maintains two hospitals—one at Brainerd, Minn., for the eastern division, and another at Missoula, Mont., for the western. For the year ending June 30th, 1902, the receipts were $165,865.77, and the expenses $161,063.40. The cases treated at the Brainerd hospital were 3,150 in number, and by the line surgeons of the eastern division, 13,323. The Missoula hospital cared for 1,994 cases, and the surgeons on the western division, for 12,966 cases. A training school for nurses is maintained at Brainerd.

For transporting the injured, several roads have equipped hospital cars which are kept constantly ready for use, and are despatched wherever they may be needed. The first one to be placed in commission seems to have been that which was installed on the Baltimore & Ohio Southwestern in 1894. A general idea of their fittings may be derived from Fig. 3925 (from Herrick's "Railway Surgery").

Nussbaum's dictum that the fate of the wounded depends on the individual who makes the first dressing is now firmly established, and railway employees often infect wounds received by them by applying to them tobacco ends, soiled waste, or dirty handkerchiefs. To guard against this, "first aid" instruction, so successful in Great Britain, has been introduced into this country and is slowly finding its way into favor. Classes of the employees are formed at convenient points and a course of lectures couched in simple language and illustrated by a manikin, etc., is delivered to them by the surgeons. A course may consist of five lectures. The first one is devoted to elementary anatomy and physiology, the second, to arrest of hemorrhage; the third, to sprains, dislocations, and fractures; the fourth, to asphyxiation, artificial respiration, poisons, etc.; and the last to transportation of the injured. Instruction is also given in stretcher drill, and those employees who are found to be proficient are, after examination, formed into ambulance corps. To keep up interest in the work annual competitions in stretcher drill are held, and the winning team retains the trophy for the year ensuing. A small manual on first aid has been compiled by C. R. Dickson especially for railroad men.

In line with this work some roads equip their trains with "emergency boxes," containing a supply of gauze, bandages, etc., which are replaced when used. These are placed in depots, freight houses, or car shops. The contents vary somewhat; the following is an average assortment:

1 Heavy rubber bandage.
12 Assorted muslin bandages.
5 Yards sublimate gauze.
1 Ounce absorbent lint.
1 Ounce styptic cotton.
4 Ounces absorbent cotton.
25 Corrosive sublimate tablets.
2 Ounces bicarbonate soda.
4 Surgical needles.
1 Pair scissors.
1 Pair forceps.
1 Case carbolized silk.
1 Roll rubber adhesive plaster.
1 Dozen safety pins.
1 Pyramid of pins.
1 Esmarch tourniquet.
1 Ounce iodoform.
1 Case for scissors, forceps, needles, etc.
Splints.

The idea is to have wounds protected by clean gauze held in place by a clean bandage, in order that they may reach the surgeon in an aseptic condition, or as nearly so as possible. Directions for using the various articles are pasted on the lid of the box. The following are those used on the Southern Pacific:

"These supplies are for temporary relief, until a surgeon can be obtained.

"In case of a broken bone straighten out the limb by stretching it, and fit a splint on it by padding with sheet cotton. Apply a bandage over the splint to hold it on.

"In case the skin is broken, making an open wound, apply moist gauze, and cover with cotton or lint and a bandage.

"If there is severe bleeding, apply the strip of duck-webbing above or toward the body from the wound, put a stick under it, and turn until the bleeding ceases. Do not stop the circulation altogether. If bleeding does not cease apply bandage on other side of wound.

"For burns or scalds, apply the oxide of zinc ointment, and cover with moist gauze, cotton or lint, and a bandage.

"In case of a cut, where the wound gaps, apply a strip of adhesive plaster so as to hold the wound together, and apply gauze and a bandage over it.

"To relieve pain, give one or two opium pills every three hours, until it is bearable.

"For pain in the eyes due to cinder: Dissolve a cocaine tablet in a few drops of water and apply to the eyeball or lids by dropping, or by means of a bit of cotton wrapped

around a piece of wood the size of a toothpick or match. The cinder will often come away with the cotton."

The physical examination of employees is becoming more and more important of late. It is claimed on one road, where the examination is rigid and great care is taken in the selection of new men, that the number of accidents and suits for damages has been lessened over one-half. Claims for damages are sometimes brought to recover for hernia or other conditions stated to have been received while at work, and proved to have been present before the litigant entered the employ of the company. Defective vision and color blindness are frequent causes of rejection, both for admission to the service and for promotion. Thus, on the Chicago & Northwestern, fifteen per cent. of the firemen, and ten per cent. of the brakemen examined were rejected for these reasons. Out of 21,473 examinations on this road since this plan was first adopted in 1895, some 2,785 applicants were found physically disqualified. Of these, 1,469 had defective vision, 664 were color-blind, and 652 were rejected for other physical defects. On some roads applicants are rejected for varicose veins, hernia, epilepsy, heart disease, and hemorrhoids; others exclude applicants with hydrocele, suppurative otitis, rheumatism, etc. The mental qualifications are generally taken into account also, and the examinations, as a rule, are repeated at stated intervals, or whenever occasion arises for promotion. In this connection the age at which applicants enter the company's employ is becoming important since the adoption of old-age pensions on a gradually increasing number of railroads. At present the extreme limit at which applications are received on most roads seems to be thirty-five years; on one road (Erie) it is forty-five. In the first two years' operation of the pension plan on the Pennsylvania road 1,574 employees were retired.

A constantly increasing field of usefulness for the railway surgeon is that of hygiene. The freedom of the ice and of the drinking-water from contamination; the disinfection of coaches after cases of contagious disease have been unwittingly transported, or where, as frequently happens on some roads, tuberculous passengers are carried to health resorts; the cleanliness of cars and depots —all these are subjects which come properly within his sphere.

In common with the members of other branches of medicine and surgery, the railway surgeons early felt the need of societies for the interchange of views and opinions, and as a result several national, state, and local societies have been organized. The first, composed of surgeons on the Wabash Railroad, was organized on January 25th, 1882, at Decatur, Ill.; in the same year the Pennsylvania system's surgeons met and organized. The National Association was formed mainly through the efforts of the late Dr. A. W. Ridenour, of Massillon, Ohio, and its first meeting was held June 28th, 1888. In 1897 it increased its scope to include surgeons from Canada and Mexico, changing the name to International, and at present it has a membership of nearly one thousand. The American Academy of Railway Surgeons, organized in 1894, limits its members, and is made up principally of chief surgeons. Flourishing state associations are those of Iowa and New York. There are numerous bodies composed of surgeons connected with the larger systems of roads; among them may be mentioned the Milwaukee & St. Paul, Wabash, Santa Fé, Pennsylvania, Erie, and Southern.

A few colleges in the West have chairs, either of railway surgery or of accident surgery in general.

The literature comprises two treatises, annual transactions of the national bodies, and a monthly journal, besides many contributions to current medical journals.

RAILWAY SPINE. See *Nervous System, Traumatic Affections of.*

RÂLES.—This term is applied to certain abnormal sounds heard in the chest. It is customary with many authors to speak of *dry* and *moist* râles. Sibilant and sonorous breath sounds are called dry râles, although there is no more reason for calling these sounds râles than there is for applying the same term to cavernous breathing. Certain authors also call these forms of breathing rhonchi, and use the word râle to designate only the moist sounds. Rhonchus, again, by others, is used as exactly synonymous with râle.

The causes of these abnormal sounds vary considerably. We may have a considerable accumulation of exudation in the trachea and larger bronchi, producing large bubbles, or the smaller bronchi may be more or less filled, giving rise to small bubbles, or perhaps the sounds may be produced in the alveoli themselves. Râles may also be produced by the rubbing of roughened pleural surfaces, by the presence of fibrinous exudate on the pleura, and by the stretching of pleuritic adhesions.

COARSE MUCOUS RÂLES are coarse bubbling sounds produced in the trachea and larger bronchi. They are heard with both inspiration and expiration. They may sometimes be made to disappear for a time by causing the patient to cough. Sometimes, especially in children, they may produce a fremitus easily felt through the chest wall. They are heard most commonly with acute bronchitis in its exudative stage, and with bronchopneumonia, also with chronic bronchitis and phthisis, some cases of œdema of the lungs, lobar pneumonia, compression of bronchi or trachea due to neoplasm or aneurism, some cases of pleurisy with effusion, and empyema, especially with perforation of the lung.

FINE MUCOUS RÂLES are sounds of the same quality as the former, but finer. They are heard under the same conditions.

SUBCREPITANT RÂLES.—These are fine, high-pitched, bubbling sounds, heard during both inspiration and expiration. They may be produced by the bursting of small bubbles in the finest bronchioles or air passages, or they may be caused by fibrin on the pleura, and by pleuritic adhesions. The cause of this râle has been a matter of considerable dispute. On the one hand, it is held that the sound is invariably produced in the finer air passages; on the other, that pleural changes alone can give rise to it. The advocates of the former view hold that sounds resembling the subcrepitant râle may be produced in the pleura, but that a good ear can distinguish these from the true subcrepitant, by a slight difference in quality. Believers in the second dictum say that there is not enough motion in the air in the finer air passages to give rise to the râle. Both of these views are extreme. There are cases in which the subcrepitant râle is heard which show, post mortem, nothing but pleurisy as a possible cause, and there are cases of œdema of the lungs, with no pleuritic changes, in which this râle has been clearly heard, and in which the serum in the lungs is the only demonstrable factor in its production. It cannot be denied that the sound may be due to either of these causes. This râle may be heard in pleurisy, in bronchitis of the smaller tubes, in bronchopneumonia, in lobar pneumonia during the stage of resolution, and occasionally, during other stages, in phthisis, and in œdema of the lungs.

CREPITANT RÂLES.—These are very fine sounds heard only at the end of inspiration, and sounding very near the ear. They occur in abrupt explosions. They are much finer than the subcrepitant râles, and are usually compared to the sound produced by rubbing a lock of hair between the fingers. The causes of this râle are the rubbing together of inflamed pleural surfaces, the entrance of air into ultimate bronchioles or alveoli, the walls of which are partly stuck together by exudate, or perhaps the breaking of very fine bubbles. Of these

Digitized by Microsoft®

three possible causes the first seems most common, and it is not unlikely that this is really the only cause. It is conceivable that if the pleura be coated with a thin layer of sticky exudation, its surfaces will tend to stick together until the motion of respiration strengthen, in slipping over one another, give rise to the sound. This râle is often said to be pathognomonic of acute lobar pneumonia. This is not so. The râle is frequently heard in the first stage of this disease, but it is also heard in pleurisy, bronchopneumonia, and phthisis. Taken in connection with a rational history of acute lobar pneumonia, the râle is of great value as a sign, especially if with it other signs be found, but it is not to be called pathognomonic.

Pleuritic Friction Sounds are râles produced in the pleura when it is diseased. They may be of a rather moist, grazing character, or may be creaking and dry. They may be heard in all diseases in which the pleura is involved. As has been mentioned, the pleural surfaces, when diseased, may give rise to crepitant and subcrepitant râles.

Pleuritic Adhesion Sounds.—In some cases of old pleurisy, with adhesions, peculiar sounds are heard, which may be accurately imitated by applying one end or a rubber band to the ear and stretching it. The adhesion sounds are probably produced by stretching of old adhesions.

The Metallic Tinkle is a sound resembling that produced by pouring water in drops into a bottle. It is produced either by drops of fluid falling from the roof of a large cavity in the lung, or from the walls of the cavity of a hydropneumothorax, or by bubbles breaking in fluid under similar circumstances. In different cases one or the other of these causes may produce the sound. It is heard over some large cavities, and, in some cases of pneumothorax, it may occur either when the patient speaks or while he is breathing.

Gurgles are coarse râles which are more liquid than mucous râles. They are sometimes heard in bronchitis, in some cases of solidified or compressed lung, and in some cavities.

The Mucous Click is a peculiar dry sound, occasionally heard at the end of inspiration. Its cause and significance are not clear.

Dry and Moist Crackles are sometimes mentioned. They are difficult to distinguish from subcrepitant râles.

Sibilant Breathing, sometimes called sibilant *rhonchus* or râle, is a whistling or hissing sound heard in cases in which a bronchus is narrowed by inflammatory thickening of its mucous membrane or by other causes.

Sonorous Breathing is produced in the same manner as the former. It is of lower pitch and softer quality.

J. West Roosevelt.

RAMSGATE AND MARGATE, ENGLAND.—These two popular though not the most fashionable English coast resorts are situated on the Isle of Thanet, about seventy-five miles east of London. Margate lies to the north, with an eastern sea exposure, while Ramsgate, about five miles to the south of it, has a southern as well as an eastern sea front. Similar but quieter resorts in the near vicinity are Broadstairs, Westgate-on-Sea, and Birchington.

The general climatic characteristics represented by these resorts are those of a cool marine climate, with moderate or quite considerable humidity. Owing to the influence of the Gulf Stream here, as throughout all England, the mean temperature is much higher than is due to latitude. The winters are mild, the summers cool; there are no great extremes of temperature; and there is great seasonal and diurnal equability. There is only a moderate amount of sunshine, and there is always wind. Such a climatic combination is stimulating and bracing, and has been found valuable for anæmia, malaria, convalescence from various diseases, dyspepsia resulting from debility, certain nervous affections, and particularly scrofula and tuberculous conditions other than pulmonary.

These resorts are available all the year, although they are naturally most frequented in the summer.

The soil is of chalk covered with a foot or two of earth, and, consequently, is dry and quickly absorbs moisture.

Ramsgate, like its neighbor Margate, presents to the sea high chalk cliffs, with an abrupt descent to the "sands," which, being thus sheltered from the winds, affords an attractive resort for the invalid and visitor, and good bathing. In general, however, here as at Margate, the winds are frequent and trying, particularly at certain seasons of the year. By the construction of terraces and crescents a certain amount of artificial shelter is obtained. Nevertheless, "even in its stillest corners the keen Thanet air is constantly moving." The southern exposure affords more sun, though the general percentage of cloudiness is 6.7. On account of its situation it is a little warmer here than at Margate.

The town contains about 25,000 inhabitants, and appears to be very healthy, as the death rate in 1891 was only 14 6, and more than one-third of the deaths occurred at over sixty years of age; the infant mortality was 118 per 1,000 births. The drainage is thorough and good, and the water supply is constant and pure. If one desired to live long this would appear to be a desirable resort, as in 1890 one-twelfth of the total number of deaths was of individuals at or upward of eighty years.

Besides the cliffs and sands there are piers for promenading; and the marine view, and the almost daily arrival of foreign fishing smacks afford a constant source of interest. There are also attractive drives in the vicinity. The temperature of the sea water is 61° F. in the summer, thus affording opportunities for bathing. Ewart ("Climates and Baths of Great Britain," 1895) says that Ramsgate has an "admirable winter climate for most invalids," and "many," he continues, "are so fortified by a winter residence as to be able to meet the spring winds without risk."

A climatic table of Ramsgate is appended; it also substantially represents that of Margate, which is only about five miles distant:

Margate (about 19,000 inhabitants) has been noted for a century for the treatment of scrofula and tuberculous diseases, especially in children, and here is situated one of the oldest and most famous seaside sanatoria for those suffering from these diseases—"The Royal Sea-Bathing Infirmary." There are also many other similar institutions. The town stands on two hills separated by a valley, and facing the north are high chalk cliffs at the base of which is a shallow beach that is quite covered at high tide. It is upon these cliffs that the new portion of the town is situated. The town also stretches some distance back from the sea over undulating ground, affording opportunities to gain a certain amount of protection from the winds. The water supply is good, and the

Digitized by Microsoft®

drainage is efficiently accomplished both by natural and by artificial means.

The table shows the various meteorological data in detail. Fogs are not frequent. It is rarely uncomfortably hot or cold in summer. January is the coldest month in the year, the average temperature being 38.9° F.

Large numbers of children are sent to this resort for the effect of the sea air and sea bathing, the majority suffering from scrofula and tuberculous diseases other than pulmonary tuberculosis. The benefits obtained in these maladies in some cases are said to be extraordinary. At the Royal Sea-Bathing Infirmary the following percentages of cures are given: 1886, 23.5 per cent.; 1887, 27.84 per cent.; 1888, 38 per cent.; 1889, 46.1 per cent.; 1890, 52.35 per cent. As it requires a certain vigor of constitution to endure this climate, weakly children would probably do better in the milder climate of the Mediterranean shores.

The accommodations at Ramsgate and Margate are good and of varying price, and there are excellent facilities for all sorts of sea-baths.

For a more extended description of this region and its climate the reader is referred to the article of Ewart in "Climates and Baths of Great Britain," to whom the writer acknowledges his indebtedness.

Edward O. Otis.

RANULA.—A cystic tumor in the floor of the mouth, formed by the dilatation of one or more of the acini of the anterior lingual glands (Ward [1]), which are known also as the "Blandin-Nuhn" glands (von Recklinghausen [2]), and are situated at the under side of the tongue on either side of the frænum linguæ, near the apex.

This definition, the correctness of which has been confirmed by later investigations,[3, 4] is founded on the result of a characteristically thorough investigation, by the accomplished Strassburg pathologist, of a typical ranula accidentally found at a necropsy made in his pathological institute. The cyst, about the size of a pigeon's egg, was found on the under side of the left half of the tongue; it extended to a little beyond the median line upon the right side, and penetrated into the intermuscular spaces in different directions. The wall of the cyst was of a nearly uniform thickness of from 1 to 3 mm.; the internal surface was nearly smooth, except in the upper part, where, anteriorly, toward the apex, there was a prominence of some 5 mm. in height, upon which were two furrows; one of these, situated near the top of the prominence, allowed the passage of a bristle to the depth of 2.5 mm., while the other, situated near the base and away from the apex, was impervious. The cyst was everywhere colorless and translucent, except at the inferior part, where there was an opaque spot of about 20 mm. in diameter, of a brownish color, having at its edges two more cysts, each about the size of a pin's head. The ducts of the various salivary glands, Wharton's and Rivinus', as well as Bartolini's, were all to be traced outside of the cyst, having no other relation with it than that of proximity. The microscopic examination showed that the epithelial lining of the cyst wall was in two layers, the inner one of ciliated cylindrical epithelium, and beneath this a layer of small polygonal cells with large nuclei. The cyst contained a clear, somewhat thick, glairy, and viscid mucus, faintly yellow in color. The morphological elements were cells of an epithelial character in various stages of "colloid" degeneration, large brownish granular bodies, and numerous hyaline corpuscles, among which were some quite large, of a diffused, faint greenish-yellow shade, permeated with countless "vacuoles." The chemical examination showed a considerable amount of mucus, but no evidence either of sulphocyanide of potassium or of any fermentative material for the saccharine conversion of starch; therefore the fluid was not saliva. This confirmed the investigation of Besanez [5] made in 1845. Föderl [6] describes a ranula which he dissected as consisting of the dilated duct of the Blandin-Nuhn gland.

Ranulæ, in general, present themselves as translucent pink or bluish tumors, generally globular in shape and fluctuating, lying either wholly in the mouth or between the mouth and chin, according to their size. They project into the floor of the mouth from beneath the tongue, at first quite to one side of the frænum linguæ; but as they increase in size toward the mouth they elevate the tongue, push it over to the opposite side, and in time present themselves against the teeth in front, and may even prevent their closure. They push the frænum toward the opposite side, but may project beyond it, giving the appearance of two tumors, or of one tumor divided into a larger and a smaller portion. As the tumor increases in size the interference with speech and deglutition becomes steadily more noticeable. The elder Cline [7] relates the case of a person who was in great danger of immediate suffocation by a large ranula which thrust the tongue back into the fauces. When not interfered with the tumor will project in the neck below the angle of the chin, and fluctuation may be felt in this situation. When the tumor is large the alteration of the patient's expression is marked; the region of his mouth looks like that of a frog, the pale bluish, translucent hue increasing the resemblance. Hence the name, from *rana*, frog (Ger., *Froschgeschwülste*; Fr., *grenouillette*).

Cysts of other organs than the Blandin-Nuhn glands are also found in this situation. Wharton's duct may be dilated by the damming back of the secretion of the submaxillary gland from the formation of a salivary concretion in the duct, either at its orifice or in its course; and dermoid cysts, often of considerable size, are also found. The latter are especially interesting pathologically, as they undoubtedly represent here the remains of a fœtal organ which normally entirely disappears. The branchial fissures of the fœtus are normally obliterated early in fœtal life, but occasionally a fold of the tegumentary or epiblastic layer becomes included in the deeper tissues in the process of closing in from the sides to form the face, and finally it becomes entirely separated from its attachment to the external skin. It may remain quiescent, giving no evidence of its presence, or the cells of the epithelial lining may be excited to growth and the interior become filled with the products, consisting of broken-down epithelium, fat, cholesterin crystals, and débris, *i.e.*, the usual contents of cysts developed from the dermoid layer. Indeed, hairs, bone, and teeth have been found in them.[8] These dermoid cysts, however, do not spring from the same point as do true ranulæ. They are situated either in the median line, between the two geniohyoglossi muscles, or between one of these and the mylohyoid; but as they grow they extend upward into the floor of the mouth, or downward in the neck, as far, perhaps, as the larynx.[9]

Diagnosis.—These various tumors present points of differentiation sufficiently marked, usually, to allow them to be recognized, and as the treatment of each is different, it is important to have them well in mind. The positions of true ranula and of the dilated Whartonian duct are, by the time they have aroused sufficient attention to be brought to the notice of the surgeon, very nearly the same; they both lie just under the tongue, to one side of the frænum, and fill up the floor of the mouth, elevating the tongue above it, and appearing as a thin-walled, fluctuating, and translucent tumor. In the case of the ranula, this tumor has upon its surface Wharton's duct, the orifice of which can usually be detected near the median line, and into which a fine probe or bristle may be passed, and be seen to glide along the surface to the submaxillary gland, external to and beyond the cyst. Careful search will often also reveal the orifices of the sublingual gland, the ducts of Rivinus. Blood-vessels are frequently seen coursing in waving lines over the cyst. When Wharton's duct is the seat of the tumor, the entrance of the probe into it will be prevented by the obstacle which is blocking it, be it salivary concretion or inflammatory product, and removal of the obstacle will usually allow the escape of the fluid. In these cases there are usually considerable pain and circumjacent swelling, with other evidences of inflammatory action in all the

Digitized by Microsoft®

parts implicated; the floor of the mouth is hot and tender, the tongue is painful on motion, and under the jaw the submaxillary gland is swollen and tender.

The clinical features of the dermoid cyst are different; indeed, there should be no confusion between them, but inasmuch as, from its situation and gross appearances, it is sometimes mistaken for ranula, it is well to point out the differences. The wall is usually thick and firm, the contents may be quite thick, even mortar-like, sometimes purulent, or the contained fluid may be thin or viscid. There may be fluctuation, but it is less distinct than in ranula, and the surface often pits on pressure. The tumor is situated more deeply under the muscles of the mouth, and, when presenting under the jaw, is embedded among those of the neck, and may penetrate even as far down as the larynx. In the mouth it arises nearer the median line, although as it grows its origin becomes obscured, and may not be readily determined at the time when the case comes under the observation of the surgeon.

TREATMENT.—No other than operative interference is of any avail in the treatment of these cysts, and it is usually necessary to do more than simply to evacuate their contents. If it be a *dilated Whartonian duct*, the removal of the concretion blocking up the orifice is usually sufficient; but this requires some care, as it is often very brittle, and if any fragments remain they set up a good deal of irritation in the duct itself, and serve as nuclei for further collections. Therefore an opening should be made in the duct sufficiently large to "shell out" the stone entire. As these are occasionally quite long, it may require a considerable incision in the length of the duct, but this is preferable to making a small opening and endeavoring to drag the stone out; for if this is attempted it is liable to break, to the subsequent annoyance of both patient and surgeon.

It is better, when practicable, to remove the *dermoid cyst* entirely, though, when it extends deeply and has very firm attachments, this will be difficult, and may be impossible with safety to the patient. When the cyst is not large it is usually easiest to make a free incision through its wall—whether in the mouth or under the chin, depends upon its accessibility—and evacuate the contents. When these are thick and tenacious this may be a matter of some difficulty. After this, the cyst wall being tolerably firm, it will bear considerable dragging upon, and may be enucleated with the handle of the scalpel, aided by occasional snips with the blade or with scissors. Cases are occasionally met, however, in which the operation of entire removal is both difficult and dangerous. In Mr. Mayo's[9] case the tumor extended down nearly to the clavicle, passing between the sterno-mastoid muscle and the trachea. After scooping out the contents and removing a part of the wall, he left the rest to suppurate, first filling the cavity with lint soaked in turpentine, in order both to arrest the hemorrhage and to hasten the suppuration. The patient recovered after a considerable time.

Sir William Fergusson's[10] case filled the mouth so as to threaten suffocation, keeping the teeth forcibly apart and projecting prominently under the chin. He feared to leave "a sac so large and thick to the certainty of a violent inflammation," . . . and "resolved instead to attempt the extraction of the whole cyst." Incisions were made both in the mouth and in the neck, but "the sac was so amalgamated with the surrounding tissues that a free use of the knife was required." No large vessel was cut, but there was much loss of blood both at the operation and subsequently; the ultimate result, however, was entirely satisfactory.

The true thin-walled ranula requires a different treatment. Simple incision is not sufficient, for the edges of the wound usually reunite and the cyst forms again. The wall is also too thin to allow its enucleation *in toto*. A seton introduced through its walls, and allowed to remain for a couple of weeks, more or less, will sometimes, but not always, cure it, and is to be tried first. This failing, some surgeons recommend the removal of a large part of the thin wall, in the expectation that the remainder of the cyst will collapse and the walls unite, thus obliterating its cavity; but, like the seton, this often fails. A sort of plastic operation has, therefore, been tried, and it has usually proved successful. This consists in forming a triangular flap by a couple of converging incisions in the anterior wall, and fastening the apex by two or three sutures to the opposite wall; adhesions are thus formed, and the cyst is kept open until the wall shrivels up. Sonnenberg recommends that the remainder of the gland be dissected out of its bed in the apex of the tongue, thus preventing the development of any other cysts afterward. This is occasionally done, with very satisfactory results, when milder measures have failed. Hippel[11] advises the removal of both cyst and gland through an incision under the chin, as being more accessible and more sure against recurrence. Felizet[12] thinks that he simplifies the procedure of extirpating the sac by first injecting a solution of boric acid into the tissues around it; after which he opens and empties the cyst, stuffs it full with a sponge, and shells it out as a solid tumor (!)

RAPE, MEDICO-LEGAL ASPECTS OF.—Rape may be defined as the carnal knowledge of a woman through force and without her consent; or, as it is generally expressed, "forcibly and against her will."

The physician is concerned but little with the legal aspects of the subject. Only the more important facts will therefore be stated, greater space being given to the duties of the medical examiner.

General Considerations.—Rape has always been regarded by civilized nations as one of the most heinous crimes. It is a felony in all the United States, and its punishment varies from fine and imprisonment for a term of years to life imprisonment or death. The severest penalty is imposed in several of the Southern States.

Assault with intent to rape is recognized as a distinct offense in some of the States, but not in others. Where so recognized, it is punished with fine and imprisonment. Handling, touching, or attempting to touch the genital organs of a female, or her breasts, forcibly and without consent, is regarded in some States as a felony or criminal assault; in others, as a misdemeanor.

If it can be shown that the woman gave her consent, the guilt of the man is removed, providing the woman is capable of legally giving consent. Under the old "common law" the age limit, under which a female was not capable of giving consent, was thirteen years. In most of the States this limit has been raised to fourteen or sixteen years; in Wyoming, to eighteen years. Carnal knowledge of a girl under this limit, even at her solicitation, is a felony. An idiotic or insane woman cannot give consent, and an assault or rape committed upon one in a state of anæsthesia or in a hypnotic sleep is generally regarded as being committed against her will. Consent obtained by fraud, as when a man represents himself, in the dark, to be the husband, or when the woman unwittingly assumes that he is her husband, does not mitigate the offense, although a decision was once given in England in which such deception was permitted to pass without punishment. Previous repeated cohabitation between the man and woman does not remove the guilt

Digitized by Microsoft®

of rape, if force has been used, for the common law holds that even a prostitute may reform or withhold her consent. A woman cannot charge her husband with rape, for the marriage contract involves her consent. Finally, all persons aiding in the commission of a rape or assault are regarded as principals in the second degree.

www.libtool.com.cn

The testimony of the prosecuting witness is accepted as competent through recognition of the fact that the crime is generally committed in secret when no other persons are near. But the character of the prosecuting witness is important and may be impeached. The witness is required to answer all questions put by the defence without privilege.

Duties of the Examiner.—The testimony of the medical examiner is generally employed to corroborate that of the prosecuting witness, and there are few positions in which greater care and discrimination must be used. It is the duty of the physician to make an impartial examination and to submit the facts just as he finds them. The statements of the victim and those of her friends are matters for the consideration of the court and should not in the least influence the examiner. In a large majority of all cases of alleged assault the allegation is accidentally or maliciously false. Amos was doubtless correct in his estimate that there are twelve false charges to every true one. The estimate is true also of cases in which a child is the principal witness. Even young children are taught by designing women to tell the story of an assault; but they are often taught to use language most unnatural to their age, and the absolute precision of their statements is often a ground for suspicion. It is rarely indeed that an adult can reiterate a false story without introducing discrepancies. The motives for such deception need not be discussed. The chief of them is revenge, and this is often for the most trivial offense, an unpaid debt, a fancied slight or insult, or a cessation of improper relations with the mother. In such cases the report of the examiner should prevent the case from coming to trial. In cities where these examinations are entrusted to a medical officer of the court or Police Department, his decision is usually accepted and the case is disposed of accordingly, but a physician is generally found by the friends of the prosecution whose sympathy masters his judgment, or one who may innocently err through lack of experience. The inexperienced physician should be exceedingly careful in all cases.

The examiner, on the other hand, would often err if he confined his opinion too rigidly to the physical condition of the victim. He can often further the ends of justice by carefully interrogating her apart from her friends and the officers in charge of the case. For his own protection, however, he should never examine her alone in a closed room. A child when privately questioned may admit that she has been instructed and perhaps injured by her mother; but the testimony of a young child is so unreliable that even this admission may be false. The slightest discrepancy should arouse suspicion, especially in the case of a girl approaching the age of consent, and in all cases a careful inquiry should be made into the possibility of a motive for false accusation. In a case examined by the writer, a girl of fifteen years charged her father with incest on two occasions. Her condition suggested more frequent intercourse, and she finally admitted that the charge had been brought through revenge for being forbidden the attentions of the young man who had been guilty of her downfall.

The examination should be made at the earliest possible moment after the assault, but in the case of an adult woman only with her consent. Refusal to submit to examination may be taken as an indication of false accusation, but no more extensive injuries were ever found by the writer than in a young woman who, after reciting a most incredible account of imprisonment and rape by five young men, was with the greatest difficulty persuaded to undergo an examination.

A complete record should be kept of the examination, including the name, residence, age, and apparent age of the subject, the exact time and place at which the assault is alleged to have been committed, and the place and exact time at which the examination is made. The injuries, if any, should be described with minuteness. The most trivial circumstances often prove of value in the hearing of the case, but particularly the time at which the crime is said to have been committed and the time which was permitted to elapse before complaint was made. An excellent form for this record is given in the "Medical Jurisprudence" of Witthaus and Becker, vol. ii., p. 419.

The principal facts to be established by the physician's examination are: (1) Marks of violence on the woman's genitals; (2) marks of violence on her person or on that of the accused; (3) stains of blood or semen on the person or clothing of either; and (4) the presence of venereal disease, gonorrhœa, syphilis, or chancroid in one or both. It is better to make the examination of the defendant with his consent and under full knowledge of its purpose, for it may otherwise be excluded as being in the nature of an involuntary confession. For the same reason the consent must be obtained without threat or promise. In a recent case the victim, a child of four years, was found to be infected with gonorrhœa, and the accused in a late stage of the disease. The latter, distinctly degenerate, willingly submitted to the examination, and admitted, in the presence of the examiner and an officer, that he had had the disease and had committed the assault. The case was closely contested, but the evidence was finally admitted entire as a voluntary confession, for it was shown that he had been informed beforehand of the purpose of the examination and of the official position of both witnesses.

The examiner is generally expected to testify that he has found, or that he has not found, evidence of the penetration of some blunt instrument. It is sufficient that the penetration has been only slight, as a separation of the labia. A recent rent of the hymen is one of the most positive signs that force has been employed and that penetration has been effected, but it is not essential. The fact that the hymen is intact is of little value as negative evidence, for its firmness must be taken into account. Repeated intercourse is sometimes possible without its rupture. And, on the other hand, the membrane may be torn in many ways other than by sexual intercourse. It is probably congenitally absent in rare instances. The vaginal wall may also be torn. Comparatively few examinations are made early enough to discover a recent bleeding rent of the hymen, and after the third day it is extremely difficult to determine the recentness of an injury. More than one examination should generally be made, and the statements made at each should be carefully compared. In many cases the injury is limited to one or more abrasions just within the labia minora. The examiner should see that this corresponds to a possible injury by sexual contact, and that it is not an excoriation such as might be made with the finger-nail. He cannot, of course, testify as to the manner in which the injury was inflicted, but he may state that the injury corresponds exactly to an injury inflicted in a forcible effort at sexual intercourse.

Complete penetration of the vagina of a young child by an adult male penis is impossible without the most extensive laceration, and this is generally prevented by the outcry. In more than one hundred examinations of young girls the writer has seen but one case in which such injury had been inflicted. When there has been recent complete defloration, complete penetration of a virgin, there are generally well-marked signs of violence. The hymen is lacerated and the external genitalia are inflamed to a variable degree. There may be only slight redness, heat, and sensitiveness, or the swelling and tenderness may be so great as to render a thorough examination almost impossible. The woman walks with difficulty, and separation of the thighs causes intense pain. In the course of from forty-eight to seventy-two hours these conditions may subside or they may become more marked as suppuration develops in the lacerations. Other evidences of a struggle are generally revealed in cases of

Digitized by Microsoft®

extreme injury, especially contusions, abrasions, and lacerations of the thighs.

Evidence of seminal emission was formerly required as a proof of guilt, but it has been abandoned. Such evidence, if present, however, is of great value as corroborative of the other facts. If stains are found upon the clothing a small piece should be cut out and submitted to careful microscopic examination. Spermatozoa may be found also in the vaginal mucus, on the skin, or on the pubic hair. (See article on *Seminal Stains.*)

Marks of violence on either person are of value chiefly in determining that consent was not given and that force was employed. They are of greater importance, therefore, in the case of a woman above the age of consent. In the case of the prosecuting witness it is necessary to exclude the possibility that the wounds were self-inflicted. This is to be suspected especially in the case of a neurotic or evidently erotic girl, and when the marks consist of parallel lines corresponding in size and position to possible positions of her own fingers.

The much-discussed question of the possibility of rape upon an able-bodied woman by a man unaided resolves itself into a question of the comparative strength and endurance of the two individuals, allowance being always made for the influence of fright and excitement upon the woman.

The presence of venereal disease in both persons is highly corroborative of the charge, providing the disease has appeared in one at a time corresponding to probable inoculation at the time of the alleged assault. Great care must be exercised, however, in the diagnostication of a muco-purulent discharge. Microscopic examination is generally necessary. It is especially important when the defendant is accused with having inoculated the victim with gonorrhea. Such inoculation is possible after the discharge from the male urethra has become extremely scant and has even lost its purulent appearance. The discovery of gonococci in it is sufficient evidence of the inoculability of the disease and goes far toward establishing the guilt of the defendant.

RASPBERRY. See *Rosacea.*

RAVENDEN SPRINGS.—Randolph County, Arkansas. Post-Office.—Ravenden Springs. Hotel Southern, and numerous smaller hotels and inns.

Access.—Viâ Kansas City, Fort Scott & Memphis Railroad to Ravenden Station, thence five miles by coach or hack to springs.

This resort is located in the northern part of Arkansas near the White River Mountains, the range in which the Eureka Springs have their origin. The elevation is twelve hundred feet. The geological formation is the same as that at Eureka, but the mountains are not so high or so rugged. The surrounding scenery is, however, exceedingly fine, and many features of interest are pointed out to visitors. The place takes its name from the "Raven's Den," a small cave with a circular opening a few feet from the top of the highest mountain. In this cave it is said that many of the feathered denizens of the forest, particularly the raven, or black crow, made their homes and hatched their young for a long period of time. Fish and game are abundant, and it is stated that many deer are killed in the vicinity during the winter months. The following analysis of the water was made by Messrs. Wright & Merritt, analytical chemists of St. Louis, in 1885: One United States gallon contains (solids): Lithium carbonate, gr. 1.26; calcium carbonate, gr. 4.61; magnesium carbonate, gr. 4.48; calcium chloride, gr. 1.24; magnesium chloride, gr. 2.99; sodium chloride, gr. 2.19; alumina, gr. 2.36; silica, gr. 0.83; iodine, iron, and calcium sulphate, of each a trace; organic matter, gr. 1.86. Total, 21.82 grains. Gases: Carbonic acid, 21.5 cubic inches; atmospheric air, 13.3 cubic inches. Temperature of water, 59° F.

James K. Crook.

RAWLEY SPRINGS.—Rockingham County, Virginia. Post-Office.—Rawley Springs. Hotel.

Access.—Viâ Baltimore & Ohio Railroad to Harrisonburg, thence a two-hours drive over a macadamized turnpike to springs.

This is one of the famous old Virginia mountain resorts, and it unites many of the best features of a summer resting-place. The elevation is two thousand feet above the sea-level, and the climate peculiarly dry and equable. The surrounding scenery is wild and rugged, but at the same time picturesquely attractive. The hotel at the springs is a comfortable and handsomely furnished building containing seventy-seven rooms, with a dining-room capacity of one hundred and fifty guests. It is well supplied with modern comforts and conveniences and facilities for amusement. The springs here are three in number. The water of each fountain seems to possess the same general characteristics. It is without odor, and possesses a strongly marked chalybeate taste. It exhibits a faintly acid odor from the presence of carbonic-acid gas. This disappears as the paper saturated with it dries. The water is perfectly clear and transparent as it flows from the earth, but on exposure to the air it soon begins to deposit a rust-colored precipitate of the oxide of iron. The temperature of the main spring is about 51° F. According to the analysis made by Prof. J. W. Mallet, one United States gallon contains: Iron protoxide, gr. 1.09; organic matter, gr. 0.03; and very small amounts of manganese protoxide, alumina, magnesia, lime, lithia, soda, potash, ammonia, sulphuric acid, chlorine, and silicic acid. The qualities of the water are improved by the presence of carbonic acid. It is a very useful, lightly carbonated, chalybeate water, and has an extensive sale even at distant points.

James K. Crook.

RAWLINS SULPHUR SPRINGS.—Carbon County, Wyoming. Post-Office.—Rawlins. Hotels.

These springs are pleasantly located about two miles from the enterprising town of Rawlins. The situation is on an elevated plateau, at an altitude of sixty-four hundred feet above the sea-level. The surrounding country is rugged and mountainous. The following analysis was made in 1894 by E. E. Slosson, of the School of Mines of the University of Wyoming, at Laramie: One United States gallon contains (solids): Potassium chloride, gr. 1.40; sodium chloride, gr. 12.18; sodium sulphate, gr. 854; magnesium sulphate, gr. 18.23; calcium sulphate, gr. 19.28; calcium carbonate, gr. 7.41; silica, gr. 8.23; carbonic acid, gr. 0.82. Total, 76.09 grains. Temperature of water at spring, 48° F.

The water is said to be highly sulphureted as it flows. The above analysis having been made at a distance from the springs, this gas was lost by volatilization. Therapeutically, the water has been fully tested in only one disease, viz., rheumatism. In this affection it is stated to be very efficacious, both when taken internally and when used in the form of hot baths. The water, as shown by the analysis, should possess very good diuretic and laxative properties. A first-class hotel and bath-house are much needed to put the resort on a good footing. The natural advantages of the place appear to offer excellent inducements for the establishment of a sanatorium.

RAY FUNGUS. See *Actinomycosis.*

RAYNAUD'S DISEASE.—Laveran was the first to apply to this disease the name of its discoverer. To the literature of the condition Raynaud made three contributions, his thesis in 1862, his article on "Gangrene," 1872, and his "New Researches," 1874. His attention was first attracted to the subject by a case of spontaneous symmetrical gangrene which came under his observation in 1861. As the result of personal observation and a searching of medical literature he brought together twenty-five cases (Monro) upon which he based his thesis. After a study of the varied phenomena of these cases, he elaborated his theory of spasm of the arterioles and venules in the

Digitized by Microsoft®

affected parts, and suggested that, therapeutically, electricity might be of value. He believed symmetry of the lesions and absence of demonstrable changes in the vessels to be two essential features in the disease. He also thought that the larger arteries might be affected by the spasm to such an extent that the radial pulse might be temporarily lost.

www.libtool.com.cn

In the "New Researches" he describes a contraction of the arteries of the fundus oculi observed in two cases. He also elucidates more fully the theory of abnormal irritability of the vaso-motor centres with consequent vascular spasm of a reflex nature.

It has long been known that under the influence of cold the fingers may undergo a change of color, becoming white and even blue. The former condition has been designated the "dead finger" (*digitus mortuus*); Raynaud called it "local syncope," and other names, such as "local anæmia" (Hardy), or "regional ischæmia" (Weiss) have been used to describe it. Raynaud applied the term "local asphyxia" to the affected part when it manifested a blue appearance; Weiss suggested the term "regional cyanosis" and Barlow that of "local cyanosis" as more appropriate than Raynaud's appellation. The same condition was called by Boiseau "uterine cyanosis" because of its relation to the suppression of the menses. Monro thinks that, one tymological grounds, Sir George Johnson's criticism of Raynaud's use of these terms was correct, viz., that "local syncope" should be called "local asphyxia" and "local asphyxia" should be termed "local apnœa," but that the attempt to put this into practice would cause much confusion. Symmetrical gangrene is the culmination, and one of the most distinctive features, of Raynaud's disease. Raynaud's clinical tripod, then, is local syncope, local asphyxia, and symmetrical gangrene. Writers have multiplied terms in their endeavor to describe the various phases of this syndrome, but the clarity of our conception of the subject will be greatly enhanced by utterly disregarding the same.

Symmetrical gangrene is a rare condition, but "Raynaud's phenomena" (Hutchinson), local syncope and local asphyxia or either, may occur for years, finally disappearing without any gangrenous manifestation. An illustration of this is Mrs. M., now under my observation. When nine years of age, were she to write, knit, sew, or do any work requiring the dexterous use of the fingers, the first phalanx of the fingers of the right hand would become white, cold, and numb, eventually assuming a purple of bluish aspect; she could not again use them until the attack had passed and feeling had returned. This condition continued until her fifteenth year when it ceased and did not again show itself until a few months ago.

Raynaud's disease usually develops before the thirtieth year. Children, even infants, may be subject to it, but I have known it to occur after the seventieth year as well. Females are more susceptible to it than males. According to Monro the ratio, as found in the medical wards of the Glasgow Royal Infirmary, has been about one in three thousand cases, but this proportion he regards as an underestimate,—*i.e.*, if the disease be considered purely as a neurosis, and not in its relation to other diseases of which it was an incident only. In my own experience "Raynaud's phenomena" constitute a not very infrequent condition.

Raynaud's disease may occur as a pure neurosis or it may be associated with a great variety of morbid conditions such as hysteria, insanity, epilepsy, tabes dorsalis, syringomyelia, myelitis, neurasthenia, spinal tumors, chorea, Graves' disease, lead poisoning, syphilis, phthisis, infectious fevers, Bright's disease, chlorosis, anæmia, diabetes insipidus, and a congenitally small aorta; it sometimes appears also in connection with certain dermatoneuroses, as urticaria, scleroderma, and erythromelalgia. Heredity is present in about eight per cent. of the cases (Monro). The most important causative agent is cold. Emotional influences, malaria, diseases of the female generative organs, and the breaking off of the morphine and chloral habits are all important etiological factors.

Local syncope comes first in the trinity of symptoms which characterize Raynaud's disease. It may exist alone or it may be associated with local asphyxia, a very frequent combination; or, as is more usual, all three symptoms—local syncope, local asphyxia, and gangrene—are present. Numbness and stiffness in the digit affected may usher in an attack, or there may have been in the extremity or parts involved, for days or even weeks previous, severe pain which is intensified as the attack develops.

The seizures are paroxysmal. The parts involved become pale or even corpse-like; they do not bleed when pricked, are cold, and movement is difficult. This latter, Raynaud suggests, is due to a defect of afferent impulses and not to muscular weakness. The nose, cheeks, chin, and ears are but seldom invaded. The case of Mr. G., who consulted me a short time ago, well illustrates this phase. In September, 1902, he noticed that the first phalanx of the thumb, first and second phalanges of the index, and first phalanx of the ring finger became cold and white when exposed to the air or on touching something cold. The local syncope was at first attended by pain in the thumb and index finger, and there were also isolated white spots distributed over the unaffected surface of the ring finger. Occasionally, should the hand become very cold, local asphyxia would occur on its dorsal surface. Sometimes, as the local syncope disappeared, local asphyxia would take its place. The involvement of the thumb here observed is very exceptional; it is usually unaffected.

Local syncope may be unilateral or bilateral. The upper extremities are more frequently involved than the lower. The syncope may attack one finger or all, or it may attack the different phalanges in an irregular manner. There is no regularity in the frequency of the seizures; they may occur once or many times daily, or there may be intervals of uncertain length. They may occur for weeks, months, or years and then cease, either absolutely or for an indefinite period. In my case of Mrs. M., already referred to, there was an interval of twenty-seven years.

The part affected is cold to the touch, tactile sense is impaired, and the various forms of sensibility are irregularly and unequally involved. Temperature sense and pain sense may be lost, or that of temperature may be present and those of touch and pain lost. Local syncope may disappear without leaving any trace or causing any pain. Frequently there occurs a decided reaction accompanied by pain and by annoying paræsthesias.

Local asphyxia constitutes the second stage of this symptom complex. Usually it is preceded by local syncope, but not invariably so. As already stated, local syncope may disappear, leaving no trace and causing but slight discomfort, or it may be followed by a blue, bluish-black, bluish-white, purple, violet or reddish discoloration of the skin affecting, sometimes symmetrically, sometimes unilaterally, the hand, fingers, feet, and toes. A livid marbling of the adjacent parts may be associated with this characteristic discoloration.

Local cyanosis differs from local syncope in not being confined chiefly to the limbs, but in attacking as well the ears, face, lips, chin, tongue, and trunk. Raynaud describes a lividity of the breasts, a painful neurosis which merits the appellation of local asphyxia of the mammæ. The extreme sluggishness of the circulation in the cyanotic area is shown by the slow disappearance of the white spot made by pressure.

The manner in which the parts are involved is most irregular, there being no definite order of sequence. The lower extremities are less frequently attacked than the upper. Sometimes an œdematous condition develops in the asphyxiated parts and instead of a blue or black discoloration of the skin, with a lowered temperature, the affected area assumes a bright red hue, is hot, and becomes covered with perspiration. The œdema pits upon pressure and may precede or even take the place of the cyanosis. One part may be cyanotic and swollen, while at the same time another may be only swollen. The œde-

Digitized by Microsoft®

ma is not confined to the extremities, as the ears, the face, and the tongue may also be affected (Monro).

Local asphyxia may or may not be attended by pain; often this is absent unless the cyanotic part is handled. The pain at times becomes neuralgic in character, or it may be continuous, www.libtool.com.cn discomfort to an intense agony. A patient of my own complained of irregular attacks of numbness for two years before the onset of the disease. In this case the pain was most agonizing from the very inception of the local syncope, which was in a few hours followed by local asphyxia, the appearance of the latter in no way mitigating the suffering.

There may be loss of motion, temperature sense, and tactile sense. Electrical sensibility may also be affected. Monro has collated some interesting cases showing that vaso-motor instability is certainly a marked feature of this condition. Calmette could readily induce an attack in the susceptible parts by putting cold water on any portion of the body. Raynaud, by using electricity on one hand, caused the disappearance of cyanosis from both, while Israel Sohn, by applying friction to the upper limbs, caused the disappearance of local asphyxia from all four extremities.

The character of the onset in local asphyxia is most erratic. Discoloration may precede or follow the pain, or the two may be associated. The development of the cyanosis may be very sudden; it may take the place of, precede, or follow the local syncope, its duration may be a few minutes, hours, or days; there is no regularity in the occurrence of the attacks. The pulse may be normal or absent. There is no fever, but occasionally there are depression, headache, insomnia, aphasia, convulsions, and even unconsciousness.

Patients who have long been subject to local asphyxia may suffer from changes in the skin called "tachetic" patches; these purple areas are very persistent, are unaffected by pressure, and are probably due to extravasated blood pigment in the deep layers of the skin (Monro). Local asphyxia, once having been developed, is very likely to recur; this liability is not, however, so great as in syncope. The Scotch verdict, "not proven" should be applied to those cases which are reported as cured.

The idea that a disturbed innervation might bear a causative relation to gangrene was entertained long before Raynaud wrote his now celebrated thesis. His contributions gave to the medical profession a new clinical concept, a disease with certain definite characteristics, viz., local syncope, local asphyxia, and symmetrical gangrene, a distinct morbid entity. For more than twenty years medical men regarded this disease as an idiopathic affection dependent upon a vaso-motor disturbance. Although the clinical entity described by Raynaud is generally accepted, it is now believed to be, in the majority of cases, merely a symptom (symptom complex) occurring in a great variety of diseases.

Symmetrical gangrene is the last and most important of this trinity of symptoms. Gangrene is usually associated with local asphyxia; in a very few instances local syncope and gangrene are combined; often the three classical symptoms are all present, while in about two per cent. of the cases gangrene occurs alone.

Raynaud emphasized its symmetrical nature, but it may occur unilaterally as well.

The parts most likely to be affected are the extremities and ears; the thumbs suffer less frequently than the fingers. The tip of the nose, the cheeks, lips, and chin may be affected. Desquamation of the epithelium may be the only evidence of the necrosis. Unfortunately this is but infrequent. The nails may fall off, but usually reappear. Raynaud describes a peculiar type of blister, a large bulla, of a deep brown color when dry, due to gangrene of the papillary layer of the derma. Necrosis may attack one or more of the phalanges of the digits, or a portion of the foot, or even the entire foot. In one of my cases both legs were gangrenous.

The attack may be so severe that spontaneous amputation of the extremities may occur. Recovery is slow, usually extending over months. If the gangrenous process is limited to small necrotic areas, the only evidence of its existence, discoverable after recovery, will be the presence of a slight scar or scars, and the number of these is an index of the number of previous attacks. The gangrene is dry and the parts become mummified. It is usually accompanied by pain which, in grave cases, is most agonizing. The general health may suffer seriously through insomnia, pain, and suppurative processes. Fortunately, "Raynaud's phenomena" often occur for years without the presence of gangrene; indeed it may never supervene, but its appearance is always a matter of grave importance.

The prognosis of Raynaud's disease, considered as a pure neurosis, is, if children are excluded, always good. When associated with other morbid conditions it is that of the underlying disease. For example, a patient of my own died during a very severe attack of Raynaud's disease, gangrene and mummification being very pronounced, but death was evidently the result of a chronic Bright's disease, from which she had suffered for years.

Diagnosis is easy when the three typical stages are present. The occurrence of local syncope and local asphyxia, either separate or associated, constitutes what is known as "Raynaud's phenomena," but the additional element of gangrene is necessary to justify a diagnosis of Raynaud's disease. The age, the sensory, motor, and trophic symptoms, together with the symmetry of evolution, will usually enable one to form a correct conclusion. Gangrene due to old age, ergot, and trauma is wanting absolutely in etiological and clinical characteristics.

There is a consensus of opinion among authors that local syncope and local asphyxia are of vaso-motor origin. Local syncope is undoubtedly due to spasm of the arterioles; authorities are at variance as to whether the venules do or do not participate in this spasm. Local asphyxia is due to an isolated spasm of the smallest venules which impedes the outflow of the venous blood from the capillaries, thus producing stasis (Weiss). The seat of these disturbances is situated in the vaso-motor centre of the medulla oblongata, which regulates blood pressure through the innervation of the muscle fibres of the blood-vessels; and this centre, like any other, may be irritated reflexly or directly, and in each case, varying with the intensity of the irritation, will there be an increased tonus of the vaso-motor constrictors and a spasm of the vessels will result (Burdach).

The explanation of the occurrence of the gangrene is more plausible on the supposition of the existence of trophic nerves and a consequent perversion of trophic influence, than it is under Raynaud's theory of insufficient nutrition due to the occurrence of local syncope and local asphyxia.

We now come to the important question: Is Raynaud's disease to be regarded in all cases as merely a symptom complex of other morbid conditions, or may it occur at times as an uncomplicated neurosis? There can be no doubt that the proper conception would be to class it under both heads, with which the present tendency is in accord. In a majority of instances it is to be regarded purely as a symptom, while in rare and exceptional cases it is, without doubt, a genuine neurosis.

Raynaud's disease offers an excellent example of pernicious habit on the part of the vaso-motor system. The therapeutic problem is how to overcome its morbid paroxysmal manifestations, and, above all, to prevent by proper hygiene and appropriate treatment the tendency to recurrence. If the attack is severe and occurs in winter, and especially if the patient is debilitated and advanced in years, a change to a warm climate is advisable. The effort should always be made, during the interval between the attacks, to build up the general and nervous strength, for by this alone can the paroxysmal tendencies be retarded and possibly overcome. Everything that favors a seizure, especially undue exposure to cold, must be carefully avoided. Appropriate clothing, suitable to the season, should be worn, constriction of the circulation guarded against, and the water used in washing ought to be at blood heat.

Digitized by Microsoft®

If the attack is at all pronounced, it would be best for the patient to remain indoors in a uniform temperature. A mixed diet is the most suitable. Great caution should be employed in the use of stimulants, as the liability on the part of the neurotic to acquire a taste for alcoholics must never be lost sight of. If the patient has been at all subject to malarial influences quinine is the remedy *par excellence;* in any event it is a drug of unquestioned value. Opium has been greatly lauded; its chief efficacy, however, lies in its power to alleviate pain, to promote sleep, and thus to conserve the strength of the patient. Should the severity of the symptoms demand morphine, it ought never to be given hypodermically at the seat of pain, as the resulting irritation may cause gangrene. Nitrite of amyl and nitroglycerin should be given a trial. The use of thyroid extract is spoken highly of by Short. Iron, arsenic, nux vomica, strychnine, cod-liver oil, and malt are all useful drugs and potential aids in the process of upbuilding.

Spinal galvanization is perhaps one of the most efficient remedies. The negative pole should remain stationary over the sacrum, while the positive is slowly moved up and down the entire length of the spine, care being taken not to interrupt the current. The current strength should not exceed fifteen milliampères; séances should be daily, lasting not over five minutes; if the room is suitably warm, it would be advantageous to vary the spinal treatment by applying the positive electrode directly over the affected area. Galvanization of the cervical sympathetic is recommended. Static electricity is an agent of no mean value, general franklinization being the method employed, together with a local application of the static spray. This form of the current is much more easily applied than faradism, and is in every way as effective.

Massage, general and local, has in certain cases proved very efficacious, but great care must be exercised in its application, as the devitalized skin is liable to ulcerate if roughly handled. Should the immediate area affected be too sensitive to allow of its use, the adjacent parts may be treated. Warm fomentations have been found useful. A fifty-per-cent. alcoholic solution of menthol applied to the members involved, which should then be wrapped in cotton and covered with oiled silk, is to be recommended. It is of first importance that the extremities affected be kept carefully wrapped in flannel. I have known this simple precaution to be of more value than all medication.

The treatment of the gangrene is a purely surgical matter. Sufficient time, however, should be allowed for the demarcation line clearly to show itself, as the actual gangrene may include but a small part of the affected extremities.

Much will depend upon the tact and resourcefulness of the physician, and with all his remedies he must not forget the therapeutic value of hope. *C. Eugene Riggs.*

REACTION OF DEGENERATION (De R) is the term applied to certain changes in electrical excitability, produced by a lesion of the spino-peripheral neuron in any part of its course (the anterior horns of the spinal cord, or the cerebral motor nuclei, the motor roots of the nerves, or the peripheral nerves). When the anatomical lesion is profound complete De R is the result. Partial De R is found in less severe lesions. The nerves and muscles exhibit different reactions to the current. In complete De R, within a few days after the onset of the primary disease, the nerve exhibits a gradual diminution of reaction to the faradic and galvanic currents, and within from one to two weeks its irritability is entirely lost. The muscles supplied by the nerve react differently to the two currents. Their faradic excitability gradually diminishes with the corresponding loss of nerve excitability. The galvanic excitability, on the other hand, presents very peculiar changes. These are best seen when an electrode (preferably a large one) is placed upon an indifferent spot, and the other small electrode is placed directly over the muscle to be tested. Normally, it is found that the muscle responds most promptly to the closure of the cathode (CaCl), then to the opening or closing of the anode (AnO or AnCl), and finally to the opening of the cathode (CaO). The contraction of the healthy muscle is quick, lightning-like. In complete De R the response of the muscle is slow and, on passing the electrode over the belly of the muscle, one set of fibres contracts after the other. This slowness is the most constant feature of the De R and in itself suffices for the diagnosis. In addition, the diseased muscle reacts to an unusually mild current. This is seen very well, for example, in Bell's palsy by placing one electrode upon the chin, when it will be found that the paralyzed chin muscles react to a current which is utterly inadequate to produce a response in the unparalyzed muscles. Complete De R is also attended by the so-called reversal of the formula. It is found that contraction (C) is obtained most readily on AnCl. CaCO also increases relatively and may be greater than AnCO. As the disease progresses and the electrical excitability is gradually lost, AnClC with very strong currents may furnish the last evidence of the all but extinct muscular vitality. This is sometimes found even after the muscle has been completely paralyzed for a year or more.

In partial De R the excitability of the nerves may be merely lessened, the muscles may still react to the faradic current, but the contraction to the galvanic current is slow and perhaps shows some changes from the normal formula. If recovery takes place there is a gradual inverse return to the normal conditions.

Leopold Putzel.

RECRUITS, EXAMINATION OF.—The army of the United States is ordinarily recruited by voluntary enlistment; in time of war enlistment may be compulsory, under Enrollment Acts.

The Recruiting Service is under the direction of the adjutant-general of the army, and is organized into two branches: the general, for infantry and artillery, and the mounted, for cavalry.

THE LEGAL REQUIREMENTS FOR ENLISTMENT.—Any male person above the age of sixteen and under the age of thirty years, effective, able-bodied, and free from disease, of good character, who does not appear to be of intemperate habits, and who has a competent knowledge of the English language, may be enlisted, due attention being given to the restrictions in this article concerning minors. This regulation, in so far as it relates to age, does not apply to soldiers who may re-enlist, nor to those who have served honestly and faithfully a previous enlistment in the army. Applicants for enlistment are required to furnish such evidence of good character as they can obtain. With a view to determine their fitness and aptitude for the service, and to give them an opportunity to secure testimonials, as well as for the inquiry and deliberation contemplated by the Second Article of War, they may be retained and provided for at rendezvous, for a period not to exceed six days, after having signed the declaration of intention to enlist and passed the medical examination. Men so retained are known as *recruits on probation.* The enlistment papers of any such recruit who may be unfit or undesirable for the service, or who may not desire to remain in the service, will not be completed. The enlistment papers of recruits who are accepted and duly sworn will bear the date on which the enlistment is *completed* by administering the oath (A. R., Art. lxxi., 908). . . . The major-general commanding the army is of opinion that if satisfactory evidence of good character, habits, and condition cannot be furnished by the recruit, or be otherwise obtained, the presumption should be against him and he should *not* be accepted; and, further, that these views are concurred in by the Secretary of War and should govern in all cases (G. O., No. 1, Headquarters Recruiting Service, 1890).

These rules and articles shall be read to every enlisted man at the time of, or within six days after, his enlistment, and he shall thereupon take an oath or affirmation in the following form: "I, A. B., do solemnly swear (or

Digitized by Microsoft®

affirm) that I will bear true faith and allegiance to the United States of America; that I will serve them honestly and faithfully against all their enemies whomsoever, and that I will obey the orders of the President of the United States and the orders of the officers appointed over me, according to the Rules and Articles of War." This oath may be taken before any commissioned officer of the army (Article of War).

www.libtool.com.cn

Every officer who knowingly enlists or musters into the military service any minor over the age of sixteen years without the written consent of his parents or guardians, or any minor under the age of sixteen, or any insane or intoxicated persons, or any deserter from the military or naval service of the United States, or any person who has been convicted of any infamous criminal offence, shall, upon conviction, be dismissed from the service, or suffer such other punishment as a court martial may direct (Article of War).

Under a recent act of Congress fraudulent enlistment is declared a military offence, and is punishable by court-martial under the Sixty-second Article of War; the provisions of this law are fully explained to every applicant presenting himself for enlistment with the information that any person procuring his enlistment on or after the 25th day of September, 1892, by false representations or other fraudulent means, will render himself liable to trial and punishment by court-martial. "Fraudulent enlistment" is defined by the law officers of the department as "an enlistment procured by means of a wilful misrepresentation in regard to a qualification or disqualification for enlistment, or by an intentional concealment of a disqualification which had the effect of causing the enlistment of a man not qualified to be a soldier, and who but for such false representation or concealment would have been rejected."

The regulations above quoted sketch in outline the requirements for admission to the enlisted branch of the military service and the duties of officers in connection therewith. For the recruiting officer an essential to success is a knowledge of men and their character, and for the medical officer a painstaking application of professional skill. The duty is a most important one, and in its faithful and thorough performance these officers share a grave responsibility. The influence of their judgment and discretion is felt throughout the entire military establishment, the efficiency of which depends in great measure upon the sound mental and physical condition and the intelligence of its enlisted force. From the varied classes and conditions of men presenting themselves for enlistment they are to eliminate not only those who are defective physically and mentally, but those who are defective morally, and if this duty be performed carelessly or indifferently, men will be admitted to the service with defects which will soon render them unfit for duty, or with moral obliquities that will induce malingering and desertion.

Re-enlistments.—Soldiers who are unable to pass the required examination *in all respects* will not be re-enlisted without special authority from the adjutant-general's office, and then only for their former commands; application for such authority should be recommended only when it is shown that any existing defects will not prevent the full discharge of duty as a soldier and that a continuance in service will be a positive benefit to the army.

Soldiers discharged as privates upon expiration of term of service and failing to re-enlist within one month, will not be again enlisted after they have passed the age of thirty-five years, unless for some good reason in the interest of the public service, and then only for their former commands upon special authority from the adjutant-general's office.

This limitation as to age will not apply to a soldier discharged as *a non-commissioned officer with excellent character*, and desiring again to enlist for assignment to a former command (not already full), either at the station thereof, or at a recruiting depot, provided he passes the required examination and furnishes satisfactory evidence in regard to character and habits since discharge.

Soldiers who have been discharged with good character under the provisions of law may be again enlisted without special authority after a period of two months from date of discharge, upon passing the required examination and furnishing satisfactory evidence in regard to character and habits since discharge, provided such enlistment is not barred by any of the above provisions.

Soldiers discharged before expiration of term of service for any other cause will not be again enlisted without special authority from the adjutant-general's office.

These restrictions, which are intended more particularly to govern re-enlistments for the line of the army, need not necessarily be applied to the hospital corps; the approval of the surgeon-general will be sufficient warrant for the re-enlistment of soldiers into that corps.

The position of a medical officer at a recruiting rendezvous is an advisory one (as a medico-military expert) to the recruiting officer; unlike the medical examiner in life insurance, he, in addition to his strictly professional inspection of an applicant for enlistment, must express an opinion upon his *aptitude*, both mentally and physically, for the military service. In times past, this latter duty was restricted entirely to the recruiting officer, who was also the sole judge of height, weight, and chest measurements; but experience has demonstrated the importance of professional skill in the formation of an opinion as to the general efficiency of a man for the military service, and it is now quite as much the province of the medical officer to decide upon the military aptitude of a recruit, as upon his freedom from grosser physical defects. Of course, his decisions are conveyed as opinions to the recruiting officer, who alone is legally authorized to make an enlistment.

In entering upon these duties, the medical officer should bear in mind the important fact that upon "the faithfulness and thoroughness" with which they are performed depends in a great measure the health of the army, its mental and physical efficiency, and especially its mobility; carelessness or inattention on his part may permit the admission to its ranks of men who soon find their way into the hospital, whose undiscovered diseases may be transmitted to innocent comrades, or whose defects may furnish groundwork for the demoralizing practice of malingering; examinations made in a perfunctory manner will surely result in the unwitting acceptance of men whose mental and physical defects are only too clearly displayed in the company organization, and whose enforced discharge from the service will bring discredit upon the professional skill of the examiner, and undeserved censure upon the recruiting officer with whom he has been associated; he should reflect that, in the sudden emergencies which our troops are so frequently required to meet on the frontier, *able-bodied* soldiers are indispensable to success, or to the saving of life and property from destruction; and that with an army so small as ours, in time of peace, every man enlisted must be relied upon to endure all the hardship of which a physically perfect human being is capable. Nor is this less a necessity in time of war with troops of the line, when celerity of movement and ability to endure great privations, as lack of food and inclemency of weather, are imperatively demanded in the manipulation of armies under the modern science of war.

"The experience of all nations has demonstrated the uselessness of attempting to conduct military operations to advantage unless the rigid scrutiny of the surgeon has been exerted to exclude such men as were subjects of, or predisposed to, disease, or were unfitted to sustain the continued fatigue and exposure of the march."[2]

There are, however, conditions of the service in time of war which warrant a departure from this standard in some respects, and the acceptance of recruits with defects which, in time of peace, would be positive disqualifications; farther on, reference will be made, under the appropriate headings, to these deviations from the peace standard.

In time of peace every enlisted man is presumed to be wholly efficient, and fit for duty at all times; he who to-

Recruits.

day is nursing the sick in hospital may to-morrow be in his place in a company, or a member of the garrison guard; in time of war men *may* be enlisted who cannot be strictly classed as "fighting men," but who may be equally effective as soldiers in other departments; a man with a hernia, which is kept in place by a truss that is well-fitting, is in every way able to cook for a company, although not fitted to wear a cartridge belt and do active duty in the field; so, also, the loss of certain members—fingers or toes—would not necessarily disqualify a man from guarding a hospital, or driving a team, and thus taking the place of an able-bodied soldier whose services are more urgently needed at the front. For this reason it has been the custom in all armies to relax in certain particulars their peace regulations, and diminish their list of disabilities in time of war, holding to service many men who in time of peace would have been rejected.

Properly to conduct his examinations the medical officer should have plenty of light, air, and time, and good floors.

The room in which the examinations are made should be well lighted and ventilated, not less than forty feet long and twenty feet wide, with a well-laid, solid floor; its furniture should consist of a fixed measuring rod and slide, good platform scales, steel tape measure, vision test cards, and a set of test wools for determining color blindness; in one corner there should be a bed arranged after the fashion of an operating table, upon which applicants can be placed for the examination of suspected strictures, and heights verified, if necessary, by horizontal measurement, etc.; the instruments required are a set of steel sounds, a Cammann's stethoscope, an ophthalmoscope, a set of Snellen's test types, an astigmatic chart, the necessary apparatus for a rough analysis of the urine in cases of suspected lesions of the kidney, and the appliances for immediate vaccination after acceptance of the recruit.

There should also be adjoining the examination room, one fitted with bath-tubs, and liberally supplied with soap and towels, where every applicant for enlistment (who must be carefully and thoroughly washed before examination) can perform his ablutions under the supervision of the recruiting sergeant.

The recruiting officer should always be present at the examinations,[3] and, for obvious reasons, all other persons excepting the recruiting sergeant should be excluded from the room.

A very considerable and important part of the examination can be made before the applicant is stripped, during which defects may be discovered that will render further procedure unnecessary; he should be closely questioned as to his personal and family history, his previous service in military or naval life, his habits, his health in the past, and the receipt of injuries or wounds, or any surgical operations which may have been performed upon him. The examiner, during this questioning, can form an opinion as to the knowledge of the English language possessed by the applicant, his age, intelligence, and general fitness, both as to physique and morale, for the duties of a soldier.

A thorough and satisfactory examination can be made only by pursuing a systematic course, without the adoption of which the most expert examiner will omit important points, and, probably, lose sight even of glaring defects. To accomplish this the War Department, upon the recommendation of the writer, adopted a "form" for the examination of recruits, which contains a series of questions, to be answered by the applicant, and recorded by the inspecting or examining officer. These forms are furnished by the adjutant-general of the army to all recruiting rendezvous.

When the applicant is ready for the inspection of the surgeon, let him take the position of a soldier in the best lighted part of the room; then examine him in the following order after the methods elsewhere set forth.

1. Inspect his general physique, skin, scalp, and cranium, ears, eyes, nose, mouth, face, neck, and chest.

2. The arms should be extended above the head, the backs of the hands being together, and the applicant be required to cough vigorously; any form of hernia may now be discovered by the eye and finger.

3. The man should be required to take a long step forward with the right foot, and bend the knee, the hands remaining extended above the head; this exposes the genital organs, and varicocele or other defects in the scrotum may be recognized by the hand.

4. The arms should now be brought to the sides, and the man required to separate his buttocks with his hands, bending forward at the same time; this exposes the anus.

5. Examine the heart.

6. The elbows should be brought firmly to the sides of the body, and the forearms extended to the front, palms of the hands uppermost. Extend and flex each finger separately; bring the points of the thumbs to the base of the little fingers; extend and flex the hands upon the wrists; rotate the hands so that the finger-nails will first be up and then down; move the hands from side to side; flex the forearms on the arms *sharply*, striking the shoulders with the fists; extend the arms outward, at right angles with the body, and flex the forearm upon the arm until the thumbs rest on the points of the shoulders, while in this position raise and lower the arms, bringing them sharply to the sides at each motion; let the arms hang loosely by the side; swing the right arm in a circle rapidly from the shoulder, first to the front and then to the rear; swing the left arm in the same manner, extend the arms fully to the front, keeping the palms of the hands together; observe carefully the elbows; carry the arms quickly back as far as possible, keeping the thumbs up, and at the same time raise the body on the toes.

7. Extend the legs alternately, resting the heel upon the floor; move all the toes; raise the heel from the floor, moving the foot up and down, then from side to side; present the sole of the foot for inspection; bend the knee and strike the shoulder with it, bending the body slightly forward at the same time; throw the leg out to the side as high as possible, keeping the body squarely to the front; take the military position "to kneel firing," first on one knee, then on the other; get down on both knees; squat sharply several times in succession; hop the length of the room on the toes, first of one foot and then of the other; take a standing jump as far as possible; jump up and strike the buttocks with the heels.

8. Auscultate the lungs.

9. Test the hearing.

10. Test the vision, and for color blindness.

11. Vaccinate the applicant, if accepted.

Mr. Marshall, in his excellent treatise on the examination of recruits, arranges the causes on account of which recruits are rejected under three headings:

First. "Diseases or deformities which a medical officer from his professional knowledge and acquaintance with the duties of soldiers considers are infirmities which disqualify men for service in the army."

Second. "Slight blemishes which do not disqualify a man for the army, but which an unwilling soldier may exaggerate, and allege that he is thereby rendered unfit for military duty."

Third. "Unimportant deviations from symmetry, or slight variations from the usual form or condition of the body; technical or nominal blemishes which do not incapacitate a man for the army, or in the slightest degree impair his efficiency."

Experienced surgeons will reject all recruits whose defects fall under the first two headings, from a conviction that they render the men unfit or ineligible for the army; but those under the third heading are frequently rejected from fear of responsibility—a dread of official correspondence if objected to, and an ultimate damage to professional reputation.

In time of war cases coming under the first heading should be rigidly excluded, while those coming under the second and third headings should be as rigidly held to service.

THE GENERAL EXAMINATION.—*Competent knowledge of the English language* is defined by the War Department as the ability of the applicant to "speak fluently, converse

Digitized by Microsoft®

intelligently, and fully understand the orders and instructions given in that language."

It would seem almost superfluous to refer to this matter, the importance of which is self-evident, were it not for the fact that so large a number of foreigners have been enlisted, who were ignorant of our language, whose blunders and mistakes have caused annoyances and impediments to the public service, and whose efficiency as soldiers has been thereby seriously impaired. It is of paramount importance that the soldier should be able clearly to understand the orders which are given to him, and to ascertain this fact beyond a doubt is one of the first duties required of the medical officer. Exception to this rule is made in the cases of skilled artisans and tailors, and more particular band musicians.

In time of war familiarity with the language is not so necessary, as foreigners are more likely to be assigned to regiments made up of their own countrymen, with officers who speak their language; they can also be made useful in the administrative departments of the army, taking the places of men better fitted for field service.

Age.—As has been already stated, the limits of age for enlistment in time of peace are, "not less than sixteen years, nor more than thirty-five years"; "minors under eighteen years will not be enlisted except for musicians, . . . and then only under authority from the superintendent."[4]

The regulations of the army require that when minors present themselves for enlistment, they shall be treated with great candor; the names and residences of their parents and guardians, if they have any, shall be ascertained, and notice sent to them of the minor's wish to enlist, that they may have an opportunity to make their objections or give their consent. When consent is given it must be in writing. All recruiting officers are enjoined to be very particular in ascertaining the true age of the recruit. If any doubt upon the point exists in the mind of the recruiting officer, he must not be satisfied with the oath of the applicant as the sole evidence of legal age, but if he cannot, in addition, furnish undoubted proof of the fact, he must be rejected.[5]

The maximum limit of age does not apply to soldiers who may re-enlist, or who have served honestly and faithfully a previous enlistment in the army.[6]

In time of war the limitations of age in compulsory enlistment, under the Enrolment Acts, are twenty and forty-five years; the question of minority between the twentieth and twenty-first years is not considered, except in voluntary enlistments, which are under the same restrictions as in time of peace.

The medical examiner must form his opinion of the age of an applicant from his personal observation of men and upon physiological grounds. It is a point about which the greatest amount of deceit is practised; concealment being attempted in voluntary enlistments with a view of getting into the service, and in compulsory enlistments with a view of exemption therefrom. He must, therefore, be always upon guard against imposition. Young men who would scorn to tell an untruth in other matters will lie about their age with the utmost effrontery, and old men will resort to every artifice to conceal theirs.

While the divisions of life into periods, by years of existence, are in a measure arbitrary, some men maturing at an earlier age than others, it is important to consider certain common evidences of maturity as fixing the period of legal majority, and furnishing a standard, indefinite though it may be, of eligibility for the military service. Among the most prominent of these evidences are the presence of the wisdom teeth, a plentiful supply of hair in the axillæ, and over the pubes, well-formed testicles, and complete corrugation of the scrotal skin. While these conditions are liable to variation in individuals, they may be regarded as common to most youth at maturity, although no one condition can be regarded as more frequently present than another. It has, however, been the experience of the writer to find a peculiarly smooth condition of the skin of the scrotum in every case of minority examined by him. This may be due to lack of development of the dartos. Men of mature age do not display it, but it is very noticeable in minors. The general appearance and bearing of a young man will, in conjunction with physical peculiarities, give the surgeon a very fair idea of his age, and there are few possessed with sufficient hardihood to deny a firm and decidedly expressed opinion by an observant surgeon upon the subject. In those whose age exceeds the maximum there will probably be found presbyopia, the arcus senilis in one or both eyes, a wrinkled skin, especially about the outer angles of the eyes and on the forehead, gray hair, and a peculiar hardness of the nails of the fingers and toes.

HEIGHT, WEIGHT, AND CHEST MEASUREMENTS.—"The *minimum height* of a recruit is at present fixed at five feet four inches for all branches of the service, although recruiting officers are allowed to exercise their discretion as to the enlistment of desirable recruits (such as band musicians, school teachers, tailors, etc.) who may fall not more than one-fourth of an inch below the minimum standard of height; the *maximum* height for the cavalry service is five feet ten inches; that for infantry and artillery is governed by the maximum of weight, to which should be applied the rule for proportion in height."

"The *minimum weight* for all recruits is 128 pounds, except for the cavalry, in which enlistments may be made without regard to a minimum of weight, provided the chest measurement and chest mobility are satisfactory. The *maximum* for infantry and artillery is 190 pounds; for cavalry and light artillery, 165 pounds."

The standards of height and weight are, however, subject to change, instructions to that effect being issued from the adjutant-general's office "from time to time as the requirements of the service may dictate."

These standards are based upon results obtained by skilled observers who, after careful study and the examination of large numbers of men in civil and military life, have established the fact that there is an *average proportion* in healthy, fully developed men between the height, weight, chest measurement, and chest mobility which will admit of slight variations without indicating a departure from health. The rules of this proportion may be formulated as follows:

For each inch of height from 5 feet 4 inches to 5 feet 7 inches, inclusive, there should be calculated 2 pounds of weight. When the height *exceeds* 5 feet 7 inches, calculate 2 pounds of weight for the *whole number* of inches of height; add to this product 5 pounds of weight for each inch of difference between 5 feet 7 inches and the actual height; the sum will be the normal weight in pounds.

The *chest measurement at expiration* in men from 5 feet 4 inches to 5 feet 7 inches in height should exceed the half height about half an inch; in those from 5 feet 8 inches to 5 feet 10 inches it should *equal* the half height, while in those from 5 feet 11 inches upward it should be slightly *less* than the half height.

The *chest mobility*—*i.e.*, the difference between the measurement at inspiration and expiration—should be *at least* 2 inches in men below 5 feet 7 inches in height, and 2½ inches in those above that height.

The following table shows this concisely:

Height.	Weight. Allow for each inch of height.	Chest measurement.	Chest mobility.
5 feet 4 to 5 feet 7 inches.	2 pounds.........	Half height plus half inch.	2 inches.
5 feet 8 to 5 feet 10 inches.	2 pounds and 5 pounds additional for each inch over 5 feet 7 inches.	Half height......	2½ inches
5 feet 11 to.........		Slightly less than half height.	2½ inches

For example, a man who measures 5 feet 4 inches should weigh 128 pounds—*i.e.*, 5 feet 4 inches = 64 inches; 64 × 2 = 128, the normal weight. He should have a chest measurement of 32½ inches at expiration, being half

Digitized by Microsoft®

Recruits.

height; 32 inches plus ½ inch = 32½; the chest mobility should be about 2 inches.

A man who measures 5 feet 9 inches should weigh 148 pounds—*i.e.*, 5 feet 9 inches = 69 inches; 69 × 2 = 138; difference between 5 feet 9 inches and 5 feet 7 inches is 2; 2 × 5 = 10; 138 + 10 = 148, the normal weight in pounds. He should have a chest measurement of 34½ inches (his half height), and a chest mobility of at least 2½ inches.

It is not necessary that the applicant should conform *exactly* to the figures indicated in the rules, a variation of a few pounds from either side of the standard in the minimum, medium, and maximum weights, and of a fraction of an inch in chest measures being permissible if the applicant is otherwise in good health and desirable as a recruit. The rules are given to show what is regarded as a fair proportion, *but the weight must be at least 125 pounds* except when less is especially authorized by the superintendent or the adjutant-general.

In such cases the recruiting officer's reasons and the superintendent's order should be noted in full on the enlistment papers. Any *considerable* disproportion, however, of *height* over *weight* is cause for rejection; but a marked disproportion of *weight* over *height* does *not* reject unless the applicant is positively obese.

In order that an intelligent application of these rules and their variations may be made, the attention of recruiting officers is called to the manner in which a man's height is made up.

The chest, containing the heart and lungs, is the most important division of the body. It contains the vital machinery and represents the *staying power* of the man. It must, therefore, be ample. The function of the legs is to transport the body; they should be well formed and sufficient, but not unduly long, for length of limb at the expense of the chest is a disadvantage. A long-legged, long-necked man with a short chest is objectionable as a recruit.

The average height of a youth of eighteen years of age, a "growing lad," is a little over 5 feet 4 inches, and increases gradually until he reaches the age of twenty-five years—the stage of physical maturity or manhood—when his average height is between 5 feet 7 inches and 5 feet 8 inches.

During the growing period the framework and vital organs receive their proper development, and considerable departures from the given average of proportionate height to weight indicate an impairment of these organs which may, and probably will, develop into positive disease after exposure to the hardships incident to the life of a soldier; hence they are of greater significance in men of these heights than in taller men, who are presumably of greater age and more mature growth.

After twenty-five years of age, the body being fully developed, the excess of nutritive material over and above that required for its maintenance in health is deposited in the tissues as fat, and it will be found that a disproportion of weight over height occurs usually in adults or men in middle life. It is rare to meet in the recruiting rendezvous with *very* fleshy *young* men.

The following table is given for convenience of reference:

TABLE OF PHYSICAL PROPORTIONS FOR HEIGHT, WEIGHT, AND CHEST MEASUREMENT.

Height.		Weight.	Chest Measurement.	
Feet.	Inches.	Pounds.	At expiration; inches.	Mobility; inches.
$5\frac{4}{12}$	64	128	32½	2
$5\frac{5}{12}$	65	130	33	2
$5\frac{6}{12}$	66	132	33½	2
$5\frac{7}{12}$	67	134	34	2
$5\frac{8}{12}$	68	141	34	2½
$5\frac{9}{12}$	69	148	34½	2½
$5\frac{10}{12}$	70	155	35	2½
$5\frac{11}{12}$	71	162	35¼	2½
6	72	169	35¾	2½
$6\frac{1}{12}$	73	176	36¼	2½

A deviation from the rules of physical proportions may be made in the examination of candidates for admission to the United States Military Academy at West Point, and for members of the graduating class, whenever this is deemed desirable by the Medical Examining Board.

Habits.—Drunkenness, or habits of intemperance, is the cause of a very large number of the rejections made at rendezvous. It is the vice of the army, as well as of most walks in civil life, and the medical examiner cannot be too careful in scrutinizing every applicant for evidences of this demoralizing habit. The regulations of the army are very emphatic on the point, declaring that every man shall be sober when enlisted, and that men *having the appearance* of being hard drinkers will be rejected, "though they may not at the time be intoxicated."[7]

Some recruiting officers go so far as to reject men on whom the smell of liquor can be detected at the time, and they are without doubt correct in their opinions and practice. It is a great mistake to "suspend a final decision . . . for a sufficient length of time to enable a man to recover from the effects of a mere temporary debauch," as is recommended by Tripler,[8] as the man who will indulge in such debauchery *before* enlistment will be pretty sure to repeat it afterward; and such men are not wanted in the army. If a man has to resort to the stimulation of alcohol to "brace himself up" for the ordeal of the examination, it is a fair presumption that his habits as to the general use of stimulants will not bear much criticism. The evil wrought to the service by men having these habits is so great that it is far better to err, and run the risk of occasionally rejecting temperate men, than, by relaxing any vigilance, to enlist those who may eventually prove themselves sots.

While it is sometimes difficult to detect the habitual drunkard, and the medical examiner is forced to rely, to some extent, upon the man himself for such information as he may be willing to give, yet the long indulgence in habits of intemperance will almost surely be indicated by persistent redness of the eyes, tremulousness of the hands, attenuation of the muscles—particularly of the lower extremities,—sluggishness of the intellect, an eczematous eruption upon the face, and purple blotches upon the legs.[9] Close and skilful questioning will often develop the facts connected with the antecedents of the applicant, and materially assist the examiner in forming his opinion of the case.

Masturbators and Sodomites are also to be looked for and rigidly excluded. In addition to the well-known general signs of physical prostration due to indulgence in masturbation, Howe, in his little work on "Excessive Venery,"[10] says, "the local signs are sufficient for a diagnosis. . . . The penis is thinner and smaller than usual. It is often elongated, and cold to the touch at different points. The glans is much larger than the rest of the organ. . . . The veins of the integumental covering are dilated and varicose. In many patients the penis is bent laterally, and the inclination is generally toward the left side. . . . The scrotum is also relaxed and elongated, the testicles are small and soft; . . . sometimes they are extremely sensitive." The air of embarrassment which so often overtakes subjects of this vice, when closely questioned, will also lead to their detection.

Sodomy may be suspected if the anus is much dilated, or is infundibuliform in shape: "The absence of the radiating folds is considered one of the best medico-legal proofs of the vice."[11] Tidy says,[12] "a peculiar, funnel-like depression or hollow of the nates toward the anus, the anus gaping and the sphincter relaxed," are signs of the practice of this vice, to which greater or less importance may be attached as the circumstances of the case demand.

Mental Disorders.—Insanity, idiocy, imbecility, and *dementia* are disorders which will call for the closest scrutiny and observation by the medical examiner; their nature is such that a careful diagnosis in the limited time allotted to the examination of a recruit is rarely possible. The necessity, therefore, of an acquaintance with their

www.libtool.com.cn
Digitized by Microsoft®

physiognomy is apparent. To one skilled in this means of diagnosis the detection of the less obscure grades is not a matter of great difficulty. The idiot, the imbecile, or the demented patient presents such well marked characteristics that an error can hardly be made. It is in those unfortunates who are upon the borderland of mental deficiency, and the insane, that the greatest difficulties of diagnosis may be expected. Unless an insane person betrays by action or speech some evidence of this disease, a correct diagnosis would be a matter of great difficulty, and no surgeon would be held responsible for accepting one who afterward manifested insanity. Should the examiner have reason to suppose that the applicant is deficient in mental capacity, or has not the aptitude to acquire readily a knowledge of his duties as a soldier, he should be rejected. It is much safer to take even an extreme view of such cases, and run the risk of an erroneous rejection, than to accept one about whom a suspicion of mental alienation can rest.

Physique.—While a decision of cases under this heading does not always fall within the province of the medical examiner, his opinion is entitled to great weight with the recruiting officer. His knowledge of anatomy and the proper proportions of the human frame, as well as his familiarity with physiognomy, eminently qualify him to form a correct opinion as to the general appearance, both physical and moral, of the applicant, and his fitness for the duties of a soldier, in cases in which no technical disability exists or can be discovered by a non-professional man. His experience with the *effects* of disease, bad habits, food, and living upon the constitution will enable him to judge as to future efficiency, although there may be no direct evidence in the case before him that the applicant has ever been subjected to such hardships.

There is probably no one class of men which furnishes such large numbers to the hospitals, the guard-house, and the list of deserters as this, designated indifferently by military men as "poor physique," "feeble constitution," or "general unfitness."

The leading characteristics of a good physique may be briefly enumerated: "A tolerably just proportion between the different parts of the trunk and members; a well shaped head, thick hair, a countenance expressive of health, with a lively eye, skin not too white, lips red, teeth white and in good condition, voice strong, skin firm, chest well formed, belly lank, parts of generation well developed, limbs muscular, feet arched and of a moderate length, hands large."[13] The gait should be sprightly and springy, speech prompt and clear, and manner cheerful. The medical examiner should endeavor to judge from the eyes, from the whole expression of the countenance, from the conformation of the limbs, which of the candidates are capable of making the best soldiers; there are as certain and as well understood indications for judging of the soldierly qualities of men as there are for ascertaining the value of a horse or a hunting-dog.[14] All lank, slight, puny men, with contracted figures, whose development is, as it were, arrested, should be set aside. The reverse of the characteristics of a good constitution, already enumerated, will indicate infirm health or a weakly habit of body; loose, flabby, white skin; long cylindrical neck; long, flat feet; very fair complexion, fine hair; wan, sallow countenance, etc.

Under our present system of recruiting in large cities a very objectionable description of men present themselves for enlistment, whose health has suffered from debauchery of various kinds. They are tramps: men who wander about over the face of the country, too lazy to work and too vicious to live in a well-regulated community—a set of Ishmaelites who seek service in the army as the easiest method of getting food, clothing, and shelter, but without the slightest design of performing any more duty than they are compelled to. They generally appear as winter approaches, driven by inclement weather to seek an asylum until the opening of spring. No more undesirable or unfit class of men come before a recruiting officer. They are seldom, after enlistment, out of the guard-house or hospital, and the company to which they belong is fortunate if, when they take their flight in the spring, they do not carry away with them all the available cash, or articles of value, upon which they can lay their hands. Another class of men, having neither apparent disease nor well-characterized physical or moral defect, are equally objectionable; there is a "something" about them which satisfies an expert that they will make either indifferent or bad soldiers, for which reason they should be rejected. The power of recognizing these two classes of men is a talent which is greatly improved by practice, and which the medical examiner should cultivate to the highest degree, persistently rejecting all about whose ultimate efficiency he has the slightest doubt.

Even in *time of war*, when the urgency for men may be ever so great, there should be no deviation from the general rule as to men of this stamp and character, who, if once admitted will serve only to encumber the army either by their shiftlessness or by their viciousness. An army, in whatever strait it may be, is vastly better without than with them.

GENERAL INTELLIGENCE.—A higher degree of intelligence is now expected from the soldier than was the case in the earlier days of the republic. Promotion is open to him, and he is encouraged in every way to improve himself; libraries are established to which he has ready access; reading-rooms, with liberal supplies of newspapers, are prepared for him, and schools are organized in which he has opportunities for study. "It is worthy of notice that much of the advantage to be derived from modern improvements in the mode of educating, training, dieting, and clothing the soldier depends upon his capability of appreciating the objects with which they have been introduced,"[14] and while it is impossible to formulate any specific standard of intelligence by which his eligibility is to be judged, such a direction can be given to the questions necessarily asked during the physical examination as will enable the medical officer to form a very good opinion of his general intelligence, and afford an opportunity to exclude men who, while they may not be exactly idiotic, are "a sort of demi-simpleton."

The remarkable strides which have been made during the past quarter of a century in the science and art of war; the superior mechanism of the rifle now in use; the attention that is paid to target practice, and the efforts that are made to instruct the soldier in the management and care of his weapon and ammunition, tend to make his profession both instructive and interesting, and justify the expectation that men of better tastes and habits than those obtained in the past will, in the future, be attracted to the profession of arms.

It is well stated by Dr. Crawford, in the article from which quotation has been made, that the criminal and invaliding statistics of the army leave no doubt as to the frequent enlistment of the fatuous and imbecile, as well as the criminally vicious, and that if the development of the head, and the symmetry of its proportions were as carefully examined and as dogmatically insisted upon as is customary in determining the form, development, and symmetry of other organs and regions, a proportion, at least, of such men might be excluded from the service.

SPECIAL EXAMINATIONS.—*The Cerebro-spinal System.*—*Epilepsy, chorea, stuttering or stammering, all forms of paralysis, tabes dorsalis, neuralgia*, disqualify.

It is not to be expected that the medical examiner will make a diagnosis of all the different forms and phases of this class of diseases. It is sufficient for practical purposes that he should recognize such general symptoms as are indicative of grave lesions of the system, and should satisfy himself of the incapacity of the applicant for military duty; in their later stages the manifestations are so well pronounced that it is hardly possible for errors of diagnosis to occur; but the earlier symptoms are in many instances obscure, requiring close observation for their detection. The personal appearance, facial expression, and gait will often betray the existence of many forms of nervous disorder, for which reason the medical examiner should require each applicant, after being stripped, to approach him from a distance, and if necessary, walk

Digitized by Microsoft®

www.libtool.com.cn

about the room, during which time he can thoroughly scan his person, observing particularly any deviations from the normal conditions. By this means the halting gait of paralysis of the lower extremities, or the shuffling unsteady step of tabes may be detected. A careful examination of the spine should be made by pressure upon the spinous processes from the cervical to the lumbar vertebræ, and any tenderness or pain manifested by flinching made mental note of. Unsteadiness of the hands and arms should suggest a suspicion of tabes dorsalis, and the simple tests of standing or walking while blindfolded, the tendon reflex, and the tactile sense, should be made with care.

Stammering may be congenital, due to habits contracted in childhood, to malformations of the vocal apparatus, or to organic lesions in the nervous system; by whatever cause it may have been produced, if it is sufficient in degree to interfere materially with ordinary conversation, the applicant should be rejected. Some care will be necessary in arriving at the degree of this affection, because the nervous excitement incident to the examination will of itself react upon the patient, whose embarrassment will increase his difficulty of speech. A little patience and kindliness of manner will, however, soon reassure him, and the true extent of the difficulty be appreciated. *In time of war* attempts will often be made to simulate disorders of this class for the purpose of securing exemption from military duty. The different forms of paralysis and tabes can, by the exercise of some patience and care, be detected; indeed, it would require a man to be possessed of great self-control, shrewdness, and a considerable knowledge of the symptomatology of disease to simulate, with any reasonable prospect of success, any form of paralysis. Ocular evidence of a convulsion should always be obtained by the examiner before he is justified in exempting a man from military service on the ground of *epilepsy*. No statements, however well substantiated, should lead him to deviate from this rule. He should satisfy himself by the absolute loss of sensibility of the conjunctivæ, the dilatation and immobility of the pupil, and the character of the convulsions, that the attack is one of true epilepsy before recommending the case for exemption. The pain of *neuralgia* may be simulated; but true neuralgia of sufficient intensity to disqualify can hardly exist without producing such decided constitutional effects as will be visible to the eye of the examiner.

Constitutional syphilis disqualifies.

The late forms of this disease, as gummata, rupia, periostitis, ostitis, caries, etc., are rarely brought to the notice of the examining surgeon, or if such cases should be presented, the cachexia will be so well marked that there can be but little difficulty in making a diagnosis. It is the early manifestations of the disease which he is to watch for with great care, particularly as men are often the subjects of syphilitic infection without being aware of its existence, and therefore truthfully disclaim any knowledge of a disability for the service on that account.

Careful examination should be made of the cervical, epitrochlear, and inguinal glands, as one of the earliest and most important manifestations of constitutional syphilis consists in their enlargement and induration. Otis, in his work on "Syphilis," states that this abnormal change extends, to a greater or less degree, throughout the entire lymphatic system. He describes the enlarged glands as varying in size from a small shot to a pigeon egg; as being hard, movable, and painless; those in the epitrochlear region being the most valuable in a diagnostic point of view, and rarely present before, or absent after, the tenth or twelfth week succeeding inoculation of syphilis, whether any roseola can be detected or not. Sometimes only one gland is enlarged, which may be above the trochlea, along the inner border of the biceps, and therefore difficult to find. There is variation, also, as to locality in the different cervical and inguinal glands that are enlarged, a patient search for which will generally be successful. The next evidence in order is the classical roseola, with its bright hue in the early stages, and its faucial inflammatory engorgement; the papular eruption with its crop of papules along the upper border of the forehead, hard to the touch, and painless (the corona veneris of Ricord); the circle of white scales arranged about the base of the papules on the body (the collarette of Biett); the coppery-colored stain left after the disappearance of this papular eruption; alopecia and mucous patches. These, either alone or taken together, should be sufficient evidence of the existence of the disease in its earlier stages to warrant the examiner in rejecting the applicant. As the cicatrices of buboes are not evidences of the existence of syphilis, they should not be made a cause for rejection, although their presence should lead to careful examination for signs of the disease, as heretofore mentioned.

In time of war this disease (syphilis) is cause for rejection.

Cancer, in whatever form or stage of development, is a cause for rejection. The "pipe-smoker's cancer," epithelioma of the lip or tongue, and cancerous affections of the testicles, are the forms most likely to be seen among men desiring enlistment. As, however, the disease is one of middle or advanced age, it is very rarely met with at recruiting rendezvous, and is only mentioned in this place as one of a class of diseases which the surgeon may be called upon to reject.

The Skin.—All chronic, contagious, and parasitic diseases of the skin; nævi; extensive, deep, and adherent cicatrices; chronic ulcers; vermin, and *indecent tattooing*, disqualify.

Although vermin may be considered to be only temporary annoyances, it will be found, as a rule, that the men upon whom they take up a residence are undesirable by reason of filthy habits. The fecundity of vermin is so great, so many opportunities are afforded for their migration where numbers of men are associated together, and their presence is so disgusting, that, in time of peace, men infested with them should either be summarily rejected, or acceptance deferred until their persons are rid of the parasites. The most common form met with at recruiting stations is the crab louse (*pediculus pubis*). Of parasitic diseases *scabies, favus, tinea tonsurans*, and *sycosis* are most frequently met with, and should be causes for rejection, or action should be deferred until a cure has been effected. The *tattooing of indecent devices* upon the skin, on any part of the body, is cause for rejection, upon the ground that a man who will voluntarily submit to such defacement is morally unfit to be a soldier. The *presence of cicatrices from cupping* should lead to a close examination of the internal organs in their vicinity, which may have been seriously damaged by disease, or are liable to become again affected after exposure to the hardships of a winter campaign. When *extensive adherent cicatrices* impede the free motions of the limbs, they are absolute causes for rejection; but when seated on other parts, as, for example, the head or trunk, they are not in themselves objections in a recruit; as indications, however, of constitutional cachexia they are important.[16] *Cicatrices, non-adherent*, white and smooth, resulting from an incised or lacerated wound, or a burn, and not involving much loss of substance or lesion of subjacent organs, are not causes for rejection. *Chronic ulcers* are not likely to be found, except in persons of broken-down constitution. Those resulting from abrasions or slight wounds, in persons who do not present any evidence of constitutional disorder, have probably been kept active from some local cause, upon the removal of which they will heal; but those involving much loss of substance, with atrophy of a limb, with a general constitutional disorder, or with varicose veins, especially when located on the lower extremities, should disqualify; even when healed they are apt to open again, so soon as the soldier is exposed to any cause of irritation, such as long marching or inclement weather. The skin of the negro seems especially prone to ichthyosis, and to keloid growths at the seat of even trivial injuries; unless the affections are extensive, or the keloid growths so situated as to interfere with the motion of limbs, or otherwise impair the efficiency of an applicant, they should not be considered causes for rejection. *In time of war* exemption should be given only on account of

Digitized by Microsoft®

long-standing or incurable diseases of the skin; the milder forms, as acne, herpes, urticaria, etc., as also some of the parasitic diseases, including scabies, may be treated with reasonable prospect of recovery in a short time, and the men accordingly should be held to service. Ulcers may be produced and purposely kept open with the view of evading service under conscription. Suspicion will naturally be aroused when an otherwise healthy man claims exemption from service on account of an ulcer of long standing, as this lesion is seldom seen except in persons of broken-down constitution, and generally in middle or advanced age. The appearance of the ulcer, and the tissues surrounding it, will furnish some evidence as to its age, active inflammation pointing to voluntary irritation and a recent lesion, while an old ulcer presents characteristics the reverse of this. Such cases should be placed under close observation in hospital, and every means taken to prevent the patient from keeping up any irritation of the parts, the fact being borne in mind that an almost endless variety of foreign substances are used for this purpose, and that the finger-nails are especially convenient for such use; it may even become necessary to put the patient into a straitjacket before a correct diagnosis can be made.

The Head.—Abnormally large head; considerable deformities, the consequence of fractures; serious lesions of the skull, the consequence of complicated wounds or the operation of trephining; caries and exfoliation of the bone; injuries of cranial nerves; tinea capitis; alopecia, disqualify.

Any injury of the skull affords ground for suspicion of consequent injury to the brain, and the existence of epilepsy or some disorder, greater or less, of the mental faculties; hence all such injuries should be carefully examined as to their extent and seat. It is well known that the skull may receive extensive injury without any subsequent impairment of the faculties, and also that very slight injuries may be followed by serious consequences, more especially by epilepsy; hence, although no positive disease may be detected, it is safe to reject any applicant who has evidence of considerable injury to the skull, if for no other reason than that its presence affords the man an opportunity for evasion of duty, and, if he choose to make it, a claim for discharge from the service on account of some alleged nervous affection, should military duty become distasteful to him after joining his command. With the evidence of an injury to the head before him, it would be difficult for a medical officer to disprove any assertion by a malingerer of the existence of disease.

Wounds of the scalp, especially if non-adherent, should not reject; *injuries of the cranial nerves*, producing paralysis or impairment of function in the parts to which they are distributed, are causes for rejection; *tinea capitis* is laid down in many works on recruiting as a disqualification. It is a disease almost exclusively confined to childhood, and is very rarely met with at a recruiting station. In the examination of several thousand men at the depot at Columbus Barracks, Ohio, the writer did not see a case, nor has he ever seen one among the soldiers with whom he has served. The discovery of any disease of this genus in the hairy scalp would be cause for rejection, not only on account of its contagiousness, but because it is both unsightly and offensive. The *papular eruption of syphilis* is frequently situated in the hairy scalp, and may be easily felt by an examination of that part with the fingers. *Alopecia* is occasionally met with in recruits, and has given rise to much difference of opinion among army surgeons as to its being a disqualifying cause; if it is the result of a pre-existing disease, which will be manifest by the appearance of the scalp, if the loss of hair is total, or if but a few tufts remain about the back of the head and in the neighborhood of the ears, the man is unfitted for service; the head coverings issued to the soldier not being sufficient, in the absence of the natural covering, to protect him from accidents resulting from exposure to the heat of the sun or to the inclemency of the weather; partial loss of the hair, either over the crown or above the forehead, is not cause for rejection; *in time of war* baldness is not cause for exemption.

The Spine.—Caries; spina bifida; lateral curvature of the cervical, dorsal, or lumbar regions; lumbar abscess; rickets; fracture and dislocation of the vertebra; angular curvatures, including gibbosity of the anterior and posterior parts of the thorax, disqualify.

Lateral curvatures of the spine are often the result of some particular trade or occupation; if the curvature is slight, and unaccompanied by signs of constitutional weakness, it should not disqualify. An appearance of lateral curvature frequently results from undue development of the muscles of one shoulder. This will be readily detected by making the recruit stoop forward from the attitude of attention, stretching out his hands over his head, and curving the back until his fingers reach the ground. A glance at the recruit's spine, when so bent, from before backward, will enable the surgeon to estimate the extent of lateral curvature, if it really exists.[17] The following good rule for the determination of the degree of curvature which demands rejection has been suggested by Major Daingerfield Parker, U. S. A. The recruit standing erect, draw an imaginary line from the base of the skull to the end of the spine; if the spinal prominences are curved one inch either side of the line, reject. Any *pronounced* angularity of the spine (gibbosity) sufficient to impair the symmetry of a man's figure, or distortion of the chest interfering with respiration, should reject. The fact that knapsacks and other heavy weights are no longer carried by soldiers upon their backs in modern campaigning removes the objection formerly made to men having this defect in a moderate degree. In young men posterior curvature may be overcome by attention to drills and gymnastics, but in men beyond twenty-five years of age it is useless to attempt an improvement.

In time of war slight curvatures, lateral or angular, should not exempt.

The Ear.—Deafness of one or both ears; all catarrhal and purulent forms of acute and chronic otitis media; polypi, and other growths or diseases of the tympanum, labyrinth, or mastoid cells; perforation of the membrana tympani; closure of the auditory canal, partial or complete, except from acute abscess or furuncle; malformation or loss of the external ear, and all diseases thereof, except those which are slight and non-progressive, disqualify.

Diseases of the ear inducing deafness are not often symmetrical, and affections of one ear are much more likely to be met with than those of both; hence the fact should be borne in mind that while an applicant for enlistment may apparently hear perfectly, a careful examination of both ears will show that he may be deaf in one.

To properly make a preliminary examination of hearing power for the voice, the examiner should stand at the side and in rear of the applicant, at least forty feet distant, while the recruiting sergeant closes the external meatus of one ear by pressing the tragus gently backward and inward. A few words are then to be addressed to the applicant, distinctly, in a middle tone, and not too rapidly. If there is any defect in the hearing of the uncovered ear, it will at once be discovered by the failure to repeat what is said; the same manœuvre should be practised with the opposite side. The voice may be heard at least fifty feet distant in a closed room when both ears are normal; should there be deafness of either ear, the applicant must be rejected.

It will be found that deafness is occasionally caused by the accumulation of cerumen in the ear; in which case, should the recruit be otherwise desirable, it would be proper to defer final action, and an opportunity given him to have the obstruction removed, when, if hearing is restored, he could be accepted.

In time of war deafness is frequently simulated. Real deafness cannot be concealed, but the detection of simulated deafness is at times a somewhat difficult matter. Here every artifice which ingenuity may suggest will be employed to deceive the examiner, whose opinion of the case must be made up of negative evidence entirely, the

Digitized by Microsoft®

only positive evidence available being the motive of the conscript, if this can be styled evidence.

Besides that by means of the voice there are three methods to be employed in testing the power of hearing, viz., the watch, the tuning-fork, and the double stethoscope of Cammann. An opinion should not be formed from any single test, but from the results obtained by all.

www.libtool.com.cn

In using the first test, the applicant should be blindfolded while one ear is closed; the watch is to be held in the air at various distances from his head—above, below, in front of, and behind the unclosed ear. The distance at which its ticking can be heard by the normal ear may be determined by the operator's sense of hearing. This being used as a standard, the degree of hearing by the applicant can be approximately determined. Each ear should be carefully tested by this method, and the result noted.

To use the second test, uniform sound can be obtained by striking the tuning-fork on the knee while the leg is flexed upon the thigh, or even by extending the palm of the hand and striking the tines of the fork upon its fleshy part. In the normal ear the tuning-fork, when placed on the central incisors, is heard equally well in both ears; the same is true if the fork is placed on the vertex or on the centre of the forehead; if placed on the mastoid process, it is heard better in the ear of the same side: it is heard longer when placed in the air near the meatus, than on the teeth, etc.

When there is some defect in the hearing dependent on disease located in the middle or external ear, the tuning-fork placed by its base upon the teeth, or on any of the central portions of the skull, will be heard better in the *diseased* ear. If placed in the air near the ear, it may not be heard as well as in the previous position. In doubtful cases, if the fork is laid a little to one side of the median line, it assists to confirm the diagnosis. For instance, the patient thinks he hears the fork best in the right ear, and it is then moved to the left side a little. If he still hears it as well in the right ear, or even hears it equally well in both ears, there is no question of his hearing it better in the right.[18]

In diseases of the labyrinth having a nervous origin these conditions are reversed, and the tuning-fork will be heard *better* in the good ear—both ears being stopped. Hence the examiner must be on his guard, when investigating a case of suspected simulation, that he does not have a case of labyrinth disease before him. In such instances ocular inspection of the middle ear will be of value in completing a diagnosis.

The third test, by the use of Cammann's binaural stethoscope, is a very ingenious one, and is best described in the language of its originator, Dr. David Coggin.[19] It is, however, serviceable only in simulated absolute deafness of one ear: "The patient affirmed that he was deaf of the left ear. I therefore inserted a tightly fitting wooden plug into the right caoutchouc tube, and then put the two caoutchouc tubes into the metal ones. When I tried the instrument on myself, I found that words spoken could not be understood by the right ear. After the patient had adjusted the stethoscope, he repeated without hesitation the words which I had whispered into the bell of the instrument, which served as a mouthpiece. The tube containing the plug was then taken out of the right ear, which was firmly closed by pressure on the tragus. When I again spoke into the stethoscope, which was still in connection with the left ear, the patient positively assured me that he could no longer distinguish the words. He was, of course, aware that the tube through which he had before heard was no longer in connection with the right ear."

It is more than probable, before the examiner has completed these tests, that the simulator will have become so confused as to betray himself, when, of course, the examination would cease. He must, however, be prepared to find men very obstinate, who have made up their minds to deceive, and he may, therefore, be obliged to employ all the methods at his command in making a diagnosis.

The preference of the writer is for the tuning-fork, about the use of which men are ordinarily ignorant, although the tests by the watch and stethoscope give excellent results. Careful inspection of the meatus should be made for evidence of inflammatory affections or for morbid growths.

In time of war cases of otitis may be placed in hospital for observation, to be exempted from service if subsequent treatment develops the fact that organic changes have taken place, or that permanent deafness has resulted; deafness of one ear is not an objection, but when both ears are thus affected the man should be exempted.

The Eyes.—Class 1. *Loss of an eye; total losss of sight of either eye; conjunctival affections, including trachoma, entropion; opacities of the cornea, if covering part of a moderately dilated pupil; pterygium, if extensive; strabismus; hydrophthalmia; exophthalmia; conical cornea; cataract; loss of crystalline lens; diseases of the lachrymal apparatus; ectropion; ptosis; incessant spasmodic motion of the lids; adhesion of the lids; large encysted tumors; abscess of the orbits; muscular asthenopia; nystagmus.*

Class 2. *Any affection of the globe of the eye or its contents; defective vision, including anomalies of accommodation and refraction; myopia; hypermetropia, if accompanied by asthenopia; presbyopia; astigmatism; amblyopia; glaucoma; diplopia; color-blindness (for the Signal Service only)*, disqualify.

For convenience of examination the foregoing list of disqualifications has been separated into two classes: the first including those defects which may be discovered by the unaided eye; the second requiring for their detection the use of special instruments. Loss of sight of the *right* eye, or loss of the entire globe, as well as other defects interfering with the vision, has been held by the War Department as cause for rejection. The writer is of the opinion that these disqualifications should apply to *either* eye, exceptions thereto being confined entirely to men desiring to re-enlist. Aside from the disfigurement, there are certain manœuvres in the drill and other exercises in military life which cannot be properly performed by recruits unless they have the perfect use of both eyes. Old soldiers are so well instructed in their duties and familiar with drills that nearly all military movements may be exercised by them without the use of both eyes, dependence being placed upon the word of command.

The acceptance of one-eyed men has been advised, provided the sight of the remaining eye is perfect, and it is asserted as a fact that some of our best rifle shots among frontiersmen are thus mutilated. This may be true, and there could be no objection to such enlistments if the terms of the proviso could be made continuous; but it is a well-known fact that when one eye has been permanently injured or diseased, the remaining organ is more or less liable to attacks of sympathetic ophthalmia, to avert which enucleation of the defective eye is often the sole resort. The slighter forms of injury or disease which may affect vision, if uncomplicated by an affection of the iris or ciliary body, are not followed by this result; but it is after the more severe injuries and diseases, particularly when these bodies are involved, that sympathetic inflammation is to be anticipated. It is not always possible for the surgeon to form an opinion as to the cause of blindness in these severe forms of injury without careful ophthalmoscopic investigation, to make which it is neither desirable nor proper for him to spend time. The fact that a disease affecting the integrity of the sound eye is likely to occur at any time would seem sufficient reason for objecting to the admission of such cases to the army. The writer is, therefore, of the opinion that loss of sight of either eye should in time of peace disqualify. Catarrhal affections of the conjunctiva, whether acute or chronic, are causes for rejection, as it is impossible to predict what their terminations may be; a very mild conjunctivitis may develop into a most violent disorder, attended with total loss of the eye; or a chronic affection may linger for years, producing trachoma, affections of the lids, etc. Pterygium, if large and encroaching upon the cornea to an extent that interferes

Digitized by Microsoft®

in the slightest degree with vision, and strabismus, either convergent or divergent, if decided, reject. Any affections of the globe of the eye, as keratitis, sclerotitis, retinitis, iritis, etc., whether acute or chronic, should reject. Careful examination should be made for the divergence of one or both eyes, when the applicant is required to look steadily at an object (asthenopia), or their oscillation (nystagmus); both of which conditions are likely to become more pronounced from the nervous excitement incident to the examination.

www.libtool.com.cn

Examination of the *sight* should be made with the utmost care, as perfectly clear vision is demanded for rifle practice as conducted at the present day. The medical examiner should have a reliable sergeant to assist him. The applicant should stand facing the surgeon, and twenty feet from him, with his face to the light, as in this position the iris is moderately contracted, and opacities of the cornea, which may cover any part of the pupil, will be more readily discovered; the sergeant should cover one eye with a card, instead of the hand, as is directed in most instances; if the hand is used, undue pressure is, unconsciously, liable to be made on the globe, the circulation is interfered with, and more or less discomfort and dimness of vision experienced when the eye is uncovered; or a careless sergeant may, when covering the eye, so spread his fingers that the applicant can see the objects placed before him with the so-called covered eye, should the one uncovered be defective.

The instructions given by the War Department for conducting this examination are contained in a general order, from which the following extract is made: "1. *Range of vision necessary in recruits.* Hereafter no recruit shall be enlisted who cannot see well, at six hundred yards, a black centre three feet in diameter on a white ground. This test will be made by means of cards prepared under the direction of the surgeon-general of the army. The black spots on the cards will be circular, four-tenths of an inch in diameter, and the recruit must be able to count them with facility at twenty feet distance."[20] In compliance with that order the surgeon-general issued instructions from which the following extract is made: "These test cards are ten in number, with black spots arranged like those on playing-cards, and ranging from one to ten on each card: . . . the surgeon . . . exposes successively the faces of two or three of the cards to the applicant, who must be able to state promptly the number of dots on each. This examination must be made with each eye separately, and may be varied by showing to the applicant one of the higher numbers, such as the nine or ten card, and covering up a part of its face with another card so as to expose one or more spots at a time. This test does not represent absolutely perfect vision, but admits recruits with minor degrees of refractive anomalies. It has been thought best, however, that recruits with these minor anomalies should not be excluded on account of them, provided their eyes are healthy in other respects."

If there should be any doubt upon the subject with this simple test, the test types of Snellen should be used.

To determine the degree of errors of refraction, either the simple optometer or the test glasses should be used.

The writer is free to confess that he has failed to obtain any satisfactory results with the optometer, and has been compelled in all cases to resort to the trial glasses for the desired information. Astigmatism may be determined by the optometer, or by the use of the astigmatic charts furnished with the cases of trial glasses. To detect color blindness a set of test wools is required, which should be used in accordance with the directions published by Holmgren, reprinted in Jeffries' work on "Color Blindness," p. 210 *et seq.*

In time of war the following defects, which disqualify in time of peace, should *not* exempt drafted men from service: *Loss of either eye; loss of sight of either eye; opacities of the cornea; strabismus, unless extreme; diseases of the lachrymal apparatus; ptosis, unless complete and indicative of serious brain lesion; asthenopia and nystagmus, unless excessive; anomalies of refraction, unless extreme.* The most common defect of vision among persons in this country is myopia, the degree of which to disqualify in time of peace, or exempt in time of war, has not been determined for the United States Army. Dr. Baxter, in his "Report of the Medical Statistics of the Provost Marshal General's Office," states that "near-sightedness does not exempt"; Dr. Bartholow states, "Myopia . . . is not a ground for exemption under the Enrolment Act, unless decided."[21] Tripler says, "Myopia is an objection to a recruit."[22]

As has been stated, the range of vision for recruits, determined by the test dot cards, admits them "with minor degrees of refractive anomalies"; so far as myopia is concerned, these degrees are such as to admit men from whom efficiency as riflemen cannot possibly be expected. A man whose degree of myopia is as high as $\frac{1}{24}$ can, with each eye separately, count the dots at twenty feet, although he does it with difficulty; but it is not possible for him to read the test types of Snellen, that should be normally seen at that distance, nor to see the bull's eye on a target at any of the ordinary firing ranges, and if accepted as a soldier, he is therefore useless as a rifleman. Even with so low a degree of myopia as $\frac{1}{36}$, the target is seen very indistinctly, and it is a question admitting of considerable doubt whether in such a case the soldier would ever become efficient as a marksman without the aid of spectacles; his vision would, however, be sufficiently acute for all ordinary purposes, and hence, if otherwise a desirable man, he might be accepted. The order promulgating the vision test is so worded that but few recruiting officers would feel themselves compelled to exact a literal compliance with its requirement for the recruit to "count with facility," and considering that he could "see well," if able to count the dots even with the difficulty encountered by a myope of $\frac{1}{24}$ degree, they would accept him.

In time of war, however, higher degrees of myopia may be admitted without serious detriment to the service, especially if a system were adopted by which men so defective could be utilized in branches of the service other than the line, as is the case in foreign armies, where, for example, as in France, myopes of $\frac{1}{4}$ and higher, and those of $\frac{1}{12}$ and higher in Italy, Austria, Switzerland, and Holland, are accepted; to do this, the use of spectacles would, of course, be necessary. In the English army recruits are admitted to the general service, and without being graded, with $\frac{1}{24}$ myopia; although Professor Longmore states it "to be very questionable whether any man with myopia = $\frac{1}{24}$ ought to be accepted as a recruit."[23]

When the facts are considered that the character of our service necessitates acuteness of vision in the use of the rifle, and that we have a vast population from which to recruit a small army, it seems proper that the highest standard of vision should be insisted upon, and that recruits should not be accepted in time of peace unless they have normal vision, as determined by test types, or are myopic to a degree not exceeding $\frac{1}{36}$, when otherwise very desirable men. In time of war all degrees of myopia above $\frac{1}{24}$ should exempt, unless the use of spectacles is permitted, in which event, of course, most higher degrees could be accepted. A very simple method for roughly determining the higher degrees of myopia in cases which are free from astigmatism and other defects of vision is to ascertain the distance at which ordinary newspaper type can be read by the myope. With the normal eye this type is distinct at forty or forty-eight inches, and the distance less than this at which vision is distinct in the myope will express the denominator of a fraction indicative of the degree of his myopia; for instance, if the type can be read at fifteen or twenty inches, the person examined is about $\frac{1}{15}$ or $\frac{1}{20}$ myopic, etc.

As in the case of deafness, the surgeon must be prepared, in the examination of a conscript's vision, for the most artfully laid schemes of deception; but if he has patience, and works systematically, he will, in a large majority of instances, be able to ascertain the true state of the case, and expose deceit if it be attempted.

Several excellent tests for the exposure of simulated

Digitized by Microsoft®

www.libtool.com.cn

defects of vision have been published, of which, doubtless, the most convenient for use at a recruiting rendezvous is that suggested by Dr. Howard Culbertson, U. S. A., and styled by him "the prismometer." He describes it as follows: "The prismometer detects errors of refraction by means of the displacement of the false image seen through a prism. Its essentials are: a perforated disc carrying a prism which covers one-half of the perforation, its truncated, thin edge dividing the perforation into two equal parts, and a sharply outlined, dead-white disc, about 22 mm. in diameter, on a black, lustreless ground placed at a distance from the prism of 15 to 20. This distance and the strength of the prism must be in such proportion that when an emmetropic eye is placed back of the perforation and directed to the white disc, a true and a false image will be formed, whose peripheries will be exactly tangent.

"In case the examined eye is hypermetropic the images will stand apart to a degree varying with the degree of hypermetropia; in the case of myopia, on the other hand, they will overlap. The degree of ametropia in either case is measured by the lens, which, when held before the perforation, will render these discs tangent. By revolving the disc bearing the prism through an angle of 180° the false image appears to revolve about the true, and in case of astigmatism the separation or overlapping is greatest in the meridian in which the astigmatism is greatest. Its axis may be determined by an index pointing to a graduated arc in contact with the disc; its degree by the spherical or cylindrical glass which renders the discs tangent in the meridian in which they varied most from tangency."

Professor Longmore[24] describes the prism test of von Graefe and the test by the stereoscope suggested by Mr. Lawrence.

All of these tests depend for their success on the confused statements of the simulator, when compelled to look with his normal eyes through a prism, or to describe objects especially prepared for view through a stereoscope. The stereoscopic objects require special preparation, and while a most excellent test upon men of more than ordinary intelligence, who may understand the effect of prism on vision, it is not always practicable; any test by a prism is a good one, but that proposed by Dr. Culbertson is not only simple but effective, both against simulation and in the detection of refractive errors; besides these are the Snellen test with colored glasses and test types; the use of various trial glasses, the ruler test, etc., the description of which may be found in most works on diseases of the eye. Valuable information may be gained by a careful examination of the pupil in simulated blindness of one eye; in an eye suffering from complete amaurosis the pupil is moderately dilated, and but feebly responds, or not at all, to the stimulus of light falling into it; but does respond to the stimulus of light thrown into the other eye. In the simulator, of course, the pupil is normal. Other defects of the eye mentioned in the foregoing list should not exempt a conscript from duty, unless the vision is very materially interfered with, or, as in the case of disease of the lachrymal apparatus, the irritation produced by them keeps up a chronic inflammation.

The Nose.—Loss of the whole or part of the nose; deformities of the nose disfiguring the face, sensibly altering the voice, and impeding respiration; stenosis and atresia of the nasal cavity; chronic rhinitis (ozæna); polypus; purulent and fœtid discharge from the nose, whether due to old and incurable ulcerations, or to any other lesion of the nasal mucous membrane, disqualify.

Loss of the nose or parts thereof may be congenital, accidental, or the result of syphilitic or scrofulous ulcerations; in the two former instances, unless the mutilation is of sufficient degree to make a noticeable disfigurement, or interfere with respiration, it is not cause for rejection; in the latter instances it would, of course, disqualify. Deformities of the nose are generally produced by accident or by disease, congenital deformities being rare; the nasal bones may be so flattened, distorted, or destroyed by caries as to interfere with respiration and speech. Syphilis creates great havoc in this location, hence these deformities should lead to suspicion of that disease, and careful investigation of the case. Stenosis and atresia are either congenital or due to alterations in the natural position of the septum, or to hypertrophies of the erectile tissue lining the cavity; in which latter condition the overgrown tissue covering the turbinated bones is forced against the septum, or projected in comb-like growths into the naso-pharyngeal space; the breathing of persons laboring under this defect is entirely by the mouth, and their facial expression is often vacant and silly; the irritation produced by the hypertrophied tissue keeps up an excessive mucous secretion, to relieve which there is an incessant hawking and spitting, and unless the cavities are cleared, decomposition takes place and is attended by its peculiar and nauseous odor. Deflection of the nasal septum is probably the most common cause of stenosis and atresia, the bone, in some instances, being forced against the side of the nostril, to which its mucous tissue may become adherent. Chronic rhinitis (ozæna) is readily detected by the horrible stench which patients carry about with them; it is generally an evidence of a low grade of constitution, and aside from its disgusting local symptom would require rejection. Polypi, purulent discharges, etc., are all causes for rejection. *In time of war,* losses and deformities of the nose and ozæna, are the only defects which should exempt from military duty.

The Face.—Nævi; unsightly hairy spots; extensive cicatrices on the face, disqualify: "their presence would subject the man to the impertinent jests of his comrades, to his personal annoyance, and to the prejudice of good order in his corps."

The Mouth and Fauces.—Harelip, simple, double, or complicated; loss of the whole or a considerable part of either lip; unsightly mutilation of the lips from wounds, burns, or disease; loss of the whole or part of either maxilla; ununited fractures; ankylosis; deformities of either jaw, interfering with mastication or speech; loss of certain teeth; cancerous or erectile tumors; hypertrophy or atrophy of the tongue; mutilation of the tongue; adhesion of the tongue to any parts, preventing its free motion; malignant disease of the tongue; chronic ulcerations; fissures or perforations of the hard palate; salivary or bucco-nasal fistula; hypertrophy of the tonsils sufficient to interfere with respiration or phonation, disqualify.

At the present day the army surgeon has to consider only the number and condition of teeth required for the proper mastication of food; the question of bygone days as to their utility or necessity in biting cartridges having been settled by the introduction of breech-loading rifles, and the substitution of metallic for paper cartridges. It is probable that for many years to come the majority of our army will be stationed in the sparsely settled Territories, and be compelled to make annual campaigns, as has been done in the past, for the protection of settlers from the lawless people and disaffected or vicious Indians among whom they have cast their lot. These campaigns, from a food standpoint, are as trying to the digestion of the men engaged in them as can be any campaigns in civilized countries in times of war; for, as the men are moving constantly from one camp to another, there is but little opportunity for the preparation of soft bread, and the hard biscuit must be used instead thereof; if cattle are driven with the command, they soon become poor from constant travel, scanty food, etc., and their meat is so tough and stringy that the best of teeth can make but little impression upon it, and the strongest stomachs have difficulty in digesting it. Since the abolition of the paper cartridge, the tendency among military writers on this subject has been to underestimate the necessity for sound teeth, apparently forgetting the fact that the soldier is often placed in circumstances in which they are an absolute necessity for his health, and certainly indispensable for his comfort. The statement made by Dr. Baxter[25] that, "as a matter of fact, there are not many days in which the soldier is not supplied with soft bread," is a grave

Digitized by Microsoft®

mistake; if he had plenty of soft bread the mastication of commissary beef in the field would still require the assistance of a goodly number of sound teeth; hard biscuit can be softened by a variety of processes, but no amount of cooking will ever succeed in doing this for the beef referred to. It has been within the experience of the writer that men have been disabled through sheer debility, while on a protracted "scout," because of their inability to masticate the food on which the command was obliged to subsist. The molars and bicuspids, as the principal agents in mastication, should therefore be in good condition; it is not necessary that they should all be present, but the smallest number should be six, viz., two upper and lower molars, and one upper and lower bicuspid on the same side, all sound, and opposed to each other; if the incisors and canines are perfect, but the molars and bicuspids gone, or extensively carious, rejection is demanded. Caries of a large number of the teeth, particularly if advanced, with destruction of considerable portions of the crowns, should reject, because it is probable that, before the expiration of an enlistment, they will be so far destroyed as seriously to interfere with mastication. The irritation of the gums caused by carious teeth is also frequently followed by abscess and troublesome swellings of the face and jaws. If artificial teeth are worn, the fact should be noted on the enlistment papers, but the artificial substitutes cannot be regarded as taking the places of the natural teeth, nor as removing the disability for the military service arising from their loss. Lesions of the hard and soft palate must be carefully looked for, and the tonsils thoroughly examined; ulcerations and consequent perforations of the hard palate are often situated in the anterior part of the roof of the mouth, and unless the head is thrown well back, and the jaws are widely separated, they may be overlooked. Ulcerations of the cheeks and gums, and especially on the sides and back of the tongue, must also be carefully searched for; in the latter situations they are often difficult to see, unless attention is called to them by the patient, as their location, either between the papillæ or following the course of the muscular fibres, conceals them from ordinary observation, especially if the tongue lies quiescent in the floor of the mouth, with its sides protected by the teeth. The subjects of excessive hypertrophy of the tonsils are undesirable as recruits, because of the likelihood that, at most inopportune times, they may be seized with an acute attack of inflammation of the parts, it being a well-established fact that previous attacks, of which the hypertrophy is the sequel, predispose to subsequent and more severe ones at any time; phonation, too, is materially interfered with, unfitting the man for certain important duties, especially while detailed as a sentinel.

In time of war, simple harelip, loss of teeth, cicatrices, hypertrophy of tonsils, should not exempt.

Exemption on account of loss of teeth is frequently claimed by conscripts, and has been regarded as good cause; men with such defects can, however, be made useful in the various administrative departments of the army, where the necessity for having sound teeth does not exist; therefore exemptions should not be granted for this cause; the wearing of artificial teeth may, under these circumstances, be favorably considered.

The Neck.—Goitre; ulcerations of the cervical glands; cicatrices of scrofulous ulcerations; tracheal openings; wry-neck, chronic laryngitis, or any other disease of the larynx which would produce aphonia; stricture of the œsophagus, disqualify.

Goitre is not often met with among the class of men who are applicants for enlistment; should it be recent and growing, or of sufficient size to interfere with respiration, or with the hooking of the coat collar, or buttoning of the coat, it is cause for rejection. The cicatrices which are found in scrofulous subjects, who in childhood have had suppuration of the cervical glands, are both unsightly and liable to become irritated in hot weather by the coat collar; of course, as being indications of the presence of scrofula either in the past or present, they render it necessary that a careful inspection should be made of the person for other signs of that disease; if none exist, and the cicatrices are healthy, the applicant, if otherwise desirable, may be accepted; but if they are numerous, purplish colored, or adherent, rejection is demanded. Any ulceration about the neck, either of the lymphatics or in the tissues, is cause for rejection; wry-neck, if permanent from any cause, should reject. Any chronic inflammation of the larynx, producing a huskiness of voice sufficient to render speech indistinct, or to induce actual aphonia, should reject. Of course the simple hoarseness of ordinary colds is not to be considered, but any well-marked alteration of the voice should lead to an examination of the larynx in which the existence of organic changes would be cause for rejection.

In time of war, only very extensive cicatrices, active ulcerations, or tracheal openings, should exempt; the presence of goitre, unless very large and unsightly, and wry-neck, if caused by rheumatism or any curable disease, should not exempt.

The Chest.—Malformation of the chest, or badly united fractures of ribs or sternum sufficient to interfere with respiration; caries or necrosis of ribs, deficient expansive mobility; evident predisposition to phthisis; phthisis pulmonalis; chronic pneumonia; emphysema, chronic pleurisy; pleural effusions; chronic bronchitis; asthma; organic diseases of the heart or large arteries; serious and protracted functional derangement of the heart; dropsy dependent upon a disease of the heart, disqualify.

In obtaining measurements of the chest the movements of inspiration and expiration should be confined entirely to the muscles of respiration; the applicant should be required to inflate the lungs to their fullest extent by an easy, though complete, inspiration; expiration should be made in the same quiet manner, and is most completely accomplished by requiring the applicant to count aloud until the necessity for a fresh supply of air compels him to inspire again. No contortions of the body should be permitted—such as throwing the chest forward and shoulders backward during inspiration, nor forcing the shoulders forward during expiration,—as these movements can do nothing more than produce erroneous results. The measurements are to be taken when the man is stripped; the arms are extended above the head, the tape is brought around the chest in such a manner as to fall just below the points of the scapulæ behind, and the nipples in front; the arms are then to be brought down by the sides of the body, and while the tape is held tight enough to lie snugly against the skin, the man is directed to respire after the manner before related.

Attention must be paid to the proper proportion of the chest; the fact, however, being borne in mind, that certain occupations have a tendency to change its shape without producing any lesion of the lung tissue; the lateral flattening of the chest walls so often found in tall, slender men, or those of slight frame, with projection of the sternum—the "pigeon breast"—is more likely to be associated with organic changes in the lungs than is the flat or hollow chest—the antero-posterior flattening. Malformations of the sternum and cartilages of the ribs are less likely to be present in the puny or phthisical subject, and have little or no significance in pulmonary disorders. It should be the object of the medical examiner to accept only men who have well-formed chests, or, as it is expressed in the Army Regulations, "whose chests are ample"; any deviation from the typical healthy thorax being considered good ground for suspicion of changes in the normal character of its contents.

It is entirely beyond the scope of this article to go into the details of a physical examination of the lungs; hence it will be sufficient to say that both auscultation and percussion should be performed before the examiner is satisfied to pronounce upon the availability of his patient for the military service; with the exception of the examination of the heart, there is none other which demands the exercise of so much care. Close questioning should be made into the family history of every applicant, as well as into his own life and habits, for any evidence of a pre-

Digitized by Microsoft®

disposition to phthisis or the occurrence of attacks of pneumonia or pleurisy; for a general susceptibility to changes of climate, weather, etc.; for the occurrence of asthmatic attacks, spitting of blood, etc.; in fine, for anything which would bring out a clew to the previous existence of any affection connected with the pulmonary apparatus. Particular stress is laid upon this subject, because it is no uncommon thing to find men seeking army life with a hope that its supposed freedom, regularity of habit, and their own location in particularly salubrious climates, might benefit an already existing lung trouble. Parents consent to the enlistment of their boys under the impression that the life of a soldier will "harden their lungs," and recruiting officers will often urge the acceptance of applicants whose skin is suspiciously clear, upon the ground that the service will "bring them out"; "make new men of them," etc.; the medical examiner must, therefore, be especially on his guard against the admission of such men into the service, and recollect that he is not required to diagnosticate any particular lesion of a lung in order to reject an applicant, but, if he has reason to *suspect* a predisposition thereto—unhesitatingly to reject.

Dr. Tripler quotes very aptly from Bézin, as follows: "It is true we run the risk of rejecting men who may afterward become very robust, and who, by a long and successful life, may contradict the prognosis we may have pronounced in their cases, but . . . you will be astonished at the number of young men who, received because no determined lesion of the thorax was recognized when they were inspected, succumb afterward with phthisis, or whom it was necessary to send back to their friends and families with broken health, after their strength had been exhausted." (Aide-Mémoire.)

Of organic diseases of the heart, those affecting the valves are easily detected, and require no detailed notice here; there is occasionally heard, however, a cardiac murmur which is not indicative of any disease of either heart or lungs, and about which the text-books on the general subject are silent. It has been described by Dr. Hamilton Osgood, in a paper read in March, 1883, before the Boston Society for Medical Improvement, and published in vol. cviii., No. 13, of the *Boston Medical and Surgical Journal*. Dr. Osgood gives to it the very appropriate name of a "misleading cardiac murmur"; it is heard during the respiratory act, with a portion of which it is synchronous (especially inspiration), and is located at the base of the heart. When respiration is temporarily suspended it may be heard, although not so distinctly as during the normal act; its true nature is to be discovered by auscultation *during forced collapse of the lungs*; mere ordinary expiration will not uncover the heart, and the patient must be instructed to force out all the air possible, continuing his efforts until air can no longer be expelled from the lungs; after which the lungs must be kept immovable. By this procedure the heart is brought more closely in contact with the ear, and is freed from the presence of lung tissue, which, in the inflated lung, partially covers it; the "misleading murmur" will now be found to have disappeared. Aside from its value in determining this point of doubt, forced expiration of the lungs is a valuable adjunct in the examination of the heart under any circumstances; when that organ is uncovered, the natural as well as morbid sounds are more sharply accentuated, and deviations from the normal will be more easily discovered. If the patient is required to put the anterior chest wall on the stretch by standing with his back against a door or post, and his hands carried forcibly behind his back, the results will be much more satisfactory.

In the diagnosis of cardiac hypertrophy, associated or not with dilatation, the inexperienced medical examiner may be easily misled. The movements of the heart are so largely under the influence of the sympathetic nervous system that any cause acting directly through that system may produce such alterations of its rhythmical action as will lead to the opinion that they are the result of organic change. When the hand is placed upon the chest of an applicant who has just passed through the preliminary questioning, and has been stripped for examination, the heart will probably be found in tumultuous action; in some instances so violent as to produce a feeling of faintness. The excessive use of tobacco and coffee, or either, will also produce so much functional disturbance, irregularity of action, and palpitation, that organic changes may be suspected. The powerful, rhythmical action of the enlarged organ in true hypertrophy, taken in connection with the permanent change in the location of its apex beat, will supply the evidence mostly to be relied upon in forming a correct opinion of the case presented. It is not, however, always possible, in the short time allotted to the preliminary examination, to decide whether the abnormal action is functional or organic, and in all cases of doubt the applicant, if otherwise desirable, should be kept under observation for two or three days, in order that he may become accustomed to his surroundings, and recover somewhat control of his nervous system. Should it become apparent that even a functional disorder of the heart is persistent, or so serious as to interfere with the usefulness of the applicant, he should be rejected. The sequelæ of cardiac lesions, dropsies, pulmonary engorgements, etc., will require close consideration, particularly in their earlier stages; but it is a rare occurrence for men in a state of disease so far advanced as these symptoms would indicate, to come to a rendezvous. In all cases of suspected cardiac lesions, the urine should be carefully examined.

The directions stated in the "mode of examination," on a previous page,—viz., to auscultate the heart before requiring the applicant to go through the violent exercise of running, jumping, etc.,—were given for the reason that the sounds of the heart are best heard when the patient is at rest. The lungs are best examined while rapid breathing is induced; hence the directions for their examination *after* the exercise mentioned. Should any lesion of the heart have been suspected, its rapid action after exercise will tend to bring out more prominently the abnormal sound. Advantage should be taken of this excessive action to examine the course of the bloodvessels in the neck and other parts of the body, with a view to the detection of aneurisms.

In time of war all diseases of the heart and lungs should be cause for exemption, without exception.

The Abdomen.—All chronic inflammations of the gastro-intestinal tract, including diarrhœa and dysentery; diseases of the liver or spleen, including those caused by malarial poisoning; ascites; obesity; dyspepsia, if confirmed; hemorrhoids; prolapsus ani; fistula in ano; considerable fissures of the anus; hernia in all situations, disqualify.

Among the list of disqualifications mentioned by Tripler and Baxter are engorgement of the mesenteric glands, chronic peritonitis, stricture of the rectum, and tæniæ. The first three of these diseases are exceedingly rare, and their diagnosis is a matter of considerable difficulty at best. It is not very likely that the subjects of them will present themselves for enlistment, and they are accordingly omitted from the disqualifying list, because they fall within the list of general affections impairing the efficiency of men for military duty, the mere mention of which would extend an article into the limits of an elaborate treatise, and the discovery of which would naturally be cause for rejection. The existence of any species of tapeworm is not considered a disqualification, their expulsion from the intestine being so easily accomplished, and their presence producing so little constitutional disturbance in the adult. To ascertain whether chronic inflammation of the gastro-intestinal tract, or dyspepsia of an aggravated form, is present, the medical examiner will be compelled to rely largely upon the statements of the man himself. Accuracy of diagnosis cannot be expected except after observations conducted for a greater or less period of time; many instances terminating only in negative results. The grosser signs of these disorders may lead to suspicion of their existence, but in men anxious for enlistment, all evidence tending to establish the fact will be concealed, although the emaciation attendant

Digitized by Microsoft®

upon long-standing and serious cases should put the examiner on his guard. Fortunately, but very few of them are presented, and the mere mention of their names is enough to draw attention to the probabilities of their presence. Affections of the liver and spleen are of more practical moment, www.libtool.com.cn the fact that a large proportion of our recruits is drawn from sections of the country in which malaria is rife, and where men whose systems are broken down by the influence of this poison are forced to quit their ordinary employments and seek a livelihood in some other and more healthful region; the army offering the easiest means for accomplishing the object. In these instances enlargements of the liver and spleen will be found, and associated with them the anæmia and generally debilitated condition characteristic of malarial poisoning. From some of the rendezvous subsidiary to the depôt at Columbus, O., which were located in malarious regions, the men enlisted were feeble and anæmic, with enlarged spleens, dropsical legs, and a mental depression which was an apparent bar to improvement under their changed condition of life; in many instances this change of climate, etc., brought about a recurrence of the periodic fever, necessitating admission to, and protracted treatment in, hospital, and leaving the men utterly useless for future service. The evil became so great that orders were finally issued to discontinue the objectionable rendezvous, and abandon the infected districts; attention, then, must be given to the condition of these organs, in all cases in which the general appearance indicates malarial poisoning. Obesity, or pendulous abdomen, impairs the efficiency of men for military duty; they cannot take active exercise without loss of breath, or in warm weather without suffering from excoriations, prickly heat, etc.; and moreover, in all such cases the presence of fatty degeneration of the heart and arteries is to be suspected. Hemorrhoids are so very common, and of so many degrees of severity, that it is impossible to lay down any fixed rule by which all cases are to be decided; each must be judged upon its own merits, and rather by the effects of the disease upon the individual, than by the size of the tumors or their age. Internal hemorrhoids, except when protruding, cannot be discovered unless they are bleeding at, or just before, the time of examination, the evidences of which will appear upon the person or clothing of the applicant; they may possibly be ulcerated, in which event there will be a purulent discharge from the anus, which, however, may occur from other causes; but its appearance should be the occasion for a careful inspection of the rectum, if the man denies being the subject of piles. Their existence is an absolute cause for rejection. External hemorrhoids, if multiple and large, ulcerated or inflamed, should reject. The small, accidental pile commonly met with in men of constipated habits; the pedunculations found in men of lax fibre, or old piles in which the former mucous lining has become transformed into a hard and insensitive covering similar to true skin, are not causes for rejection, if the man states that they have not given him trouble. These statements should, however, be taken with many doubts, as the desire to enlist will lead men to prevaricate about that point, and the medical examiner will be obliged to form his own opinion from the appearances presented by the tumors, and from their effects upon the surrounding parts.

Although fistula in ano may be discovered by means of the discharge from its track in most cases, a careful inspection of the parts near the anus, for the external opening of the fistula, is necessary; in very hairy men, the hair must be pushed aside and every point suggestive of the appearance of a fistula explored with a probe.

There should be but little difficulty in discovering any well developed forms of hernia; it is those cases which are incomplete or partially developed about which the surgeon may be perplexed. The examination should always be made while the man is standing, and with his hands extended above his head; the surgeon should examine the umbilicus, and afterward each inguinal canal, carrying his finger well up to the internal ring, and requiring the man to cough vigorously; if the bowel protrudes to any degree from the abdominal cavity into the canal, it can easily be felt. There can be no doubt as to the unfitness for service, in time of peace, of an applicant who has a hernia, all varieties of which, whether complete or incomplete, are absolute causes for rejection; cases, however, in which the inguinal rings are relaxed, in which there is supposed to exist a "tendency to hernia," are not so easily disposed of; the question as to the acceptance of men having this tendency being still an open one. In some foreign armies it is considered a sufficient cause for rejection, but in our service the judgment of most medical officers is adverse to such an opinion. While it is true that the exertion incident to certain phases of military life may produce a hernia in men having relaxed inguinal rings, it is equally true that the accident may happen quite as often (relatively) to men who do not have this defect; indeed, there is no especial evidence to show that this is more frequently a predisposing cause than is any other. The experience of the writer fully confirms the statement made by Tripler,[26] that "by far the greater number of herniæ that have fallen under our observation have occurred in comparatively robust, thick set men; just the men who rarely have relaxed external rings." The exclusion of this class of cases would, it is believed, result in the loss to the service of many excellent men, and until it is shown that they are more liable to the defect than others, rejection is not demanded. The examination for a hernia should, however, be very carefully made, and the applicant required previously thereto to run, jump, or take other violent exercise; care must be used in the examination of a scrotal hernia, that a mistake be not made in confounding it with other tumors connected with the cord or testicle—an error one might very easily fall into when examining any large number of men. The tissues covering an umbilical hernia are so very thin that there can be but little room for error in diagnosis; indeed, the fact is that any thinning of the abdominal walls in that vicinity amounts practically to a hernia; but one must not confound with a hernia a not uncommon malformation of the umbilicus, in which, through some morbid process during the separation of the cord, a nipple-like tumor has been left that bears no small resemblance to an umbilical hernia.

In time of war it would not be proper to reject men who had hemorrhoids, unless, if internal, they were very large, and the constitutional effects produced by the bleeding, or the irritation set up by their presence, was plainly visible; in case of external hemorrhoids they should be very large, painful, and of long standing, to be cause for rejection. Herniæ which are easily reducible and retained in position by a well-fitting truss, or those which are incomplete, should not be cause for exemption. All other defects which disqualify in time of peace do so equally in time of war.

The Genito-Urinary Organs.—Any acute affection of the genital organs, including gonorrhœa and venereal sores; loss of the penis; phimosis; stricture of the urethra; loss of both testicles; permanent retraction of one or both testicles within the external ring; any chronic disease of the testicle; hydrocele of the tunic and cord; atrophy of the testicle; varicocele; malformations of the genitalia; incontinence of urine; urinary fistulæ; enlargement of the prostate; stone in the bladder; chronic cystitis; all diseases of the kidney, disqualify.

The existence of gonorrhœa, or a venereal sore upon the penis, should be cause for rejection; aside from the fact that the subject of either of these affections is liable at any time to communicate it to his comrades, it is not possible for any one to foresee the complications which may arise during the course of either form, nor the sequelæ it may leave behind. Venereal diseases are so very common, and held in such light estimation by the laity, and indeed by many of the profession, that their existence is looked upon rather as an incident in the ordinary life of a soldier, than as a serious matter which may disable the victim for life. Men who have been inadver

Digitized by Microsoft®

tently enlisted with some form of venereal disease should be placed in hospital at once, both as a measure of cure and for the purpose of isolation. It is to the interest of the service that such cases should receive prompt attention as, even if their progress toward a cure is not delayed by complications, their terminations are liable to be marked by permanent disabilities, demanding final discharge. Cases of gonorrhœa are frequently followed by stricture of the urethra, and venereal sores are almost as likely to prove syphilitic as innocent. The instructions laid down in text-books for the differential diagnosis between chancroids and chancres will prove but a poor defence should a recruit who at the time of enlistment is the subject of a chancroid be afterward discharged on account of constitutional syphilis. The principle that the Government is justified in caring for such cases in its hospitals, for the purpose of securing the services of good men temporarily unfortunate, is entirely wrong, and the desired result is seldom attained. The experience of the writer is to the effect that the large majority of such cases terminate by discharge, before the subject has been able to render any considerable portion of the service for which he was enlisted.

www.libtool.com.cn

The existence of any stricture of the urethra is cause for rejection; its presence can be definitely determined only by the use of the sound, a procedure demanded in all cases giving ground for a suspicion of disease; the condition of the stream passed in urinating must be carefully inquired into, and all information relative to a history of the case elicited by closely questioning the patient, before resorting to the use of an instrument. Simple narrowing of the meatus, which is congenital in many persons, should not be considered a cause for rejection.

Phimosis, if complete, is liable to give a great deal of trouble to a soldier by repeated attacks of balanitis; if there is adhesion between the prepuce and the glans, partial or complete, graver symptoms may present themselves, and his efficiency may be impaired by reflex paralyses, epilepsy, or other nervous affections, for the relief of which surgery is required; for these reasons it is made a cause for rejection. When both testicles are absent from the scrotum, the inguinal canals must be carefully examined for evidence of their retention therein; loss by injury may be known by the scar remaining on the scrotum; should one or both testicles be found permanently resting in the inguinal canal, or absent from the scrotum from any cause, the applicant should be rejected. In affections of the testicle, discrimination must be made between true diseases of this organ and morbid changes in the epididymis, the result of inflammatory action. The most common defect among the class of men who present themselves for enlistment is the enlargement from interstitial deposits following orchitis—sarcocele—which, when inconsiderable in size, is not a cause for rejection; a diagnosis must, however, be made between it and other enlargements of the testicle, either syphilitic or malignant; and should there be reason to believe that the enlargement is due to either of the latter causes, or should its size be such as to give annoyance to the patient, rejection is demanded. A hydrocele may mislead one in cases of this nature, and the test by transmission of light should therefore not be omitted in any examination of the organs.

It is exceedingly rare to find a varicocele of such size as to become a real disability to a willing soldier in any branch of the service, excepting perhaps that requiring him to be mounted—under which circumstances he may injure it or the testicle—which in these cases hangs very low—against the saddle; but as it is a defect which may be made to appear a disability, the soldier has an ever-present excuse for the evasion of duty, or a ground upon which to base an application for discharge. So long as he can demonstrate the existence of a disease or defect in any organ, so long will it be impracticable to insist upon a performance of his duty, and it is this circumstance rather than any well-grounded belief in the disqualifying nature of a varicocele, as well as the more general principle that no men should be enlisted who are the subjects of any recognizable physical defects, which leads to its being placed upon the list of causes for rejection. The rule laid down by Tripler is an excellent one for the determination of the degree of varicocele which should reject: "If the testicle on that side is atrophied, whatever may be the volume of the circocele (varicocele), or if the volume of the latter exceed that of the former, the recruit should be rejected." [21]

Among malformations may be mentioned epi- and hypospadia, where the urethra terminates at a distance nearer the body than one-fourth the length of the penis. Incontinence of urine may be suspected by a urinous odor about the person of the applicant, or by the appearance of his clothing, which may be stained; of course there can be no evidence of the fact except after certain observation, and, therefore, the statement of the man must be taken as to its absence before he can be accepted.

If any disease of the kidney is suspected, a careful examination of the urine should be made by chemical reagents, extended if necessary to an examination by the microscope. It is, of course, presumed that the applicant will be closely questioned as to the existence of any symptom which would point to renal trouble; the presence of albumin, sugar, blood, or pus in the urine, although due to temporary ailments, is ground for absolute rejection, as would also be dropsical effusions into any of the tissues in the body.

In time of war acute affections of the generative organs should not exempt; the subjects thereof can be placed in hospital until cured of the primary difficulty, and those who are free from constitutional taint, or who have very slight strictures, should be sent to active duty. Phimosis, loss of testicles, hydrocele of the tunics and cord, unless interfering with locomotion, and spermatorrhœa, are not causes for exemption, as men suffering from these defects can be made useful in the administrative department, and in some cases in the line of the army.

Affections Common to both Upper and Lower Extremities.—Chronic rheumatism; chronic diseases of joints; old or irreducible dislocations or false joints; severe sprains; relaxation of the ligaments or capsules of joints; dislocations; fistulæ connected with joints or any part of bones; dropsy of joints; badly united fractures; defective or excessive curvature of long bones; rickets; caries; necrosis; exostosis; atrophy or paralysis of a limb; extensive, deep, or adherent cicatrices; contraction or permanent retraction of a limb or portion thereof; loss of a limb or portion thereof, disqualify.

Nearly all defects in the extremities are apparent by some impairment of the natural shape or motion of the limb, and can hardly escape the notice of one who examines attentively his cases; indeed, in the inspection of large numbers of men one becomes so expert as to discover departures from normal shape and motion as if by intuition. Diseases which affect the continuity of limbs but which do not necessarily interfere with motion or alter shape, may occasionally require careful search for their detection.

It is more frequently the case that the surgeon is called upon to exercise his judgment in deciding how far an existing blemish may impair the efficiency of an applicant, than he is to exercise his skill in searching for hidden or obscure disqualifications; this is particularly the case in severe sprains, dislocations, large cicatrices, and chronic rheumatism. It should be remembered, in the preliminary examination of the shoulder-joints, that it occasionally happens that men cannot touch the point of the shoulder with their fingers, and a careful search fails to reveal any imperfection of the joints of the extremity. It is important, in such a case, that the elbow and wrist should receive special inspection, as a defect is most likely located at one or both of these points; but rejection is not demanded unless a defect is clearly made out, as an extreme muscular development may be the cause, or a congenital shortening of some of the bones exists without an interference with any other than this particular movement. Men desiring to enlist will seldom, if ever, admit the presence of chronic rheumatism, and it is

Digitized by Microsoft®

only when, as a result of this disease, one or more joints are swollen or otherwise disabled, that the surgeon can be aware of its existence. The absence of any of these evidences will occasionally enable a man to enlist who has been previously discharged from the service on account of alleged chronic rheumatism, in which event the medical examiner would be blameless of the charge of carelessness, as in all probability the discharge was procured through fraud and malingering. Chronic rheumatism of sufficient severity to warrant a discharge from service should be followed by tangible evidence, in the shape of swollen or distorted limbs, deposits in the joints, or enlargements in the surrounding tissues, and these are not likely to disappear; close inspection must be made of all joints to discover any swelling or other evidence of sprain; lameness of an inferior extremity, or stiffness of a superior one, should be an indication for careful questioning as to the receipt of injury.

www.libtool.com.cn

It is not always wise to place too much confidence in the statements of men as to their freedom from pain or ability to move joints which have been injured. It is well known that the remote effects of sprains and other joint injuries, particularly of the ankle and wrist, are liable to manifest themselves, even at a late period, in swellings or pain after severe exertion; and however honest one may be in the belief of his perfect cure from such an injury, and ability to perform all duty required of him, there may be an actual defect of which he is ignorant. The medical examiner, therefore, must exercise his own judgment from the appearance of the parts, their sensitiveness, etc., as to whether this is the case or not, and he should reject in all instances which give room for doubt. Fractures which have been properly treated, and have united without deformity, are not of themselves causes for rejection, but when they are followed by neuralgic pains, or if there has been much displacement of fragments, so that the symmetry of the limb is destroyed, or if from excessive bony deposits there is impairment of motion, they *are* causes for rejection. Fractures of the bones of the forearm are very likely to give trouble by interference with the motions of pronation and supination, both of which are necessary in handling the rifle during the exercises in the manual of arms. Malformations of the limbs, as excessive curvature—bow-legs—are objections rather because of the awkward gait they induce than from any interference with the ability of the man to march; when the curvature is caused by a constitutional taint, as rickets, etc., there can be no question as to the propriety of a rejection. Abnormal cartilaginous or bony formations in the muscles, or loose cartilages in the knee-joint, are objections when they impair the use of the joint.

In time of war especial care is necessary, particularly in those affections which present but little external evidence of injury, to detect deception; chronic rheumatism, sprains, alleged dislocations and fractures, must not be made causes for exemption unless the evidences of impaired strength and motion of the parts in which they are located are indisputable. Allegations of pain, loss of motion, involuntary contractions, etc., will constantly be made, and if the surgeon has no other means of completing his diagnosis in a case of suspicion, he should resort to the use of anæsthetics, under which simulation ceases, and the true state of an alleged disability will be made apparent. One must, however, bear in mind the fact that in central lesions of the brain contractions disappear during chloroform narcosis. It should be stated that authority for the use of anæsthetics is limited "to cases of professed rheumatic contraction of joints when unattended with perceptible alteration of form or structure,"[2] although it is recommended in a wider range of cases by Tripler and Bartholow, both authorities recognized by the War Department. An ingenious test for simulated contractions of limbs—flexures—has been suggested by a Russian military surgeon, and is published by Zuber.[23] It consists in applying tightly to the affected limb an Esmarch bandage, as if for amputation; when the bandage is removed, the rubber cord remaining, the limb straightens itself involuntarily. The test has been tried in but few cases, and may not invariably succeed, but it is worthy of further trial.

All officers of experience in the examination of malingering soldiers agree upon the fact that their most vulnerable point is in an exaggeration of the symptoms which they endeavor to simulate. When a man comes limping before a surgeon with every expression of pain upon his countenance, or assumes the most unnatural and constrained positions of body or limb, he may, in nine instances out of ten, be set down as a malingerer, if he presents no external physical signs of disease; there is something about a real sufferer or cripple which is very hard to describe, but which every surgeon will recognize; and in a large number of instances the problem will be, not so much in recognizing the deception, as in compelling the subject to admit it.

The Superior Extremities.—Fracture of the clavicle; fracture of the radius and ulna; webbed fingers; permanent flexion or extension of one or more fingers, as well as irremediable loss of motion of these parts; total loss of either thumb; mutilation of right thumb; total loss of the index finger of the right hand; loss of the first and second phalanges of all the fingers of either hand; total loss of any two fingers of the same hand, disqualify.

Fractures of the clavicle, which are almost invariably followed by more or less deformity, are causes for rejection in consequence of the painful pressure made at the seat of injury by the rifle, during certain movements in the manual of arms, and by the "sling straps" when carrying the knapsack or haversack. The mere fact that the clavicle has been fractured is not of itself cause for rejection, and even the presence of a slight deformity should not be objectionable, provided there is neither pain on pressure nor interference with the free motion of the arm. The improved means of transporting the baggage of the soldier have in a great measure done away with the necessity for his knapsack; the few articles of clothing which he requires in the field are rolled in his blanket, which is slung over the shoulder and across the chest, and thus carried without inconvenience or pain to any part of the clavicle which may have sustained an injury. The haversack strap may, however, on long marches, or when the sack is well filled, produce painful pressure, or even excoriate the skin, and the gun is very liable to injure a prominent deformity on this bone. Therefore a tumor at the seat of fracture, from whatever cause, if considerable, would be a valid objection to enlistment. Any fracture of the radius and ulna, particularly Colles', is liable to be followed by impairment of the motions of pronation and supination of the forearm—movements indispensably necessary in the drill of the manual of arms, the "set up" drill, and other military exercises. Should this be the case, rejection is demanded; otherwise, union and motion being perfect, the injury is not a cause for rejection. The degree of mutilation of the hand which should disqualify can be determined only by the facility with which a man so injured can handle a rifle. In loading the Springfield (army) rifle, the breech block is thrown open and the cartridge thrust home by pressure of the right thumb, the rifle is also cocked by the same member; hence it is very important that it should be intact; and any injury which materially interferes with its flexion or strength is a cause for rejection. The common distortion of the extremity due to contusion or felon need not disqualify; the loss of the entire member would, of course, reject; loss or mutilation of the last phalanx of the left thumb need not disqualify. The first and second phalanges of the right index finger may be lost or mutilated without necessarily disqualifying an otherwise very desirable recruit, or a soldier who desired to re-enlist; it is ordinarily the finger used in pulling the trigger, but this can be done with facility by a stump, or by the middle finger, as is the case with many marksmen whose fingers are perfect; it should, however, be the rule for recruits to have a perfect right forefinger, departures from which rule should be made only in rare instances and for very good reasons. Permanent flexion or extension, or loss of motion of any fingers, so materially interferes

Digitized by Microsoft®

with a military use of the hand as to demand rejection. The congenital malformation of the little finger of one or both hands, which is so common, is not considered a disqualification.

In time of war, the loss of the right thumb; loss of any two fingers of the same hand; loss of the first and second phalanges of the fingers on the right hand; permanent flexion or extension of two fingers of the right hand, or all the fingers united (webbed), are causes for exemption.

The Lower Extremities.—Varicose veins; knock-knees; club-feet; splay or flat feet; webbed toes; the toes double or branching; the great toe crossing the other toes; bunions; corns; overriding or superposition of any of the toes to an extreme degree; loss of a great toe; loss of any two toes of the same foot; permanent retraction of the last phalanx of any of the toes, or flexion at a right angle of the first phalanx of a toe upon the second, with ankylosis of the articulation; ingrowing of the nail of the great toe; bad-smelling feet, disqualify.

Dr. Baxter, in his "Report of the Provost Marshal General's Bureau," says that to be cause for rejection varicose veins must be "voluminous and multiplied." There is no doubt of the fact that the judgment of many surgeons is in error as to the degree of varicosity of the veins of the leg which should disqualify, and men have been discarded with veins so slightly enlarged that they could hardly be called varicose. The network of small veins so often seen in the popliteal space, and inside of the thigh, upon men of spare habit, or in those whose occupations have required them to stand a great deal, are not sufficient in degree to cause rejection; nor, indeed, is such the case when a single vein may be more or less enlarged without the function of its valves being impaired. It is only when several veins are very large and tortuous, with failure of their valves, or when there is œdema, thickening of the integument, or much ulceration, that they become disqualifications. An exception to this rule should be made in cases in which hemorrhoids are present, when even slightly varicose veins are causes for rejection. One may see occasionally an instance in a very muscular man, where there has been a rupture of the sheath of some muscles in the leg, which closely resembles a varix; if the finger is placed over such a tumor during the contraction of the muscle, its true nature will be apparent. Knock-knees, if existing to such a degree as to interfere with the free use of the limbs, should disqualify; as a general rule, if the inner borders of the feet, from the heel to the ball of the great toe, cannot be brought within one inch of each other without passing the inner condyles of the femur, respectively, in front of and behind each other, the applicant should be rejected. Flatness of the feet to a degree requiring rejection is very seldom met with among applicants for enlistment, notwithstanding the fact that it is supposed to be very common among the laboring population; as a cause for rejection it has been very much exaggerated; the ordinary flatness of foot so often seen, especially among negroes, is not more likely to become a cause of disability in marching than is the more shapely foot, unless an ill-fitting shoe is worn; the anatomical peculiarity which disqualifies has been described by Goreke, of the Prussian service, substantially as follows: The inner ankle is very prominent, and is placed lower than usual; a hollow exists below the outer ankle of a greater or less extent; the dorsum of the foot is not sufficiently arched; the foot is broader at the ankle than near the toes; the inner side is flat and sometimes convex, and when the foot is placed on the ground the sole projects so much on the inside that the finger cannot be introduced below it; the body rests on the inner side of the sole, and the usual motion of the ankle-joint is impeded.

Bunions, if large and presenting evidences of old or recent inflammation, should always reject; they are a fruitful source of disability on long marches and in hot weather, the pain produced by the pressure of the shoe setting up an irritation which extends to the entire foot. The same may be said of corns when located on the sole of the foot; those under the head of the metatarsal bone of the great toe are the most painful, and produce lameness sooner than any others; they are, moreover, very intractable. Of the malpositions of the toes, that in which the first phalanx is flexed at right angles upon the second to such an extent that the man walks upon the end of the nail (hammer toe) is the most painful, and will disable more speedily than the others; there is no shoe which can be made that will remedy the defect, and it is in consequence an absolute cause for rejection. Ingrowing of the nail of the great toe, if deep and accompanied with signs of irritation, inflammation, or suppuration, renders a man unfit for service; if, however, he is very desirable otherwise, the simple operation of shaving away the redundant tissue on the border of the toe, in a majority of instances effectually cures the disease, after which he may be accepted.

The fetid odor exhaled from the feet of some men is such as to make their presence in a squad-room unbearable to their comrades. The excessive perspiration causing this odor keeps the toes and under surface of the feet soft and the skin macerated, for which reason very slight exercise produces painful excoriations and unfits the man for duty. When the feet show evidence of this condition the applicant should be rejected.

In time of war very large varicose veins, club-feet, an excessive knock-knee, loss of great toe, and flexion of the phalanges of the other toes to an extreme degree should exempt; men having other defects of the feet, if unfit to join the active line, can be made useful in the administrative departments and should be held to service.

RECTO-VAGINAL FISTULÆ. See *Vagina, Diseases of.*

RECTUM, MANUAL EXPLORATION OF THE.—In 1872 Professor Simon, of Heidelberg, published, in the *Archiv für klin. Chirurgie*, an article "On the Artificial Dilatation of the Anus and Rectum for Exploration and Operation," in which he first described a method of exploring the lower bowel by the introduction of the entire hand. By this method of examination he asserted that not only was he able to explore all of the pelvic organs and to distinguish any pathological changes they might have undergone, but that the greater part of the abdominal cavity could also be reached. He further asserted that this method was so entirely free from danger that he had not hesitated to practise it on patients anæsthetized for other purposes.

Manual exploration of the rectum is now only of historical interest. It is no longer employed, and has been superseded by the no more dangerous and much more wide-reaching and satisfactory method of exploration, viz., by abdominal section. *N. P. Dandridge.*

RED BOILING SPRINGS.—Macon County, Tennessee.

POST-OFFICE.—Red Boiling Springs. Hotel.

ACCESS.—Viâ Louisville and Nashville Railroad to Gallatin; thence by private conveyance to the springs.

This resort is located in the foothills of the Cumberland Mountains, sixty-five miles northeast of Nashville www.libtool.com.cn and seven miles from the Kentucky line. It has an elevation of about twelve hundred feet above the sea-level. The visitor will at this resort find a cool and pleasant retreat for the summer months. The hotel is said to be well kept and comfortable, and the cuisine of an excellent character. There are three springs in the group—two red sulphur springs and one black sulphur spring. Those most generally used are the "Little Red" and the "Black Sulphur" Springs. The former was analyzed by Lucius Pitkin, analytical and consulting chemist, of New York City, in 1890, with the following results:

Little Red Spring.—One United States gallon contains (solids): Sodium chloride, gr. 5.57; sodium sulphate, gr. 0.94; calcium sulphate, gr. 8.18; potassium sulphate, gr. 0.41; calcium bicarbonate, gr. 3.20; magnesium bicarbonate, gr. 4.55; iron bicarbonate, gr. 0.15; silica, gr. 0.80. Total, 23.80 grains.

Sulphureted hydrogen gas is present in large quantities.

The following analysis was made by James T. Anderson, of the Alabama State Agricultural and Mechanical College at Auburn:

Red Spring No. 2.—One United States gallon contains (solids): Sodium chloride, gr. 10.73; sodium carbonate, gr. 1.03; calcium carbonate, gr. 9.64; calcium sulphate, gr. 15.36; magnesium sulphate, gr. 7.97; alumina, gr. 0.12; iron oxide, gr. 0.08; silica, gr. 0.58; organic and volatile matter, gr. 2.31. Total, 47.82 grains. Sulphureted hydrogen gas is present in only small quantity. The temperatures of the waters are 54° and 52° F., respectively, and they do not vary during the year.

These waters are said to be actively diuretic, and to exert a general tonic and alterative effect upon the system. Hot and cold sulphur baths may also be had at all hours. A competent physician is always at hand to explain the proper use of the waters. *James K. Crook.*

REDLANDS AND RIVERSIDE, SOUTHERN CALIFORNIA.—These two places may be taken as representing the climate of the eastern foothills of Southern California, where are to be found many resorts favorable for a winter or an all-the-year round residence.

Redlands (1,350 feet), in San Bernardino County, lies in the East San Bernardino valley, and is surrounded by mountains from 5,000 to 12,000 feet high on the north, east, and south, and lies open to the sea on the west, from which it is distant about eighty miles. The city is beautifully situated and substantially built, and contains about six thousand inhabitants. It is a favorite place of winter residence for Eastern people, and in attractiveness of situation and the character of its inhabitants and residences is comparable to Pasadena. Parks, many churches, a fine public library, excellent schools, clubs, golf links, good hotels, are all to be found here. The soil is porous and rich, and especially favorable for the cultivation of the orange, which is the principal fruit grown here. The water-supply is a fine one, and affords irrigation for the orange groves. There is a sewer and storm-water system, and the sanitary condition appears to be of the best.

Redlands has good railroad connections and electric roads, and from it one can easily reach the various attractive mountain resorts on the one side and those of the coast on the other.

One rarely meets with a more attractive town, even in Southern California, than Redlands, exhibiting as it does so many of the natural attractions peculiar to all this region. Wherever there is irrigation, flowers of endless variety abound, and the most luxuriant vegetation flourishes. The dust of the streets is laid by the crude petroleum, so abundant in Southern California. By this process an almost perfectly dustless road is obtained, and remains so for many weeks from a single application of the oil.

The characteristics of the climate of Redlands, as, indeed, of all this eastern foothill region, are equability, comparative dryness, abundant sunshine, and a small rainfall occurring mostly in the winter and spring. Early morning fogs, so-called "high fogs," may also be considered a climatic characteristic, for they are not of infrequent occurrence here, as elsewhere in Southern California.

The average rainfall is 15.59 inches, of which 7.45 inches falls in the spring and 6.55 in the winter. The mean annual relative humidity as given by Bridge ("The Climate of Southern California," Transactions of the American Climatological Association, 1901) is 64.4 per cent. The average mean winter temperature as given by the same authority is 54.7°; for summer, 75.3°; spring, 63°; autumn, 66° F. (Solly). Sanborn ("The Climate of the Eastern Foothills," by Dr. C. A. Sanborn, Redlands, Cal., Transactions of the American Climatological Association, 1902) gives for Redlands the following extremes of temperature from an average of three years for the three months exhibiting the greatest extremes of heat and cold:

January	Mean maximum temperature	62 degrees.
	Mean minimum "	40 "
February	Mean maximum "	about 69 "
	Mean minimum "	42 "
July	Mean maximum "	about 95 "
	Mean minimum "	59 "
August	Mean maximum "	about 91 "
	Mean minimum "	58 "

The average mean relative humidity of Redlands for these months is given by the same authority as 55.7 per cent.

In the summer the temperature occasionally goes above 100° F. in the middle of the day, but with the dry atmosphere this is not so uncomfortable as might be supposed. The difference between the day and night temperatures is great, something like 20° to 30°. Similarly, there is a great difference between the night humidity and the day humidity. "This means to an invalid," as Solly remarks ("Medical Climatology"), "a climate possessing, in the course of the day, perhaps six hours of moderate dryness, and eighteen hours of positive dampness."

These two characteristics of the fall in temperature and increase in dampness at night probably account for the apparent chariness with which the residents open and keep open their windows, and the fear they have of sitting out of doors at night. As paradoxical as it may seem, one can evidently sit out of doors more evenings in the year in New England than in Southern California; or else the New Englander is more venturesome and hardened in enduring the evening air than is the Californian of the South.

Freezing weather is very rare.

The mountains to the north of this valley shut off the winds from the desert, but the sea breeze blows daily, beginning usually about ten o'clock in the forenoon, and lasts until sunset. There are said to be over three hundred sunshiny days in the year at Redlands. At San Bernardino, about eight miles to the northwest, the total number of clear days, as given by Dr. A. K. Johnson, a volunteer observer (period not given), is 235; fair days, 95; cloudy, 35; rainy, 33½. According to Sanborn (*loc. cit.*) "patients with pulmonary lesions, not far advanced, do well in this climate (Redlands and vicinity), especially in that part of the valley where orange growing and the consequent dampness from irrigation do not prevail." Sanborn also refers to the irritation of the respiratory tract brought about by the extensive use of commercial fertilizers. He has noticed a prevalence of tonsillitis and pharyngitis occurring at the time of using this material. "Nervousness" is said to be increasing here as well as in other portions of Southern California, and it is attributed by Sanborn to various causes, climatic and others, such as eye strain from a succession of bright days, and nostalgia.

Five miles from Redlands, on the line of the Southern

Digitized by Microsoft®

Pacific Railroad, is the *Loma Linda Sanatorium* (about twelve hundred feet), beautifully situated on the hillside about two hundred feet above the surrounding country. It is approached through a stately avenue of pepper trees, and is surrounded by orange groves and beautiful gardens. The view from the sanatorium is extensive and grand, the lofty "Arrowhead" and its hot springs lying directly in front. The buildings of this institution are well equipped, containing operating-rooms, etc., and excellent accommodations are offered to the nervous and other invalids, as well as to those who only desire to rest under such favorable conditions of situation and climate. The tuberculous are not received here.

Riverside (elevation eight hundred and fifty feet) is a city of ten thousand inhabitants, about sixteen miles by rail southwest from Redlands. It is the most famous orange-growing district in Southern California, and is well supplied with water for irrigation and domestic purposes, from a number of artesian wells near the mountains. The drainage is good, and the city affords every opportunity for comfortable living, either for the transient or for the permanent resident. There are attractive parks, in one of which is the curious "cacti garden." There are also beautiful estates, many churches, fine school buildings, a Carnegie library, miles of pleasant roads through the orange groves, and avenues shaded by the eucalyptus, the pepper, and the palm, among them the famous Magnolia Avenue.

The vegetation, as at Redlands, is most luxuriant, and besides the orange, the pomegranate, olive, persimmon, fig, and other fruits are found here. Flowers abound in a wild profusion, and this whole area seems like one vast park or garden.

The accommodations are good. Besides the lovely drives and walks, there are opportunities for golf, polo, and tennis.

The climate is similar to that of Redlands. The average yearly rainfall for fourteen years was ten inches, February and March being the rainiest months (Solly, "Medical Climatology"). The relative humidity for the year 1888 was 65.5 per cent. The mean monthly temperature for the seasons, covering a period of twelve years is as follows: Spring, 60 ; summer, 74 ; autumn, 71 ; winter, 51° F.* The mean for July is 76° ; maximum, 106 ; mean for August, 76° ; maximum, 104° ; mean for January, 50° ; minimum, 29°. The average variation between the day and night temperatures, as given by Sawyer ("A Study of Riverside Climate," etc., Southern California *Practitioner*, 1887), for January is 20°, and for July, 34°. "The ordinary wet season at Riverside," says the same author, "is much drier, has less rain, and a larger proportion of dry, clear sunshiny days than the average summer in New York, Boston, or Chicago." The amount of sunshine is great, and, according to Sawyer, there were two hundred and eighty absolutely clear days from July, 1885, to July, 1886.

Thirty-five miles southeast of Colton, which is eight miles north of Riverside, is the little town of Hemet, the starting-point for the carriage ride to the health resort of *Idyllwild*. This is a journey of twenty miles, the last ten of which are up a steep mountain road. Idyllwild has an elevation of 5,250 feet, and is situated in the Strawberry Valley, in a large forest tract of fifteen hundred acres, which is again bounded by extensive government forest reservations. The valley is well timbered, the pine, cedar, and live oak predominating. The climate possesses the characteristics of the high altitudes in a comparatively warm latitude, the atmosphere being dry and pure ; and the temperature warm but not hot in summer, and in winter cool, but not generally going below the freezing point. As is generally true of this whole region the majority of the days are sunny.

The Idyllwild Sanatorium occupies a well-protected situation, and besides a large, well-appointed central building containing fifty-one rooms, there are several cottages of three and six rooms, tents, etc. There are appliances for furnishing steam heat and electricity, an ice plant, and a steam laundry. Families who come with their invalids can also find accommodations here, and means of recreation in riding, golf, tennis, etc. There is also a school for the younger children. The sanitary conditions are well looked after. The water comes from a pure mountain spring, and there is a well-constructed sewer system. The plumbing is modern and good.

Pulmonary tuberculosis in the curable stages is the principal disease treated here, and there are a resident physician and nurses.

From a personal visit the writer can testify to the wild beauty of the scenery, the delicious purity of the air, and the energy and devotion of the managers in building on this mountain plateau a well-equipped and extensive sanatorium, with all modern improvements. For one who desires to take the open-air treatment in the high altitudes, and at the same time avoid the severity of the winter climate found in the altitudes farther north, such as at Colorado and in the Alpine resorts of Europe, Idyllwild would seem to afford ideal conditions, not only of climate, but of accommodations. The only drawback is the long, tiresome carriage ride, but this in time will probably be obviated by a mountain railway.

Edward O. Otis.

RED SULPHUR SPRINGS.—Monroe County, West Virginia. Post-Office.—Red Sulphur Springs. Hotel.

Access.—Viâ Chesapeake and Ohio Railroad to Alderson's, thence by stage to springs.

These springs are beautifully situated on Indian Creek, and are surrounded by pine-clad mountains. They are two in number, and flow two hundred and ten gallons per hour. The water has a temperature of 51° F. It was analyzed in 1842, but the results were not very satisfactory. The total solids found to be present in one United States gallon amounted to about twenty-four grains, and approximately one-third of this consisted of sulphur.

A new analysis of this water is very much to be desired. Its virtues are presumed to rest to a great extent upon the sulphur which it contains. Aside from this substance it contains ingredients which justify us in classing it as a light saline calcic water. From abundant corroborative medical testimony there seems to be no doubt that the water causes a decided slowing of the heart's action in an excited state of the circulation. The water further seems to exert a soothing influence upon the mucous membrane of the lungs and bronchi, allaying irritation and diminishing expectoration. In virtue of these properties it has often proved decidedly beneficial in hæmoptysis, early phthisis, chronic bronchitis, chronic pharyngitis, and chronic laryngitis. In small quantities the water is said to be cathartic, while in larger doses it is diuretic.

James K. Crook.

REDUCTION-DIVISION.—When in the course of cell division the chromatin is distributed to the daughter nuclei in such a way that the material forming one daughter nucleus has a different ancestral history from the material forming the other, the division is called a reduction, or, better, *reducing division* ; and is thus distinguished from the ordinary *equal division*, in which every particle of the chromatin is divided equally between the two daughter nuclei (see article *Cell*).

Theoretical.—If we suppose that the physical basis of heredity consists of distinct units in the chromatin material of the nuclei of the germ cells, then at each union of two germ cells in sexual reproduction the number of ancestral units, or ancestral germ-plasms, will be doubled. And, unless prevented in some way, this doubling will continue with each successive sexual union, until either the germ cells will be increased to an enormous size, or else the units will be reduced in size so much that they are smaller than the proteid molecule.

Roux in 1884 published an elaborate review of the whole subject of mitotic cell division, so far as it had

* Quoted by Solly from a meteorological record issued by the Riverside Board of Trade.

Digitized by Microsoft®

www.libtool.com.cn

been developed at that time, and his conclusion was that the *longitudinal splitting* of the chromosomes and the whole mechanism by which the two halves of an originally single chromosome are always carried to opposite poles of the spindle, has for its object the distribution of the chromatin, both as to quantity and as to quality, in exactly equal proportions to the two daughter cells (see *Chromosome*).

www.tiptool.com.cn

A study of the phenomena of heredity led Weismann to suppose the chromatin to be made up of elements as indicated in the previous paragraph (see also article *Heredity*) and that these ancestral germ-plasms maintain their individuality through successive generations. And this led to the further supposition that sexual reproduction can be continued only in case there is a reduction in the number of ancestral germ plasms, a reduction that must be repeated in every generation. But Roux's conclusions would seem to make such a reduction improbable so long as the division takes place by the ordinary method accompanied by a longitudinal splitting of the chromosomes.

Writing in 1887, Weismann says: "This is the only kind of karyokinesis which has been observed until recently; but if the supposed nuclear division leading to a reduction in the number of ancestral germ-plasms has any real existence, there must be yet another kind of karyokinesis in which the primary equatorial loops are not split longitudinally, but are separated without division into two groups, each of which forms one of the two daughter nuclei. In such a case the required reduction in the number of ancestral germ-plasms would take place, for each daughter nucleus would receive only half the number which was contained in the mother nucleus." After discussing the work of van Beneden (1883) and Carnoy (1886), then recently published, Weismann defines the terms "reducing division" and "equal division," and then adds the following explanation of his prediction: "The 'reducing division' must be always accompanied by a reduction of the loops to half their original number, or by a transverse division of the loops (if such division ever occurs); although reduction can only occur when the loops are not made up of identical pairs. And it will not always be easy to decide whether this is the case. On the other hand, the form of karyokinesis to which a longitudinal splitting of the loops takes place *before* they

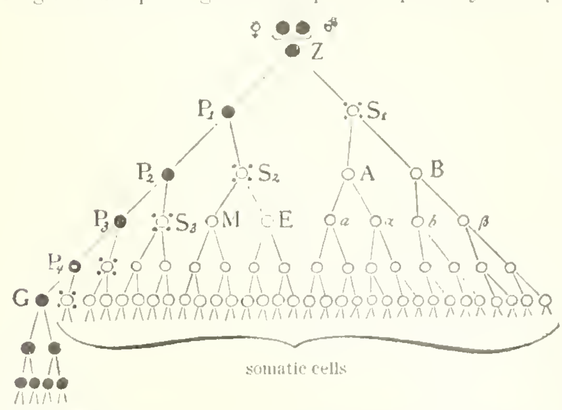

FIG. 3926. —Diagram showing the Pedigree of the Germ Cells of Ascaris. *Z*, Fertilized egg; P_1, P_2, etc., protogonocytes; *G*, primordial germ cell (P_5, Fig. 2611, article *Heredity*); S_1, S_2, etc., primary somatic cells; *A* and *B*, primary ectodermal cells; *E*, primary endodermal cell; *M*, cell which produces mesoderm and part of ectoderm. (Modified from Boveri.)

separate to form the daughter nuclei must always, as far as I can see, be considered as an 'equal division.'"

This prophecy is one of the most famous in the annals of science, because it has been one of those most fertile of results, having furnished the stimulus for a large number of very careful investigations. It is the purpose of the present article to describe some of these results, and to consider whether they show a fulfilment of this prediction.

The Germinal Cycle.—The complete history of the germ cells has not yet been followed through all its stages in any animal or plant. But enough is known to make it

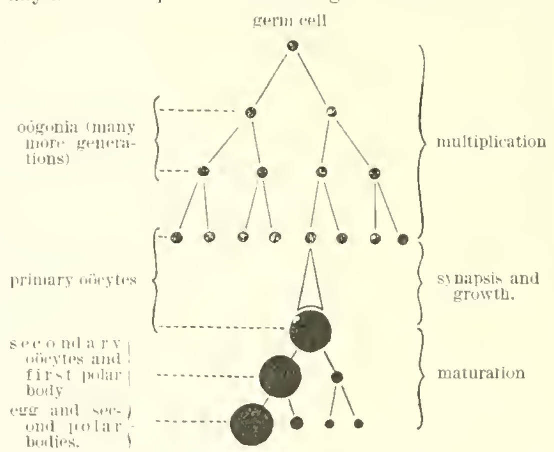

FIG. 3927. Diagram showing the Genesis of the Egg. (Modified from Boveri.)

clear that there is a complete continuity of generations of cells in this history, which consists of a series of cycles, and we may consider each cycle as having its beginning and its end in the act of fertilization. These cycles follow one another in unending sequence so long as the race remains extant.

The *germ cells* are those which have for their purpose the provision of the material out of which future generations are to be produced, and they form but a small portion of the body of any multicellular organism. The greater part of the body is made up of *somatic cells*, which serve to shelter and nourish the germ cells. The history of the somatic cells is likewise a series of cycles having their beginnings in the act of fertilization. But there is no continuity between the cycles. For the somatic cells, having fulfilled the purpose of their being, die, and have no genetic relation to the cells forming the body of the next generation, except community of origin in the ancestral germ cells.

In the history of the germ cells each cycle may be divided into several periods, and the cells in each period have been given distinctive names. We shall follow in the main the terminology recently adopted by Waldeyer (1902).

By the union of an ovum and a spermatozoon there is formed a single cell with a nucleus of double origin (see *Impregnation*). This cell is the fertilized egg, or *oöspermium*. Immediately after fertilization there follows a series of cell divisions resulting in what is known as the segmentation of the ovum (see article *Segmentation of the Ovum*). The result of the first division is the formation of two cells—the first primary somatic cell and the first stem cell, or *protogonocyte* (S_1 and P_1, Fig. 3926). The latter divides again to form a second primary somatic cell and the second protogonocyte (S_2 and P_2). This series of divisions continues through a series of generations of cells, the number of which varies with the species (see *Heredity*), until finally the last protogonocyte gives rise to a primary somatic cell and the primary germ cell or *archigonocyte* (S_5 and *G*, Fig. 3926). In the mean time, of course, the somatic cells have been dividing to form the tissues of the embryo.

The second period begins with the division of the archigonocyte to form two *gonocytes*. These continue to multiply by division until, according to Beard, they reach a certain number, which may be approximately constant for the species. Finally, whether by migration or otherwise, the gonocytes come to lie in the germinal epithelium upon the genital ridge. (For the sake of clearness we

Digitized by Microsoft®

Reduction-Division.

will confine our attention to the higher animals for the present.)

The beginning of the third period coincides with the differentiation of the genital ridge into ovary or testis, and in this period the history of the germ cells begins to diverge in the two sexes. In the female the last generation of the gonocytes may produce two kinds of cells. Some produce follicle cells or other cells serving to nourish the eggs, while others give rise to the first generation of *oögonia*, or primordial eggs. The oögonia continue to multiply for an undetermined number of generations. Finally this period of multiplication is followed by a period of growth during which division ceases. The oögonia have now become *primary* oöcytes (see Fig. 3927).

www.libtool.com.cn

The period of growth is followed by the period of maturation, during which two cell divisions occur, usually in rapid succession. The primary oöcyte, having attained its full size, divides very unequally to form the *secondary* oöcyte and the first polar body. Then the oöcyte divides again unequally, forming the second polar body and the ripe ovum, or *ovium* (Greek ὠίον, egg), as Waldeyer prefers to call it. The first polar body may divide also at the same time, so the maturation divisions result in the formation of four cells—the relatively large ripe egg and three very small polar bodies. The view now universally held, that the polar bodies are abortive eggs, was first stated by Mark in 1881.

These periods in the history of the egg are exactly parallel in the history of the spermatozoon. In the male the last generation of gonocytes may likewise give rise to nutritive cells and to *spermatogonia*. The latter multiply by division for an indefinite number of generations of cells and the last generation gives rise to primary *spermatocytes*, which then enter upon a period of growth (Fig. 3928). This is followed, as in the egg, by two maturation divisions. In the first the primary spermatocyte separates into two secondary spermatocytes, and by the second division each secondary spermatocyte produces two *spermatids*. Thus the maturation divisions result in the production of four cells, but in the male these are all of the same size and all are capable of becoming functional.

But in order to become functional the cell must pass through another period, not represented in the history of the egg. This is the period of histogenesis, during which

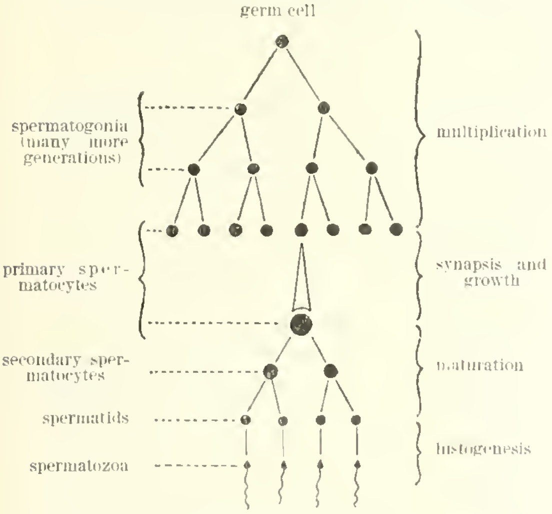

FIG. 3928.—Diagram showing the Genesis of the Spermatozoa. (Modified from Boveri.)

the spermatid undergoes a remarkable metamorphosis by which it becomes transformed into a *spermatozoon* with the characteristics peculiar to its species (see article *Spermatozoa*). With the entrance of the spermatozoon into the egg and the union of the sperm nucleus with the egg nucleus the old cycle ends and a new one begins.

During the periods from the first cleavage of the ovum to the last division of the oögonia or spermatogonia the number of chromosomes present during the prophases of division is always the same in individuals of the same species and is, with rare exceptions, the same as the number found in the somatic cells (Figs. 3936, 3937, and 3929, *B*). But at the beginning of the growth period the nuclei of the germ cells undergo a remarkable series of transformations, which result in the reduction of the number of chromosomes to one-half the number present in the earlier periods; and the reduced number is found in the oöcytes, spermatocytes, and spermatids, and in the egg and sperm nuclei previous to their union. (Compare the figures cited above with Figs. 3938, 3940, and 3929 *L*.)

Therefore, if a reducing division, as defined by Weismann, really occurs, it is to be sought for in one of the two divisions immediately following the growth period. These are the maturation divisions.

In considering the results of investigations upon this subject, the reader should bear in mind that before the material can be studied it must be killed, hardened, embedded in paraffin, cut into sections, stained, and mounted in balsam; and that each one of these operations is a possible source of error. Moreover, the objects are so minute that they can be studied only with the aid of a microscope of high magnifying power, and, further, it is impossible to view any one of these objects from more than one side. It is doubtless due to these difficulties of observation that the published descriptions of what takes place during this most interesting and important period in the history of the germ cells are so diverse and so often contradict one another. Although much has been written on the subject, the diversity of results is so confusing that it is impossible to formulate any general description that will apply to all species. Nevertheless there is sufficient agreement to encourage the hope that the progress in the improvement of methods will eventually lead to such a uniformity of results as to make it possible to formulate a general law applicable alike to all species of animals and plants.

At present the most complete and consistent account is to be found in a series of papers by Montgomery, who has studied the spermatogenesis in forty-two species of bugs, hemiptera heteroptera, and in Peripatus, a form of special interest on account of its supposed relation to the ancestral type of the insects and their allies. The following general description will be based, therefore, chiefly upon Montgomery's results, supplemented by the work of Paulmier upon spermatogenesis in the squash bug, *Anasa tristis* (Fig. 3929). The general account will be followed by sections, treating briefly of the parallel phenomena in oögenesis, and by others referring to variations to be found in other animals and in plants.

The Last Spermatogonic Division.—In the resting spermatogonia the chromatin appears to be scattered irregularly throughout the nucleus, but the granules are connected by the threads of linin. The nucleus is like a lacework ball made of strings of beads, in which the thread is the linin and beads the chromatin. In the early prophase of division the chromatin becomes arranged in a single long winding thread covering; according to Montgomery, a single strand of linin. This is the dense spireme stage. The spireme continues to shorten, and at the same time the chromatin becomes segmented into the number of chromosomes characteristic of the species. This number varies from eleven to twenty-eight in the bugs. But the linin remains intact and connects the chromosomes by their ends. The achromatic spindle is formed, the chromosomes are arranged in the equatorial plane, split longitudinally, and the halves are drawn to opposite poles in the typical manner.

In Peripatus the chromosomes are rod-shaped at this stage, and in the late anaphase they lie parallel to the spindle fibres. The ends pointing toward the centrosome are called the *central ends* and the opposite ones are

Digitized by Microsoft®

the *distal ends*. The distal ends of sister chromosomes are joined by "connecting fibres" of linin, and although unable to prove it, Montgomery thinks that probably the linin in each daughter group of chromosomes still forms a continuous spireme, so that each chromosome is connected by it at the central end with its neighbor on one side, and at the distal end to the neighbor on the other side. Finally the chromosomes become massed in a dense group, but not fused, near each centrosome, and the cell body becomes constricted in the middle. The two daughter cells are primary spermatocytes.

Synapsis.—The young primary spermatocytes are easily distinguished from young spermatogonia by the peculiar condition of the nucleus. The changes which take place at this stage were first described by J. E. S. Moore in 1895, under the title *synapsis* (συνάπτω, to fuse together). And it now seems probable that the synapsis is a stage of universal occurrence in the history of the germ cells of both animals and plants. An especially characteristic feature of the synapsis is the grouping of the chromatin in a dense mass on one side of the nucleus, leaving a large clear space on the other side, between the chromatin and the nuclear membrane. (Compare Figs. 3929 *D* and *E*, 3933 *B*, 3934, and 3938.) The interest attached to this phase is due to the fact that when the chromatin emerges from this tangle it is found to be divided into segments of just *half* the number present in the previous anaphase, and these segments are either split longitudinally or soon after become split. It is at this time, then, that the *reduction* in the number of chromosomes takes place; and it would seem that this reduction without division, as has been held by Moore, Farmer, and others, destroys all ground for Weismann's theory of a reducing division.

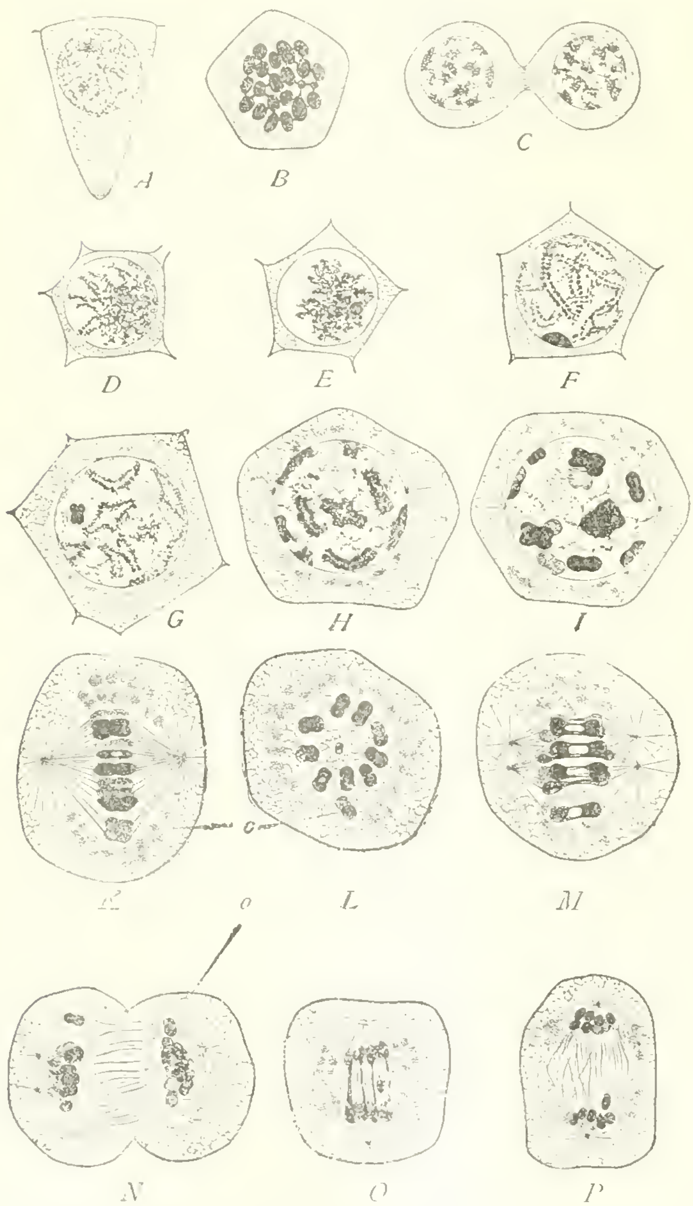

FIG. 3929.—Various Stages in Spermatogenesis from Sections of the Testes of the Squash Bug. *A*, Spermatogonium; *B*, spermatogonium preparing for division, cross section of equatorial plate showing twenty-two chromosomes; *C*, division of spermatogonium nearly completed; *D* and *E*, primary spermatocyte in synapsis; *F*, *G*, *H*, and *I*, stages in the formation of tetrads; *K*, *L*, *M*, and *N*, first division of spermatocyte; *O* and *P*, second division of spermatocyte; *c*, accessory chromosome. (From Wilson, after Paulmier.)

In most forms the mass of chromatin during the synapsis is so dense that it is impossible to see what takes place within it. But in Peripatus Montgomery was so fortunate as to find a form in which it is possible to distinguish the individual chromosomes, and he was able to determine that they become *fused in pairs by their central ends*, and a similar result has been obtained by Sutton in the grasshopper (Fig. 3938). Thus if the twenty-eight chromosomes that enter the synapsis stage in Peripatus are univalent, the fourteen that emerge from it are bivalent, and no true reduction has taken place after all, for there has been no discharge of chromatin from the nucleus. The bivalent chromosomes have the form of the letter V or U, and the angle of the V or U marks the position of the central ends, which in some cases can be seen to be connected by a short band of linin.

On emerging from the synapsis stage the chromosomes gradually elongate, and finally fill the nuclear space again. During this process the chromatin becomes separated into granules, all connected by an axial band of linin. Then the granules become flattened and finally divide in the plane of the longitudinal axis of the chromosome, forming a row of granules on each of the opposite edges of the now flattened axial band (Figs. 3929 *F* and 3939).

Finally the axial band splits and the rows of chromatin granules become more widely separated. At the same time very fine filaments of linin appear to connect each pair of granules, and to connect these in turn with pairs of granules in neighboring chromosomes. Thus the nucleus passes gradually into the resting condition of the growth period, in which it is rarely possible to distinguish the boundaries of individual chromosomes. In exceptional cases the resting condition of the nucleus appears to be entirely omitted at this stage, as in two families of bugs, the Coreidæ and Reduviidæ, and also in plants (Figs. 3929 and 3938).

The First Maturation Division.—The prophase of the first maturation division in Peripatus begins with the coming together of the chromatin granules to form an irregular reticulum. There is no spireme, but the reticulum appears to give rise to the chromosomes directly, and

www.libtool.com.cn
Digitized by Microsoft®

Montgomery gives reasons for believing that the reticulum is only apparent, and is really formed of overlapping and interlacing chromosomes that have never lost

www.libtool.com.cn

FIG. 3930.—Chromosomes from Primary Spermatocytes of the Squash Bug, showing changes of shape leading to the formation of tetrad. *a*, Distal end; *b*, central end; 6, completed tetrad with long axis corresponding to the longitudinal split. (After Paulmier.)

their identity. The chromosomes shorten and assume a great variety of form, most of them being more or less U- or V-shaped. Sometimes the two limbs of the U are twisted together, sometimes they are united at the ends to form a ring. These chromosomes are seen to be bivalent, that is, composed of two univalent chromosomes united by a band of linin at the bend of the U, and each univalent component is split longitudinally. The chromosomes which take part in the first maturation division are therefore similar in form as well as equal in number to those at the end of synapsis.

By the time that the chromosomes reach the equators of the spindle they have become very much condensed, so that the central linin band is covered with chromatin and the longitudinal split is represented by a mere notch at the distal end. In Peripatus the chromosomes at this stage most frequently have the form of a bent dumbbell,

FIG. 3931.—Primary Spermatocyte of Batrachoseps in a Stage Immediately Preceding the Metaphase. Eight of the twelve chromosomes are seen approaching the equator of the spindle. × about 1,500. (After Eisen.)

sometimes it is a straight dumbbell, sometimes two thick parallel rods, and more rarely a ring-shaped chromosome is found. In many insects and crustacea the chromosomes at this stage have the form of *tetrads* (Fig. 3929 *K*); that is, each bivalent chromosome is seen to be composed of four minute balls of chromatin more or less closely pressed together. In vertebrates and in the higher plants the chromosomes are more or less ring-shaped at this stage (Fig. 3931).

The chromosomes now divide in a plane at right angles to the axis of the spindle, and the halves are drawn toward the opposite centrosomes. In the case of Peripatus the dumbbells are divided transversely. Where the tetrads are present, the daughter chromosomes are *dyads*, each composed of two balls of chromatin (*M* and *N*, Fig. 3929). The ringshaped chromosomes are broken so as to form two horseshoe-shaped bodies (Fig. 3932).

If this division of the bivalent chromosomes takes place in such a way that their original univalent components are separated, we have here a *reducing division*, as de-

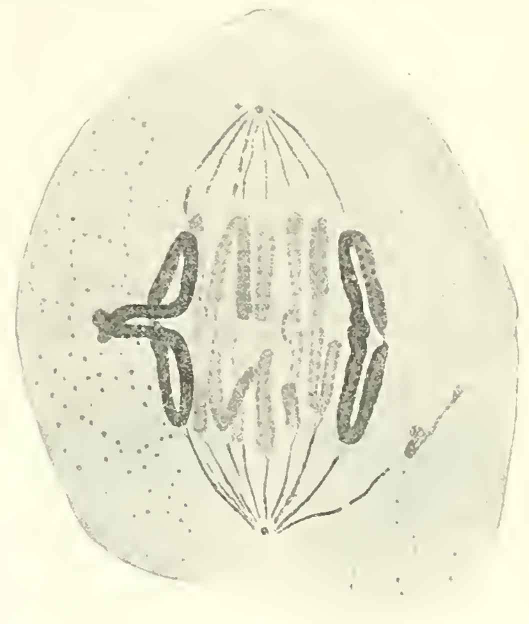

FIG. 3932.—Primary Spermatocyte of Batrachoseps in the Metaphase, Chromosomes Dividing. × about 1,500. (After Eisen.)

scribed by Weismann. But if the daughter chromosomes consist of parts of two originally separate chromosomes, then we shall have to seek farther for the reducing division.

The question can be decided only by very careful study of the changes in form and structure exhibited by the chromosomes from the beginning of the synapsis to the completion of this division. This has been done by Paulmier in the case of the squash bug, and by Montgomery in forty-two Hemiptera and in Peripatus. They find that in all of these species the first maturation division is transverse, and is a *true reducing division*, separating each bivalent chromosome into its original components.

Both Montgomery and Paulmier figure each daughter chromosome as being drawn toward its respective centrosome by two spindle fibres (*K*, Fig. 3929). Soon each centrosome divides into two preparatory to the next cell division, and it is found in Euchistus and in the squash bug that of each pair of spindle fibres one is connected with one daughter centrosome, and the other fibre is attached to the other one (*M*, Fig. 3929). With the division of the cell bodies the first maturation division is completed, forming two *secondary spermatocytes*.

The Second Maturation Division.—Usually there is no resting condition of the nucleus between the first and second maturation divisions. The longitudinal split which appeared in the chromosomes during the prophase

Digitized by Microsoft®

of the first division has reappeared during the anaphase. At the beginning of the second division the daughter centrosomes move through an angle of ninety degrees, and a spindle is formed with the chromosomes arranged in an equatorial plate. They are arranged now so that the split is at right angles to the spindle. During the anaphase the halves of the chromosomes are drawn to opposite poles (*O* and *P*, Fig. 3929).

www.libtool.com.cn

The secondary spermatocyte then divides, forming two *spermatids*. The change from a group of chromosomes to a resting nucleus, which ensues at this stage, is peculiar in that it is effected by the swelling of the chromosomes. A vacuole appears in each chromosome, so that each one becomes a small vesicle. These vesicles uniting form the resting nucleus, around which there is finally developed a nuclear membrane.

The history of the spermatid in the final period of histogenesis, during which it becomes transformed into a functional spermatozoon, will be treated elsewhere (see article *Spermatozoa*).

The Maturation of the Egg.—The parallel between the course of development of the egg and that of the spermatozoon in their external features has been pointed out in a preceding paragraph. The parallel extends also to the nuclear changes, as was first clearly suggested by Platner in 1889. Comparison of the processes of spermatogenesis and oögenesis in Ascaris led Boveri to make a more positive statement in 1890, and its truth was completely demonstrated, so far as Ascaris is concerned, by O. Hertwig a few months later.

These discoveries relate chiefly to the divisions of the chromosomes. The synapsis stage was first clearly recognized in the development of eggs by Woltereck (1898) through his studies on the Ostracoda. In 1900 von

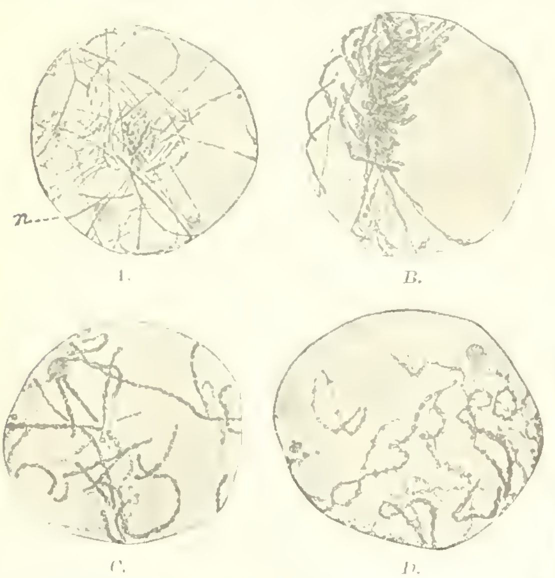

FIG. 3933. Nuclei from the Ovary of a Human Fœtus of about Seven Months, showing consecutive stages in the development of the oöcyte. *B*, synapsis; *n*, nucleolus. × 1700. (After Winiwarter.)

Winiwarter published an elaborate description of this stage in the history of mammalian ova (Fig. 3933). An abstract of his results is given in the article *Ovum*.

As in the corresponding stages in spermatogenesis, shortly after the last division of oögonia, the nuclei of the young oöcytes pass through the synapsis stage, characterized by the massing of chromatin filaments at one side of the nucleus (Fig. 3933 *B*). The chromosomes emerge from the tangle with their number reduced to half the number present during the previous anaphase. These chromosomes are, or soon become, split longitudinally. They continue to elongate, and finally the nucleus enters into the resting condition. It remains in this condition during the growth period, during which the oöcyte increases enormously in size. This period may extend through many years, as in man.

Just before, or very soon after, the egg is discharged from the ovary the first maturation division occurs, which results in the budding off of the very small first polar body from the egg, which then becomes a secondary oöcyte. The nuclear phenomena at this time are exactly like those to be observed during the division of the primary spermatocytes of the same species.

In the same way the process of formation of the second polar body is like the division of the secondary spermatocytes of the same species.

Thus the processes of oögenesis and spermatogenesis are parallel in every essential particular; the main difference being that in the maturation divisions of the spermatocytes, the resulting cells are equal in size, while those that result from the divisions of the oöcytes are very unequal; and the spermatids undergo a further metamorphosis associated with the special function of the spermatozoa, a change which the special function of the egg renders entirely unnecessary.

Variations in the Process of Maturation.—The forms of the chromosomes and the details of their divisions during maturation differ widely in different groups of animals, and this has resulted in various interpretations of the process by different writers.

Many authors have confirmed Weismann's prediction that a reducing division takes place. But they are not all agreed as to the time when the reducing division occurs. Weissmann predicted on theoretical grounds that the reducing division would occur during the formation of the second polar body. Paulmier and Montgomery found, on the contrary, that in Hemiptera the first is a reducing division, the second an equal division. Similar results were obtained previously by Korscheldt in an annelid, Ophryotrocha, by Wilcox in a grasshopper, Caloptenus, and by Henking in a firefly, Pyrrhocoris. On the other hand, Häcker, von Rath, and Rückert are agreed that in the copepoda the reducing division comes after an equal division, as predicted by Weismann. Similar results have been obtained by von Rath in the mole cricket, Gryllotalpa, by Calkins in the earth-worm, Lumbricus, by Griffin in Thalassema, and by Sutton in Brachystola.

In Ascaris and various vertebrates, chiefly selachians and amphibia, it has been found that both maturation divisions are accompanied by longitudinal splitting of the chromosomes, and authors working upon these forms have been led thus to deny the existence of any reducing division. In Ascaris the two chromosomes, which appear in the oöcyte preparing for division, are elongated and split longitudinally in two planes at right angles to one another. By the shortening of these rods each chromosome becomes a typical tetrad, which divides in the usual manner; that is, in the first maturation each tetrad divides, forming two dyads. One dyad of each pair remains in the egg and separates into two single chromosomes, one of each pair going to the second polar body, so that the first polar body receives two dyads, the second polar body and the ripe egg each two single chromosomes.

In the vertebrates the chromosomes in the spermatocytes preparing for the first division are U-shaped. At an early period a longitudinal split appears at the bend of the U, but the two halves remain united at the ends and open out to form a ring (Fig. 3931). In the metaphase the ring shaped chromosomes separate into two U's by breaking across at the points of union (Fig. 3932). This form of mitosis was called *heterotypical* by Flemming, and is highly characteristic of this stage in the vertebrates. In the next division each chromosome again splits longitudinally. Montgomery has rightly contended that it does not necessarily follow that both divisions are equal, even if they are both longitudinal. In the Hemiptera it was shown that the chromosomes of the first spermatocyte are bivalent having been formed by the union

Digitized by Microsoft®

of two univalent chromosomes end to end, and it is perfectly possible that in the vertebrates the corresponding bivalent chromosomes are formed by the union of two univalent ones side by side. In this case one of the longitudinal splittings would be a true reducing division, separating the original chromosomes or the halves of originally separate ones. This question can be settled only by a very careful study of the fusion of the chromosomes during synapsis.

FIG. 3934.—Pollen Mother-Cell of the Lily with Nucleus in Synapsis. × 585. (After Sargant.)

Reduction in Plants.—In the vascular cryptogams and the flowering plants the phenomena attending a reduction in the number of chromosomes preparatory to sexual reproduction are closely parallel with those found in animals, but present interesting differences.

In these plants the cell corresponding to the last generation of oögonia or spermatogonia in animals usually lies just beneath the epidermis and divides parallel to the surface into an outer *tapetal cell* and an inner cell, the *archesporium*. The mitosis is typical with the normal number of chromosomes. When the archesporium prepares for division the chromosomes reappear reduced in number to one-half, and the normal number is not restored until the male and female pronuclei unite in fertilization. Usually the archesporium divides twice in rapid succession. The result in the Hepaticæ and ferns is the production of four spores. Each spore may then divide by typical mitosis, but with half the normal number of chromosomes. It thus, by continued cell division, forms a prothallium, which exists for some time as an independent plant, and bears the sexual organs, in which the ova and spermatozoa are produced.

In the male flowering plants, the archesporium gives rise to four pollen grains. It is not, however, the primary nucleus of the pollen grain that forms the male pronucleus, but it is its granddaughter nucleus. In the female flowering plants Schniewind-Thies (1901) has found three types of development. In the first the archesporium divides into two daughter cells, and each of these divides into two, making four cells in a row perpendicular to the surface. One of these cells is the young "embryo sac," the others are cover cells, which subsequently undergo degeneration, and may be compared to the polar bodies of animals. Within the embryo sac three nuclear divisions occur, and one of the resulting nuclei is the female pronucleus. In the second type the archesporium divides into two daughter cells, one of which becomes the embyro sac, in which three divisions occur as before. Finally in the third type the archesporium itself becomes the embryo sac. In each case the reduced number of chromosomes first appears in the archesporium and the divisions of the archesporium and its two daughter cells differ from the typical mitoses, being described as heterotypical and homeotypical respectively. These terms were applied originally to the first and second maturation divisions in vertebrates, and their use here indicates the striking similarity of the phenomena.

FIG. 3935.—Section of a Pollen Mother-Cell in a Later Stage, showing twisted chromosomes with double row of granules. *n*, Nucleolus. × 585. (After Sargant.)

As to whether a reducing division does or does not take place, opinion is much divided. Some good observers, notably Ishikawa and Belajeff, regard the first as an equal division and the second as a reducing division. But the majority of authorities, led by Strasburger, insist that both divisions are equal.

This result may be due in part to the fact that most of these authors have completely ignored the synapsis stage, and in their search for a reducing division, undoubtedly influenced by Weismann and Häcker, have concentrated their attention upon the daughter cells instead of upon the archesporium.

The history of both the pollen grain and the embryo sac of *Lilium martagon* has been studied and described with great care by Miss Sargant. In both series she finds a typical synapsis; but it is at the end, instead of at the beginning, of the growth period (Fig. 3934). The chromatic filaments, which showed signs of splitting before the synapsis, emerge from that stage as long flattened bands of linin bearing a row of chromatin granules upon each edge, as in Peripatus. These bands are bent and twisted together (Fig. 3935). As the chromosomes become more condensed the granules merge into a solid mass of chromatin, apparently covering up the linin; and when it reaches its place at the equator of the spindle, each chromosome is composed of two limbs tightly twisted together, giving the appearance of a minute skein of yarn; or, better, a very much twisted doughnut. In the metaphase the two limbs of the chromosomes are separated, and as they are pulled apart, they often assume a V shape; and apparently the original longitudinal split may reappear at this stage, as is indicated by Strasburger's figures. At any rate Miss Sargant finds, and her results are confirmed by many others, that in the second division the chromosomes are separated into two equal halves by a longitudinal split.

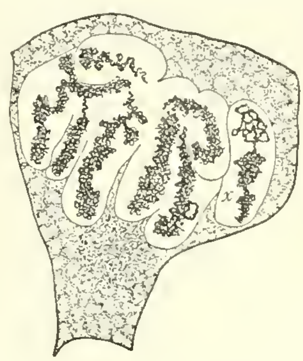

FIG. 3936.—Spermatogonium of Lubber Grasshopper in Early Prophase, showing very fine spiremes arranged in their respective diverticula of the nucleus. From a section. (After Sutton.)

But, aside from their inferences to the contrary, the writer is unable to find anything in the facts, as shown by the descriptions and figures published by Miss Sargant, Strasburger, Farmer, and Schniewind-Thies, that is inconsistent with the inference that the chromosomes previous to the first division are bivalent, formed by the union during synapsis of two univalent chromosomes end to end, and that the two limbs separated during the anaphase are originally independent chromosomes.

That the apparent reduction in the archesporium previous to division may be due to fusion of pairs of chromosomes end to end, was suggested by Strasburger in 1894, and Farmer, who first clearly recognized the synapsis stage in plants, suggested in 1895 that the *first* one might be a true reducing division, separating the univalent constituents of bivalent chromosomes. But he regarded this view as untenable, "for in animals no 'reduction' is claimed at this stage." Now the work of Montgomery, Paulmier, and others has made it clear that reduction may occur in animals at this stage, the first maturation division, and thus the chief ground for deny-

FIG. 3937.—Polar View of Equatorial Plate of Spermatogonium, showing twenty-two chromosomes and accessory, *x*; *i*, *j*, *k*, three pairs of small chromosomes. From a section. (After Sutton.)

Digitized by Microsoft®

ing the existence of reducing division in plants appears to have been removed. Moreover, the similarity is so close at this stage that many of the figures drawn by Strasburger, Miss Sargant, and Schniewind-Thies to illustrate forms of chromosomes in plants might be substituted for some of Paulmier's or Montgomery's figures, representing corresponding stages, with very little change.

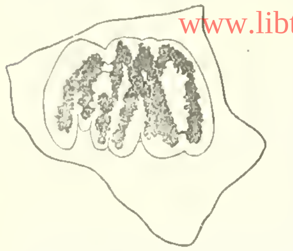

FIG. 3938. Primary Spermatocyte of Lubber Grasshopper in Synapsis (telophase of spermatogonium). Only a few of the chromosomes are shown. (After Sutton.)

Synapsis, Reduction, and Heredity.—As stated in the introduction, the conception "reducing division" had its origin in an attempt to satisfy the requirements of a theory of heredity. The conception has very recently gained new interest and importance through an announcement made by E. B. Wilson (1902) and the publication of preliminary papers by Sutton and Cannon. It was found by Montgomery that in certain species of bugs the spermatogonia contain a pair of chromosomes that

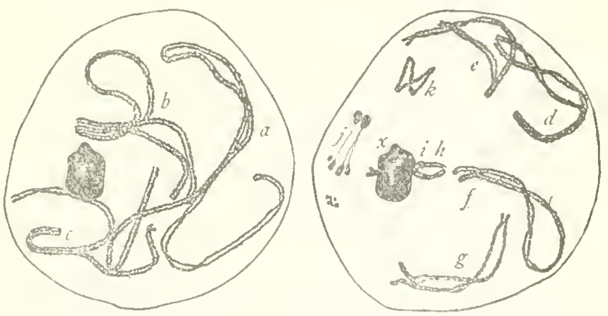

FIG. 3939.—Spiremes, or Chromosomes, from a Primary Spermatocyte in Early Prophase. Drawn in two groups to avoid confusion. From a smear preparation. (After Sutton.)

are unusually large or otherwise peculiar, and that after the synapsis in these cases there is only one large chromosome. Evidently the two peculiar ones have united. As a result of the maturation divisions each spermatid likewise contains one peculiar chromosome. The same is probably true of the egg. So one of these bodies in the spermatogonium is probably of paternal and the other of maternal origin. For this and other reasons Montgomery reaches the important conclusion that during the synapsis each bivalent chromosome formed is half of paternal and half of maternal origin, and the subsequent reducing division results in the separation of homologous paternal and maternal elements and their final isolation in separate germ cells.

FIG. 3940.—Chromosomes from Primary Spermatocyte in Middle Prophase, showing Longitudinal Split. *a*, *b*, *c*, etc., same as in Fig. 3939. (After Sutton.)

Now, as announced by Wilson, W. S. Sutton has found in the study of the spermatogenesis of a grasshopper, Brachystola, nearly complete proof of this inference, and W. A. Cannon has come to the same conclusion from the study of the maturation divisions of hybrid cotton plants. The chief results of Sutton's work are illustrated by Figs. 3936 to 3941. The last generation of spermatogonia have lobed nuclei, and each chromosome is formed in a separate diverticulum (Fig. 3936). In the late prophase of division the chromosomes are seen to be of different sizes, and there is one pair of each size, as *i*, *j*, *k*, Fig. 3937. In the following synapsis stage the chromosomes are seen to unite in pairs by their ends (Fig. 3938) and in the subsequent prophase there are eleven bivalent chromosomes, *a*, *b*, *c* . . . *k*, Figs. 3939 and 3940, corresponding to the pairs in the spermatogonium. The second maturation division is a true reducing division (Fig. 3941). If the oögenesis is the same, and the individuality of the chromosomes is maintained throughout the germinal cycle, then, of the two chromosomes that unite in synapsis, one must be of paternal and the other of maternal origin.

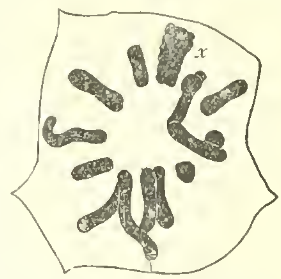

FIG. 3941.—Polar View of Equatorial Plate of Secondary Spermatocyte, showing eleven chromosomes and the accessory, *x*. (After Sutton.)

It was discovered recently by Boveri, that when the chromosomes in the segmenting ovum of a sea urchin have become disarranged as the result of double fertilization, and consequently unequally distributed to the blastomeres, abnormal larvæ result. He inferred from this that the chromosomes differ qualitatively and stand in definite relation to inheritable characters.

Taking all these results together, Wilson points out that they seem to confirm and to show a physical basis for Mendel's principle of heredity, which is being much discussed at present (see *Reversion*). Whether Mendel's theory be true or not, it is certain, as was shown in the article dealing with heredity, that it is in the nucleus of the germ cells, and especially in their chromatin constituents, that we must look to find the physical basis for heredity, and therefore the changes which these constituents undergo in the course of sexual reproduction possess the deepest interest for all students of biology.

REEDY CREEK SPRINGS.—Marion County, South Carolina. Post-Office.—Latla. Hotel and cottages.

This resort is located about three-quarters of a mile from the Atlantic Coast Line Railroad. The surrounding country is level and covered by the long-leafed pine. The springs are three in number, and have had a local reputation for more than thirty years. The water has a constant temperature of 45° F., and its flow is very large. Mr. John L. Dew, of the springs, sends us the following list of ingredients resulting from a partial analysis by former State Chemist Chizzell: Iron carbonate, calcium, magnesium, and sulphur. The water is used more particularly for stomach, liver, and kidney disorders and debilitated states of the system. *James K. Crook.*

REFLEX ACTIONS OR REFLEXES. See *Knee-Jerk.*

REFLEXES. (CLINICAL.)—Descartes introduced the conception of reflexes into biological literature. In "Passions de l'âme" he stated that stimulation of a sensory nerve impulse may be transmitted through the brain to motor nerves and thereby give rise to contraction of muscles, and that this contraction takes place without volition, and even contrary to it. The general reflex centre he believed to be the glandula pinealis.

This definition of reflexes was correct in the early days of biology, but, with the advance of knowledge, our conception of the reflexes has been enlarged.

The term is used in medical literature to-day in a twofold sense:

1. *Specifically*, as in pupillary, knee, plantar reflexes, etc.

2. *Generically*, as in reflex neurosis, reflex spasms, reflex cough, etc.

In both the strict sense (pupillary and knee reflexes, etc.) and in the broader sense (reflex cough, reflex neurosis, etc.) reflexes are centrifugal phenomena produced by reflexion and eventual transmutation of centripetal stimulation. In other words, reflexes are physiological or pathological, motor, vaso-motor, visceromotor, secretory or trophic phenomena, the cause of which is to be found in sensory stimulation.

There is still another group of phenomena called "reflex," to which the foregoing definition does not apply. This group is represented by a set of *centripetal* phenomena—reflex pains, reflex neuralgias, etc. Investigation shows that these phenomena are not genuine reflexes. One group of them, for instance pain in the distribution of the fifth nerve due to disease of the teeth or other structures of the head, or arm pain accompanying an anginoid attack, is, according to Head, an irradiation of a sensory stimulus to other parts or branches of the peripheral sensory apparatus of the affected locality.

Another group, for instance headache due to disease of the abdominal viscera, is, according to the same author, due to irradiations of the sensory stimulation to a central sensory station, and from here to allied sensory structures. Thus the difference between the two types becomes quite apparent.

The genuine reflex phenomena consist of neural stimulation that is reflected from one set of neurones (centripetal neurones) to a physiologically different set of neurones (centrifugal neurones).

The other type consists of neural stimulation that is irradiated and propagated from one set of neurones (centripetal) to another physiologically homologous set (centripetal neurones).

Finally, the term reflex is used promiscuously in medical literature to denote a phenomenon, the cause of which operates at some distance from where its effects are manifest.

According to the conception of genuine reflexes outlined above, all organic functions, save perhaps the distinctly voluntary functions, and some automatic visceral functions, may be looked upon as reflexes. Whether this be fully so or not, we will not attempt to decide. The considerable interest bestowed upon these phenomena, since the times of Descartes, testifies to the great importance of reflexes. (For further details in regard to these, consult the article on *Knee-Jerk* in Vol. V.)

In 1875 Erb and Westphal, working independently, demonstrated the clinical value of reflex phenomena, and since then their importance is daily more appreciated.

Prior to the publications of Erb and Westphal reflexes were observed and registered at the bedside in Charcot's Clinic. Charcot apparently divined their importance, but he had not yet appreciated their clinical significance.

Abundant clinical, experimental, and histological facts have been collected for the proper theoretical interpretation of reflex phenomena. However, a unanimity of opinion has not yet been reached. Some accept the original teachings of Erb, who interpreted reflexes, particularly tendon reflexes, as true reflexes; others adhere to Westphal's teaching, who believed that they were not true reflexes, but phenomena dependent upon the muscle tonus. Gowers calls the tendon reflexes myotatic phenomena, and his conception is akin to that of Westphal.

We shall not consider here the evidence which tends to substantiate either of these theoretical views. Here the theoretical basis of the reflex phenomena will be discussed only in so far as is necessary for a proper and intelligent interpretation of these phenomena at the bedside. The best-known and most studied of all reflexes are the tendon reflexes, and their classical representative is the knee-jerk.

The subsequent remarks apply to tendon reflexes in general, and to the knee-jerk in particular.

A reflex is a neural phenomenon which originates in a sensory end organ, travels along a centripetal pathway, passes a ganglionic station, and leaves it changed or unchanged in quality or quantity, and pursues its way outward on a centrifugal pathway to a centrifugal end organ. The anatomical structure subserving this consists of: A sensory end organ, a peripheral sensory fibre, a ganglion cell, a peripheral motor fibre, a motor end-organ—in other words, a sensory and a motor neurone of the peripheral kind.

This anatomical structure is called a reflex arc. The primary reflex arc is under the influence of one or more secondary arcs, which are represented by an analogous arrangement of secondary neurones.

The centrifugal branch of one of the supposed secondary arcs is represented by the fibres of the pyramidal tracts. The centripetal partner and the central connection of the two are not fully known. The former is probably found in the ascending cerebral and cerebellar tracts, and the central station is probably situated in the gray matter of the cerebrum and cerebellum, and in the nuclei and gray matter of the mesencephalon. The tendon phenomena are accompanied by conscious sensation. Whether this sensation is carried up along the centripetal pathways above mentioned or not is not known. Usually, when a reflex arc is spoken of, only the strict neural elements are understood to represent it, while the sensory and motor end-organs are not included. The ganglionic stations are spoken of as reflex centres. In addition a reflex arc is under the modifying influence of individual segments of the spinal cord above it.

In the lowest forms of life the anatomical substratum of most reflexes is represented by one reflex arc only. This is the case also in some of the simpler forms of reflexes.

All that has been said thus far applies particularly to the tendon phenomena. For other reflexes, skin reflexes, visceral reflexes, etc., analogous anatomical structures are supposed to exist. Their exact location and connections are fully known in some instances, not entirely in others, while in still others they are altogether hypothetical.

Digitized by Microsoft®

Reflex centres are constituted either by the gray matter of the cerebro-spinal axis, or by the gray matter of the sympathetic (visceral) system. The afferent and efferent pathways are either exclusively cerebrospinal, or exclusively sympathetic (visceral) or mixed.

It is believed that a reflex arc is constantly traversed by neural energy which establishes in this arc a sort of functional equilibrium. Under normal conditions this equilibrium is altered in consequence of changes in the secondary reflex arcs, and this results in voluntary action or reflex action. Within physiological limits a variety of general and local causes, acting on all or some parts of the reflex arcs, will greatly modify reflex activity. This will be still more so in the domain of pathology.

www.libtool.com.cn

It is thus seen that the semeiological value of reflexes is not exclusively reserved for neuropathology. Diagnostic and particularly prognostic aid is occasionally received from a study of reflex phenomena in general diseases. Attention has lately been drawn to this fact by Pfaundler and Luethye in their investigations on the behavior of reflexes in pneumonia and other acute infectious diseases (*Münch. med. Wochenschrift*, July, August, 1902).

The systematic study of reflexes in neuro-visceral diseases will probably yield valuable information.

The theoretical controversy about the nature of reflexes is exclusively concerned with tendon reflexes and hinges upon the question of the interrelation and interdependence of tendon phenomena and so-called muscle tonus. The nature of all other reflexes (skin and visceral) is apparently undisputed; they are believed to be genuine reflexes.

According to Jendrassik reflexes investigated at the bedside may be divided into three categories, according to the supposed situation of their centres.

1. *Spinal:* Tendon, muscle, periosteum, bone reflexes, jaw-jerk.

2. *Cerebral* (cortical) cutaneous reflexes: Scapular, abdominal, cremasteric, scrotal, gluteal, plantar, palpebral, conjunctival, pharyngeal, anal.

3. *Visceral* (sympathetic): Sneezing, swallowing, vomiting, coughing, erection, ejaculation, etc.

The first group, also called physiological spinal reflexes, is characterized by the following points:

(1) The reflex is elicited from moderately sensitive areas.

(2) The reflex movement is usually not accompanied by specific sensation.

(3) The exciting stimulus is a simple mechanical irritation.

(4) The intensity of the reflex movement is not so variable as in the second group.

(5) It can be elicited on one's self as well as on others.

(6) The period of latency is the shortest.

(7) The reflex movement is a simple twitch and is apparently not adapted to certain ends.

(8) Muscular exertion increases this reflex.

(9) In diseases of the brain (after a certain time) these reflexes are increased.

(10) Delay is not observed

(11) Mental influences are of little effect. Distraction of attention makes the demonstration easier.

Reflexes of the second group are characterized by the following points:

(1) The elicitation of the reflexes takes place from very sensitive localities.

(2) The reflex is accompanied by sensation.

(3) The exciting stimulus must be of sufficient duration to produce a distinct sensation

(4) The intensity of the exciting stimulus is not always proportionate to the result. Individual variations are great.

(5) These reflexes can be elicited on one's self only with great difficulty.

(6) The period of latency is longer than in the first group and not as constant. The period of latency is proportionate to the speed of the sensory conduction.

(7) The resulting movement is more complicated and seems to have the purpose of removing the irritated parts from the source of irritation.

(8) Increased muscular activity frequently diminishes these reflexes.

(9) These reflexes are diminished or absent in cerebral lesions.

(10) They are delayed in appearance when the sensory conduction is delayed.

(11) Mental influences increase or diminish these reflexes. Distraction of attention frequently diminishes them.

Reflexes of the third group are characterized by the following points:

(1) These reflexes are elicited from sensitive points.

(2) They are accompanied by specific sensation. The sensation here is of greater importance than in the reflexes of the second group.

(3) The time for the necessary stimulation is here the longest.

(4) These reflexes have great individual variations.

(5) They are elicitable on one's self, but depend upon specific stimulation.

(6) The time of latency is the longest.

(7) The resulting movement is very complicated—bilateral.

(8) Muscular exertion diminishes these reflexes.

(9) In cerebral lesions they are increased or diminished.

(10) Mental influences are of great importance.

Dejerine divides reflexes, according to the nature of the peripheral parts of the reflex arc, into four groups:

1. Reflexes, the centripetal and centrifugal branches of whose arc are represented by cerebrospinal fibres: tendon reflexes, cutaneous reflexes, reflexes of deglutition.

2. Reflexes, the centripetal branch of whose arc is a cerebrospinal fibre, and the centrifugal branch a sympathetic (visceral) fibre: salivation, blushing, intestinal contraction, pain reaction of the iris.

3. Reflexes, the centripetal branch of whose arc is a sympathetic (visceral) fibre, and the centrifugal branch a cerebrospinal fibre. This group is represented mostly by pathological reflexes: reflex phenomena due to irritation or disease of the abdominal viscera.

4. A group which logically would be presented by reflexes, the centripetal and centrifugal branches of whose arc are built up of sympathetic or visceral fibres. Physiological: secretion of digestive juices. Pathological: Visceral congestion, redness or pallor of the skin in consequence of hepatic colic, etc.

In Dejerine's original article,* however, this last-named group is thus characterized:

4. In the last group can be placed the reflex acts whose paths of conduction do not arise from the sympathetic system. Physiological: The secretion of intestinal juices in the course of digestion. Pathological: The phenomena of visceral congestion, blushing, pallor, coldness of the skin produced by organic affections (colics, etc.).

For the clinical understanding of the tendon phenomena, Sherrington's classification seems helpful. He believes that one ought to distinguish under the name of tendon reflexes two different varieties of phenomena:

1. True spinal and cerebrospinal reflexes, excited by stimuli applied to the tendons.

2. Pseudo-reflexes, commonly called tendon phenomena or tendon concussions.

The true tendon reflexes have no considerable clinical importance. The pseudo-reflexes are not genuine reflexes because: (1) The time occupied for their production is very short. (2) The muscular contraction is a simple twitch and not prolonged or tetanic; therefore the knee phenomenon is not a true spinal reflex, but a direct response of the muscle to a sudden mechanical tension. Only when the muscle is in connection with its neural supply can this response be obtained. For the production of the knee phenomenon the tonus of the muscle is indispensable.

* Ch. Bouchard: "Semeiologie des Reflexes." "Traité de Pathologie générale," tome v., p. 939, 1901.

Digitized by Microsoft®

The number of reflexes so far described is quite considerable. Additions are constantly being made, and the future will undoubtedly bring more. Only a few of this large number have general clinical importance. The others gain in importance and prove useful and reliable guides in segmental and topical diagnosis, in proportion to their anatomical definition.

www.libtool.com.cn

The following reflexes are among the older and better known:

A. *Superficial Reflexes:* Palpebral, corneal, conjunctival, pharyngeal, interscapular, epigastric; upper, lower, middle abdominal; cremasteric, scrotal, anal, gluteal, lumbar, pilomotor or goose-skin reflex.

B. *Deep or Tendon Reflexes:* Patellar, Achilles, triceps or olecranon, biceps, ulnar, radial, masseter or jaw-jerk.

C. *Visceral Reflexes:* Pupillary, bladder, rectal, sexual.

Some of the newest reflexes are: The lumbo-femoral of Bechterew, the infraspinatus of Steiner, the supra-orbital of McCarthy.

The exciting stimulus necessary for the production of a reflex varies in quality and quantity. The pupillary reflexes respond to specific irritation of the optic nerve—photic stimuli. The superficial reflexes are evoked by stimulation of the tactile or algetic senses. The tendon reflexes are the result of mechanical stimulation of the tendon. Under certain conditions mechanical stimulation of the adjacent structures (periosteum, bone, articulatory surface) yields a reflex contraction.

The sensory (tactile or algetic) stimulation of the skin around the knee occasionally gives rise to a contraction of the quadriceps muscle. This is not a genuine tendon phenomenon, but is known under the name of pseudo-knee-jerk, and has been described by Wespthal, with a note of warning to keep this phenomenon distinct from the genuine tendon jerk. The pseudo-knee phenomenon may be observed even when the genuine knee-jerk is absent.

The intensity of the sensory stimulation necessary for the production of a reflex has an upper and lower limit of efficacy. Below a certain limit of irritation the reflex phenomenon dependent upon this irritation naturally does not ensue. Equally disturbed is the reflex response in its clearness, or it is even entirely frustrated when the sensory stimulus is above a certain limit of intensity. Therefore the intensity of the sensory stimulus may be looked upon as an index of the reflex activity of the centres or arcs, which vary considerably within physiological limits. The intensity and extensity of the reflex response are also quite variable. The muscular contraction is sometimes vigorous, quick and lightning-like, at other times sluggish and less active. When the reflex response is considerably exaggerated, the irritation is followed by a succession of contractions, known as clonus (patellar clonus, ankle clonus, wrist clonus). In a still higher degree of increased reflex irritability, this clonic response spreads over wide territories, and is then called "epilepsie spinale."

Under certain conditions the muscular contraction is limited to one muscle only, and at other times it spreads to neighboring muscles, or even to homologous muscles of the opposite side of the body. Furthermore, a cumulative quality of the sensory stimulation is occasionally observed. A reflex occurring at times from one stimulation will need at other times a repeated stimulation for its production. Sometimes the reflex response shows a peculiar exhaustibility. This is seen when the same stimulation is followed at one time by a normal contraction, at another by a much weaker one or by none at all. Another expression of the same tendency is to be seen when a reflex that responds to a stimulus becomes exhausted after frequent stimulation, then reappears again after a short interval of rest. These variations when occurring under the same conditions of stimulation also permit the inference as to the state of the reflex activity of the centres or arcs. At the same time these variations of the reflex response may be profitably kept distinct from the variations of the response depending upon the intensity of the stimulation. The latter may be designated as variations of the reflex irritability, and the former as variations of reflex mobility.

Frequently the attempt has been made to express the described variations of the sensory stimulation and motor response of the reflex phenomena in more exact terms. Apparatuses have been devised for the purpose of measuring the one as well as the other; these investigations have aided the physiological conception of reflexes; but clinically they have not been of much value.

If all of the foregoing be borne in mind, the following propositions will be self-evident:

Reflexes are Increased.—1. When the sensory end apparatus, or the centripetal fibre, or the centrifugal fibre, or the primary reflex centre, is in a more or less marked state of irritation.

2. When the inhibitory influence of the secondary reflex arc is diminished or paralyzed.

Reflexes are Diminished or Absent.—1. When the sensory end-apparatus, or the centripetal fibre, or the centrifugal fibre, or the primary reflex centre, is in a state of more or less marked paresis or paralysis.

2. When the stimulating influence of the secondary reflex arc is diminished or paralyzed.

Lastly, reflexes will be increased or diminished according to the increase or diminution of the exciting stimulus.

There are a maximum and a minimum of conditions favorable to the elicitation and demonstration of reflexes. For the pupillary reflexes it is necessary that the difference between the stimulations (light and dark) be quite marked. The skin and tendon reflexes are considerably impeded by the will and by concentrated attention; the skin reflexes less so than the tendon reflexes. Difficulties encountered clinically in the demonstration of pupillary reflexes are obviated by examining the patient in a dark room, with artificial light, and by taking care that accommodation is excluded.

In the case of skin and tendon reflexes, various means have been devised for distracting the patient's attention during the examination. To obviate these difficulties recourse is had to what is commonly called the method of reinforcement, or the Jendrassik method. This consists of the following: The patient is directed to link his hands into each other and then to attempt to pull the hands forcibly apart. Care must be taken that the tap of the tendon is synchronous with the greatest effort of the patient.

A characteristic and peculiar degree of muscular contraction is indispensable for the demonstration of tendon reflexes. A muscle contracted above a certain limit is incapable of expressing an additional contraction, and a muscle relaxed beyond a certain limit is also irresponsive to reflex stimulation. Finally it is not to be forgotten that recent or previous disease of the structures around the knee- or ankle-joint is carefully to be excluded.

It should not be said that a reflex is absent unless the examination has been made with the above-mentioned precautions.

At the end of this article will be found a list of all reflexes with their respective anatomical locations and constituents, and their clinical significance.

It remains only to discuss in detail the most important reflexes: the pupillary phenomena, the knee-jerk, the Achilles jerk, and the plantar reflex.

Pupillary Phenomena.

The following points are noted in the examination of pupillary phenomena:

1. The size of the pupils.
2. Their shape and outline.
3. The light reactions (direct and consensual).
4. The accommodative and convergence reactions.
5. The pain reaction.

Recent or previous disease of the structures of the eyeball (cornea and iris, anterior chamber, etc.) must be carefully excluded before any conclusions are drawn. Under average physiological conditions both pupils are of medium dilatation and equal when exposed to diffused daylight. Inequality of the pupils (anisocoria) is, as a rule,

Digitized by Microsoft®

pathological. Exceptions to this rule are few and not fully understood. Very wide pupils (mydriasis) are sometimes within physiological limits, but are most often observed in sensitive neurotic subjects. Very small pupils (myosis) are more often pathological than the preceding. It is not to be forgotten that drugs are occasionally the cause of the mentioned states of the pupils (belladonna, opiates).

www.libtool.com.cn

Normally the outline of the pupil is circular, and the free border smooth. Serrations of outline and imperfections of the circle are significant. As a rule this denotes previous syphilitic infection.

The direct reaction consists of dilatation of the pupil when light is shut out, and of contraction of the pupil when light is admitted.

To ascertain this reaction, the patient is directed not to accommodate for any near object, and both pupils are alternately exposed to and protected from the light, and the result is watched. This reaction, "reaction to light," is never absent in health.

When the light reaction does not ensue, and care has been taken to avoid the mentioned possibilities of error, the pupils are said to be "stiff." This constitutes the Argyll-Robertson phenomenon.

The consensual reaction consists of contraction or dilatation of the pupil of the opposite side, following the admission or exclusion of light from the other pupil. This is best examined for as follows: The pupil is watched while the lid of the other eye is raised or lowered. This reaction is rarely disturbed alone. It is seen sometimes in conjunction with other disturbances of the pupillary play.

The accommodation reaction consists of contraction of the pupil on fixation of near objects and of dilatation of the pupil when looking into the distance.

The convergence reaction is a contraction of the pupil on convergence of the eyeballs (simultaneous innervation of both internal recti).

The pain reaction consists of a dilatation of the pupil upon painful stimulation of face or neck, or sometimes upon painful stimulation of any part of the body.

The hemiopic pupillary reaction of Wernicke is a rare pupillary phenomenon. It occurs in cases of hemianopsia, central or peripheral.

Light reaction occurs only on stimulation of the sensitive half of the retina, and does not ensue when the non-sensitive half is irritated. It is best demonstrated when one-half of the pupil is protected by a small shield and the other is alternately stimulated by admission and exclusion of light.

Occasionally one finds in literature the term paradoxical pupillary reaction. The reaction is said to be paradoxical when the pupil dilates on admission and contracts on exclusion of light.

Sluggish and lively pupillary reactions are likewise spoken of. These depend of course upon the speed with which, and extent to which, reactions take place.

Lastly a phenomenon has been described by Strasburger and Saenger (*Neurol. Centralbl.*, 1902) under the name of myotonic pupillary reaction. They mean reactions that occur in such a way that the iris remains for a short time in dilatation or contraction, as the case may be, before changing.

Pupillary reactions have also been observed as a type of associated movements coincident with looking upward or upon forcible closure of the eyes.

It has further been stated, by good authority, that even the mere suggestion of light and dark, for instance to totally blind people, is sometimes followed by the corresponding pupillary reaction.

A state of unrest and constant change of width of pupil has also been noticed at times, and been given the name of hippus.

Knee-Jerk.

The knee-jerk (knee kick, knee reflex, patellar reflex, knee phenomenon, Erb or Westphal phenomenon) is the name given to a contraction of the quadriceps femoris, that follows a blow upon the patellar tendon. The contraction is more marked in the internal division of the muscle (vastus internus). The knee-jerk is rarely absent in health.

In order to demonstrate this phenomenon, it is necessary, as was explained before, to prevent inhibition on the part of the patient.

The knee phenomenon is elicited in the following way:

1. The knee is allowed to swing freely on the examiner's hand, or the foot is put flatly upon the floor, so that the leg and thigh form a slightly obtuse angle, or one leg is crossed upon the other, and the leg is allowed to swing freely.

2. A sharp tap is made upon the patellar tendon with the tips of the fingers, with the ulnar border of the hand, with a percussion hammer, or with any other suitable instrument. Thereupon a contraction of the quadriceps muscle ensues, more or less quick and vigorous. This contraction can frequently be seen and felt, and it gives rise to a more or less marked excursion of the leg. This reflex varies quite considerably within physiological and pathological limits. These variations are designated by the names of normal, lively, increased, diminished, exaggerated, etc. In states of exaggeration, a reflex response is elicited not only upon mechanical stimulation of the tendon, but also upon irritation of a wider area around the knee and the upper part of the tibia. In states of diminution of the reflex response, the reflexogenic zone is considerably narrowed, and the reflex response is more liable to occur upon stimulation of the median than upon stimulation of the lateral half of the patellar tendon.

Evidence of greater exaggeration of the knee reflex is patellar clonus. This is demonstrated in the following way:

The lower extremity is slightly hyperextended and the patella is pushed quickly downward, and percussed or tapped in this position. A sharp clonic contraction is the result. Sometimes the reflex contraction is not limited to the quadriceps muscle alone, but is observed in the adductor group of muscles of the same side, or occasionally of the opposite side of the body. Rarely the contraction occurs even in the quadriceps muscle of the other side. The latter phenomena are called crossed adductor and crossed knee-jerk respectively.

Direct mechanical stimulation of the belly of the muscle is also followed by contraction of the muscle. This is, however, the expression of the so-called mechanical muscular irritability, and reveals itself clinically in two forms:

1. The contraction is fascicular and limited to the site of the irritation.

2. The entire muscle contracts.

This last-named contraction is not to be confounded with the true knee reflex. It is frequently found, for instance, in cases of tabes, in which the reflex is absent.

The occurrence of a pseudo knee phenomenon—a contraction of the quadriceps upon algetic stimulation of the skin around the knee—has been mentioned above.

Achilles Jerk.

The Achilles jerk consists of a contraction of the calf muscles upon tapping of the Achilles tendon. This reflex is examined for in the following way:

1. The foot is slightly dorsiflexed, the knee is slightly flexed, and the Achilles tendon is tapped. A plantar flexion of the foot ensues.

2. The lower extremity is slightly flexed at hip and totally flexed at knee, and in this position the entire leg rests on a chair while the foot is free. In this position the Achilles tendon is tapped, and a plantar flexion of the foot is the result.

When this reflex is exaggerated, a forced dorsiflexion of the foot is followed by a succession of contractions. This is called the ankle clonus. This clonic contraction keeps up as long as the dorsiflexion of the foot is maintained. At other times it soon ceases and may or may not reappear. The ankle clonus which is difficult to de-

Digitized by Microsoft®

monstrate, and in which the clonic contractions are not vigorous and are easily exhaustible, are sometimes spoken of as pseudo-ankle clonus.

Sometimes difficulties are encountered in the demonstration of ankle clonus, and then it is well to use the following procedure: Bend the lower extremity slightly at hip- and knee-joints; exert sharp dorsiflexion of the foot, and in addition tap repeatedly the Achilles tendon.

www.libtool.com.cn

The pseudo-ankle clonus is very rarely evidence of organic disease, although undoubtedly cases of disease of the pyramidal tracts occur in which the ankle clonus is of a pseudo type.

On the other hand, the genuine ankle clonus which is expressed by vigorous clonic contractions, which persist as long as the dorsiflexion of the foot is kept up, is usually, though not always, evidence of organic disease.

The question of the occurrence of genuine ankle clonus in hysteria is not fully decided. There are undoubtedly a few cases of hysteria with marked ankle clonus on record.

Care should be taken not to confound the genuine Achilles reflex with the expression of the mechanical irritation of the muscle. The Achilles reflex is rarely, if ever, absent in health, although it is not believed to be as constant as the knee-jerk.

Plantar Reflex.

The plantar reflex is the most constant representative of the skin reflexes. It consists of a sequence of contractions of a variety of muscles of the lower extremities, following tactile or algetic stimulation of the sole of the foot.

For the production of the reflex, the median half of the sole is more sensitive than the lateral half. Under normal conditions, and under mild stimulation, the muscles most frequently seen to contract are the tensor fasciæ and the plantar flexors of toes and foot.

In states of increased reflex excitability the whole foot is dorsiflexed, and in a still higher degree the entire lower extremity is removed from the source of irritation.

The same takes place when the exciting stimulus is stronger or frequently repeated in succession.

Reflexes.	Neural Mechanism.			Demonstration.	Remarks.
	Afferent.	Efferent.	Centre.		
Corneal and conjunctival.	Fifth nerve......	Seventh nerve...	Nucleus of seventh nerve.	Irritation of conjunctiva or cornea, followed by contraction of orbicularis oculi.	Diminished in Basedow disease. (Stellweg phenomenon.)
Pupillary (light)	Optic nerve......	Oculomotor......	Ciliary ganglion (?).	Alternately illuminating and shading the pupil.	Absent in tabes and general paresis.
Pain reaction of pupil.	Cerebral or spinal sensory nerves.	Cervical sympathetic fibres.	Cilio-spinal centre, fourth to seventh cervical	Painful stimulation of skin anywhere, particularly around neck, followed by dilatation of pupil.	Absent in diseases of cervical sympathetic.
Pharyngeal.....	Ninth nerve	Seventh nerve...	Nucleus of seventh nerve.	Tickling of palate, followed by contraction of velum.	Believed to be absent or diminished in hysteria.
Jaw-jerk (chin phenomenon).	Fifth nerve......	Motor portion of fifth.	Motor nucleus of fifth.	Percussion of lower jaw, with mouth slightly opened, followed by contraction of masseters.	Inconstant in health. Exaggeration observed in disease of upper part of pyramidal tracts.
Mimetic reflex of face.	Nerves of special senses. Psychic stimuli.	Facial nerve.....	Thalamus opticus (?).	Laughing or crying on appropriate mental stimulation.	Absent in disease of thalamus. In exaggerated states, impulsive laughter and impulsive crying. In intracranial disease, particularly of basal ganglia.
Scapular........	Sensory roots, fifth cervical to first dorsal.	Same motor roots	Anterior horns, seventh cervical to first dorsal.	Tactile or algetic stimulation of skin, along inner border of scapula. Adduction of scapula.	Absent in disease at this level. Inconstant.
Palmar.........	Sensory nerves, seventh cervical to first dorsal.	Motor nerves, seventh cervical to first dorsal.	Anterior horns, seventh cervical to first dorsal.	Tickling of palmar surface of hand, followed by closure of hand.	Very inconstant.
Epigastric......	Sensory nerves, fourth to seventh dorsal.	Motor nerves, fourth to seventh dorsal.	Anterior horns, fourth to seventh dorsal.	Tactile or algetic stimulation of upper abdomen. Contraction of abdominal muscles.	Absent in disease of this level of the cord. Diminished or absent on one side in disease of contralateral cerebral hemisphere.
Abdominal.....	Sensory nerves, seventh to eleventh dorsal.	Motor nerves, seventh to eleventh dorsal.	Anterior horns, seventh to eleventh dorsal.	Tactile or algetic stimulation of lower abdomen (below umbilicus). Contraction of abdominal muscles.	Absent in disease of this level of the cord. Diminished or absent on one side in disease of contralateral cerebral hemisphere.
Cremasteric	Sensory nerves, first to third lumbar.	Motor nerves, first to third lumbar.	Anterior horns, first to third lumbar.	Tactile or algetic stimulation of skin around inner and upper part of thigh, followed by pulling up of testicle.	Absent in disease of this level of the cord. Diminished or absent on one side, in disease of contralateral cerebral hemisphere. Not to be confounded with the tunica dartos reflex.
Gluteal.........	Sensory nerves, fourth to fifth lumbar.	Motor nerves, fourth to fifth lumbar.	Anterior horns, fourth to fifth lumbar.	Sensory or algetic stimulation of skin of buttocks. Contraction of glutei.	
Plantar.........	Sensory nerves, first to second sacral.	Motor nerves, first to second sacral.	Anterior horns, first to second sacral.	Tactile or algetic stimulation of sole of foot, followed by contraction of various muscles of lower extremities.	Babinski phenomenon.
Triceps.........	Sensory nerves, sixth cervical.	Motor nerves, sixth cervical.	Anterior horns, sixth cervical.	Relaxed and semiflexed upper extremity. Tapping of tendon of triceps. Contraction of triceps.	Inconstant. Exaggerated in disease of pyramidal tracts.
Biceps..........	Sensory nerves, sixth cervical.	Motor nerves, sixth cervical.	Anterior horns, sixth cervical.	Relaxed and semiflexed upper extremity. Tapping of tendon of biceps. Contraction of biceps.	Inconstant. Exaggerated in disease of pyramidal tracts.
Wrist-jerks.....	Sensory nerves, sixth to eighth cervical.	Motor nerves, sixth to eighth cervical.	Anterior horns, sixth to eighth cervical.	Tapping of ends of ulna or radius, followed by flexion or extension, respectively.	Inconstant. Exaggerated in disease of pyramidal tracts. Occasionally wrist clonus. Forcible dorsiflexion of hand followed by clonic palmar flexion.
Patellar reflex..	Sensory nerves, second to fourth lumbar.	Motor nerves, second to fourth lumbar.	Anterior horns, second to fourth lumbar.	Mechanical irritation of the patellar tendon followed by contraction of the quadriceps femoris.	
Achilles reflex..	Sensory nerves, third to fifth sacral.	Motor nerves, third to fifth sacral.	Anterior horns, third to fifth sacral.	Plantar flexion of foot upon tapping of Achilles tendon.

Refuse Disposal.

The plantar reflex has lately been invested with considerable clinical importance through the investigations of Babinski. Under the name of Babinski phenomenon, or big toe phenomenon, the following variations of the plantar reflex have been described:

www.libtool.com.cn

Upon stimulation of the sole of the foot, the big toe is dorsiflexed, and the other four toes are plantar-flexed. When this occurs slowly this is the typical Babinski phenomenon. It is believed to denote disease of the pyramidal tracts.

In children below two years of age, in whom the pyramidal tracts are not fully medullated, this variety of plantar reflex is normal.

While the typical *Babinski phenomenon*, as just described, is believed to be undisputed evidence of disease of the pyramidal tracts, with the mentioned exception in children, its absence does not prove that the pyramidal tracts are not diseased.

There are many combinations and changes of the Babinski phenomenon, and the significance of all of them is still under dispute.

At present it is best for clinical purposes to accept the following guide:

The Babinski phenomenon is positive, and the inference therefrom justified:

1. When upon stimulation of the sole of the foot there is dorsiflexion of the big toe and plantar flexion of the other toes.
2. When upon stimulation of the sole of the foot there is dorsiflexion of the big toe only.
3. When upon stimulation of the sole of the foot, there is dorsiflexion of all the toes.

The significance of the third variety is doubtful. All authorities do not agree that the Babinski phenomenon is always an indication of organic disease of the pyramidal tracts.

In examining for the plantar reflex, it is well to observe carefully the result of the first stimulation. After repeated stimulations, the patient's attention and conscious interference can never be fully excluded and a variety of cerebral reflexes occur which obscure considerably the interpretation of the result.

As a result and consequence of disturbed and changed reflex activity, a set of phenomena have received clinical study and attention. These phenomena are comprised under the name of associated movements and contractures. From among them the so-called Strümpell phenomenon is of clinical value, although limited.

The *Strumpell phenomenon* consists of the following:

When the patient is asked to flex the thigh upon the hip, and the leg upon the knee, there is an associated plantar flexion of the foot observed in cases of disease of the pyramidal tracts.

Under physiological conditions, or when there is no disease of the pyramidal tracts, the foot is dorsiflexed under the above-mentioned conditions. The so-called Kernig sign, which is believed to be pathognomonic of cerebrospinal meningitis, also belongs to this group. The Kernig sign is an inability on the part of the patient to extend the leg when the thigh is flexed.

Contractures and muscular rigidity are frequent accompaniments of exaggeration of tendon reflexes; the exceptions to this rule are few.

The state of the reflexes has been of considerable value for diagnosis and correct anatomical interpretation of pathological motor phenomena.

The terms flaccid and spastic paralysis refer particularly to the state of the reflexes of the paralyzed muscles.

A flaccid paralysis is a more or less marked motor paralysis, with loss of reflex activity and diminution of the reflex tone.

A spastic paralysis is a more or less marked motor paralysis with increase of reflex activity, and increase of tonus.

REFUSE DISPOSAL.—By this term is here meant the disposal of the waste matters of a city, town, village, or family, not including the sewage which is deposited in and escapes through the underground system of sewers. The items usually embraced in the term "refuse," as distinguished from "sewage," are the following:

Garbage or offal, consisting of the organic waste matter from kitchens; ashes; house dust; waste paper and rags; tin cans, crockery, bottles, and broken glass; street sweepings; night soil, or contents of vaults, cesspools, and pail systems.

Broadly speaking, the term refuse includes sewage, but since this form of waste product is usually disposed of by a distinct system of underground pipes managed by a board of sewer commissioners, the term refuse will here be limited to its usual significance, that of the material gathered periodically from houses, hotels, and streets, by a system of collection intended for this purpose. The municipal management necessary for conducting this class of work often constitutes a serious problem, in consequence of the liability of causing nuisance, either in the methods of storage, collection, and transportation, or in the final disposal of the material.

FIG. 3942. Push-Cart Used for Collection of Street Sweepings. (From report of Street Department, Boston, 1900.)

GARBAGE.—Garbage is usually defined as the waste products of food material. In addition to this, Chapin[1] enumerates, under the head of "refuse," such waste materials as glass, crockery, street sweepings, oyster and clam shells, sawdust, corkdust, old boots and shoes, dead

Digitized by Microsoft®

Refuse Disposal.

animals, lawn clippings, bottles, earthen, tin or iron ware, rubbish, tin cans, poisonous matter, excrement, urine, coal, and dirt. Dead animals and slaughterhouse refuse add value to garbage if it is to be made into fertilizers.

www.libtool.com.cn

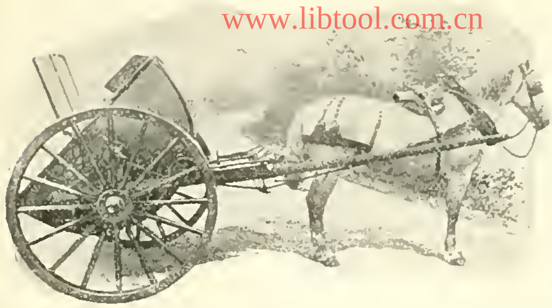

FIG. 3943.—Garbage Cart at an Angle for Washing or Easy Loading.

If the materials are sorted and such articles as tin cans, bones, and paper are selected out for utilization, then there is no objection to the deposit of such articles with garbage. But if the garbage is to be fed to hogs, or ploughed into the ground, tin cans are usually excluded. The rules and regulations in force at Lowell provide that "kitchen refuse, apple and potato parings, corn husks, cabbage leaves, shoes, rubbers, old bedding, soiled linen or cotton, and all refuse that can be burned shall be placed in the garbage vessels."

Household Storage.—In order that nuisance may be prevented, it is desirable that proper receptacles shall be provided by householders, hotel and restaurant keepers, and others for the storage of ashes, garbage, waste paper, etc., and that these be placed in convenient and accessible places for collection. Receptacles for ashes are best

FIG. 3944.—"Columbian" Dumping Cart showing Use of Dumping Lever.

made of metal. Those intended for garbage should be water-tight and provided with a well-fitting cover to exclude rain, prevent leakage, escape of odors, and access of dogs and other animals. In some cities separation of ashes, garbage, and paper is required by regulation; in others such separation is not so required.

Frequency of Removal.—Garbage is usually collected three times a week, but in some cities collection is made oftener, and in others not so often. In some cities definite hours are specified for such removal.

Vehicles of Removal.—The best form of vehicle for removal of garbage is made of metal, and so constructed as to admit of dumping instead of shovelling the contents. In some cities stout wooden barrels or iron casks are used, ten or more making a load.

In some large English cities where the pail system of collection for the removal of excremental waste is employed, the receptacle is removed from each house with the contents, and replaced with an empty or clean pail or tub. These receptacles are usually of metal painted and have a capacity of about a half-bushel. (Fig. 3943.)

The vehicles used for this purpose should always be provided with covers, either fixed or movable, for use when driving through the public streets.

Collection of Garbage.—In some cities garbage is collected by contract, and in others by some city authority. Municipal removal, however, as a general rule secures the most satisfactory service.

The following data present the cost and amount of collection of garbage in some of the largest American cities, the data referring either to 1898, 1899, or 1900. The following table relates to garbage only:

City.	Amount collected—tons.	Cost of collection.
Brooklyn	102,000	$120,000*
Baltimore	49,000	65,404
Boston	60,000	112,641
Buffalo	22,881	33,000*
Cleveland	22,375	69,400*
Milwaukee	28,716	61,883
New York (Borough of Manhattan)	152,000	101,840
Philadelphia	199,357	398,000*
Pittsburg	25,000	92,000*
St. Louis	69,634	99,673
New Orleans	67,500	97,200*

* Cost of collection and disposal.

The Separation of Refuse.—In very many cities it is the custom to separate the refuse into two or three or even more sorts; a very common method requiring the separation of the ashes, garbage, and paper or light combustible rubbish into three classes, the ashes being usually disposed of as a filling for waste lands, the garbage being fed to hogs, and the paper or light rubbish sold or burned. In addition to other classes, it is quite a common practice to separate the tin cans, bones, old iron and glassware, each of which has a certain market value. Such separation is often made a requirement by city regulations, and may be enforced by a penalty.

The English law relating to refuse is as follows (Section 42 of the Public Health Act, 1875): "Every local authority may, and when required by order of the Local Government Board, *shall* themselves undertake or contract for the removal of house refuse from premises; the cleansing of earth closets, privies, ashpits, and cesspools, either for the whole or for any part of their district."

By Section 43 of the same act, the local authority is made liable to a penalty of five shillings per day, payable to the occupant of a house, for failure to remove refuse after notice in writing from such occupant.

The street refuse of London is removed daily by boys with shovels and brush, and placed in iron dust bins, which are stationed at intervals along the edge of the pavement. In dry weather the streets are watered before being swept. The manure and dirt are removed by carts and taken to depots generally close to the river or to a railway station.

Each house has its dust bin or ashpit for the house refuse, from which the contents are collected periodically. The necessary depots for refuse are subject to the following general regulations:

1. The depots must be as distant as possible from inhabited places.
2. The refuse must not be put into pits, but above the ground level. If necessary, a special floor, three inches above the ground, must be made.
3. The ground should be drained and paved with impermeable material.
4. The depots should be sheltered from sun and rain, but the air should enter freely.
5. The ground leading to the depot should be well paved, so as to prevent pollution of the soil.

The custom of sorting refuse is vigorously opposed by some authorities. Mr. Goodrich[2] quotes Dr. Sedgwick Saunders as follows: "When the dust carts arrive at the wharf their contents are tipped into heaps at a place most

Digitized by Microsoft®

convenient to the people who are engaged as sorters. About seventy persons, chiefly women, were engaged in this degrading and loathsome work, most of whom are paid by piece work, but female sifters received seven shillings and a little coal and wood weekly. The appearance of the women is most deplorable, standing in the midst of the dust piled up to their waists, with faces and upper extremities begrimed with black filth, and surrounded by, and breathing, a foul, moist, hot air, surcharged with the gaseous emanations of disintegrating organic compounds. I shall not forget visiting some of these poor creatures in a hospital, and witnessing the condition of their skins."

In Paris, previous to 1887, the refuse was put into the street in the evening. The ragpickers came and collected the rags, paper, bones, and glass. The refuse thus became scattered about the streets, rendering the collection difficult. The custom was forbidden by a decree of March 7th, 1887. The greater part of the refuse is taken to depots outside the city, where it is allowed to decay for five or six months, at the end of which time it becomes valuable as manure. Part is taken in boats to Corbeil, up the river, and to Pontoise, below the city. The removal of these heaps is done at much expense, the loss to the city averaging 2,000,000 francs ($400,000.)

In Brussels the refuse is collected at 7 A.M. from October 1st to March 1st, at 6:30 A.M. from March to September, and again at 6 P.M. from April 1st to September 1st. All refuse is conveyed in carts daily to the ash yard on the landing step of one of the canals, whence it is conveyed in boats directly to farmers, or to a depot at Evère outside the city.[3]

The Disposal of Garbage.—Briefly enumerated, the methods of final disposal of the garbage of cities are the following: Private or individual disposal, dumping at places designated for the purpose, ploughing into land, depositing in water, feeding to animals, economic reduction, and cremation or burning.

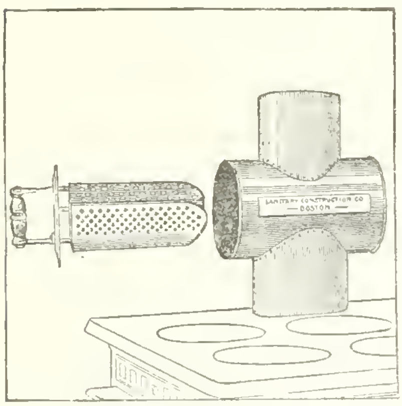

FIG. 3945.—Domestic Garbage Carbonizer as Applied to Kitchen Stove or Range.

The method which is practised in some households, of disposing of the garbage *by burning* it either in the kitchen range or stove, or in some appliance connected with the same, is both neat and cleanly, and avoids the foul odor which invariably attends the storage of such material in receptacles of any sort. Several appliances have been invented for the purpose of facilitating this method of disposal (see Fig. 3945).

The disposal of refuse *by dumping* at places designated for the purpose is the most objectionable, and unsanitary of all methods so far as organic or putrescible refuse is concerned, since it is sure to give rise to foul odors, and thus to become a source of complaint, even to persons living at a considerable distance. The habit of wild and domestic animals, of visiting such places and scattering the deposit, increases the nuisance. Frequent covering with earth in some degree obviates the trouble. Such disposal of ashes unmixed with organic matter, however, is not objectionable, nor is their use for the filling of waste lands to be condemned. This method, usually called "tipping" in England, is acknowledged, however, to be extremely unsatisfactory. Over eight hundred local authorities in England and Wales alone, each with a population exceeding two thousand, still either tip their refuse or dispose of it in some other equally primitive manner.[2]

With reference to the economy of using coal ashes for the purpose of filling waste land, the following quotation is worthy of note: "It is said that from the Manhattan and Bronx Boroughs, New York, there could be recovered one hundred and fifty thousand net tons annually of small coal, thrown away with ashes from domestic and other fires. What wasteful people the Americans must be if these figures are correct. Viewed in the light of modern practice in this country, such use for land development is quite astounding."[2]

Ploughing into the Land.—This method of disposal allows the garbage to be used as a fertilizer for growing crops, and is less objectionable than dumping. Chapin gives a list of eighteen cities where it is practised either as a whole or in part. In several other places it was once disposed of in this way until it became a nuisance, and was then abandoned.

Depositing in Water, either Salt or Fresh.—Several cities situated either upon the sea coast or near great rivers or lakes find it convenient to deposit garbage directly into the water, either directly from a wharf or by towing it to a distance in scows or other vessels designed especially for such work. Coal ashes and other heavy material thus treated sink to the bottom, but light material floats upon the surface, and while this method may be satisfactory to the city which adopts it, other places may find it a source of annoyance when favoring winds, tides, or currents deposit the floating matter upon their shores.

Feeding to Animals.—While this is perhaps the most economical mode of getting rid of the waste food products of a community, it is open to serious objections in consequence of the liability to cause a nuisance wheresoever large numbers of swine are kept for this purpose, and because of its liability to produce disease in such animals. The feeding of city offal to milch cows is forbidden by law in some States, and should not be permitted except in such institutions as require the very careful selection and separation of bread and vegetables from the waste food immediately after it is received from the tables, and the use of the same before decomposition has begun. In the neighborhood of many large cities, piggeries exist having one thousand animals and more in each, to which the foul and offensive offal of cities is conveyed for feeding such animals. This process cannot be conducted without causing a nuisance to neighboring communities. So urgent has this matter become in the metropolitan district of Boston as to induce one large raiser of hogs to purchase a tract of unoccupied land in a neighboring State, where he proposes to feed ten thousand to fifteen thousand hogs, and to transport thither by rail the garbage of a large part of the district.

Pork raised in this manner, however, is much more liable to become infected with trichinæ than that which is produced by feeding good and wholesome food.

Cremation.—When the question of expense is not considered, burning by fire is undoubtedly the most satisfactory mode of refuse disposal. Great Britain is the principal country where this process is employed more than any other. Goodrich enumerates one hundred and twelve cities in which the refuse is treated by destruction by fire (all in England and Scotland). The material, however, which is sent to the crematory, differs essentially from that which is so treated in America, since in England the ashes (mostly of soft coal) are quite generally mixed with other refuse, and burned in the destructors. The product of such destruction is an ash or cinder, which may be used for making roads or walks, and to some extent for building construction. There is also added in some cities the material from the pail closet system, where this plan of disposal still exists. This primitive system is rapidly diminishing in its extent, and giving way to the introduction of water-carried sewage in all large cities. In some places, as at Ealing, the sewage sludge from precipitation works is burned in the destructor. In Manchester, England, the dried excreta from the pail closets

sell for £3 per ton. At Liverpool the bulk of the refuse is sent to sea in steam barges, each carrying four hundred and fifty tons at a load. The deposit of this material causes complaint along the Welsh coast. It is rare to find in the reports of any of the English cities instances in which the destructors are of sufficient capacity to deal
www.libtool.com.cn

second fire pass downward and underneath the grate, and are finally discharged through the chimney. By this second fire the liquids which drop through the grates from the garbage upon the hearth are also evaporated.

The general features of the Dixon furnace do not differ essentially from those of the Engle, but the Smith de-

with the entire refuse of the city. The following list shows the disposal of the refuse of Birmingham for 1897:

	Tons.
Refuse sent to the tips, principally barged	34,703
Refuse dealt with by destructor	96,309
Mixed manure, ashpit manure, fish, sweepings sent to tips by boat, to fields by cart, or sent away by rail	74,855
Brickbats sent to tips	416
Material sold:—	
Oyster shells	15
Glass	19
Scrap tin	296
	206,613

In consequence of the location of English destructors in or near the populous parts of large cities much attention has been given to the subject of avoiding the nuisance arising from foul odors. This has been accomplished by the use of tall chimneys, high temperatures for combustion, and by the provision of secondary fires.

At present much attention is being given in England to the secondary use of refuse, that of steam raising for the purpose of generating electricity, sewage and water pumping, and other purposes.

The principal types of destructors employed in England are the Fryer, Horsfall, Warner, and Meldrum, while in America preference is given to the Engle, the Dixon, and the Smith.

The Engle consists of a brick furnace with chimney at one end, seventy-five to one hundred feet high. Several circular openings are made upon the top of the furnace, one being large enough to admit the carcass of a large animal. Driveways lead to the platform upon the top, the whole being enclosed in a covering house of brick or iron. On one side of the furnace there are doors for fuel, and another set of doors below them for removal of ashes. Between these two sets of doors are placed the grate bars upon which the refuse is dumped through the openings in the top. At each end of the furnace a fire box is placed. Below the garbage grates is a long combustion flue connecting with the base of the chimney, and controlled by a damper. A similar damper governs the admission of heat from above. (Fig. 3946.)

When the furnace is charged with a quantity of garbage, the flames from the firebox near the chimney (the upper damper being closed) pass over and through the refuse, driving the smoke and gases into and across the second fire where they are consumed. The flames of this

structor is constructed on an entirely different plan from either. It consists of two sets of furnaces to which gas is supplied as fuel from a generating apparatus. Each furnace is a simple pot or tank lined with fire brick. There are no grates, the garbage resting upon the bottom. The gas is made to pass into the furnace, which is charged with refuse, the gases of combustion then pass on to the empty furnace of the pair, and thence to the flue leading to the chimney. This flue is filled with open brickwork, which being heated to a white heat burns the resulting gases, and deprives them of foul odor. When the charge is consumed, the process is reversed, the empty furnace being filled and the gases passed in the opposite direction, the same chimney being used in each instance.

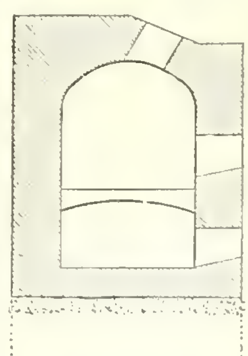

FIG. 3947.—Cross Section showing Location of Charging Door, Stoke and Ash-doors.

Reduction.—The refuse of cities contains a considerable proportion of material which is utilizable. Hence various processes have been devised by which this material may be recovered and sold. The valuable portions are the fat or grease, the nitrogen, phosphate and potash, these latter ingredients being useful for conversion into fertilizers. Colonel Waring, under whose supervision the collection of refuse was efficiently carried on in New York, estimated the average composition of 3,000 tons of summer garbage as follows:

	Pounds.	Per cent.
Rubbish	140	7
Water	1,420	71
Grease	40	2
Tankage	400	20
	2,000	100

The tankage of one ton contained about 13 lbs. ammonia, 13 lbs. phosphoric acid, and 3 lbs. potash; if these

Digitized by Microsoft®

Refuse Disposal.

ingredients could be utilized, garbage would be worth according to Waring $2.47 per ton.

The following estimates are made of the amount, in pounds, of garbage collected per capita annually in large cities:

www.libtool.com.cn

Boston	247
Buffalo	137
Milwaukee	205
New York	147
Paterson	80
Philadelphia	321
St. Louis	223

Dr. Chapin makes the following just comment upon the foregoing figures: "If the above average be correct, millions of tons must be collected annually from our large cities, worth double that number of millions of dollars. It is not to be wondered that energetic efforts have been made to save this waste."

From Waring's figures it appears that more than seventy per cent. of the garbage consists of water, which must be removed before salable products are obtained. Hence the practice in some cities of allowing the garbage to drain before it is treated, either by reduction or cremation. In Ealing near London, the garbage, ashes, and sludge from the town sewage works are stacked in pens for some time before treatment, by which means the mass is deprived of much of its water.

The following brief description relates to one of the more common methods employed for the reduction of

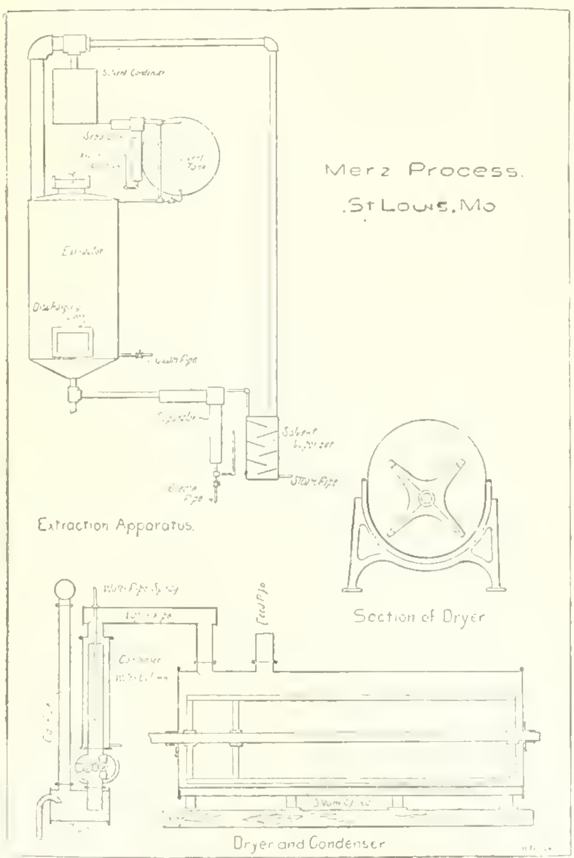

FIG. 3948.—Merz Reduction Apparatus. (From "Report of Brooklyn Health Department," 1896.)

garbage the Merz process: When first received at the works, the garbage is put into a steel hopper and the superfluous water is allowed to drain into the sewer. The rags, bones, tin cans, etc., are then selected out and sold, and the garbage is put into the dryers, which consist of jacketed cylinders with revolving shafts and arms sto stir the garbage while drying. Each dryer holds about three tons. The dark-brown product is then put into the extractors, which consist of closed tanks with false bottoms. Naphtha percolates through the mass to extract the grease. The grease in solution is drawn off, the naphtha separated from it and the grease barrelled for sale. This grease is of a brownish color and of inferior quality. The dry residue after separation of the grease is ground, and sold to fertilizer manufacturers. The Simonin process, like the Merz process, extracts the grease from the garbage by the use of naphtha. It has this advantage over the Merz process, in that the garbage can be at once placed in the extractors without previous drying. It was carried on at Providence and at New Orleans, but was abandoned at both places. This method is now conducted at Cincinnati, but the advance in the price of naphtha has made it unprofitable.

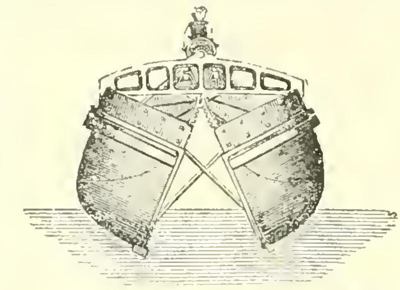

FIG. 3949.—Barney Dumping-Boat, after Discharging at Sea.

Chapin believes that this method can be successfully conducted with a moderate degree of profit, even without the payment of a bonus; but that this can be done only in a city where the garbage is very carefully separated.[1]

Another process, known as the Arnold process, is conducted at Boston, New York, and Philadelphia. It consists in rendering the garbage to recover the grease and drying the residue to be used as a fertilizer. Little attempt is made to prevent odors arising from the process. It is evidently considered by the operators to be cheaper, not to try to prevent nuisance, but to seek a location where the nuisance will affect only a few persons.

The cost of collection and disposal of garbage varies greatly in different cities, from a minimum of about 60 cents per ton to a maximum of $3.40 per ton, and from a minimum of 10 cents per capita to about 30 cents or more per capita.

Dry Refuse.—Dry refuse in many cities includes ashes and all the rubbish which accumulates in private homes and in stores, markets, etc. Manufacturing wastes are not usually removed by municipal collection. At the present day it is quite customary to require that three receptacles be provided, by the householder—one for ashes, one for garbage, and one for paper and other light refuse. The receptacles should be made of galvanized iron or other metal.

Usually dry refuse is disposed of by using it as a filling for lowlands, the owners of which are glad to have it disposed of in this manner.

In a few instances a small revenue of 10 to 15 cents per load has been received from the sale of ashes.

Experiments made in New York showed that the average ash of that city contains twenty per cent. of unburned coal, but probably some of this is finely divided and cannot be recovered with ordinary sifting processes. In some cities situated upon the seacoast and upon large rivers, the dry refuse is dumped into the water. In Boston the Barney dumping-boat is used, the material being dumped in the water at a distance of at least ten miles from the city on the ebb tide. On arriving at the point of disposal the two halves of the boat are separated by means of a hinge motion, very much like that of a clam shell. The towboat is started forward and the dumping boat is rapidly flushed out by the swiftly running water, and the two halves are brought together again. The boat is provided with water-tight compartments (see Fig. 3949).

FIG. 3950.—Unloading Garbage into Scow at Wharf.

In Boston and New York attempts are made to utilize a portion of the material found in dry refuse. The plant for this purpose at Boston consists of a large room in which the wagons deposit their loads.

A long travelling apron, four feet wide, runs from the front of this room, through it into the furnace-room, where it discharges into the furnace. The power for moving the apron, for baling, and for furnishing light is obtained from the furnace. The persons who cull out the paper, rags, metal, glass, rubber, etc., and sort and prepare it for sale, stand at the sides of the moving apron. About eighty per cent. of this refuse is marketable, and the value of the daily collection is about $60.

The following are the prices obtained for the principal marketable portions of this dry refuse:[4]

Manilla paper	$0.50	per 100 pounds.
Newspapers	.35	" 100 "
Mixed paper	.25	" 100 "
Straw board paper	.25	" 100 "
Black rags	.30	" 100 "
White rags	1.50	" 100 "
Mixed rags	.90	" 100 "
Woollen rags	7.00	" 100 "
Soft-back carpets	.90	" 100 "
Hard-back carpets	.30	" 100 "
Linsey carpets	.65	" 100 "
Twine	.11	" 100 "
Old shoes, good	.12	" 100 "
Old shoes, poor	.11	" 100 "
Bagging	.40	" 100 "
Mixed bottles	.45	per barrel.
Old iron	9.00	per ton.
Copper	.11	per pound.
Brass	.10	" "
Lead	.04	" "
Zinc	.10	" "

In New York (Manhattan district) the amount of rubbish collected and disposed of in a similar manner in 1898 was 94,000 tons, and for this the sum of $63,500 was obtained.

Mixed Refuse.—In some cities the garbage and dry refuse are collected and disposed of together. This was for many years the plan adopted in New York, and is still in use in several quite large cities. When thus collected the garbage, ashes, and dry refuse are mixed together in the receptacles, which are usually of metal and are provided with covers, but quite often nothing better than ordinary barrels and boxes are employed. Regulations provide for the location of the full receptacles either on the sidewalk or upon the householder's premises. Provision is also made for regular hours and frequency of collection. Disposal is usually

FIG. 3951.—Night-Soil Barrel, Used in Connection with Odorless Excavation Apparatus. (From Chapin's "Municipal Sanitation.")

Digitized by Microsoft®

made by dumping either upon lowlands or into water. The former usually creates more or less nuisance, but is tolerated because of its economy. In San Francisco the mixed refuse is cremated. In Troy a portion only (the most offensive part) is cremated, while in a few Southern cities parts of the garbage and dry refuse are burned in the open air at the dump.

www.libtool.com.cn

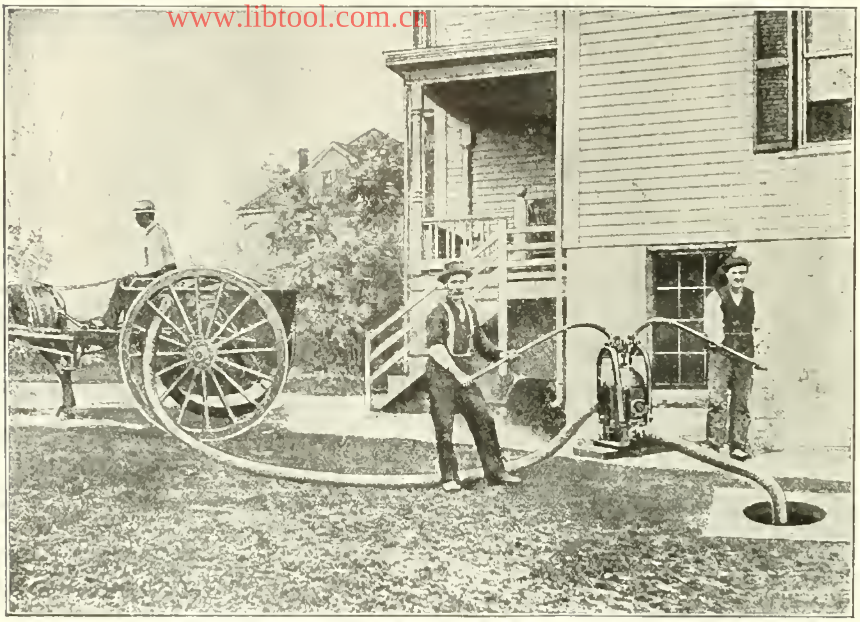

FIG. 3952.—Odorless Excavating Apparatus in Operation.

Night Soil.—By this term is meant the liquid or semi-liquid contents of privy vaults and cesspools, derived from the household wastes of the water-closets, bath-tubs, and other fixtures, including that of the kitchen sink. The latter often proves troublesome in consequence of its greasy character and its liability to clog the traps and pipes through which it flows.

On account of the liability to cause nuisance in the performance of this work it is customary to require that the scavengers, or other persons who conduct it, shall be licensed and placed under careful supervision.

It is customary to require the use of tight receptacles for the removal of night soil, either barrels or tubs provided with handles and tight-fitting covers. (Fig. 3951.) Boxes or movable tanks are also employed. The so-called pneumatic odorless pumps are well adapted for this class of work. (Fig. 3952.) Tubs and barrels are conveniently handled, ten or twelve of such receptacles usually constituting a load.

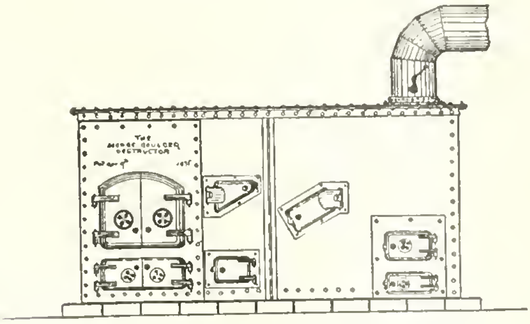

FIG. 3953.—Garbage Destructor for Use in Public Institutions, Factories, etc.

It was formerly customary to remove such material only at night, but this practice is gradually being substituted by removal in the daytime, when with improved apparatus it is practicable to do the work in a more cleanly manner.

Disposal.—In some cities the night soil is taken to suburban districts and there used upon farms as a fertilizer, a practice liable to cause nuisance to the neighborhood, if thus disposed of in the vicinity of dwellings. In some places it is dumped into water, either a large river, lake, or the ocean. In a few English cities where the pail system of excrement removal is still in use, the contents of the pails are taken to the crematory and burned together with other sorts of refuse.

The Refuse-disposal of Public Institutions and Other Establishments.—Special destructors are now made of smaller size than those in use by cities, for the destruction of the waste products of public institutions, hotels, department stores, factories, medical colleges, and other isolated establishments. Such forms of apparatus (Fig. 3953) are specially adapted to the destruction of infected bedding, clothing, rags, and other infected material which is not worth the trouble and expense of saving by any process of disinfection.

REGENERATION.—Regeneration is the process which leads to the replacement of lost tissue. The term is applied equally to the reproduction of cells to take the place of those cast off under normal physiological conditions on the one hand, and to the repair of tissue destroyed by lesion on the other. In both cases the process is essentially the same. The new tissue is formed by the proliferation of cells in the immediate neighborhood of the area from which the cells have been cast off or destroyed. Moreover, the new tissue is derived from remaining tissue of like kind, connective tissue from connective tissue, epithelium from epithelium. Where reproduction of epithelial tissue does not take place, or where the reproduction is incomplete, the defect, it is true, is filled with connective tissue forming a scar; but this scar tissue is derived from the connective tissue around the defect, and not from the epithelium. Physiological regeneration goes on continuously to supply tissue waste; regeneration after lesion occurs in the healing of wounds, in the restoration of the mucosa after catarrh, and in similar processes.

There are two methods of multiplication of cells, direct division or amitosis, and indirect cell division or karyokinesis, mitosis or karyomitosis. In the former of these two methods the mother cell simply increases in size and

Digitized by Microsoft ®

Regeneration.

finally divides into two daughter cells after a division of the nucleus. In karyokinesis the process is more complicated, consisting as it does of a cycle of definite changes in the chromatin of the nucleus preceding the division. Direct division or amitosis is said by some authorities to take place only in cells which are no longer capable of forming new tissue, whereas mitosis occurs in active vigorous cells which form new tissue. Other authorities, on the contrary, regard the two processes as of equal significance.

www.libtool.com.cn

The power of reproduction differs in different tissues. Surface epithelium and epithelium lining glands are capable of regeneration to a very large extent, as are also nerve fibres and many of the other tissues of the connective-tissue group generally. Of the latter, the periosteum is capable of the greatest degree of regeneration, whereas cartilage has only a limited power of regeneration. Ganglion cells once destroyed are probably never replaced by ganglion cells in the adult, and glandular epithelium is completely restored only where the defect is slight and where some of the original cells remain uninjured in the area of the lesion.

Regeneration of Epithelium.—In regeneration of epithelium the protoplasm of the cell divides in the later stages of karyokinesis, or after this is complete. In some cases the cell sends out processes of protoplasm, and the new nuclei wander out from the parent cell into these before the protoplasm is constricted off to form the new cell.

In a lesion of an epithelial surface, where the area destroyed is not too great in extent, the epithelial cells proliferating from all sides completely repair the defect; if it is more extensive, the defect is incompletely filled by connective tissue, thus forming a permanent scar. In the latter case, the connective tissue forming the scar results, as in all cases, from the proliferation of pre-existing connective tissue, not from proliferation of epithelium. Epithelium reproduces epithelium, never connective tissue, but it is also true that the character of epithelium reproduced is not always the same as that which is lost; for squamous epithelium may replace cylindrical epithelium, as is seen in atrophy of the mucosa of the bronchi and stomach in chronic inflammation of these surfaces.

Minor defects of epithelial surfaces, where underlying tissues are not destroyed, are quickly and completely restored by the proliferation of the surrounding epithelium. In recovery from acute Bright's disease, or in the healing of an ulcer of the stomach or intestines, the epithelium is often completely restored by the multiplication of the remaining mucous glands as well as by growth downward of the epithelium on the surface. Lesions of the liver are also completely restored by multiplication of the cells of the parenchyma and by the formation of new bile ducts.

Larger defects of epithelial tissue, particularly where the underlying structures are involved, result in a scar, with more or less incomplete reproduction of glands which are for the most part usually atypical.

Regeneration of Structures Consisting of Connective Tissue.—Defects of structures made up of connective tissue in any of its various forms may under favorable circumstances, as where the lesion is not too extensive, or in lesions of certain of the tissues of this group, even though they be extensive, be completely restored by the new formation of tissue identical in character with that originally present. Where the lesion is more extensive, particularly in one that occurs in certain of the connective-tissue structures, the defect is more or less filled up by connective tissue of a different type from that originally present. Connective-tissue structures such as the periosteum, bone marrow, blood and lymphadenoid tissue, are all readily restored completely after lesion. On the other hand, cartilage does not readily reform, and defects in this structure are replaced by ordinary scar tissue or by bone. New bone is formed not from pre-existing bone but from the remaining periosteum and from the bone marrow. Sometimes new bone is formed in other connective tissue, as in the intermuscular connective tissue and from the perichondrium. But muscle tissue is formed only from pre-existing muscle, never from connective tissue of any other kind. Ganglion cells are probably never restored after injury, defects in this tissue being replaced by scar tissue or by glia cells; but nerve trunks are readily restored, provided that the ganglion cells from which they spring are uninjured, for the regeneration is brought about by the growth of the axis-cylinder processes. The peripheral portion of a severed nerve always undergoes degeneration, it is never restored; all parts of it finally break down into granules and are dissolved away. The central portion of a severed nerve, on the contrary, undergoes degeneration for only a short distance from the end, back to the first or second Ranvier constriction from the end. In a few days after the occurrence of the lesion the axis cylinder in the central portion of the severed nerve begins active proliferation. At first the new axis cylinders are naked save for a layer of protoplasm rich in nuclei, but sooner or later the proper sheaths are reformed. If the degeneration of the peripheral segment of the severed nerve has not yet affected the Schwann's sheath, the new axis-cylinder processes may enter these and fill them out again. The regeneration of nerves takes weeks or months for completion.

In regeneration of connective tissue, as in reconstruction of other tissues, the proliferating cells are always much larger than the cells at rest. The proliferating cells, or formative cells as they are also called, not only possess a relatively large amount of protoplasm, but the nuclei are large and vesicular and contain nuclear bodies, many of them showing, by proper methods of hardening and staining, the various stages of karyokinesis. Frequently the formative cells contain more than one nucleus, sometimes even a large number of nuclei, forming giant cells (Fig. 3954, *i*). The tissue made up of these

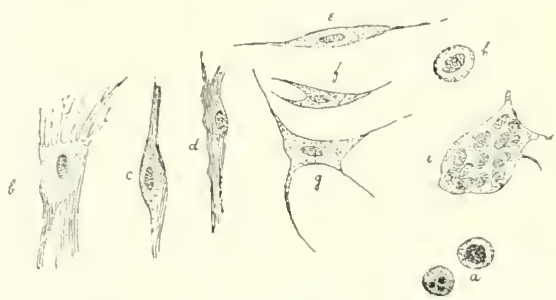

FIG. 3954.—Cells met with in New Formation of Connective Tissue. (After Ziegler.)

formative cells is appropriately called embryonic tissue, and the character of the permanent tissue arising from the development of the embryonic tissue is determined by the nature of the embryonic cells. If the formative cells are destined to form scar tissue they are called fibroblasts; if they are to form cartilage they are called chondroblasts; if bone, osteoblasts.

The formative cells are of many different shapes; some are large, round, or oval masses of protoplasm (Fig. 3954, *h*), others spindle-shaped (Fig. 3954, *e*), others roughly star-shaped (Fig. 3954, *g*), others irregular with long processes (Fig. 3954, *c*, *d*, *f*), or bundles of fibres at the ends as if the protoplasm were frayed out (Fig. 3954, *b*).

If fibrillated connective tissue develops from the embryonic tissue, fibres make their appearance between the formative cells, and by continuous increase they encroach more and more upon the latter till the formative cells finally lie compressed in fissures between the densely packed fibres.

Cartilage develops by the formation of a homogeneous intercellular substance instead of fibres, but the formative cells are encroached upon and compressed just as in the case of ordinary fibrillar connective tissue. The

Digitized by Microsoft®

formative cells become much reduced in size, and finally lie in the characteristic openings in the homogeneous intercellular substance.

The process of new formation of bone is similar to the new formation of cartilage; the lime salts are finally deposited in the intercellular substance.

Mucous, lymphadenoid, and fatty tissues may all arise from embryonic connective tissue.

www.libtool.com.cn

Fibrillated connective tissue may arise from any form of connective tissue that has suffered lesion, and has been converted into embryonic tissue.

From what has been said, it is evident that the stage which is preliminary to the new formation of permanent tissue after lesion is characterized by the appearance of embryonic tissue. The further development of this embryonic tissue is not the same in all cases; in some instances there is perfect reproduction of tissue in all respects like the original, or *restitutio ad integrum*. In many cases the restitution is only partial; in others again there is replacement of the original structure by connective tissue of a different type from the original. The replacement of the original structure by connective tissue of a different type from the original may occur in any kind of connective tissue, and is in truth a very common occurrence, constituting the formation of a scar, where the original structure is replaced by dense fibrous connective tissue, whose only function is to fill a gap. Where the original structure is endowed with any special function, the scar tissue is incapable of taking on this function. If, for example, the scar tissue is formed to fill up a defect caused by a lesion in a muscle, the scar tissue serves only to unite the divided ends of the muscle fibres, but is not itself capable of contraction. Scar tissue formed in the brain, in the liver, in the kidney, in the spleen, or in the lung does not perform the peculiar function of the tissues of these organs. The substitution of connective tissue of lower functional power than that originally present constitutes a form of degeneration, and is met with in cirrhosis of the liver and other organs. But although these processes are spoken of as degeneration, it would perhaps be more correct to regard them as hypertrophies of the connective tissue, for this is what they are in fact.

Regeneration of the formed elements of the blood does not differ essentially from regeneration of the other connective tissues. The leucocytes are reproduced in the lymphadenoid tissue in various parts of the body as well as in the circulating blood, as is shown by the fact that white corpuscles showing karyokinetic figures are met with abundantly in these situations. Direct nuclear division and fragmentation also occur, as is shown in the lobed and disrupted nuclei of the polymorphic nuclear leucocytes.

New Formation of Blood-Vessels.—A very important factor in regeneration is the new formation of blood-vessels.

FIG. 3955.—New Formation of Blood-Vessels. (After Tillman.)

These are formed by sprouts arising from the vessels beneath the injured area. Each sprout is at first a solid arch, in reality a long cone or horn, of protoplasm projecting from the wall of the vessel (Fig. 3955, *a*) terminating in a long-pointed process. The solid arch may even send out several long processes (Fig. 3955, *b*, *c*). Sooner or later the solid arch becomes hollowed out by liquefaction of the interior, forming a cavity which finally opens into the parent vessel, or the arch may be hollow from the start and consist merely of a bulging of the wall of the parent vessel (Fig. 3955, *c*). In either case the arch next becomes a tube by the pressure of blood flowing in from the parent vessel, and this also causes the long processes to split and form hollow, conical tubes. Meanwhile nuclei formed by karyokinesis of the cells of the endothelium of the parent vessel wander into the walls of the hollow tube and convert it in this way into a capillary. The capillaries produced in this way have walls consisting of flat endothelial cells, but these cells are frequently quite thick; and when this is the case, the new-formed capillary resembles a tubular gland on cross section. The long, slender processes from the arches unite freely with the similar processes from other vessels (Fig. 3955, *b*) and even directly with the walls of other vessels, or they may unite with the parent vessel at a different point from the origin (Fig. 3955, *c*). In this way abundant anastomosis between the vessels is formed.

This is not the only origin of the new capillaries, for certain cells which at first have no connection with blood-vessels also take part in the process. These cells are spindle- or club-shaped masses of protoplasm which lie free in the tissue at first, but later become united with the long processes from the arches (Fig. 3955, *b*). After they become united with the processes from the arches they become perforated by a central canal and finally assume the character of capillaries.

Many of these new-formed capillaries subsequently change to arteries and veins by thickening of their wall through proliferation of the cells of the walls. The different coats finally become differentiated.

The account here given of the new formation of blood-vessels is that given by Ziegler, and is the one that has found universal acceptance. But some authorities claim that the blood-vessels are also formed in other ways. They maintain that the cells that wander into the area of the lesion unite to form capillary vessels, and that they also form new red blood corpuscles in a manner similar to the formation of vessels and blood in embryonic tissue. This method of new formation is not recognized by Ziegler in pathological regeneration.

Another process of new formation of blood-vessels claimed by some authorities is that certain spindle-shaped cells form in parallel rows, leaving a canal between them. Vessels apparently formed in this way may be seen in organizing blood clot, but Ziegler regards these as really deceptive offshoots from pre-existing blood-vessels.

B. Meade Bolton.

REGISTRATION OF DISEASES. See *Vital Statistics.*

RELAPSING FEVER.—(Synonyms: Febris recidiva; typhus recurrens; famine fever; bilious typhoid; spirillum fever; epidemic remittent fever; remitting icteric fever; fièvre à rechute; fièvre récurrente; typhus à rechute; Hungerpest; Rückfallsfieber; Wiederkehrendes Fieber; Armentyphus; tifo recidivo, etc.)

DEFINITION.—A specific, contagious fever, which may prevail as an epidemic among the destitute, and especially among those who live in overcrowded tenements, during seasons of unusual scarcity of food; hence the name famine fever. It is characterized by the presence of a mobile spiral filament in the blood—a spirillum or spirochæte (*S. Obermeieri*)—which is found during the relapses as well as during the initial paroxysm, but is absent during the apyretic intervals. The first febrile paroxysm lasts for from five to seven, or even nine days, and is terminated abruptly in profuse perspiration; after an apyretic interval of a week or more a relapse commonly occurs, which is similar to the initial paroxysm, but of shorter duration; in some instances a second, a third, or even a fourth relapse occurs.

Digitized by Microsoft®

HISTORY.—The attempt has been made (Spittal, 1844) to show that some of the fevers described by Hippocrates correspond with relapsing fever. This view is considered by Hirsch to be quite erroneous. He says: "It is clear that Hippocrates speaks there of bilious remittent malarial fever." The first notice of the occurrence of relapsing fever in Europe is found in the writings of the Scotch and Irish physicians of the early part of the eighteenth century. Hirsch says: "I have searched in vain, in the descriptions which the physicians of the sixteenth and seventeenth centuries have given of the fever epidemics observed by them, for any indications of relapsing fever that would be in some measure precise." The fact that the disease was not recognized, and differentiated from other specific febrile affections, cannot, however, be taken as evidence that it did not exist prior to the date of the first clearly recorded epidemic in Ireland (1739). An account of this epidemic has been given by Rutty, who wrote in 1770. The earliest accounts of the disease in Scotland date from 1741 (Hirsch). But the literature relating to relapsing fever belongs for the most part to the past century. It prevailed in Ireland and in Scotland during the years 1799–1800, 1817–19, 1826–27, 1842–48, and in the latter year (1848) it invaded several of the larger towns of England. In 1868–70 it again prevailed in England and Scotland, and cases are reported to have occurred in London as recently as the year 1873. On the Continent the first accounts we have come from Russia—Odessa, in 1833; Moscow, 1840–41. In the autumn of 1863 the disease reappeared in Odessa; the following year it became epidemic over extensive areas in Russia, and extended to Livonia and Finland (1865), to Siberia (1866), and to Poland (1868). According to Hirsch, the disease continued to prevail in Russia over extensive areas during subsequent years, and was observed among the Russian troops as late as 1878–79. In Germany an extensive epidemic broke out in 1868, as a result of importation from Russia (Hirsch). A second, more restricted, epidemic occurred in 1871–72, and a third in 1878–79. In the west and southwest of Europe—Switzerland, France, Italy, Spain—the disease is as yet unknown. In India relapsing fever has, no doubt, prevailed for many years, but the differential diagnosis between it and remittent fever, or the specific continued fevers which prevail there so largely, was not clearly made out by the earlier observers. During the last forty years, however, numerous outbreaks of this disease in various parts of India have been recorded, and Carter has demonstrated that the disease, as it occurs in that country, is identical, as regards its clinical history, with relapsing fever as described by recent European authorities, and also that it is characterized by the constant presence of the spirillum discovered by Obermeier in blood drawn during a febrile paroxysm. Relapsing fever has several times been imported to the United States, but its prevalence has been limited to restricted areas in our largest seaport cities. In 1844 fifteen cases were received into the Philadelphia Hospital from an emigrant ship sailing from Liverpool; in 1848 a few cases arrived in New York, and in 1850–51 Dr. Austin Flint saw a number of cases, among recently arrived Irish emigrants, received into the Buffalo City Hospital; but no epidemic resulted from these importations, and it was not until some years later (1869–70) that the disease became epidemic in certain sections of the cities of New York and Philadelphia. Parry, who made a careful investigation with reference to the origin of the first cases in Philadelphia, was unable to trace it to importation; but this can scarcely be questioned in view of what is known of the history and etiology of the disease, and in consideration of the fact that Philadelphia is a seaport city which has constant communication with ports on the other side of the Atlantic which at that time were known to be infected. Parry and Pepper have given us admirable accounts of this epidemic in Philadelphia. We quote from a recent article by the last-named author the following statement, relating to its progress and extent: "In Philadelphia, of 1,176 cases in which the date of occurrence is known, there occurred in September (1869), 4 cases; December, 6 cases; January (1870), 5 cases; February, 13 cases; March, 124 cases; April, 209 cases; May, 325 cases; June, 293 cases; July, 115 cases; August, 19 cases; September, 28 cases; October, 15 cases; November, 1 case; December, 2 cases; January (1871), 2 cases; February, 1 case; March, 2 cases; May, 7 cases; June, 2 cases; September, 7 cases; October, 2 cases.

The coincidence of relapsing fever and typhus has been noted in many of the epidemics which have occurred in Europe, but the history of this coincidence does not justify the supposition that there is any etiological relation between these diseases other than that furnished by common predisposing causes, viz., the depressing effects of overcrowding, insufficient food, and filthy surroundings. This view is supported by the fact that either disease may occur alone, and by the circumstance that sometimes one and sometimes the other has the precedence in time in those epidemics in which coincidence has been observed.

FIG. 3956.—Spirilla of Relapsing Fever. (After Soudakewitsch, *Annales de l'Institut Pasteur*, vol. v., 1890.)

ETIOLOGY.—The discovery by Obermeier, in 1873, of a minute vegetable parasite—*Spirochæte Obermeieri*—in the blood of patients suffering from relapsing fever, and the subsequent demonstration, by numerous observers in various parts of the world, that this micro-organism is constantly present in the blood of relapsing-fever patients during the febrile paroxysms, has thrown a flood of light upon the etiology of this disease, and is one of the most significant facts with reference to the etiology of the infectious diseases in general which have been brought to light by modern microscopical researches. Conservatism suggests the possibility that the parasite may be simply an accompaniment of the disease, and not directly concerned in its etiology as the essential and specific cause. This hypothesis seems to us to be hardly tenable in view of what is now known of the pathogenic action of certain other micro-parasites of the same class, and of the following facts: (*a*) The parasite is constantly present in the blood during the febrile paroxysms, and in smaller numbers during the latter part of the period of incubation, and is absent during the apyretic intervals. (*b*) This parasitic organism is peculiar to the disease under consideration, *i.e.*, repeated researches by competent microscopists have failed to demonstrate the presence of a similar organism in any other disease. (*c*) The parasite is present in the blood in such numbers that its pathogenic power can scarcely be questioned. Carter says: "During specific fever several organisms (*e.g.*, five to ten) are visible in the field at one time; not seldom they are too numerous to count, and occasionally they are present in swarms, being apparently nearly half as common as the red discs themselves." (*d*) The disease may be communicated to man (Motschutkoffsky) and to the monkey (experiments of Koch and of Carter) by inoculations with blood containing the spirillum, and the parasite is found in great numbers in the blood of the inoculated individuals during the febrile paroxysm which results—after an incubation period of three or four days (Carter)—from such inoculations. The morphology of the relapsing fever "germ" is shown in Fig. 3956. The spiral filaments are exceedingly slender, their diameter being not more than 1 μ (0.001 mm., Lebert), or, according to Carter, $\frac{1}{50000}$ to $\frac{1}{40000}$ of an inch. The length varies from two to six times the diameter of a red blood disc (Carter). The motion of these spiral filaments, in blood recently drawn, is very lively, "rotary, twisting, and rapidly progressive, but soon ceases under the ordinary condi-

Digitized by Microsoft®

tions of microscopic examination" (Lebert). According to Carter, the movements may continue for from a few hours to one or two days or longer.

A good objective and a certain amount of skill in the use of the microscope are required for the detection of the spirillum in fresh blood. This is shown by the fact that Obermeier himself failed to recognize the presence of the parasite in the microscopic researches made by him some years prior to the date of his discovery; and by the failure reported by some of those who have since attempted to verify his observations. Carter says: "That, as regards the examination of fresh blood, obstacles do exist, is proved by the fact of the organism being originally found only after long-repeated scrutinies; and at Bombay I have met with observers, not unaccustomed to the use of the microscope, who could never clearly see the filaments." The demonstration is more readily made when a thin film of dried blood attached to a cover-glass is stained, *secundum artem*, with one of the aniline colors—an aqueous solution of methyl violet, or of Bismarck brown, or fuchsin.

It is not yet certain whether the spirillum of relapsing fever is reproduced by spores as well as by "spontaneous fission," but it seems extremely probable that this is the case. Carter supposes that certain short filaments which he has observed in the blood are germinating spores, and remarks that "the practical facts of contagion require the presence of fertile spores, since spiral filaments are absent in the *secreta* and *excreta* of the body, and propagation by blood inoculation is obviously not the rule in common life." The same author gives several instances in which an attack is supposed to have been due to accidental inoculation while making an autopsy. Other cases are ascribed to simple contact with the dead body, independently of any wound. That the disease may be transmitted from individual to individual by direct contagion, or indirectly through fomites, is demonstrated by a multitude of observations; and, indeed, we have no satisfactory evidence that it is transmitted in any other way, or that the specific infective agent—spirillum—is capable of multiplication in an external nidus, and thus of giving rise to an epidemic independently of direct contagion, as is undoubtedly the case in certain other diseases, *e. g.*, typhoid fever, cholera, yellow fever. On the other hand, the evidence on record shows that in well-ventilated apartments and hospital wards the attendants upon the sick and patients suffering from other diseases are not very liable to contract the disease. Where, however, the sick are massed together in insufficiently ventilated hospitals, or when cases occur in the overcrowded tenements of the poor, the transmission of the disease to attendants and others exposed to contagion is far more frequent.

Up to the present time attempts to reproduce the spirillum of relapsing fever in a series of *cultures* have not been successful. Carter has, however, observed a growth of the spirilia in length, and the development of a tangled network of long filaments in a culture cell containing aqueous humor, kept in a warm chamber at a temperature of 40.5° C. (105° F.).

PREDISPOSING CAUSES.—There is no evidence that *climate* or *season* has any marked influence upon the prevalence of relapsing fever; the disease has prevailed in Siberia as well as in India, and its preference for certain localities is quite independent of climatic conditions, relating rather to circumstances connected with the mode of life and hygienic surroundings of the population. No *age* is exempt, and *sex* has no apparent influence; but children are more subject to be attacked than adults, and susceptibility seems to diminish to some extent with advancing age. According to Murchison, only 195 out of 2,111 cases received into the London Fever Hospital, in twenty-three years, were over fifty years of age. To appreciate the value of these figures it would evidently be necessary to know how large a proportion of the exposed population were over fifty years of age.

Insufficient food is generally recognized by medical writers as a potent predisposing cause, and epidemics have so frequently been observed to coincide with periods of unusual scarcity that the name "famine fever" has been applied to the disease. Some authors have even gone so far as to ascribe to starvation and its accompaniments, overcrowding and filthy surroundings, an essential rôle in the development of the disease. But, as in the case of other specific contagious diseases, there seems to be very little foundation for the idea that relapsing fever may be developed *de novo* in times of famine, and its epidemic prevalence at such times is to be ascribed rather to increased vulnerability, on the part of the starving population, to the action of the specific exciting cause of the disease. We know that under favorable hygienic conditions the disease has but little disposition to spread, and that in the severest epidemics it finds its victims almost exclusively among the destitute. On the other hand, in the numerous instances in which shipwrecked mariners, Arctic explorers, etc., have been subjected to absolute starvation, we have no account of the development of any such disease as relapsing fever. *Overcrowding* is considered by Parry to be a more potent predisposing cause than starvation, and his careful study of the circumstances of those who were taken sick during the prevalence of the disease in Philadelphia (1870) seems to justify this conclusion—which is, moreover, supported by the observations of Muirhead, Bennett, Lebert, and others.

One attack of relapsing fever does not protect the individual from subsequent attacks, and second, or even third, attacks during the same epidemic have been noted.

Carter's experiments upon the monkey have led him to the conclusion that "the human virus becomes intensified in its passage through this animal." It is noticeable that, with one or two exceptions, there was but a single febrile paroxysm in the numerous successful inoculation experiments made by the author quoted. This does not invalidate the value of the evidence furnished by his experiments as to the identity of the disease produced in the monkey with the specific infectious disease of man known as relapsing fever, for this single paroxysm was characteristic in its origin, duration, and termination, and in the constant presence of the blood parasite which is peculiar to this disease. Moreover, in man the relapse is not an essential feature of the disease. Thus Carter, out of a total of 411 cases, found that in 98 (23.8 per cent.) there was but a single febrile paroxysm. Pepper has recorded the fact that in 10 out of 181 cases observed in Philadelphia there was no relapse; and Murchison, in a series of 2,425 cases collected from various sources, found that there was but a single paroxysm in 30 per cent.

CLINICAL HISTORY.—As a rule, the primary febrile paroxysm begins abruptly, without noticeable *prodromes*. In certain cases, however, the patient experiences a certain amount of malaise, loss of appetite and headache, for a day or two prior to the sudden access of fever. The *period of incubation* has usually a duration of from five to seven days (five to nine days—Murchison), but instances of a longer or shorter incubation are not infrequent. In several cases of accidental inoculation, at autopsies, which came under the observation of Carter, the period of incubation was from three and a half to seven days; and in the successful inoculations in the monkey, made by the same author, the mean duration of this period was about ninety hours. Speaking of these experiments, the author referred to says: "My experiments showed conclusively that prior to the onset of the fever there always occurs a more or less prolonged period of visible blood contamination; and hence that the interval between infection and fever is divisible into two parts, viz., an earlier and usually longer non-spirillar stage, and a final stage of spirillar manifestation during which the body heat, so far from being augmented, is often rather depressed."

The *initial paroxysm* of fever is commonly inaugurated by a decided chill, or at least by slight chilly sensations, accompanied by headache, pain in the back and limbs, and a feeling of weakness, with indisposition to exertion.

Relapsing Fever.

The tongue is coated; nausea and vomiting are of common occurrence; and there is usually a certain amount of tenderness on pressure in the epigastric region. Enlargement of the spleen occurs early in the attack, and usually a certain amount of enlargement of the liver may also be detected after the second or third day. Jaundice is of frequent occurrence in certain epidemics, and in others is quite rare. The abrupt seizure usually occurs during the daytime, and is marked by a rapid rise of temperature and a correspondingly rapid pulse. The pyretic movement exhibits a somewhat remittent character, the evening temperature being one or two degrees higher than the morning temperature, and attaining a maximum of 103.5° to 105° F. during the first twenty-four hours—a maximum which may be exceeded by a degree or two during subsequent evening exacerbations. The distinctive character of the pyrexia is its sudden termination by crisis, as a rule on the fifth or seventh day—more rarely as early as the third or as late as the twelfth day. This sudden termination of the febrile paroxysm is commonly attended with profuse perspiration, and occasionally by a critical diarrhœa, or hemorrhage from the nose, rectum, or vagina. The temperature frequently falls, during this termination of the paroxysm by crisis, as much as 10° or 12° F. in a few hours, and, as a rule, a subnormal temperature is quickly reached, and may persist at the morning observation for two or three days. *Defervescence* may occur at any time during the twenty-four hours, but the observations of Carter indicate that in a majority of the cases (66.6 per cent.) it happens between the hours of 4 P.M. and 7 A.M., or in other words, that it is most likely to occur during the night. It is attended by a complete relief of the distressing symptoms which marked the febrile paroxysm, and with the exception of a feeling of lassitude the patient has nothing to complain of, his tongue cleans up, his appetite returns, and within three or four days he might be considered convalescent, were it not for the known tendency of the disease to relapse after an apyretic interval of about a week. In one hundred and ninety cases analyzed by Carter the mean duration of the *apyretic interval* was 7.4 days, the extreme range being from three to twelve days.

The *relapse*, occurring commonly on the fourteenth day from the date of seizure, resembles the initial paroxysm in its sudden onset and abrupt termination, but is usually of shorter duration—three to seven days. The temperature not infrequently attains a higher point than during the initial paroxysm, and there is a correspondingly rapid pulse, but with the exception of increased debility the other symptoms are, for the most part, of a milder character. Defervescence is attended with profuse perspiration, and, as in the first apyretic interval, a subnormal temperature is quickly reached. After a *second apyretic period*, of from six to fourteen days, a *second relapse* of still milder character and briefer duration may occur, and, in exceptional cases, this may be followed by a third or even a fourth relapse.

SPECIAL SYMPTOMS.—The characteristic features of the *pyrexia* are shown by the accompanying chart (Fig. 3957) of a case reported by Murchison, which, however, cannot be taken as entirely typical, inasmuch as the initial paroxysm and the relapse are of about the same duration, whereas the rule is that the relapse is not so protracted, and the date of its occurrence is more commonly the fourteenth rather than the twelfth day, as in this case. Variations from the typical form are, however, the rule rather than the exception, and the most we can say is that there is a tendency to crisis on the seventh day, and to relapse on the fourteenth day. The remittent character of the pyretic movement is often more marked than in this case, and especially so in the relapses. We remark, also, that the subnormal temperature which follows crisis and sudden defervescence is less marked than usual in this case, after the first febrile paroxysm, although shown very well in that part of the chart which represents the second apyretic interval. This is a very noticeable feature of the disease, although not peculiar to it, a subnormal temperature being quite common during the "calm stage" of yellow fever. We have the authority of Murchison for the statement that the temperature may fall as much as 14.4° in the course of twelve hours, reaching as low a point in certain cases as 94°, 93°, or even 92° F.

Pepper has observed a fall from 107.2° to 95°, and states that this is as low a point as is commonly reached. The observations of Carter, also, indicate that a fall below 95°, in non-fatal cases, must be extremely rare. The acme of temperature is commonly reached during the twenty-four hours immediately preceding the crisis, and in certain cases a sudden rise of several degrees has been noted to occur just before the abrupt fall which terminates a paroxysm. In a typical series of cases analyzed by Carter the maximum temperature observed during the initial paroxysm was 108°, on the evening of the sixth day; the maximum temperature noted during the relapse in the same series of cases was 106° F. Pepper has recorded a temperature of 107.5° as having come under his observation, and in a typical case, of which he gives a chart (*op. cit.*, p. 380), a temperature of 107° was reached at the termination of the initial paroxysm, and also during the relapse. In this chart a slight febrile movement is seen to follow the subnormal depression after the relapse. "Reactionary fever" of this kind, of moderate degree and irregular in its course, is commonly seen to follow the febrile paroxysm and subsequent subnormal depression of temperature in yellow fever. In relapsing fever it is not perhaps so common, but is sufficiently so to have attracted the notice of Carter, who speaks of it as the "rebound" or "secondary fever," and states that it was observed in about one out of six of his cases. "Its duration is brief, and the blood spirillum is invariably absent."

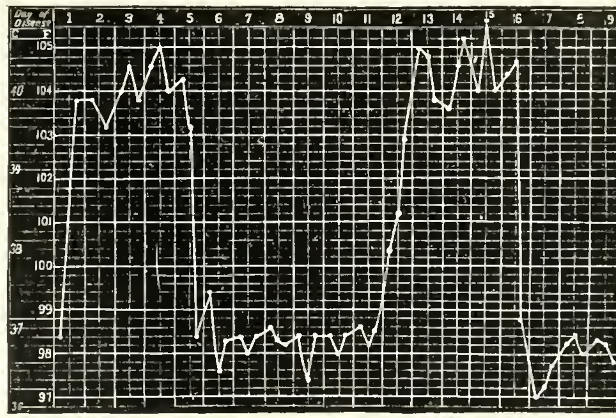

FIG. 3957.—Temperature Curve in a Case of Relapsing Fever.

The *pulse* in relapsing fever presents no distinctive character. During the pyretic movement it is very frequent, and at the outset is commonly full and tense; but with defervescence there is a rapid reduction in its frequency, and during the first portion of the apyretic intervals, when the temperature is subnormal and the patient is in a state of partial collapse, it becomes small and feeble, and occasionally extremely slow—as slow even as in the corresponding stage in cases of yellow fever. Thus, Obermeier has seen it as low as 44, and other observers have seen it even lower than this—Muirhead 34, Stillé 30. While, in general, the rapidity of the pulse corresponds with the pyretic movement, yet this is not an invariable rule, and according to Murchison is less true as regards the relapse than in the initial paroxysm; thus, he has seen a pulse of 90 when the temperature was 106°. On the other hand, Carter has noted that in the

Digitized by Microsoft®

Bombay epidemic the sudden fall of temperature marking the crisis was not attended with a corresponding decline in the frequency of the pulse. During the height of the fever the number of pulsations per minute, in adults, may be stated as from 110 to 140, while in children it often reaches 160 or even 170. After the crisis, an irregular or dicrotic pulse is not infrequent, and as a rule it is feeble and compressible. At this time there is danger of sudden death from syncope. A soft systolic murmur heard over the base of the heart and along the large vessels is frequently discovered, both during the primary paroxysm and during the relapse.

Pain in the back and limbs is complained of during the first days of the primary attack, and to a less extent during the relapse. Articular pains, unaccompanied by swelling, may also persist during the apyretic interval. But the most distressing pain is felt in the head. *Headache* is usually frontal; it is an early and often very persistent symptom, disappearing only with the crisis, and recurring with less severity with the relapse. Other symptoms referable to the nervous system are: *Vertigo*, induced by assuming an erect position; especially common at the outset of the attack, and often persisting throughout the paroxysm; *delirium*, usually of an hysterical character, and most common among the victims of chronic alcoholism; or the low muttering delirium which accompanies suppression of urine, and which, in the absence of relief, passes into stupor and coma; *convulsions*, the result of uræmic poisoning or of extreme nervous irritation due to severe and protracted pyrexia; *insomnia*, due largely to the distressing pains, and not readily controlled by hypnotics; *paralysis*, limited to single muscles or to groups of muscles—of rare occurrence. Of these symptoms vertigo and insomnia are the only ones which are so common as to constitute a characteristic feature of the disease.

The symptoms referable to the *digestive system* are those common to febrile complaints generally, viz., thirst, loss of appetite, a coated tongue, torpid bowels, and nausea, with vomiting of ingesta and bilious matters. The *tongue* usually remains moist and is coated with a thick white fur which may become yellowish or, in cases having a typhoid tendency, brown and dry. It is usually somewhat swollen and indented at its edges by contact with the teeth. This appearance, together with the frequent absence of coating upon the edges and over a triangular space at the tip, which remains bright and red, has been regarded by some authors as of diagnostic value. Occasionally the tongue is red and glazed, and it may become deeply fissured, or in severe and protracted cases dry and brown. The tongue quickly clears up and appetite returns when the febrile paroxysm has terminated by crisis, and when a relapse occurs it again becomes coated and there is a return of anorexia and gastric disturbance. *Nausea* and *vomiting* are almost constant symptoms at the outset of the attack, and, less frequently, recur during the relapse. Occasionally a considerable quantity of bile is ejected; more commonly the vomited matters consist of ingesta or glairy mucus tinged with bile. "Black vomit," due to the presence of blood in the vomited matters, has been seen by several observers, and in certain epidemics seems to have been not very infrequent. It is a symptom of grave import. Three cases out of four in which it was noted by Pepper terminated fatally. This author observes that, "judging from the frequency with which in fatal cases we find ecchymoses of the gastric mucous membrane, with blood-stained mucus in the cavity of the stomach, we should expect black vomit to be more often observed than is the case." More or less tenderness and pain on pressure in the epigastric region is a common symptom during the early part of the febrile paroxysm; in this particular, as in several others, there is a noticeable resemblance to yellow fever.

The *bowels* are commonly constipated at the outset of the attack, but later diarrhœa is not infrequent, and this may be profuse and of a critical character, occurring at the close of a febrile paroxysm, and to a greater or less extent taking the place of the usual critical sweating.

Enlargement of the liver may usually be demonstrated by careful percussion, and in some instances this organ extends to three inches below the margin of the ribs toward the close of the febrile paroxysm. Pressure in the hepatic region causes pain, and occasionally hepatic tenderness is quite a constant cause of distress. *Jaundice* is a prominent symptom in certain epidemics, occurring in from twenty to twenty-five per cent. of the cases. At other times it is comparatively rare. It appears toward the close of the primary paroxysm, or in one of the succeeding febrile paroxysms, and usually disappears after the crisis. According to the observations of Pepper and of Stillé, it is more frequent in the negro than in the white man.

Enlargement of the spleen is a constant and early symptom, and it is not unusual for this organ to attain from three to four times its normal bulk. It may be detected as early as the second day, projecting below the margin of the ribs, and toward the close of the febrile paroxysm it often forms a visible tumefaction on the left side of the abdomen. During the apyretic interval its volume rapidly diminishes, to increase again during the relapse.

The *skin* is free from any characteristic eruption, but occasionally an eruption of pinkish or rose-colored spots has been observed (Carter), and "true petechiæ have been quite common in some epidemics" (Pepper). Sudamina and herpetic eruptions about the mouth and nostrils are of common occurrence. Desquamation of the cuticle, especially from the hands and face, is not infrequent. Several observers have noted a peculiar odor, exhaled from the body of the patient, which is said to resemble that given off by "burning straw with a musty odor."

The *urine* is somewhat scanty and high-colored during the febrile paroxysms, and, as is usual in such cases, has a higher specific gravity than normal; its reaction is usually acid, and it deposits, on standing, a more or less copious sediment of urates, associated sometimes with crystals of oxalate of lime. The amount of urea present is subject to considerable variations, but the general rule seems to be that it is increased during the paroxysms, and decreased at the time of the crisis, to increase again during the first part of the apyretic interval. In certain cases the critical sweating is replaced by an abundant discharge of light-colored urine of low specific gravity, but under ordinary circumstances the amount of urine is greatly reduced at the time of crisis; subsequently the quantity is increased and the specific gravity is reduced to a minimum, and this may persist for some time after convalescence is established. Thus, Carter reports a case in which the daily amount, for two weeks after the relapse, was one hundred and thirty ounces, while the specific gravity was only 1002.6. Slight *albuminuria* has been noted by several observers as commonly occurring toward the close of the febrile paroxysm, or shortly after its termination. According to Carter, other evidence of acute renal congestion, such as blood discs and tubular casts, is almost never found. Other observers, however, have reported the presence of tube casts in those cases in which the urine is albuminous, and Obermeier has claimed that acute desquamative nephritis is one of the ordinary phenomena of the disease under consideration.

Epistaxis is of rather frequent occurrence in relapsing fever, and hemorrhage from the stomach, from the bowels, and from the kidneys, has been noted in rare cases. Pepper reports fifteen cases in which very profuse epistaxis occurred at the crisis, evidently as a critical discharge, replacing to some extent the usual perspiration.

Convalescence is usually rapid in the absence of any complication, but, after very severe and prolonged attacks, a considerable interval must elapse before the emaciated patient regains his usual strength. The average duration of the period included between the date of seizure and complete convalescence is about six weeks (Wilson).

VARIETIES.—At least one relapse, occurring after an apyretic interval, is necessary to constitute a typical case of relapsing fever. But in a certain proportion of the

www.libtool.com.cn
Digitized by Microsoft®

cases occurring during an epidemic, there is but a single febrile paroxysm—*abortive form* (Carter)—which, however, is undoubtedly due to the same specific cause, as is shown by the constant presence of the spirillum of Obermeier in blood drawn during the pyrexia. These cases are often mild in character, and in the absence of a microscopic examination of the blood and demonstration of the presence of the spirillum, the diagnosis would remain uncertain. The form of fever denominated *bilious typhoid* by Griesinger and other German authors is undoubtedly a variety of relapsing fever. It is characterized by intense jaundice, a tendency to suppression of of the urinary secretion, to hemorrhages from mucous surfaces, and to those grave symptoms which constitute the typhoid state, viz., great prostration, muttering delirium passing into stupor and coma, hypostatic congestion of the lungs, a dry and brown tongue, etc. These symptoms may be developed during the primary febrile paroxysm in such a manner as to interfere with the termination of this paroxysm by crisis, and to render obscure the apyretic interval which, in typical cases of relapsing fever, distinctly separates the initial paroxysm from the relapse.

Complications.—One of the most frequent and fatal complications of relapsing fever is *pneumonia*. It commonly occurs after the crisis of the primary paroxysm, but may also follow the relapse, or may occur as a more remote sequel of the disease—three or four weeks after the close of specific pyrexia. In 97 autopsies Carter found evidence of pneumonia in 27 instances. Out of 23 autopsies, Pepper found the lesions of this complication in 8. It is more frequent in adult males than in females and children. *Pleurisy* was found by Carter to coexist with pneumonia 13 times in 21 autopsies in which inflammation of the lungs was verified. Deaths from pneumonia commonly occur within a week or ten days after the first crisis. The onset of this grave complication is marked by the usual symptoms and physical signs, and by pyrexia, which may be confounded with that of the relapse due to specific blood contamination. The pyrexia attending this complication is, however, distinguished from that of the preceding or subsequent specific febrile paroxysm by the absence of spirilla from the blood. The same is true of the "secondary" or "reactionary" fever, which in severe cases sometimes follows the critical defervescence, and which is independent of any recognizable organic complication.

Diarrhœa, in certain epidemics, is rather common as a complication or sequel, and may be the immediate cause of death. It occurred in 33 per cent. of the cases observed by Pepper in Philadelphia, and in 50 per cent. of the cases in the Königsberg epidemic. *Parotitis* occurred in from 2 to 3 per cent. of the cases collected by Carter, and was observed by Pepper in 3 cases out of 185. It may result in resolution, or more commonly in suppuration. As a rule, it is developed during the first apyretic interval. *Hiccough* is a distressing complication which frequently occurs in severe cases, especially in those attended with jaundice. It is most common toward the end of a febrile paroxysm, and usually disappears after the termination of the paroxysm by crisis. *Bronchitis* of a moderate degree of intensity is a frequent complication which is developed, for the most part, during the febrile paroxysms, as a result of congestion of the bronchial mucous membrane, and disappears, or is greatly modified in degree, during the apyretic intervals. *Acute laryngitis*, with œdema, is an occasional complication. *Enlargement of the spleen* is so constant that it may be considered an essential feature of the disease, rather than a complication. In certain cases the enlargement persists for many weeks, and is attended with marked debility and anæmia. *Rupture of the spleen* has been reported by several authors, and *splenic abscess* has been noted in certain rare cases. The former accident is marked by suddenly developed pain and collapse, and is quickly fatal; the latter commonly gives rise to pyæmia, or may induce acute peritonitis or pleurisy, by discharging into the cavity of the abdomen or the left pleural cavity. Other complications which have been noted as events of rare occurrence are: hemorrhage from the stomach; metastatic abscesses of the lung; suppuration of the mesenteric glands; general peritonitis; thrombosis of veins, and cerebral hemorrhage. When pregnant women are attacked with relapsing fever, *abortion* is almost sure to occur; and in those cases in which menstruation occurs during the attack, it is usually profuse, and sometimes dangerously so. Among the sequelæ of the disease, we may mention as most prominent: diarrhœa, dysentery, anæmia, neuralgic pains, local palsies, keratitis, and inflammation of the deeper tissues of the eyeball, mental hebetude, mania, and in rare instances gangrene of the feet, nose, or ears, as a result of arterial thrombosis (Wilson).

Diagnosis.—The early diagnosis of relapsing fever is made easy by the discovery of Obermeier, and by the fact, now verified by numerous observers, that the spirillum peculiar to this disease is found in the blood during the entire period of pyrexia—including the relapses—and usually for a short time in advance of the febrile paroxysms. Without this test the diagnosis must always remain somewhat uncertain for some days, inasmuch as there are no pathognomonic symptoms marking the outset of the attack. The sudden termination of the initial paroxysms by crisis, and the relapse after an apyretic interval of five to twelve days, will, however, be sufficient to establish the diagnosis in typical cases; but, as in other specific febrile diseases, there are many atypical cases in which the diagnosis might remain uncertain if it depended upon the clinical history alone. This is especially true of the so-called "abortive form," in which there is but a single paroxysm, in that form which has been denominated bilious typhoid, and in cases in which the typical character of the pyrexia is masked by complications of one kind or another. In countries where severe forms of malarial fever prevail there can be no doubt that cases of relapsing fever, especially at the outset of an epidemic, before the prevalence of this disease has been generally recognized, are often ascribed to malarial poisoning, and fall under the denomination "remittent fever" —a term which in former years, and in the absence of precise knowledge, has been made to do duty in tabular statements of disease and mortality for more than one specific disease, *e.g.*, typhoid fever, yellow fever, relapsing fever. The investigations of Carter make it appear probable that relapsing fever is by no means a new disease in India, yet it has been only recognized during recent years, and the available records of an epidemic which prevailed in Bombay so recently as 1863–64–65 do not permit the author mentioned to decide positively whether the enormous mortality from "fever termed remittent" was in truth due to relapsing fever or to typhus, as was claimed by some of the local practitioners. The differential diagnosis between relapsing fever and true malarial remittent presents no serious difficulties, although there are many symptoms—such as headache, vomiting, epigastric tenderness, enlargement of the spleen, and jaundice—which are common to both diseases. The character of the pyretic movement, the sudden termination by crisis, the failure of quinine favorably to influence the course of the disease, the protracted apyretic interval, and the relapse, will suffice. But in addition to these facts relating to the clinical history, there are various circumstances relating to the epidemic prevalence of the disease which will aid greatly in its recognition. Thus, relapsing fever is transmitted from individual to individual by contagion, and is a disease of towns, and especially of the overcrowded portions of such towns where the poorer classes of the population are congregated under unfavorable sanitary conditions; whereas remittent fever is especially a disease of the country, the prevalence of which depends upon circumstances relating to locality, climate, and season, and not upon personal intercourse and social condition. As a rule, it may be said that a fatal epidemic disease which prevails among the crowded population of a large city is not remittent fever, whatever else it may be.

Digitized by Microsoft®

Typhus fever and relapsing fever are often associated as regards their epidemic prevalence, although there is no evidence that they bear any etiological relation other than that due to common predisposing causes. That they are specifically distinct is well established, and the clinical history of each is sufficiently characteristic. The eruption of typhus, the continuous course of the pyretic movement, and the fatal tendency of the disease are all in contrast with relapsing fever. A more detailed account of the clinical points of difference is hardly necessary in view of what has preceded, and of the ready means of establishing the differential diagnosis which is furnished by the microscope. The same may be said as regards enteric fever, which disease is also characterized by a less abrupt onset, and a pyrexia which presents peculiar features essentially different from that of relapsing fever, together with special symptoms, such as a tendency to delirium, abdominal distention, an eruption of rose spots, etc. The differential diagnosis in that form of relapsing fever which is denominated by Griesinger "bilious typhoid" may perhaps present greater difficulties, and, before the discovery of the spirillum of Obermeier, much uncertainty existed as to the etiological relations of this fatal form of disease. In addition to the presence of the spirillum it is distinguished from enteric fever by its mode of onset, by the early appearance of jaundice, and by the character of the pyrexia, together with a tendency to hemorrhage from mucous surfaces, a more decided enlargement of the spleen, and the absence of rose-colored spots.

www.libtool.com.cn

Bilious typhoid might very easily be mistaken for yellow fever in countries where this disease prevails, and we have the authority of Murchison for the statement that this mistake has been made by Graves, Stokes, and Cormack. The two diseases have many features in common, but also essential points of difference. Thus, yellow fever prevails only in certain latitudes and during the summer season, while relapsing fever is quite independent of climatic conditions. Yellow fever is extremely fatal, and a single attack protects from subsequent attacks; the reverse is true of relapsing fever. Relapsing fever is propagated by direct transmission from individual to individual; yellow fever is not, and its extension depends upon external conditions. The negro has a partial immunity from the effects of the yellow-fever poison, but is especially susceptible to relapsing fever. There are also essential differences in the clinical history of the two diseases. In one—yellow fever—the acme of temperature is commonly reached during the first twenty-four hours, and defervescence is gradual; in the other defervescence is rapid and accompanied by a critical discharge, and the acme of temperature occurs, as a rule, shortly before the crisis.

The "stage of calm" in yellow fever is a period of the gravest danger, the urine is scanty and highly albuminous, and complete suppression is a common, and almost invariably a fatal, event. the febrile paroxysm is usually not so protracted as in relapsing fever, and is attended with less distress, but the effects of the specific poison upon the blood, the kidneys, and the mucous membrane of the stomach are of such a nature as to place the life of the patient in the greatest jeopardy. The apyretic interval in relapsing fever is, on the other hand, a period of comparative safety and comfort; the urinary secretion is abundant, the appetite returns, and the stomach resumes its functions. This apyretic interval is, however, not so clearly defined in severe cases of bilious typhoid, as death occurs in from thirty to fifty per cent. of these cases, and most frequently during the initial paroxysm, or as a result of complications which interfere with the normal course of the disease; and as there are jaundice, albuminous urine, and a tendency to hemorrhages from mucous membranes, it is easy to see how mistakes may arise, and the diagnostic value of the microscopic test, demonstrating the presence or absence of the spirillum, becomes apparent. It must be remembered, however, that the spirillum is not found during the reactionary fever which sometimes follows the crisis, or during the pyrexia attending a complication.

Prognosis and Mortality.—The mortality from relapsing fever, in the absence of complications, is low. Out of 2,115 cases admitted to the London Fever Hospital in twenty-three years (1847–70), there were 39 deaths (1.84 per cent.). Murchison, to whom we are indebted for these figures, has also analyzed the statistics furnished by Scotch physicians. In a series of 6,300 cases the mortality was 4.12 per cent., and in a second series of 10,444 cases it was 4.42 per cent. According to Pepper, the mortality in the Philadelphia epidemic was 14.4 per cent., the total number of cases being 1,174. These figures scarcely sustain the statement that relapsing fever is a comparatively mild disease, and the mortality in the cases in which jaundice was a prominent symptom—"bilious typhoid"—which is said to have been not less than fifty per cent., places this form of the disease on a level with yellow fever and typhus, so far as its fatality is concerned. In India, out of 616 cases collected by Carter, there were 111 deaths (18.02 per cent.). It is evident from these figures that it is only by excluding cases complicated by jaundice, pneumonia, etc., that the statement is justified that "the death rate in relapsing fever is low." Death may occur during the initial paroxysm, the apyretic interval, the relapse, or subsequently to this. In an analysis of 99 fatal cases Carter ascertained that in 48 death occurred during the primary paroxysm, and of these 37 died at or about the apparent acme of fever, and at the stage of defervescence 11; 24 deaths occurred during the first apyretic interval; 6 during the first relapse; 11 during the second interval, and 1 in a second relapse. The apparent *cause of death* in these cases is said to have been in 63 cases exhaustion, resulting from the immediate effects of the pyrexia and its attendant symptoms; in 17 cases pneumonia as a complication; in 2 copious gastric hemorrhage; in 1 femoral thrombosis; in 7 cerebral hemorrhage was ascertained by autopsy; there was acute dysentery in 8 cases, and hepatic abscess in 1.

The influence of age upon mortality is shown by the following table, which we copy from Wilson (*op. cit.*), who obtained it from the statistics of the London Fever Hospital as given by Murchison.

Of the 2,115 cases admitted there were:

	Cases.	Deaths.	Per cent.
Under 20 years	804	3	0.37
Between 20 and 30 years	562	4	.71
" 40 " 50 "	322	8	2.48
" 50 " 60 "	119	9	7.56
" 60 " 70 "	66	7	10.60
" 70 " 80 "	6	2	33.33

The favorable influence of youth, as shown in this table—0.37 per cent. for all cases below the age of 20—is not in correspondence with the data obtained by Carter in India. He says: "The influence of age was apparent in the greater comparative mortality at both extremes of the scale of years; thus, the general mean death rate being about 18 per cent., the rate was 27 per cent. up to the age of ten years, and then in the two succeeding decennia declining to 11 per cent. (11 to 20 years), and 16 per cent. (21 to 30 years), it rose with advancing age above the mean to 24.5 per cent. (31 to 40 years), 29.4 per cent. (41 to 50 years), and 37.5 per cent. (51 to 60 years).

The mortality is greatest at the outset of an epidemic, and the proportion of cases complicated with jaundice is larger at this time. *Sex* has no apparent influence upon the death rate, when we exclude the decided influence of intemperate habits, and take account of the fact that more males than females are attacked.

Anatomical Lesions.—Most authors assert that there are no constant anatomical lesions in relapsing fever, but Ponfick, of Berlin, who has made the most elaborate researches yet published, based upon sixty-five autopsies made during the epidemic of 1872–73, asserts "that certain changes in the spleen, the marrow of bones, the

Digitized by Microsoft®

blood (large granule cells); also those of the liver, kidneys, and muscles (especially of the heart), pertain directly to relapsing fever, and taken together are pathognomonic." The splenic changes are said to be absolutely constant, and this assertion at once disposes of the commonly repeated statement that there are no constant local lesions in relapsing fever. Liver changes, too, were invariable; but some difficulty here arose from the likelihood of prior lesion due to alcoholism. It is evident that the epidemic at Berlin was a severe one, there being seen several examples of *typhus biliosus*. The following is a summary of Ponfick's results. *Liver:* The turgescence ensuing during specific pyrexia may be greater than occurs in any other infectious disease; the individual lobules become enlarged, their outlines indistinct, and tint a grayish-red. Microscopically, the increased volume is due to cloudy swelling of the hepatic cells (always present), to their peripheral fatty degeneration, and lastly, to an infiltration of small cells in the portal canals; from an anatomical point of view, no distinction here is possible between the mild and the severe forms of relapsing fever; jaundice was present sixteen times (twenty-four per cent.), and it results from biliary engorgement. *Kidneys:* Changed without exception, and in correspondence with alterations noted in the urine; they may be doubled in size; parenchyma flabby; the cortex broad and clouded; the Malpighian tufts pallid. Or parts alone may be changed, and when dark streaks are visible, then not only is the tubular epithelium more or less fatty, but the lumen of the tubes is occupied by fibrinous or blood-tinged plugs. Such cylinders with red discs have been found in the urine (not at Bombay, H. V. C.). There is also evident, in the extreme degree of swelling, a copious small-cell infiltration of the intertubular tissue; and besides, an amyloid thickening of the vessels, which may be attributed to previous *morbus Brightii*. *Striated muscles:* Lesion of the myocardium is very frequent, its consistence flabby, tint pale gray or brownish, wholly or in streaks, where the fibres have undergone fatty degeneration; such degeneration may be as extreme as in the most virulent kind of infectious disease, or even in poisoning by phosphorus. Dr. Ponfick naturally applies these data in explanation of certain fatal cases of fever, where death occurs by syncope, and no other lesion is found after death. I have above remarked that the like were not witnessed among the temperate natives of West India. *Spleen:* Changes here are localized or diffused; the latter are always present, and induce a swelling of the organ, sometimes greater than occurs in *leukæmia*. The pulp is then dark, livid, and projecting; the Malpighian bodies much enlarged or even effaced, their tint gray or yellowish; at a later stage of fever their outlines become more defined. In cases of unusually rapid turgescence of the spleen, rupture of its capsule may occur, and death, with or without peritonitis; this change is compared with that taking place in enteric fever. Swelling is due to distention of blood-vessels, and to a great increase of the cell elements, including large multinucleated forms in near relationship to the cavernous veins. Dr. Ponfick could not find any spirilla among these cells. Numerous pulp cells were seen containing red blood discs and pigment; and others filled with bright granules which look like spores, but probably are not such; these structures are not peculiar to relapsing fever, though found here in relatively larger numbers than in other fevers; they may be seen in the blood circulating during life, and when very abundant, may be concerned with death of patient. Cases are quoted such as occurred at Bombay. There is also another contamination of the blood which can be demonstrated during life in severe cases, viz., by vascular endothelium cells in a state of fatty degeneration; this, too, is not absolutely peculiar. As to localized splenic changes, the chief pertain to the venous system and comprise the so-called 'infarcts,' which were present in forty per cent. of all autopsies; they resemble closely embolic infarcts, but arise from another cause than arterial obstruction, and hence are peculiar to relapsing fever." (Quoted from Carter, *op. cit.*)

Ponfick also describes certain changes in the marrow of bones which he considers peculiar to relapsing fever. "These changes consist in proliferation and subsequent degeneration of the lymphoid cells of the marrow, with multiplication of the nuclei in the walls of the minute vessels and fatty degeneration of their coats. As a result of these changes spots of puriform softening may form, chiefly in the cancellous tissue of the extremities of long bones, with the production of localized necrosis, and possibly with extension of inflammation to the neighboring articular cavity." (Quoted from Pepper, *op. cit.*)

In addition to these constant changes, a variety of lesions are found which appertain to the complications which occur in this disease with greater or less frequency. Most prominent among these are the lesions due to pneumonia. Pepper found evidence of lobar pneumonia in thirty-three per cent. of his autopsies, Carter in twenty-eight per cent., and Ponfick in twenty per cent.

TREATMENT.—All efforts to cut short an attack of relapsing fever by specific medication have thus far proved unsuccessful, and the knowledge that the disease is due to the presence of a minute vegetable parasite in the blood has not resulted in any decided improvement in our therapeutic resources. The evident indication is to destroy or restrain the development of this blood parasite; but in the list of known therapeutic agents there is not one which can be safely administered in sufficient quantity to accomplish this purpose. Quinine in full doses has been tried again and again, but the testimony of Murchison, of Pepper, and of Carter is in accord as to its failure to exercise any specific therapeutic power. The last-named observer says that "the blood spirillum and the febrile symptoms remain unaffected after quinine given largely to cinchonism, after narcotism by chloral, and after the freest exhibition of spirituous liquors; also after the administration of the carbolates and very large doses of the salicylates." We have no precise data showing the action of germicidal agents upon the spirillum of Obermeier; but Carter states that he once found that weak neutral solutions of quinine seemed to kill the spirillum; and Dr. Litten has ascertained that the movements of the parasite are arrested by a one-per-cent. solution of carbolic acid. The experiments of Ceri show that the development of schizomycetes is prevented by the presence of muriate of quinine in the proportion of 1 to 800 in a culture solution. The development of certain species is prevented by a considerably smaller amount, but so far as our experimental data go the indications are that at least one part in two thousand will be required to prevent the development of organisms of this class in the blood. This would require the *constant* presence of something more than a drachm of muriate of quinine *in solution in the blood* to prevent the multiplication of bacterial parasites present in this fluid. The therapeutic possibilities in the case of carbolic acid are not so favorable as this, and the writer has elsewhere estimated the amount of this agent which would be necessary to restrain the development of pathogenic organisms in the blood to be something more than two drachms. Arsenic was fairly tried by Pepper in the Philadelphia epidemic, and his conclusion is that "there seems to be no reason whatever for any further use of this drug in relapsing fever." Large doses of sodium salicylate have been demonstrated by Unterberger and by Riess to exercise a marked antipyretic effect, but to be impotent for the arrest of the febrile paroxysm or for the destruction of the blood parasite. "Unterberger has seen the temperature brought down 3° C. (5.4° F.), yet the attack was not apparently cut short, or splenic enlargement prevented, or the active blood spirillum visibly affected. Dr. L. Reiss, after essay on twenty-six cases, thinks that it is possible to cut short or mitigate the symptoms (especially the temperature) of specific relapses by very large doses (one hundred grains or more daily), noting, however, that even when the heat is reduced to normal or below it, the spirillum still persists." (Quoted from Carter.) Another remedy, tried by Pepper in a large number of cases, is the hyposulphite of

Digitized by Microsoft®

soda; his verdict is that "it is certain that it exerted no specific effect upon the disease."

In the absence of any known specific, our therapeutic resources are reduced to those measures which are best adapted to the control of the most distressing symptoms, and to that watchful care and anticipation of complications which enable us to conduct the patient safely through the critical stages of an infectious disease, and to save many lives, notwithstanding our acknowledged inability to cure these diseases. Although the high pyrexia is not so immediately dangerous to life as is the case in certain other continued fevers, it will always be advisable to keep it within bounds, and the tendency to death toward the close of the febrile paroxysm, primary or secondary, should be borne in mind. The evidence on record is in favor of sodium salicylate, rather than quinine, as an antipyretic medicine; it may be given to the extent of one hundred grains, or more, in the twenty-four hours, and is said to be well borne. Its persistent use, however, interferes with the patient's appetite, and it will be best to reserve it for those cases which are marked by a specially high pyrexia, and to administer it, in full doses, only when the temperature approaches 106° F. For a more moderate elevation of temperature, cold sponging of the surface, and the administration of simple febrifuge remedies, such as effervescing draught, or solution of spirit of nitrous ether, will suffice. Aconite, in small and repeated doses, may be given—one drop every two hours—in combination with moderate doses of spirit of nitrous ether, and if any routine treatment for the fever is considered necessary this may be recommended, as less liable to disturb the stomach than certain other drugs which are sometimes used in similar conditions, *e.g.*, veratrum viride, digitalis. There is a tendency to constipation, and a mild aperient will commonly be required at the outset of the attack; a dose of castor oil, or a simple saline purgative, will answer the purpose; later the bowels may be moved, if necessary, by enemata; emetics, as a rule, do more harm than good. *Headache* is to be combated by cold applications to the head. *Insomnia* is a marked and distressing feature of the disease; Carter prefers to administer chloral and bromide of potassium for the relief of this symptom, rather than to give opiates. Pepper, on the contrary, says that "opium and morphine must be regarded as the basis of the rational treatment of relapsing fever. It is called for by the insomnia, the severe headache, and the pains in various parts of the body, the nausea and vomiting, and the pyrexia." One-fourth of a grain of morphine, given at intervals of six to twelve hours, was found by the author last mentioned to relieve pain and vomiting, and often to induce refreshing sleep. It is contraindicated in those cases having a typhoid tendency, as shown by a disposition to stupor and deficient urinary secretion. In the experience of Pepper during the Philadelphia epidemic, bromide of potassium in full doses failed to produce sleep or relieve headache, and chloral, in doses of twenty to forty grains, could not be depended upon, although it sometimes gave relief. In view of the tendency to heart failure in this disease, the author named very properly points out the possible danger which may attend the administration of chloral. For the relief of excessive *tenderness of the liver or spleen*, Carter recommends hot fomentations and poultices in preference to cold applications, "which are seldom grateful to the patient." To control excessive *irritability of the stomach*, Pepper advises the use of small doses of calomel, gr. $\frac{1}{4}$–$\frac{1}{6}$ every two hours, or gr. $\frac{1}{12}$ of nitrate of silver, dissolved in thin mucilage of acacia, administered at intervals of three or four hours. *Hiccough* is a distressing symptom, which often defies all remedial measures. In Pepper's experience, chloroform is the most useful remedy for its relief. As death from *heart failure* may occur at the acme of the pyrexia, or during the depression, often amounting to collapse, which follows crisis, it will be necessary to watch carefully for the slightest indications of such failure, and to guard against it by the administration of digitalis, or strychnia, and the early use of alcoholic stimulants. When the symptoms of *collapse* are developed, it will be necessary to resort to the subcutaneous injection of ether, or of strychnia, and to apply artificial heat to the surface of the body.

In this as in other specific febrile diseases running a protracted course, it is necessary to commence with a *supporting treatment* at an early date. As soon as the stomach will retain it, liquid nourishment should be administered at stated intervals—every two or three hours; meat broths, milk, or gruel may be given if the condition of the stomach admits of their being retained; if not, koumiss, chicken water, or skimmed milk diluted with lime water, may be given in small quantities and at shorter intervals. When the stomach is very irritable, it is probable that iced champagne, or a teaspoonful of good brandy poured upon broken ice in a glass, and taken as cold as ice will make it, will be found the best form of stimulant. Whiskey toddy or milk punch may be given during the apyretic interval, or until convalescence is fairly established, or a good wine may be substituted for these if the patient prefers. In this disease, as in yellow fever, sudden death is liable to occur from cardiac syncope, as a result of very trifling exertion made when the patient is apparently out of danger. It therefore becomes necessary to insist upon absolute quiet and the maintenance of a recumbent position until such time as the strength of the patient is fairly restored. This precaution is especially imperative at the time of crisis, and during the period immediately following it, when there are a subnormal temperature and other evidence of a state of collapse. *George M. Sternberg.*

REMITTENT MALARIAL FEVER. See *Malarial Diseases*.

RENNIN.—This name for the milk-curdling enzyme of the gastric juice was first proposed in Foster's "Textbook of Physiology," and is now in common use in English-speaking countries. The name of *chymosin* was that given to it by Deschamps; it was later termed *lab* by Hammarsten, and this name is occasionally used by English writers.

The most valuable researches into its mode of action and isolation are due to Hammarsten, who was the first to show that it is distinct from pepsin. This view is now almost universally accepted, although it has recently been stated by Pawlow that rennin and pepsin are identical. Pawlow's experiments, which consist chiefly in a demonstration of a parallelism of intensity of action of gastric juice in digesting proteid and coagulating milk, are not, however, very convincing against the careful experimentation of Hammarsten in the separation of the two enzymes, as described later on in this article.

Digitized by Microsoft®

www.libtool.com.cn

Rennin and milk-coagulating ferments allied to it are very widely distributed, for rennin occurs not only in the mucous membrane of the stomachs of all mammalia which have been tested for it, but is also found in the stomachs of birds and fishes where its function is at present unknown. A similar if not identical ferment is found in the cell sap of many plants, such as the butterwort, fig-tree, and artichoke, and in certain of the Schizomycetes.

It is usually prepared commercially as rennet in the form of solution, powder, or tabloids, preserved with boracic acid, from the fourth stomach of the calf; carefully prepared products preserve their power of coagulating milk almost indefinitely, and long after proteid decomposition may have taken place in the other constituents admixed with the rennin.

Rennin is present in man at birth, and in this respect differs from pepsin. In its distribution in the gastric mucous membrane it closely resembles pepsin, being present only in small quantities at the pyloric region. Like pepsin, also, it is present in the gland cells as a zymogen; in fact, it was in the case of rennin that a precursory form or zymogen (Labzymogen) was first demonstrated by Hammarsten in 1872, some years before a similar demonstration was made in the case of pepsin by Langley and Edkins.

The zymogen appears to exist in a more stable form in some animals than in others, for while a neutral extract of the mucous membrane of the sheep or calf contains the enzyme in an active form, similar extracts from birds, fishes, and certain mammalia exert an action upon milk only after these extracts have first been treated with very dilute acid and again neutralized.

Rennin and pepsin and their corresponding zymogens behave very similarly on treatment with dilute alkalies; thus both rennin and pepsin are very rapidly destroyed by traces of caustic alkalies. The active ferments are also destroyed in both cases much more rapidly than their zymogens by the alkaline carbonates in dilute solutions, and this fact has been utilized, especially in the case of pepsin and pepsinogen, for proving the existence of the zymogen.

Rennin differs from pepsin in that it will act in a neutral or even in a faintly alkaline medium, but it acts most quickly when the medium possesses a slightly acid reaction. Excess of acid destroys its activity.

The *optimum* temperature lies at 37° C. to 40° C.; at this temperature the reaction takes place with three times as great rapidity as at 25° C.; activity ceases at 50° C., but the enzyme is not destroyed very rapidly at this temperature, and becomes active again as the temperature is lowered toward the optimum. The enzyme is destroyed, however, in five minutes when heated to 70° C. in neutral solution, or at 65° C. in acid solution. Its activity is also removed by standing under alcohol, but less rapidly than is the case with pepsin.

That the action is a truly enzymic one is shown not only by the above-mentioned destructions of activity, but also by the fact that it can occur in the presence of antiseptics, and by the infinitesimally small amount necessary to evoke the coagulation, one part of "purified" rennin being capable of coagulating, according to Söldner, ten million parts of casein.

The most successful attempt at its isolation was made by Hammarsten, who utilized Brücke's principle of mechanical precipitation by first neutralizing a gastric infusion with magnesium carbonate which precipitates the greater part of the pepsin. The filtrate was then partially precipitated by solution of acetate of lead to remove the remainder of the pepsin, and finally the rennin was thrown out by further addition of lead acetate and ammonia. This last precipitate was dissolved in very dilute sulphuric acid, and the rennin again mechanically thrown out with stearic acid by the addition of a solution of an alkaline stearate. The rennin was then finally obtained in solution in water by suspending the stearic acid in water and shaking up with ether, which dissolved the stearic acid and left the rennin behind in the aqueous layer.

The solution obtained finally did not act at all upon fibrin, but powerfully coagulated milk in neutral solution. This solution behaved in many important respects differently from a proteid solution, viz., it was not coagulated by heat, did not give a xantho-proteic reaction, and was not precipitated by alcohol, tannin, iodine, or neutral acetate of lead.

The chief facts as to the chemistry of the action of rennin upon milk are to be ascribed also to Hammarsten's researches upon the subject. When milk clots the greater part of the proteid separates in an insoluble form as casein (paracasein of Hammarsten), which entangles all the fat in its meshes as it contracts and so expresses a clear fluid called the whey, while the coagulated casein and entangled fat are called the curd. The whey contains the inorganic salts, lactose, and a small amount of albumen and globulin, which are called lactalbumin and lacto-globulin. Hence the casein is that important constituent which is chemically concerned in the process of coagulation.

The proteid from which the casein is formed in the act of clotting is termed *caseinogen* (casein of Hammarsten), and is present, according to some observers, in suspension in fine globules, and, according to others, as a colloidal solution. This proteid body has the properties of a very weak acid which is in fresh milk present as an alkaline salt; when it is set free from its combination it becomes insoluble. It is naturally so set free in the souring of milk, when lactic acid is formed by bacterial action on the milk sugar, and it is for this reason that sour milk curdles. For experimental purposes, such as the study of the properties of caseinogen and its changes during coagulation, it is best precipitated by the addition of a few drops of acetic acid. It can then be redissolved, after washing away the acetic acid, with distilled water, by the addition of water containing traces of alkali or by rubbing up with precipitated chalk.

As in the formation of fibrin from fibrinogen in blood clotting, it is found that calcium salts are necessary for the coagulation to take place, but more exact research has demonstrated that the rôle of the calcium salt is different in the two cases. For while the calcium salt has been shown by Hammarsten to be necessary for the formation of the *thrombosin* which acts as a ferment in blood coagulation, the same observer has also demonstrated that the calcium salt in milk coagulation does not share in forming the ferment, but has its purpose in a second stage of the reaction in actually combining with the caseinogen which has been modified in the first part of the reaction (soluble casein) to form the insoluble casein.

Hammarsten's two stages can easily be demonstrated by taking either a solution of caseinogen, or pure milk to which a few drops of ammonium oxalate have been added to throw down the soluble calcium salts, adding in either case a few drops of rennet, and then warming in a water bath to body temperature for ten to fifteen minutes, when no apparent change will be observed. Still a change has occurred, for if the milk be now boiled so as to throw the ferment out of action in the subsequent operation, and then a few drops of calcium chloride be added so that there is a calcium salt in solution in the fluid, on warming again for a few minutes a clot forms. Here no ferment action can take place in the second process, and as the addition of calcium salt only, and subsequent warming, produce no effect upon milk which has no been treated with rennin as in the first part of the process, it follows that the rennin must in the first portion of the experiment have formed some soluble modification of the caseinogen, which is then thrown out as insoluble casein in the second portion of the experiment.

Working with caseinogen solutions Hammarsten further demonstrated that in the action of rennin upon caseinogen there is detached from the caseinogen a soluble portion, which he termed "whey-proteid," that does not undergo any coagulation, and hence is found afterward in the clear fluid, or admixed in the whey with the lactalbumin when milk is used instead of caseinogen

Digitized by Microsoft®

solution. This proteid has been referred to as lacto-protein by other workers upon the subject.

The process may hence be summarized as follows: 1. The rennin acts upon the caseinogen of the milk and forms two soluble proteids (calcium salts being absent), "soluble casein" and lacto-protein. 2. The "soluble casein" combines with calcium when calcium salts are present, so forming casein. 3. In the coagulation of whole milk the casein entangles the fat globules forming the curd, and on contracting presses out the water, inorganic salts, lactose, lactalbumin, lacto-protein, and lacto-globulin which form together the whey.

Benjamin Moore.

REPARATIVE SURGERY.—Plastic reparative surgery is that department of the operative art which contemplates the repair of defects and deformities, congenital or acquired. Limited in its early history to the restoration of parts destroyed by trauma, plastic surgery has, in the course of centuries, widened its range of utility until its present achievements have been carried to all parts of the body covered by the general integument and to many of the cavities lined with mucous membrane. When the nose is destroyed by lupus, the eyelid shrivelled out of all semblance by chronic inflammation, the palate cleft, the fingers webbed, or the arm bound down by the scars of a burn; when a gastric or vesico-vaginal fistula, an eversion of the bladder, or a ruptured perineum makes life a burden—a plastic operation is the only measure of relief.

History.—The history of plastic operations presents fluctuations of use and oblivion unknown to the generality of operative measures. For its earliest development we must look to the shores of the Ganges, where from time immemorial mutilations of the face were inflicted in the way of punishment or revenge.

Later, the practice became the portion of the potters and brickmakers, who knew nothing of sutures, but retained the parts in position by the application of clay. There is no evidence that the skill of any of the operators of antiquity went beyond the restoration of mutilated noses, or that they attempted the repair of other parts. It is generally believed that before the Christian era the Brahmins had achieved great proficiency in the restoration of noses, forming them from integument brought down from the forehead or transplanted from another individual, and preferably from the gluteal region. What is truth and what is fiction as regards the rhinoplastic skill of the early priests of India, only appears from the recent translations of relevant parts of the *Süsrutäs Ayurveda*, according to which the nose was formed from the integument covering the cheeks. "The physician takes a leaf the size of the nose to be formed, and, placing it on the cheek for a measure, raises a flap of skin in such a manner as to leave it attached at one part. After vivifying the scarred part the new nose is quickly brought in position, elevated, and retained by placing two tubes in the nostrils."[1] The classical writers of Greece and Rome were for the most part unacquainted with transplantation of skin as a method of relieving defects, which were treated only by freshening the edges by incisions and drawing contiguous portions of skin together.

On the other hand, Celsus certainly entertained a rational idea of the gliding of flaps. He advised that the defect be removed in the form of a square and that two parallel incisions be continued transversely outward and inward, so that the loosened edges might be easily united. If this could not be done, he recommended that two semilunar lateral incisions, which should involve only the skin, be made with the concavity looking toward the defect.[2]

Although Galen and Paul of Ægina repeated the precepts of Celsus, the little that was known of plastic operations lapsed into an oblivion even greater than that which befell general surgery, and from which it was not recovered for over a thousand years. In 1442 Pietro Lonzano, bishop of Lu, published a statement in the *Annales du Monde* that a Sicilian named Branca had found a new method of supplying the loss of a nose. Whence he derived his knowledge does not appear. Among the pupils of Branca was his son Antonio, who had improved and extended his father's method by taking the integument from the arm, and by replacing the loss of lips and of ears in the same way. Plastic surgery doubtless spread rapidly in Italy from the time of the elder Branca, since Vesalius, Fallopius, and others make mention of it. It remained, however, for Gaspardus Taliacotius or Tagliacozzi, professor of anatomy at Bologna, to develop plastic surgery to a degree unknown before him, and to publish the first scientific work on it two years before his death in 1599. In it are described his methods of operating and of retaining the parts in position; and the illustrations accompanying the text have been utilized from century to century by almost all authorities who have written upon the subject. A father of conservative surgery in its best sense, respected by his confrères and beloved by his students, Tagliacozzi well merited the marble statue erected after his death in the amphitheatre of Bologna. In this monument he contemplates a nose which he holds in his hand. The methods of Tagliacozzi failed to obtain a permanent foothold—Paré, Fabricius, Heister, and many others denied the possibility of success. A little over a hundred years after Tagliacozzi's death, the art which he had perfected had again fallen into disuse. Dionys, Desault, Richter, and Chopart only mentioned his practices to condemn them. Such was the state of plastic surgery when, in 1794, a Madras journal brought to England the account of a successful rhinoplasty practised by one of the Koomas, who transplanted skin from the forehead. Although the first rhinoplasty in England was made by Lucas, it was not a success. In 1814 Carpue was more successful in replacing the lower portion of the nose. In 1816 von Graefe introduced plastic operations on the Continent, giving preference to the method of Tagliacozzi. Since the last-mentioned date the utility and feasibility of plastic surgery have not been seriously questioned, and particularly within the last twenty-five years so many additions and improvements have been made that the achievements of the present day doubtless eclipse the best efforts of all former masters in this special art. Associated with the more recent progress of plastic operations are the names of Skey, Liston, and Fergusson in England; Sédillot and Jobert in France; Dieffenbach, B. von Langenbeck, Fritze, and Thiersch in Germany; and the elder Pancoast and Gurdon Buck in this country.

Indications.—Congenital or acquired defects and deformities demand the resources of plastic surgery when, from their exposed position, æsthetic reasons make their removal desirable, or when disturbances of function and impaired utility are plainly due to them in parts that are hidden from view. Hence it is evident that, regarding the imperativeness of plastic operations, cases in which they are indicated may properly be divided into two groups, in which the necessity to interfere varies as much as the end to be obtained. In the first class of cases the operation is designed merely to improve the appearance of the patient by removing a distorting scar, by suturing the fissured lobule of an ear, or by elevating a depressed nose. Here the indications for an operation are far from imperative, and it is not infrequently the importunity of the patient that impels the surgeon to operate. It is well to remember that operations done solely for cosmetic effects are ordinarily the least satisfactory; it is within the experience of almost every surgeon that results obtained by plastic operations in this group of cases, although eminently gratifying to himself and deemed excellent by his colleagues, are sources of deep disappointment to the patients themselves. In the second group of cases the chief indication for operative measures is the repair of defective function or the protection of parts that are exposed. When the absence of the lower lip, destroyed by lupus or noma, permits of the continuous loss of saliva, derangements of the digestion and of the general health necessarily follow. When the lower eyelid is everted or lost, the defect causes characteristic

Digitized by Microsoft®

Reparative Surgery.

changes in the eye and face which often make vision imperfect, and the overflow of tears adds the suffering from an eczema to the other ills of the patient. A large urethral fistula at the peno-scrotal angle, while neither disfiguring nor detrimental to health, is a bar to the full exercise of the procreative function. In each of these cases the indication for recourse to plastic surgery is apparent, and its imperativeness is commensurate with the impairment of function caused by the deformity. To this group of cases belong extensive destruction of the lips, the nose, or the eyelids; cleft palate, cicatrix from burns, or webbing of the fingers; fistulæ, urethral, vesico-vaginal, or recto-vaginal; lacerated perineum, and exstrophy of the bladder. In this group of cases must also be included those in which the operative production of a defect is to be immediately followed by its closure by plastic means. Thus an ulcer of the leg that has proven refractory to all other means frequently yields to excision and immediate transplantation of skin; or an extensive epithelioma of the lip can be relieved only by extensive ablation of the part, the large defect being at once closed by dermatoplasty.

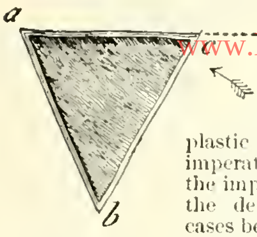

FIG. 3958.

www.libtool.com.cn

In considering the urgency of a plastic operation, it is necessary to consider the pathological nature of the defect which it is intended to overcome. A loss of substance may be congenital, traumatic, or the result of destructive neoplasms, like lupus, ulcerative syphilides, or epithelioma. In congenital deformities plastic operations are generally not urgently demanded, unless, as in the case of deficiency of the rectum, the life of the child depends upon their correction. But there are milder cases, congenital in character, in which greater deformity can be avoided by early interference. This is true in cases of harelip associated with cleft palate. In simple fissure of the lip the surgeon may abide his time. In complicated cases, on the other hand, early closure of the labial cleft must be advocated, since it has an undoubted influence in approximating the edges of the bony cleft and greatly increases the probability of success in subsequent attempts to close it. In two complicated cases in which I have thus operated during the first week the result was eminently satisfactory. Due regard should necessarily be paid to the general nutrition of the child before a plastic operation of considerable severity and entailing the loss of no slight amount of blood is performed. Defects that are traumatic in origin almost invariably demand removal by plastic operation while the wound is in condition to promise immediate union. This applies particularly to wounds of the face, the soft parts of which are so mobile that they may be stretched to almost any extent, provided the soft structures be thoroughly lifted from the bone. When suppurative processes have been established it is, as a rule, best to delay operative procedures until complete cicatrization shall have taken place. When the loss of substance is inflicted by the surgeon in the removal of malignant growths, its immediate repair is indicated, since there is every reason for believing that when this is accomplished the danger of recurrence of the primary disease is materially decreased. In such cases the all-important object of the operation is the removal of all diseased tissue, irrespective of the size and form of the wound that remains. In the category of defects that result from destructive inflammations, or from tuberculous or syphilitic ulcerations, operative measures are never indicated until the complete cessation of the original disease has taken place. It is in these cases that patients are most importunate in their demands for relief, and injudicious haste on the part of the surgeon is most frequently followed by disaster. Until a lupous or syphilitic ulceration is entirely under control, until, indeed, the whiteness of the cicatrix and the absence of other evidences of constitutional vice give us reasonable assurance that there is no tendency to recurrence, a plastic operation should not be attempted. An operation too soon performed will often give a new impetus to a disease that has simply been dormant.

NOMENCLATURE.—A number of terms have been suggested as suitable for designating plastic operations. French and German writers generally prefer the word autoplasty (*αὐτός*, self, and *πλάσσειν*, to form). In rare cases, in which the transplanted tissue is taken from a subject other than the patient, this term is evidently inappropriate. To overcome this objection, Velpeau and Guérin have suggested the word anaplasty, signifying to form anew or again. In this country and in England these terms have been generally discarded for the less objectionable one of plastic surgery. When, however, such an operation is performed for the repair or new formation of a particular part, the latter properly gives to the operation a particular name. Thus the formation of a nose is called rhinoplasty; of the lip, cheiloplasty; of the eyelid, blepharoplasty; of the mouth, stomatoplasty; of the urethra, urethroplasty, etc. The scope of this article will not permit the consideration of all the plastic operations. Those of the palate, fingers, urethra, perineum, and vagina are treated of in other parts of the HANDBOOK, while in the following pages will be studied the principles underlying plastic operations in general, and the methods of repairing deformities and defects of the face only.

The underlying basis of plastic surgery is the inherent vitality of the various tissues of the body. This permits them, after partial or total separation, to maintain an independent existence for a greater or less period, and to form new and permanent attachments when brought into contact with freshly wounded surfaces in proximity to, or at a distance from, their original sites. The introduction into defects of strips of epidermis, of the cutis vera, of tendon, of nerve, or of bone, which have been entirely severed from their former connections, constitutes transplantation or grafting. In plastic operations proper, this severance is never complete, a small bridge always being left through which the part to be utilized in the closure of a defect continues to live under the influence of the circulatory, and probably, also, of the nervous, apparatus of the structures whence it was taken, until perfect agglutination in its new position ensues. This occurs in from twenty-four to forty-eight hours, when no untoward complications in the process of wound repair supervene. By the end of a week the union is solidified by the free interchange of blood-vessels between the edges of the defect and the part inserted into it. In wounds of skin more than in those of any other structure is there a manifest tendency to early and firm repair, without which plastic operations would rarely succeed.

METHODS.—The pathology, nature, and extent of a cutaneous defect, and the condition of contiguous parts, will direct the surgeon in the choice of one of a number of methods that are at his disposal. Thus he may utilize the integument from a near or distant part of the body for its closure. Referring, for the present, to the former method only, I will state that the skin in the vicinity may be made serviceable by (1) traction, (2) by gliding, and (3) by transplantation of skin flaps. While typical illustrations of each of these methods differ sufficiently from each other to warrant a separate consideration of each, it is well to bear in mind that in their practical application the simpler often verges into the more complicated procedure.

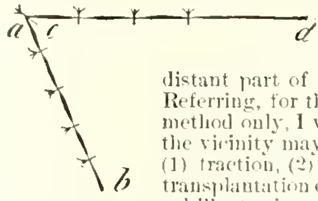

FIG. 3959.

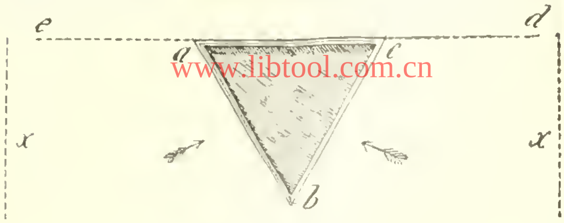
1. The method of closing a cutaneous defect by traction on the vivified edges of the integument surrounding it is based on the extent to which skin can be stretched and yet retain its vitality. This is well illustrated after removal of the breast, in which even the largest wounds can ordinarily be readily closed. In the surgery of the

Digitized by Microsoft®

face, however, plastic procedures by traction alone are justified only in wedge-shaped or oval defects, the margins of which can be easily approximated and retained



www.libtool.com.cn

FIG. 3960.

in position without dangerous traction on the sutures. If there be any strain on them after complete closure of the wound, it may be relieved by an incision through the skin on either side of the wound, parallel with, and at a short distance from it. This method is therefore applicable for the closure of fissures and fistulæ, and for the removal of prominent and ungainly cicatrices.

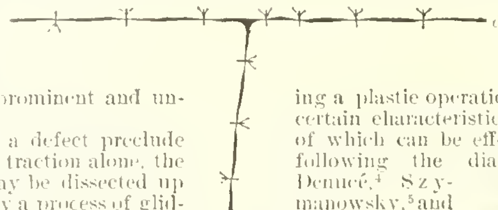


FIG. 3961.

2. When the size and form of a defect preclude the possibility of its closure by traction alone, the skin in the immediate vicinity may be dissected up in a patch of requisite size, and by a process of gliding be brought edgewise into the position of the part to be repaired, where, after proper adjustment, it is retained by sutures. Triangular and rectangular defects, such as result from the partial removal of the lower and upper lip, respectively, can be best remedied in this way. This method of operating by gliding, although mentioned by Celsus, as Linhart suggests, was probably practised before his time, since every operator, even if without previous knowledge, would naturally adopt it.

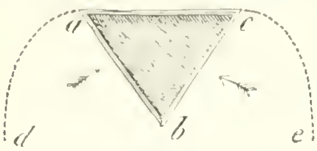

FIG. 3962.

3. The above methods are applicable only when the integument in the *immediate* vicinity of the defect can be utilized. If this is not feasible the borrowed integument, after being given the shape of the defect and being raised from its substructure, is transferred into the defect, but retained in relation with the tissues of its former position by means of a pedicle. Around this latter the flap must then necessarily be turned or twisted. Such a flap, in being transferred to its new site, may be made to describe an arc of

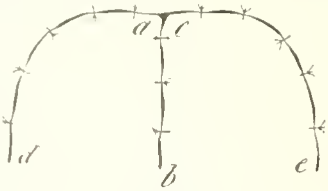

FIG. 3963.

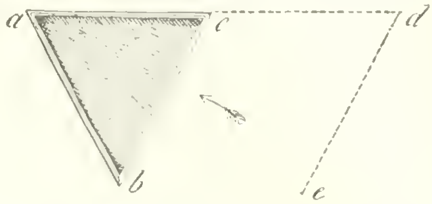

FIG. 3964.

90° or even 180°. In order that the raw under surface of the flap may be everywhere in contact with the subjacent surface, the skin bounding this must in part be displaced. "This displacement, however, should be effected in such a way that the displaced skin, retaining a connecting pedicle for its support, may be made to change

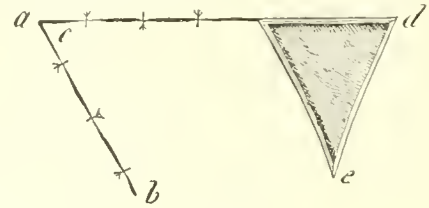

FIG. 3965.

places with the transplanted flap, and thus contribute, as far as it can, a covering for the surface that has been left bare." [3] As illustrations of this method may be cited the formation of a nose from the forehead, and of the upper eyelid from the integument of the temple.

Although every case requiring a plastic operation is a law unto itself, there are certain characteristic forms of defect the effacement of which can be effected in well-defined ways. In following the diagrammatic representations of Dennucé,[4] Szymanowsky,[5] and König,[6] the reader must bear in mind that the shaded parts of each illustration represent the defect, that the dotted lines indicate the incision, and the arrow the direction in which a flap is to be displaced. The supplementary illustration, in each case, indicates the appearance of the parts after union. (König.)

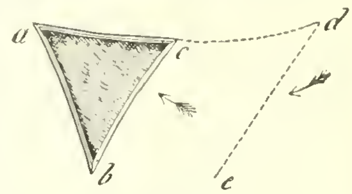

FIG. 3966.

(*a*) Small triangular defects may often be closed by gliding the angles of the wound toward its centre, and suturing the edges, which, when the integument is freely movable, can readily be brought in contact with each other in the form of a small triradiate star. If the defect is too large to be closed in this manner, one or two flaps may be easily prepared by carrying a straight or curvilinear incision from one or two angles of the triangular defect. Figs. 3958, 3959, 3960, 3961, 3962, and 3963 illustrate the manner of sliding the flaps into position. Should the tension of the flaps be too great, liberating incisions may be made (Fig. 3964, *a*), the wounds thus left healing by granulation. If, in addition to the incision *c d*, a second incision (Figs. 3965 and 3966, *d e*) be made, parallel to the side of the triangle, a quadrangular flap will be obtained for the closure of the defect (Dieffenbach, blepharoplasty), and a small triangular wound left to granulate. If the first incision be made at an angle to the margin of the defect, and the second be made in the manner already described, the wound can generally be entirely closed by sutures (Figs. 3967 and 3968). When the triangular defect has a large

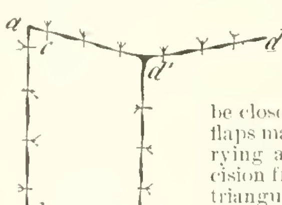

FIG. 3967.

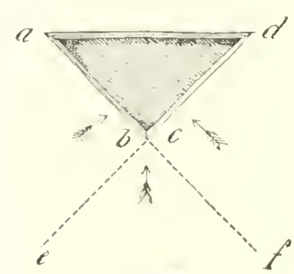

FIG. 3968.

Reparative Surgery.

www.libtool.com.cn

base, as is often the case after removal of an epithelioma from the lower lip, straight or semilunar incisions carried from the apex in the direction of its sides (Figs. 3969 and 3970) will outline two flaps that, by sliding, can be brought into apposition along a line at right angles to the base of the original defect. Burow, of Königsberg, has devised a method of closing triangular defects which, probably because it sacrifices healthy tissues, has not received the attention which it merits. It is practised as follows: From the base of the defect, and continuous with it, a straight or curvilinear incision is made (*b d*, Fig. 3971), somewhat larger than the base of the defect. From the side opposite to this a triangular piece of integument (*f e d*), equal in dimensions to the defect, is removed. The flaps *c b d* and *a f e*, being then dissected up and glided along the base line *a d*, readily close the wound. The line of suture is shown in Fig. 3972. If the defect is a large one, Burow sacrifices two smaller triangles of healthy integument, as shown in Figs. 3972 and 3973.

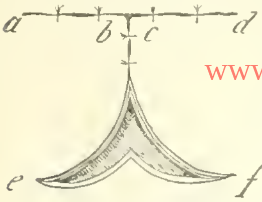

FIG. 3969.

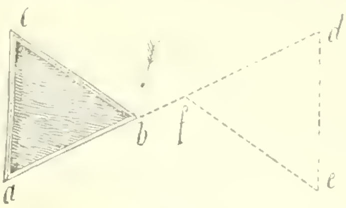

FIG. 3970.

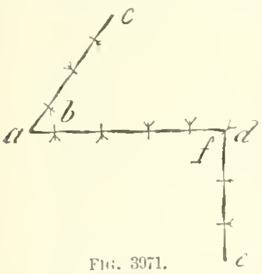

FIG. 3971.

(*b*) Quadrangular defects can, as a rule, not be effaced by suture alone. It is usually necessary to continue the incision in one or two directions, making one or two flaps, after the method of Celsus (Figs. 3974, 3975, 3976, 3977). The tension on these flaps will be materially decreased by making angular or semilunar liberating incisions as indicated in Figs. 3978 and 3979 When the defect is a large one, smaller flaps may be obtained from three directions as illustrated in Figs. 3980, 3981. Quadrangular defects may often be closed by the formation of one or two flaps, which are turned into their new positions around a broad pedicle (Figs. 3982, 3983, 3984, 3985, and 3986).

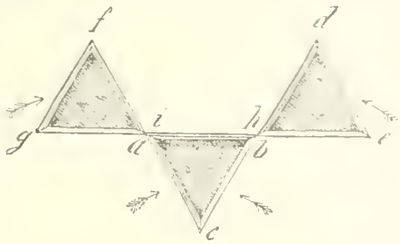

FIG. 3972.

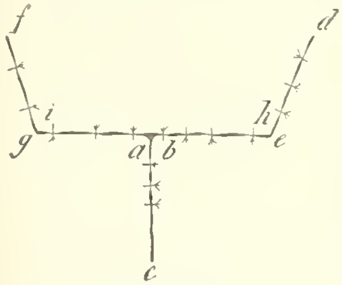

FIG. 3973.

(*c*) Oval and elliptical defects can generally be closed by a little traction along the line of their long axes. If the defect is broader, a liberating incision (Figs. 3987 and 3988) may be made, for the purpose of overcoming dangerous tension in the sutures. Lisfranc closed defects by constructing two flaps from one side of the ellipse by an incision perpendicular to its axis (Figs. 3989 and 3990). If this does not suffice, two curvilinear incisions, *b d*, *b c* (Figs. 3991, 3992), will facilitate the closure of the wound by two flaps that can easily be displaced to cover the wound. The flaps may also be so devised that they can be obtained from both sides, if the integument on one side be insufficient. Thus, by the incisions *a c* and *b d* (Figs. 3993 and 3994), two semilunar flaps will be formed that almost completely cover the defect. Weber's method of obtaining two flaps from one side, the one underneath the other, is shown in Fig. 3995. It is especially serviceable in defects of the lips.

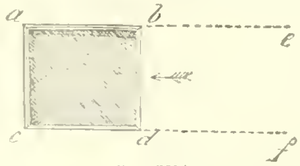

FIG. 3974.

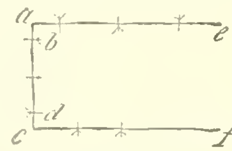

FIG. 3975.

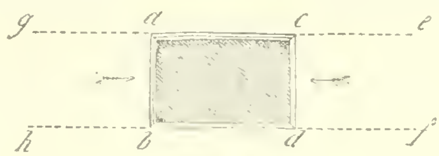

FIG. 3976.

(*d*) Circular defects, if not too large, are most readily overcome by converting them into oval or triangular wounds, preferably oval. If the defect is large, a semicircular flap must be obtained from the vicinity, and turned into the wound in the manner in which the quadrangular defect was closed.

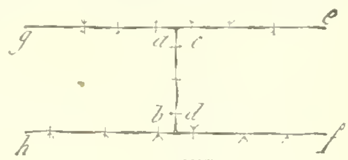

FIG. 3977.

It frequently happens that the integument in the immediate vicinity of the defect is unavailable for plastic purposes. This applies particularly to the extensive ravages made in the face by lupus and noma. After the cure of these diseases, extensive cicatrices often remain in the skin for a considerable distance around the defect. It then becomes necessary to go to a part farther removed from the latter for healthy skin. Thus the surgeon may be forced to fashion an eyelid from the skin of the temple, or a nose from that of the forehead (Indian method). In exceptional cases, it may even be deemed advisable to go still farther from the defect for a flap of healthy skin, as in the Italian method of rhinoplasty, in which the nose is formed from the skin of the arm. In the same manner, the place of a cicatrix from a burn of the wrist may be supplied by skin taken from the abdomen, or, as Maas[?]

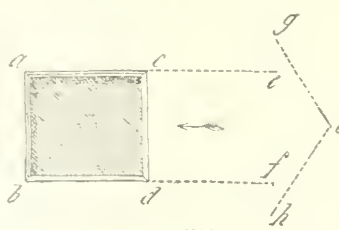

FIG. 3978.

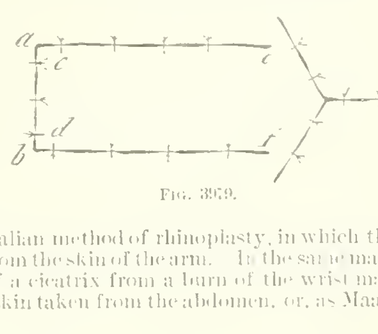

FIG. 3979.

Digitized by Microsoft®

demonstrated to the congress of German surgeons in 1886, otherwise incurable crural ulcers may readily be closed with a flap of skin obtained from the sound leg. In every case in which flaps are thus brought from a

www.libtool.com.cn

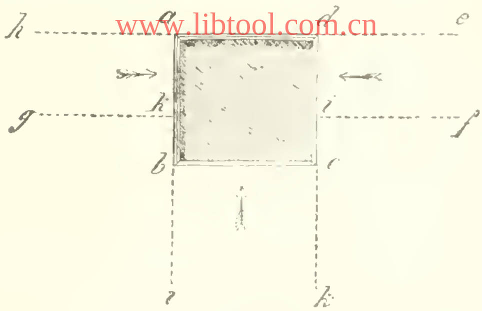

FIG. 3980.

considerable distance, the part whence the integument is to be borrowed must be retained in relation with the defect for a varying length of time. In rhinoplasty after the Italian method, this is accomplished by appropriate bandages. In the case of Maas, the parts were retained in position by a plaster-of-Paris dressing until union was secured.

Nearly all plastic operations may be subdivided into a number of steps which refer, respectively, (1) to the preparation of the defect; (2) the formation and transplantation of a flap and the methods of assuring its vitality; and (3) the permanent and speedy closure of the wound.

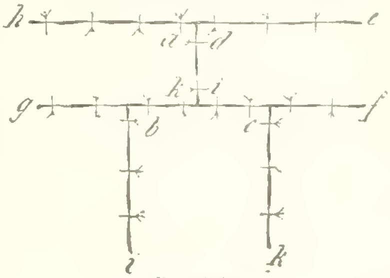

FIG. 3981.

1. The apposition of freshly wounded surfaces being practically an essential of success in plastic surgery, the first step in any operation of this kind is the freshening or vivifying of the defect. In recent traumatic defects, accidentally inflicted or produced intentionally by the surgeon in the removal of a neoplasm, this step of the operation is sufficiently simple. In cases of accident, it is well to bear in mind that the wounds are often irregular in the extreme and their margins bruised, lacerated, and ill suited to primary union. Here it is al-

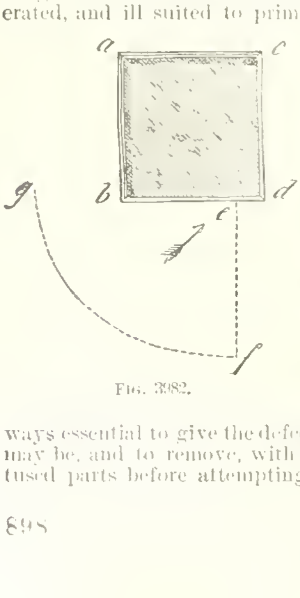

FIG. 3982.

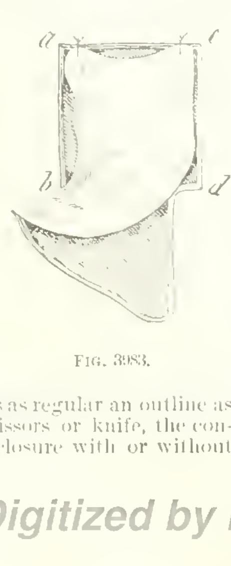

FIG. 3983.

ways essential to give the defects as regular an outline as may be, and to remove, with scissors or knife, the contused parts before attempting closure with or without the aid of a flap. When the defect follows the extirpation of a growth, and is to be closed at once by a plastic operation, every sacrifice must be made to procure radical removal of the neoplasm. The size of the defect is of secondary importance. Nevertheless, the incisions may be so arranged that the closure of the wound may be greatly facilitated. A glance at Fig. 3996 will make this sufficiently evident. In many cicatricial contractions and in congenital deformities, as in polydactylism, the preliminary step is also the formation of the defect for immediate closure. This is easily effected by the linear division of the cicatrix or connecting bands, and the restitution of the parts to their normal positions. When the defect has a free border, on the other hand, as in harelip, fistulæ, oral deformities, etc., the initial step of the operation is the paring or vivification of this margin, whereby the mucous, cutaneous, or cicatricial tissues are removed in such a manner as to procure a surface that is clean, smooth, and well adapted for primary union. Whether the paring be accomplished with scissors or knife, it is an essential of success that the border be removed in its entire thickness, since the presence of any undenuded spot in the line of proposed union destroys the possibility of a perfect result. To insure a broader surface for contact, and thereby greater probability of firm union, it is advisable to vivify the defect obliquely. This is particularly serviceable when, as in defects of a mucous membrane or of old cicatrices about the face, the margins are thin and would, if divided perpendicularly, offer a small surface for adhesion.

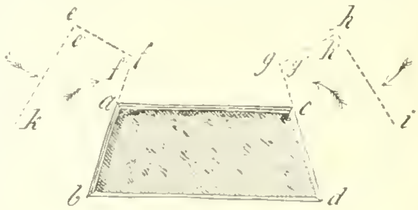

FIG. 3984.

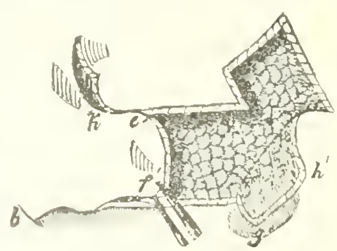

FIG. 3985.

2. The most available material should be selected in forming a flap; its size should be such that tension is nowhere exerted, and every precaution must be taken to insure a sufficient blood supply. The shape and size of the flap vary according to the defect. It is to be remembered, however, that integumentary flaps invariably shrink after, and often before, their transplantation. The amount of retraction varies with the subsequent disposition of the flap. If a raw surface is brought in contact with a plane surface or denuded bone to which it can form adhesions, the danger of primary retraction is less imminent. Thus it is certain that a periosteal flap only slightly larger than a fissure in the palate will easily suffice for its closure, whereas almost twice the integument must be taken from the temple to form an eyelid. In all other cases it is well to make the flap one-fourth or one-third larger than the breach it is intended to cover. Operators of large experience can fashion the flap without a pattern. Dief-

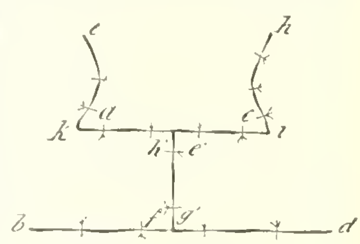

FIG. 3986.

Reparative Surgery.

fenbach always condemned its use, giving to the part to be formed ample dimensions at first, and remodelling it by supplementary incisions. It is certainly safer in all cases to make an accurate model of the part to be replaced, of paper, leather, adhesive plaster, or soft wax, which can be directly applied to the part from which the integument is to be taken, and serve as a guide to the lines of incision. The closest attention is required in the delineation and management of the pedicle. It should never, in a formal plastic operation, measure less than one-third of an inch in width, the probability of the survival of the flap being in direct proportion to the width of its pedicle and its capacity for arterial supply. As far as possible, therefore, the flap should be so outlined that the incisions will not necessitate the division of large arterial twigs. For the same reason, excessive torsion of the pedicle must be scrupulously avoided. Verneuil[8] aptly proposes the name of hilum for this portion of the flap, since this term expresses its important function in the nutrition of the flap.

www.libtool.com.cn

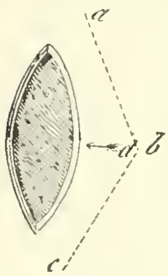

FIG. 3987.

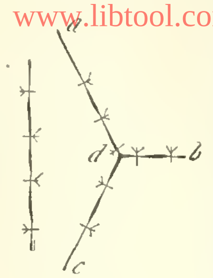

FIG. 3988.

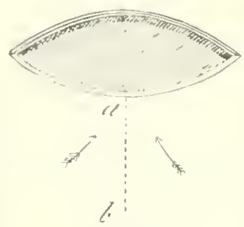

FIG. 3989.

Into the composition of the flap there should enter, as far as possible, tissues histologically analogous to those of the part to be repaired. Skin should therefore, as a rule, be replaced by skin, and mucous membrane by mucous membrane; although the possibility of the convertibility, in the course of time, of the one into the other, should be borne in mind. Thus the integument may, without difficulty, be made to substitute the mucosa of the bladder or of the nares. Mucous membranes, however, do not, as a rule, assume the characteristics of common integument, although that of the vagina forms an exception. The mucous lining of the nares, of the lips, of the nose, and of the bladder may be exposed for years without sensibly approaching the appearance of the skin. When skin enters into the composition of a flap it should, as far as may be, resemble that of the part lost. The delicate integument of the eyelid would not be suitable for repairing defects of the upper lip, nor would the appearance of the nose be improved by a patch of hair on its end. Above all things, the integument to be utilized for the flap should be healthy and freely movable.

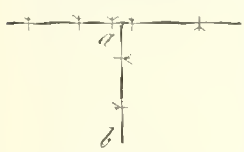

FIG. 3990.

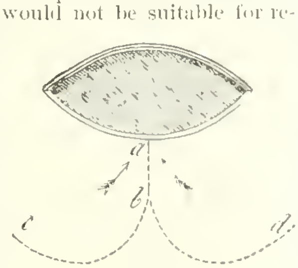

FIG. 3991.

The incisions being made, the integument, together with more or less of the subcutaneous cellular tissue, is to be dissected up from the underlying structures. The thickness of the flap should always be commensurate with its other dimensions. Large and thin flaps often succumb to defective nutrition. The subcutaneous cellular layer is an essential of all large flaps, since it is the medium through which the skin receives its nutrition. An excess of adipose tissue, however, is an element of danger to the vitality of the flap. It has been claimed that muscular tissue should not enter into the composition of a flap when it can be avoided, on the ground that muscle without function is speedily converted into fibrous tissue, and the presence of this cicatricial tissue may become an important factor in marring the final result in many plastic operations.[9] In those upon the face muscular elements cannot be excluded, since they are directly inserted into the skin; nor would their exclusion be advisable, since without them the mobility of a newly formed lip or eyelid would be out of the question. The periosteum may also, in exceptional cases, be included in the flap in plastic operations. B. von Langenbeck[10] and Ollier[11] have thus sought to utilize the osteogenetic function of the periosteum in rhinoplasty and uranoplasty, in the belief that the new bone developed by it would give the normal resistance to the repaired part.

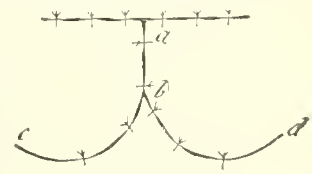

FIG. 3992.

Verneuil, Sédillot, and others question the utility of this procedure, believing, and in some instances with good reason, that the inclusion of the periosteum in a flap is an element of danger to the vitality of the part whence it is taken, and that it increases the probability of sepsis. With modern wound treatment this is excluded. Regarding operations on the palate, the danger of necrosis after periosteal denudations is certainly theoretical. Langenbeck,[12] who has probably operated oftener than any one else for cleft palate, by this method, has never seen the bone exfoliate. He has, however, noticed such an accident after rhinoplasty. Nor can there be any question as to the formation of new bone from periosteal flaps. In every congenital defect of the palate operated upon by this distinguished surgeon which was under observation more than four weeks after uranoplasty the formation of new bone was confirmed. It begins about the third week, and is completed at about the fourth week, although it subsequently gains in solidity. So far as time is concerned, the periosteal regeneration of bone after plastic operations may then be said to be chronologically analogous to that which takes place in the repair of fractures. Nor, any more than after fractures, is there any danger that the newly formed bone will subsequently undergo retrograde changes.

Digitized by Microsoft®

To increase the thickness and, therefore, the vitality of large flaps, and at the same time approximate the repaired part to the normal structure and function, very thick and even duplex flaps must often be formed. Thus, while a large defect of the lower lip may be covered with a flap from the neck, the new lip will be thin, devoid of muscular fibre, and therefore of movement, and soon becomes firmly attached to the lower jaw. It is preferable, therefore, when possible, to make the flaps of the entire thickness of the cheek, covered with skin and mucous membrane, which, when brought into position, subserve in the best manner possible the purposes of the part destroyed. Or it may be practicable, if it be deemed best to use the flap from the chin, to reflect the mucous covering of the alveolar border for a lining to the cutaneous flap. As will be seen in operations for rhinoplasty and exstrophy of the bladder, this doubling of the flap may be practised with two folds of skin, the lower of which subsequently becomes converted into mucous membrane. For this method Ad. Richard, in 1854, proposed the term "autoplastie par doublure."

www.libtool.com.cn

Fig. 3996.—Plastic Operation for Cancer of Lip. Showing (A) the proposed lines of incision, and (B) the completed operation.

3. The transplantation and permanent attachment of the flap constitute the last steps of formal plastic operations. At present all authors are agreed that, save in exceptional cases, the fixation of the flap should at once follow its formation as soon as all oozing has ceased. Tagliacozzi, however, in his rhinoplasties, allowed the under surface of the flap, taken from the arm, to suppurate before fixing it in the new position. Graefe, on the other hand, successfully practised fixation while the surfaces were fresh. In very rare cases the old operation may be followed by good results. Thus the author, in 1876, saw Billroth close a gastric fistula with a flap that had been lifted from its surface one week before fixation, the reason given for this being that the suppurating surface would be less affected by the deleterious influence of the gastric juice than one recently prepared.

In 1889 Mr. Croft described an operation which was based on this principle, and which was particularly useful in relieving the scars following extensive burns. The writer employed it to relieve a dense scar which held the thigh firmly bound to the abdomen. A broad strip of skin, six, eight, or ten inches long, is lifted between parallel incisions from the underlying structures, but left attached above and below. Strips of gauze are inserted underneath for six or seven days until granulations have formed. The flap thereby becomes thickened. At the second operation, after the defect is vivified, the granulations are curetted from the flap, its attachment at one end is severed, and the placing in position follows as in the one-time operation (Med.-Chirurg. Trans., 1889).

In 1854 Roux was compelled by circumstances, in a defect of lip and chin, to resort to a practice which some writers have sought to elevate into a special method, that by successive migrations. "It consists in fixing a flap temporarily in a new position, from which, after the lapse of several weeks, it is removed by a second operation to a part nearer the defect, where, after a number of migrations, it is finally deposited."[14] Buck has resorted to a somewhat similar expedient in extensive deformities of the face. It is only in these that it is ever practicable.

To facilitate the transplantation of a flap and to relieve tension, liberating incisions are often required. Thus, in harelip, success is not generally attainable without freely liberating the segments of the lip which are more or less bound down to the maxilla. Such liberating incisions cannot always be concealed, as in the instance cited. They should then be made as small as is consistent with the effect desired, and in the manner indicated (*g i h*, in Fig. 3978).

To close the wounds resulting from these liberating incisions is permissible only after the defect has been covered and when it is evident that closing the secondary incisions does not cause traction on the more important line of sutures closing the primary wound. Where there is any doubt, it is best to leave the liberating incisions unsutured, and the wounds to heal by granulation. In very many cases these wounds can at once be closed by skin-grafting or by using a Wolff or Krause flap. (See *Skin-grafting*.)

The fixation of the flap by sutures forms the final step of the plastic operation. The care and accuracy in apposition of the raw surfaces observed in other surgical procedures are particularly demanded here. The absence of blood within the wound is an essential to success. Hence Dieffenbach, Lisfranc, and others often postponed fixation for two or three hours until all oozing had ceased. As Verneuil justly says, while admitting the value of this method in former times, "in our day operations are generally made under anaesthesia, from which, when the patients awake, they like to believe that the operation is completed; hence it is a source of great suffering to mind and body to delay the completion of the operation."

In closing the wound the continuous or interrupted suture may be employed. Whenever applicable, the buried subcuticular suture should be used. Suture marks are in themselves often quite disfiguring. As a rule, small needles should be used. The angles of the surfaces are first approximated. While the number of sutures must be sufficient for accurate apposition and the avoidance of wrinkles in the flap, an excessive number is doubtless harmful, since every suture, however fine, interferes in a measure with the circulation in the part, and every suture may become a source of suppuration. When considerable traction must be made to hold the flap in position, one or even two deep sutures of heavy silk may profitably be inserted far from the edges of the wound as after amputation. In this way the tension on the more numerous superficial sutures is effectually removed. The material used for sutures varies according to the length of time they are to remain. In plastic operations about the face an iron-dyed silk probably answers the best purposes. These sutures can be removed, a few at a time, in from forty-eight hours to five or six

Digitized by Microsoft®

Reparative Surgery.

days after the operation, according to the union obtained. When it is desirable to retain the sutures longer, as in operations on the vagina, silver wire is to be preferred, since metals produce vastly less reaction in the tissues than silk.

Regarding the after-treatment, little need be said. The wounds are fre[illegible]re aseptic measures cannot be successfully carried out; as, for example, about the lips or nose. In these cases dry gauze compresses, held in position by properly adjusted bandages or adhesive strips, will go far toward supporting the parts and assuring primary adhesion. The writer has found gauze strips steeped in collodion an excellent dressing in many small plastic operations on the face. Wounds made for plastic purposes should be frequently examined to determine the condition of the parts, and particularly if a flap has been utilized. Immediately after its application a flap is cool, pale, and insensitive. Within from twelve to twenty-four hours, as circulation is established, its temperature rises, and a marked redness distinguishes it from the integument surrounding it. This redness easily yields to a bluish discoloration and excessive swelling, both indications of venous stasis, which, if not checked, often leads to sloughing. Loosening one or two sutures, or scarification of the flap itself, may avert such a result. If suppuration under the flap is suspected, the most dependent sutures must be removed for proper drainage. With proper precaution the presence of suppuration does not necessarily entail failure of the operation, since the flap may be held in position with small strips of adhesive plaster or by a number of sutures inserted at its salient points.

Supplementary treatment and even operations are often necessary after complete closure of the wound. Thus constant attention must be given the nostrils after rhinoplasty, the lower lip after cheiloplasty, lest the former close, or the latter become adherent. Or it may be that the contraction of the flap has not ensued to the degree anticipated, and the newly formed organ presents wrinkles of redundant skin. In the same way, the pedicle of a flap which has subserved its purposes must be excised if at all prominent. Such redundant masses can always be easily removed by oval incisions. In the case of the pedicle, several months must elapse before its excision is even to be thought of. A premature attempt in this direction of improving the result of a plastic operation may easily annul the advantages already obtained.

As has already been observed, every case requiring a plastic operation is a law unto itself. The more complicated the defect, the greater the study and practice required in overcoming it. When the destruction of tissue has been very extensive, as in noma, lupus, or burns, a single operation rarely suffices. Three, four, and even more operations may be necessary before the appearance of the face is in a measure restored. In these complicated cases, too much should not be attempted at one time, and an interval of from one to six months may often be advantageously observed between the different operations. It is in this way that the most successful workers in this field have, by repeated efforts, often extending over a period of two or three years, given a new life to individuals who, from very extensive destructions of prominent parts of the face, have been objects of disgust to themselves and of horror to those with whom it was their misfortune to come in contact.

Blepharoplasty.—Plastic operations in the eyelids as a rule come under the care of the ophthalmic surgeon. A full description of the various methods of blepharoplasty is given in the article by Dr. Van Fleet on *Eyelids, etc.*

Cheiloplasty.—The reconstruction of a lip after its partial or total destruction by injury or disease is termed cheiloplasty. In the preponderance of cases it is performed for epithelioma, and for the most part, therefore, is practised on the lower lip. The upper lip, also, at times is destroyed by noma, lupus, burns, or wounds, and thus becomes the subject of plastic repair. Except in cases of epithelioma these operations are particularly complicated, and tax the ingenuity of the surgeon through the involvement and distortion of the angle of the mouth and of more or less of the integument of the cheek or of the nose. Owing to the great variety displayed by individual defects of the lips, many methods have been devised for their relief. Only those are very serviceable in which a flap covered by integument without and mucous membrane within can be utilized. In all other methods, although at times they must be followed, the flap speedily becomes adherent to the maxilla, immovable, useless for mastication, and incompetent to retain the saliva. Another defect in the immediate result that appertains to almost all methods is the disparity in size between the sound and the reconstructed lip. The latter usually being smaller, the other projects far beyond, while the mouth presents an unnaturally contracted appearance. Still, this abnormal condition is recovered from after the lapse of a few months, the mouth being spontaneously remodelled.

In all cheiloplastics it is essential that the flap be obtained from the immediate vicinity of the defect, since failure is certain to follow any attempt to obtain it from a distance. The mobility of the parts during mastication is such that fixation of the arm cannot be maintained for a sufficiently long time or accurately enough to prevent the loss of the flap.

Cheiloplastic operations may be divided into: (1) Those that affect the lower lip; (2) those that affect the upper lip; and (3) those that affect the angles of the mouth, or the mouth as a whole (stomatoplasty).

1. Since the lower lip is repaired most frequently for epithelioma, the surgeon can often shape the defect in a way to facilitate its closure. If the neoplasm involve only a slight extent of lip, it should be removed by a V-shaped incision, when, ordinarily, no difficulty will obtain in closing the gap with deep sutures, even if the entire thickness of the lip has been removed. When the disease, however, covers a large area but is superficial, removal by a curvilinear incision is preferable, since the defect thereby produced will readily be supplied without plastic procedures. When the entire lip is involved, in thickness as well as in height, rectangular or curvilinear incisions alone are serviceable for the removal of the neoplasm. When, as is often the case, the disease involves the angle of the mouth, the incisions must necessarily be more complicated and altogether regulated by the extent of the disease. Even in extreme cases the gap can often be closed by a combination of V- or W-shaped incisions. Weber mentions a case in which the disease was very extensive. When circumstances compel the surgeon to borrow the material for the flap from the chin or neck, the methods of Chopart, of Lisfranc, or of Berg may be adopted. In Chopart's operation the diseased tissue is included between two parallel perpendicular incisions carried over the chin and on to the neck as far as the hyoid bone, if necessary (Fig. 3997) (Nélaton). When the diseased part is then removed by a horizontal incision, there remains a quadrangular flap which, when dissected up, is brought by a process of gliding to the level of the labial commissures, where it is retained by sutures. Lisfranc preferred to remove the neoplasm by a curved incision, from the centre of which (Fig. 3998) a perpendicular cut of greater or less length, carried downward, outlined two flaps which, when detached, were brought into position. Berg also gave the defect a curvilinear outline, but preferred to use a single flap from the chin and side of the neck. Fig. 3999 shows the manner of delineating the flap, of bringing it into position, and of closing the primary and secondary wounds. If the upper margins of the flap be covered, from each angle of the mouth, by a portion of the ver-

Fig. 3997.

milion border borrowed from the upper lip, the result will be excellent, although the oral aperture may temporarily be materially decreased in size. To accomplish

www.libtool.com.cn

FIG. 3998.

the same end Serre, in an extensive epithelioma of the lower lip, practised Chopart's operation, preserving the mucous membrane of the lip for a covering to the flap.

FIG. 3999.

It is almost needless to say that it is only in exceptional cases of very superficial neoplasmata that this method is at all applicable.

When the defect after removal of an epithelioma is triangular, with base involving the greater part of the lip, the operations of Dieffenbach or Malgaigne may be pro-

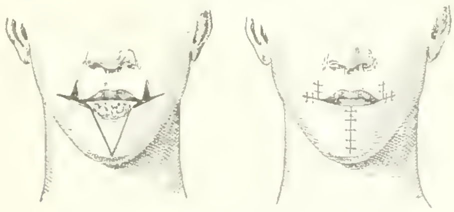

FIG. 4000.

fitably resorted to. That of the German surgeon consists in making an incision on each side from the angle of the mouth toward the masseter and in the line of the labial fissure. The length of the horizontal incision is half that of the base of the defect. The quadrilateral flaps thus raised are brought together in the median line by their

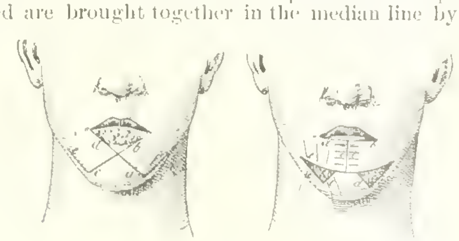

FIG. 4001.

internal borders. The operation of Malgaigne differs from this in that he refrains from the use of the perpendicular incision. To overcome the redundancy of the upper lip, a triangular portion may be excised (Fig. 4000). In either operation the new lip can easily be lined with mucous membrane, if that of the cheek be divided at a higher level than the integument in the horizontal incisions from the angles of the mouth. In cases in which the defect is triangular and shallow its closure by later incisions, after the method of Syme, presents many advantages. By this method the incisions are prolonged downward and outward for an inch, whence they are carried upward and outward for a varying distance. The flaps thus outlined are dissected off the bone and brought together in the median line. The mucous membrane and skin are stitched together along the upper edge, and the triangular interval on each side is left to heal by granulations. To facilitate union of the flaps, the tip of the spur left below the apex of the defect may

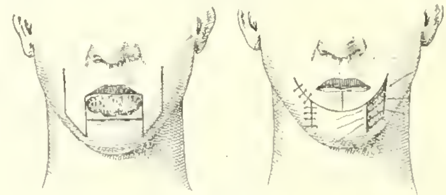

FIG. 4002.

be removed after the flaps have been raised (Fig. 4001) (Nélaton). The very great advantage of this method over those preceding it is that, since the integument covering the chin is not disturbed, the flaps cannot sink or be drawn downward toward the neck, and the new lip will maintain its original height. Quadrangular defects of the lower lip may be successfully overcome by resorting to two rectangular flaps taken from the chin or from the side of the chin. Sédillot (Fig. 4002) made the flaps at right angles to the line of the mouth from the side of the chin, while Bruns preferred to make them obliquely and from the cheek. When the flaps are raised they are turned on their respective pedicles, when their inner borders meet in the median line. When circumstances permit of a choice between the method of Sédillot and that of Bruns (Fig. 3984, diagrammatic), the former should be preferred, since in the latter there is considerable danger of traction on the cheeks with a resulting deformity. The operation of

FIG. 4003.

Sédillot also offers a better opportunity for covering the upper edges of the flaps with part of the vermilion border of the upper lip. When this is severed for half an inch or more on each side from the upper lip, the flaps forming the lower lip can be almost entirely covered. Schuh's practice of tattooing the edge of the lip for cosmetic purposes has probably never been followed by other operators. In 1869 Langenbeck first practised a cheiloplasty which has gained many followers in Germany. In this method the diseased lip is removed by a curvilinear incision (Fig. 4003). A flap is then prepared from the integument of the chin (1) the base of which is on the side of the oral angle. The free extremity of the defect is not directly under the oral defect, but separated from it by a triangular portion of skin (2). Both flaps being raised, the lower is elevated into the defect, while the other is utilized in closing the breach below (Fig. 4004). The presence of the spur prevents the sinking of the lip.

FIG. 4004.

When it is desirable, the upper edge of the flap may be covered with a portion of the mucous border of the upper lip. Gurdon Buck ("Rep. Surg.," p. 22), and Est-

länder (*Arch. f. Chir.*, xii.), closed defects of the lower lip with flaps taken from the upper. Buck, after removing the growth by a V-shaped incision, or by one horizontal and two perpendicular incisions in more compli-

www.libtool.com.cn

FIG. 4005.

cated cases, brought the sides of the gap together directly, or, in the case of the quadrangular defect, by forming two horizontal lateral flaps which were secured to each other in the median line by pin sutures. After closure of the wound had been effected, a secondary operation was performed to transfer the redundant tissue of the upper to the deficient lower lip, and thus to restore the symmetry of the mouth. This operation is performed as follows: A point is selected about a finger's breadth below, and a little without, the oral angle on each side, and marked by the insertion of a pin through the skin. Another pin is inserted on each side at the junction of the vermilion border of the upper lip with the skin, about one-fifth of the distance from the angle of the mouth to

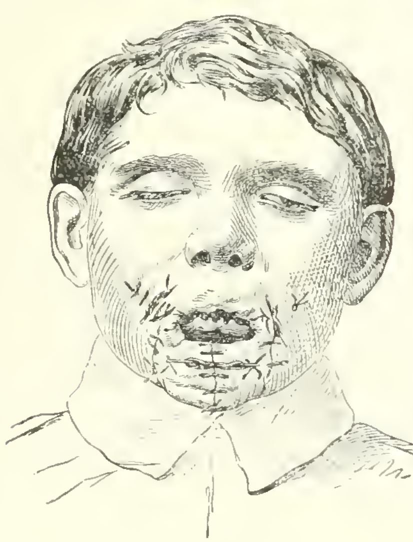

FIG. 4006.

the median line of the lip; and a third pin on each side is inserted into the integument of the cheek, about an inch and a half above and without the angle of the mouth. The points indicated by the first and third pins are then to be united by an incision through the entire thickness of the cheek, and in like manner the points indicated by the second and third pins. A triangular flap is thus formed, with its base toward the angle of the mouth. From the point indicated by the first pin, a vertical incision is now made to the base of the jaw. The integument in this region being in a state of great tension, the edges recede and form a space for the reception of the

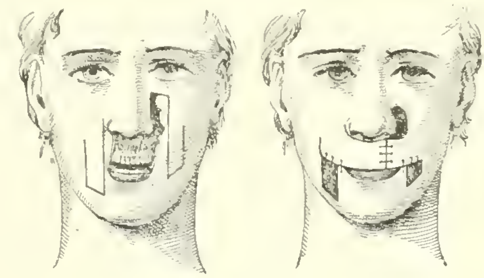

FIG. 4007.

triangular flap, with its apex toward the base of the jaw, and its base, including a portion of the vermilion border of the upper lip, supplying the deficiency of the corresponding side of the lower lip. When the operation on both sides is completed the configuration of the mouth is nearly normal. (Figs. 4005 and 4006, from Buck.)

Estländer's operation differs from that of Buck in that the outer incision is curvilinear, and that the plastic operation at once follows the extirpation of the tumor.

(2) In reconstructing the upper lip, the operator has the choice of a number of methods. In cases of total deficiency, the method of Bruns, already referred to (Fig. 3984), yields excellent results. Bérard utilized two lateral flaps from the cheeks, including them between parallel horizontal incisions, carried outward to the masseter, the upper from the angle of the nose, the lower from the angle of the mouth. The flaps thus formed are brought into position by gliding, and united by pin sutures in the median line. A better operation for severe cases is that of Sédillot (Fig. 4007), which is performed as follows: On each side of the oral angle a quadrilateral flap, of the width and half the length of the lip, is outlined by two perpendicular incisions and one horizontal incision on each side. The inner of the perpendicular incisions is carried higher than the outer. When the flaps have been thus outlined, they are raised from the underlying tissues. The entire thickness of the cheek is

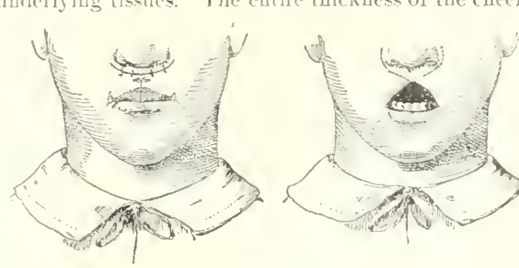

FIG. 4008.

included in the flaps, which are therefore lined with mucous membrane. When the flaps are brought into position, their lower borders meet in the median line, the inner borders are sutured to the upper margin of the defect beneath the nose, while the outer borders assume the position of the free border of the lip. With a little traction the mucous membrane and the integument of this border can be united by a number of very fine sutures.

When the defect of the upper lip is central and not very extensive, the method of Dieffenbach presents much to recommend it. It consists in transfixing the cheek on each side of the angle of the nose, and forming a flap on

Digitized by Microsoft®

Reparative Surgery.

each side by a curvilinear incision (Fig. 4008). When these flaps are raised from their attachments to the alveolar border, they are easily brought into apposition by their internal margins in the median line. The method of fixing the flap beneath the nose is also shown in the illustration. The advantage of this method, when it is applicable, is in the greater height given by the curvilinear incision into the flap in the median line, and in the fact that its free border is naturally covered by mucous membrane.

www.libtool.com.cn

FIG. 4009.

Ledran and Roux utilized one-half of the lower lip for repairing deformities in which the outer half of the upper lip was lost. Both of these operators transplanted a quadrangular flap with its pedicle outward. This method was greatly improved upon by Buck, who, placing the pedicle internally, temporarily reduced the length of the oral fissure. This method of operation is shown in Fig. 4009. The extremity of the lower lip, where it joins the right cheek, is divided through its entire thickness at right angles to its border, and for a distance of an inch (*a b*). A second incision is made from the end of the first, parallel to the labial border, for a distance of one inch and a half (*b c*); from *c* a short incision (*c d*) is made toward the free border of the under lip, and parallel to the incision (*a b*). The quadrilateral flap thus formed from the lower lip is now turned upon its pedicle to meet the remaining portion of the upper lip, to which it is attached by its free extremity (*a b*). Fig. 4010 shows the result of this operation, and the method of overcoming the deformity of the angle of the mouth which results.

3. STOMATOPLASTY.—Destructive ulcerative processes about the lips and angles of the mouth occasionally give rise to deformities which, by greater or less closure of the oral aperture, interfere with the process of mastication, and eventually threaten the life of the individual. In extreme cases the labial fissure is contracted to a degree which compels the patient to live on liquid food alone. Until Dieffenbach's remarkable contributions to plastic surgery, it was customary to treat these cases by the insertion of a seton of silk or of wire. As in cases of syndactylism treated in this way, the result was generally unfortunate. Dieffenbach's method, which, unless the mucous membrane is everywhere adherent to the alveolar border, is as a rule successful, is performed as follows: On each side of the contracted oral orifice a narrow triangular strip is excised from the skin. The base of the triangle is internal, its rounded apex external and at the point where the angle of the mouth is to be. The excised triangular portion should include everything down to the mucous membrane, which remains intact in the floor of the wound. The mucous membrane is then divided in the floor of the triangle, thus forming an upper and a lower flap, which, when everted, will clothe the free borders of the new lips and meet externally at the angle of the mouth. The excess of mucous membrane is thus utilized in forming the vermilion borders of the lips.

Buck's method of stomatoplasty, already alluded to, differs somewhat from that of Dieffenbach. He makes an incision along the line of the vermilion border circumscribing half of the mouth, and extending to an equal distance above and below (Fig. 4010, *a b*). This incision should divide the skin and subcutaneous tissue, but not involve the mucous membrane. A sharp-pointed double-edged knife is then inserted between the skin and the mucous membrane, and these parts are separated from each other as far outward as the point proposed for the angle of the mouth. The skin alone is then divided with strong scissors along the line which is to separate the upper from the lower lip (*c d*). The mucous membrane is next divided along the same line, but not so far outward, the difference in the length of the division of skin and mucous membrane being a little less than the thickness of the cheek. The angles at the outer ends of the two incisions are then carefully united by a single-thread suture, and the operation is completed as in Dieffenbach's method. To accommodate the mucous membrane to the borders of the lips, thin slices of integument must, as a rule, be pared from the upper and lower borders of the wound.

RHINOPLASTY.—The nose gives character to the face by its prominence and central position. Its absence or deformity is therefore more naturally observed than that of any other feature. It is only through familiarity with the nasal defects caused by syphilis or lupus that one without unusual vanity can understand why Tagliacozzi devoted a special chapter to the "dignity of the nose," and can appreciate the saying of Lavater, that "a beautiful nose is worth a kingdom." Passion, disease, love of honor, and punishment for crime, have all, in times past, contributed to producing the greatest facial disfigurements by attacking the nose. Hence the surgical art was taxed early to repair the deformed part, and rhinoplasty became the foundation of plastic surgery in general. In previous centuries, when the loss of a nose was a punishment for crime, or was voluntarily inflicted to preserve virtue, rhinoplasty was doubtless a more common operation than now. Sixtus V. freed Rome of its bandits by cutting off the noses of all who were caught. The Abbess of St. Cyr disfigured herself and forty of her nuns in the same manner, to preserve their virtue when the Saracens raided Marseilles. In our more civilized times, nearly every case requiring rhinoplasty is one in which the defect is the result of disease; although, in exceptional instances, a vicious bite or, as in Germany, a duel, is the cause for plastic interference.

Notwithstanding the accumulated experience of generations of surgeons, and the closest attention to every technical detail that could further the results of rhinoplasty, it must still be admitted that the best nose that can be formed by a plastic operation is hardly as presentable as the natural feature that is even far removed from the ideal. It is far preferable, however, to the artificial nose formed of vulcanized rubber, and retained in position with collodion or by means of a spring. After a rhinoplasty that is at all successful, the catarrhal condition of the nose and pharynx is improved, the senses of smell and of hearing return, and the irritating cough which so often is present in extensive defects of the nose, rapidly disappears. A successful rhinoplasty is productive of benefits which cannot follow the use of any nose fashioned by prosthetic skill.

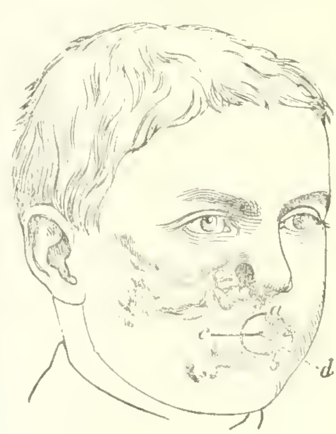

FIG. 4010.

Since the time of Dieffenbach, rhinoplastic operations have been divided into the total and the partial. It is particularly in partial rhinoplasty that great strides have been made within the last half century. To consider systematically the different operations for repair of the

Digitized by Microsoft®

Reparative Surgery.

nose, nasal deficiencies, according to Gross, may be classified as follows: (1) Loss of the entire organ, bones as well as soft parts. (2) Destruction of the whole or greater portion of the cartilages, the bridge remaining intact. (3) Mutilations of the tip, as when a small piece is cut or bitten off, including a part of the wings. (4) Loss of one wing, either www.libtool.com.cn the nasal column. (5) Perforation of the nose, either on top or at the side; in the latter case with or without participation of the cheek. (6) Sinking of the organ from destruction of the cartilaginous septum of the nose, the soft structures being but little, if at all, affected. (7) Loss of the column. (8) Mutilation of the nose and upper lip, or the nose, lip, and cheek.

FIG. 4011.

When the entire nose has been lost, there is generally a large pyriform aperture which allows free inspection of the nares and nasopharynx. For the alleviation of this condition, it is always best to fashion the nose from a flap taken from the forehead, by what is known as the Indian method. Before proceeding to a total rhinoplasty, the defects should be covered with a model of clay, wax, or dough, which should approximate as much as possible in size and form an ideal nose. Over this is accurately fitted a piece of soft leather or moleskin plaster, the lower margin of which is pressed into the nostrils and made to cover the nasal column. The shape of this piece of leather or plaster, when removed from the model, is pyriform, with its base below and apex above. A second piece of leather or of plaster, one-third larger in all its dimensions, should then be prepared from the first, the increased dimensions being allowed for shrinkage. The model thus prepared, when applied to the forehead, is shown in Fig. 4011 (Linhart). The plastic operation proper is preceded by freshening the edges of the defect. This must be done as liberally as possible, in order to procure a wide surface of contact for the flap. The vivified border should everywhere measure one-third or even half an inch in width. When this step of the operation is completed, the leather or moleskin model is applied either perpendicularly or obliquely to the forehead. The latter is probably the better method, since less rotation of the flap is required to bring it into position. When the forehead is decidedly low, no alternative is presented to the operator, since the central excision of the flap would necessitate the inclusion in it of a considerable portion of the hairy scalp. König and others maintain, however, that the frontal scar resulting from central location of the flap is less disfiguring than that which follows the other procedure. Lisfranc, Linhart, and von Langenbeck prefer to take it from the side. When the operator has applied his model in the desired position, an incision down to the periosteum is carried around it. The incision, as shown in the figure, begins at the right margin of the defect, is carried obliquely over the right eyebrow, and descends on the left side of the model, terminating above the internal end of the left brow. In terminating this incision, it is essential not to interfere with the angular artery, since the vascular supply of the new nose, in a large measure, depends upon the integrity of this vessel. The pedicle left between the ends of the incisions should measure from one-half to three-fourths of an inch in width. The flap thus outlined is now rapidly raised, being made to include, besides the integument, the aponeurosis and fibres of the occipito-frontal. In the lower part of the flap the periosteum can safely be included. Langenbeck included it in the entire width of the flap, except in the parts of which the column and alæ of the nose were to be formed. When hemorrhage from the edges and raw surface of the flap has been controlled, it is rotated into position in such a way that the raw surface looks backward, and its base naturally comes in contact with the freshened margin of the upper lip. The next step of the operation is the formation of the septum and alæ. This is readily accomplished by two oblique incisions, one inch in length (dotted line in Fig. 4011), which, running toward each other, are separated at their central ends by an undivided interval nearly an inch wide. When the triangular flap included between these incisions is doubled upon itself, the column and septum of the nose are perfectly formed. By an upward duplication of the lateral parts of the flap, the alæ and nostrils are next formed, and maintained by transfixing sutures. To facilitate the closure of the frontal wound and to obtain larger nostrils, Langenbeck does not remove the small triangular portions seen on each side of the base of the flap, but makes the central portion, from which the septum is made, rectangular and one inch wide. When the nose has thus been formed and the raw surfaces have been thoroughly cleansed, the new organ is brought into position and retaining sutures are applied. The most important sutures are those which hold the alæ of the nose to the cheek and the septum to the upper lid. For each wing and the septum three sutures are requisite; for the wings one externally, one internally toward the nostril, and one beneath toward the lip. Since it is the septum that most frequently fails to unite with the upper lip, unless extraordinary care be taken, it is advisable to make a special groove in the central part of the upper lip, three to five lines in length, into which the lower end of the septum is firmly implanted after it has been divested of cuticle. The operation is then completed by suturing the lateral margins of the new nose to those of the cheek, particular care being given to securing a good apposition of the pedicle in the upper end of the defect. If the wound in the forehead is very large, it may in part be closed by sutures, although the greatest caution must be observed to prevent traction on the pedicle. If the entire wound of the forehead is left to granulate no harm results, and the scar is probably not more ungainly than that which follows what is ordinarily an unsuccessful attempt at obtaining its closure by primary union. To maintain the patency of the nostrils, and at the same time to further adhesion of the double integumentary folds, it is well to introduce portions of a drainage tube into the nostrils after the operation is complete. The new nose may then be lightly covered with oiled silk and antiseptic gauze or lint, care being taken that no foreign material becomes adherent to the sutures.

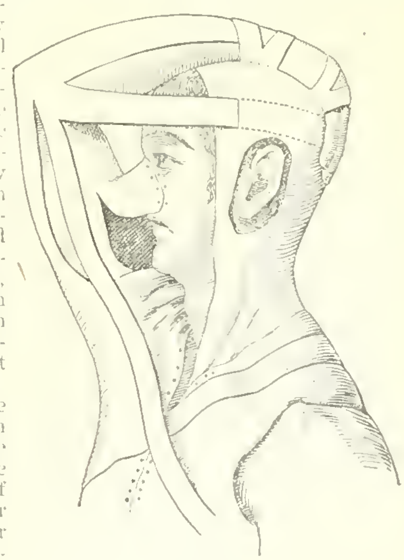

FIG. 4012.

There are rare cases in which previous disease has unfitted the integument of the forehead or of the cheek for rhinoplastic purposes. Under such circumstances only is one justified in resorting to the Italian operation of rhinoplasty from the arm. The first step in this procedure is to outline a flap of integument from the inner surface of the middle of the arm, measuring four inches in length and three in width. The flap is raised between two parallel longitudinal incisions, but retained above

Digitized by Microsoft®

and below in relation with the remaining integument. To prevent reunion a piece of oiled lint is placed underneath the flap. The inflammatory process which follows the elevation of the flap causes this greatly to increase in thickness, while its interior surface, in from two to three weeks, becomes clothed with granulations and eventually cicatrized. When, [illegible]ne, the flap is sufficiently thickened, its upper connection with the arm is severed by a transverse incision which leaves a wide raw margin at the upper end of the flap, which is sutured to the vivified margins of the nasal defect. This part of the operation Tagliacozzi usually performed in the fourth week after the first operation. Since it requires from one to two weeks before the lower end of the flap can be safely severed from the arm, the latter must be supported in relation with the head and face. Fig. 4012 shows Tagliacozzi's method of accomplishing fixation of the arm by means of a cap and jacket. Wutzer's apparatus for obtaining a similar end is shown in Fig. 4013. In taking the skin from the forearm or back of the wrist, he found it necessary to support the arm and forearm in splints. When such an apparatus has been worn for from one to three weeks, the upper end of the flap will have become firmly united to the apex and sides of the triangular nasal defect, and it is then safe to sever its brachial connections, when the formation of the wings and septum can be completed as in the Indian method. Graefe modified the Taliacotian operation by at once fixing the flap to the vivified edges of the defect, thereby apparently curtailing the period of fixation of the arm. This, which is known as the German method, has found even fewer followers in recent times than the older operations. It manifestly gives greater opportunity of shrinkage of the flap and subjects the patient to the annoyance of a large suppurating surface near the mouth, which by the older operation is cicatrized before it is transplanted. Dieffenbach exceeded both Tagliacozzi and Graefe in the extent to which he reformed the nose from a brachial flap, in that the entire nose, with the exception of one ala, was formed as the first step of the operation. After shrinkage and cicatrization had followed, the actual transplantation of the nose was effected in from six to eight weeks.

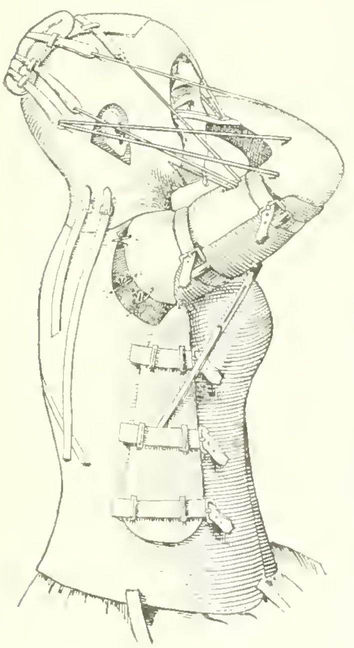

FIG. 4013.

The operations thus far described, unless gangrene supervene in the flap, effectually close the nasal defect. For the most part, however, the newly formed nose, irrespective of its original prominence, sinks and contracts until eventually little more than an integumentary curtain closes the defect. To obviate this result a number of procedures have been adopted, among which that of Thiersch probably deserves most prominent mention. As the first step of the operation, he forms on each side of the defect a rhomboid flap from the cheek, the attached base of which is in relation with the freshened edge of the defect, its free border being external. When these flaps are raised from the cheek on each side they are inverted, so that the cutaneous surfaces look toward the nares, the raw surfaces outward, and in the median line are in contact with each other. The nostrils and septum being thus formed, a frontal flap is brought down to cover the flaps from the cheeks, the operation being completed in the ordinary way. Verneuil procured a permanent elevation of the bridge of the nose by a somewhat similar operation of superposition of the flaps. In this case the frontal flap was taken from the median line, and deflected in such a manner that the cutaneous surface looked backward. Over the raw surface two quadrilateral flaps from the cheeks were brought by a process of gliding and united along the median line. Finally, Langenbeck and Ollier have given the new nose an osseous substructure by sawing a strip one-fourth of an inch wide from the nasal processes on each side. This strip, after being broken through its attachments below, is deflected toward the median line, where it meets its fellow of the opposite side. If the nasal bones are present and only depressed, which they generally are, they must be brought into position by the free use of the elevator.

FIG. 4014.

Quite recently König (*Langenb. Arch.*, vol. xxxiv., p. 165) presented to the Congress of German Surgeons a method of obtaining an osseous framework for the repair of sunken noses, and for the permanent elevation of the nose after total rhinoplasty. The method is virtually one of superimposed flaps, both being taken from the forehead. A median flap of the requisite length and half an inch in width is formed from the forehead in the median line. The incisions bounding this narrow strip are carried down to the bone. When this flap is raised the external table of the frontal bone is raised with it as far as the root of the nose. The flap thus elevated is inverted, so that the cutaneous surface faces the nasal fossæ. Over the raw external surface a second frontal flap is then placed and fixed as in the ordinary Indian operation. In four cases in which König performed this operation for a sunken condition of the nose, the repaired organ retained its solidity after from one to nearly four years had elapsed from the time of the operation.

The partial destruction of the nose also presents many interesting peculiarities that require partial rhinoplasty. When the tip and alæ of the nose are intact, while the body and bridge are lost, the defect should be closed by a frontal flap (Figs. 4014 and 4015). In this case Linhart removed an epithelioma involving almost all the cartilages and a portion of the bony framework of the nose—only the margin of the nostrils on each side was preserved. Mutilations of the tip of the nose can also be repaired by a frontal flap. Figs. 4016, 4017, and 4018 illustrate the defect and the results of operation in a case of Buck's, in which the tip of the nose was bitten away. In this case the freshening of the edges of the defect was followed by the elevation of the patch of skin above the defect as far as the root of the nose between the eyebrows. A frontal flap of requisite length and width was then brought into

Reparative Surgery.

the breach, the skin previously displaced from the nose being fitted into the frontal wound. In Fig. 4017, *a* and *b* indicate the disfiguring prominences resulting from rotation of the flaps. When these were excised the admirable result shown in Fig. 4018 was obtained.

The tip of the nose may also be repaired with a flap from the cheek (Linhart, Fig. 4019). The pedicle of this

www.libtool.com.cn

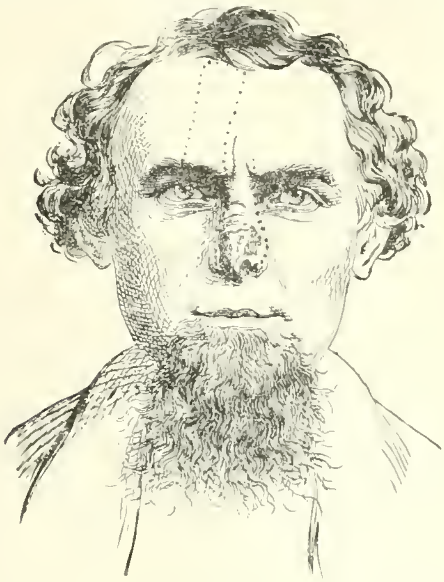

Fig. 4016.

flap extends quite to the root of the nose; its broad end may be divided by two incisions (dotted lines) for forming parts of the nostrils and septum, as in total rhinoplasty. Before the flap can be inserted, the remaining integument of the nose must be divided in the median line and reflected on each side. It frequently happens that with the tip one of the nasal alæ and the column are

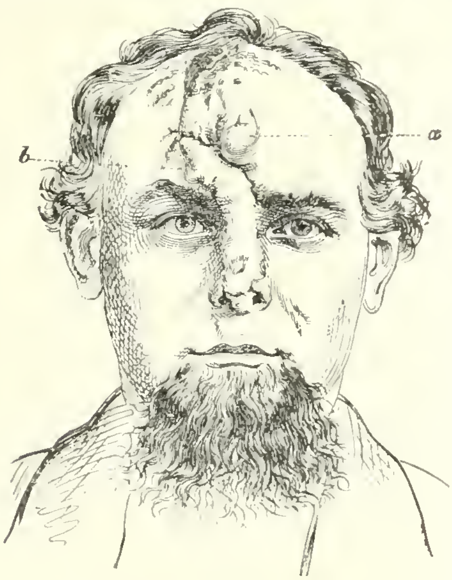

Fig. 4017.

lost. To repair this defect the integument of the root of the nose, of the glabella, and of the internal angle of the orbit was utilized by Busch (Fig. 4020). The pedicle of the flap is placed on the healthy side of the nose, low down, and on a level with the defect. When the flap is brought into position, its lower portion forms the tip and column of the nose, while its upper part, when duplicated, replaces the lost ala. The repair of defects of the nasal wings can be accomplished by a number of procedures. When the defect is long but narrow, it is prob-

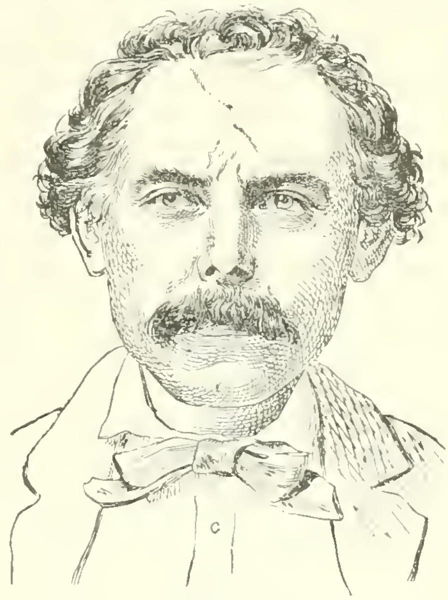

Fig. 4018.

ably best, as Dieffenbach taught, to refrain from attempting a plastic operation, and to produce a similar defect on the opposite wing. In some cases it is advisable to excise the defect in a triangular way, and to close the breach with a flap from the side of the nose. Fig. 4021 illustrates the method of obtaining it and the incisions (dotted lines) necessary for placing it in position. In larger defects of a nasal wing it is advisable to procure

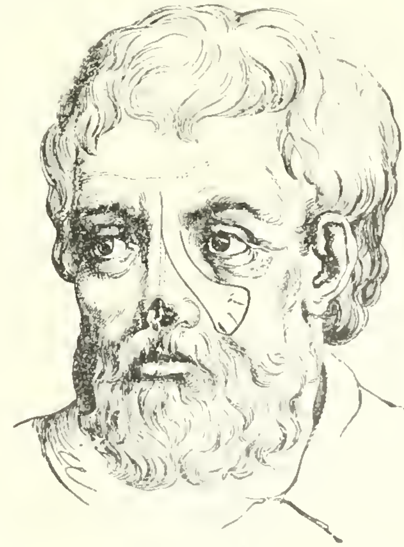

Fig. 4019.

a flap, quadrilateral in shape, from the cheek or from the upper lip. In Figs. 4022 and 4023 the method of Bonnet is shown; to give the angle of the nose a more shapely

Digitized by Microsoft®

form, and to facilitate the rotation of the flap, a wedge-shaped portion (*b*) may be excised from the base of the flap. In this operation the vermilion border of the flap must be removed, and the fissure in the lip is to be closed at once. Perforations of the nose resulting from wounds or ulcerations are generally seated at the sides of the nose. They may readily be closed by flaps of suitable shape and size, taken from the forehead, from the cheek, or from the opposite side of the nose.

www.libtool.com.cn

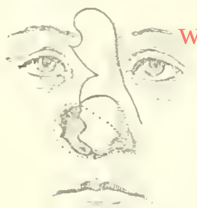

FIG. 4020.

The nasal column, when it alone is defective, can be admirably repaired from the central portion of the upper lip, which must be included between parallel perpendicular incisions. When the flap thus formed is brought in contact with the nasal septum, its mucous surface is of course exposed and is eventually converted into skin.

In the most complicated of nasal defects, finally, other parts of the face are also, as a rule, deficient. This is particularly true of the upper lip, of portions of the palate, and of the cheek. In such complicated cases, as has already been intimated, many operations are required before the face can be made at all presentable. In cases of this character the lip, the angle of the mouth, and the nose all require separate operative treatment. If, however, from one to three years be devoted to the judicious management of such a case, the result will in every way repay patient and operator for the patience displayed.

Paraffin Injections in Reparative Surgery.—In order to fill up the scrotum of a very sensitive young man, which had been left empty after a castration, Gersuny[15] in 1900 devised the ingenious method of injecting vaseline. Encouraged by the good result obtained in this case, he extended the procedure to cases in which other than the distinct cosmetic effect was desired. The result which Gersuny[16] obtained in a case of urinary incontinence in a female, which had resisted all other methods of treatment, was so brilliant that other surgeons at once took up the new procedure, and so its use soon became widespread. A considerable amount of good work has been done at von Bergmann's Klinik by Stein.[17] He prepares paraffin, which should have a melting point between 42° and 43° C., by melting and filtering with a hot water funnel, such as is used in the filtration of bacteriological culture media. The filtered paraffin should be put into wide-mouthed flasks, such as Erlenmeyer's, and plugged with cotton wool. In these it is sterilized in the hot air oven at a temperature of 200° C. for a half hour, and can then be preserved indefinitely, ready for use at any time. Before using, the flasks containing the paraffin are heated in a water bath to the melting point. The injection is made with a Pravaz syringe, wholly made of glass, holding about 1 gm. The object is to have a syringe devoid of all sharp corners and edges, so that the paraffin does not so easily congeal. Before injecting the paraffin, the filled syringe is again put into hot water and then the needle is screwed on. The injection is made by lifting up a fold of skin with the left hand and with the right inserting the needle and injecting slowly until the desired amount has been used. The needle is then withdrawn and a small piece of plaster fastened over the puncture. The paraffin is now moulded into the desired shape, while an assistant allows the ethyl chloride spray to play upon the part. Several injections may be made at different times, but care must be used not to insert the needle over the area previously injected, as it should be inserted to the side of it. According to Juckoff[18] paraffin after its injection acts like any foreign body, and causes a reactionary inflammation with the formation of new tissue. Some of the paraffin is absorbed here and there, so that finally we have the mass pervaded by connective-tissue strands, which emanate from a fibrous capsule around the whole. This capsule is fused with the adjacent tissue.

FIG. 4021.

This excellent method is not without a small amount of danger. The following unfortunate occurrences have taken place: Embolism of lung and intestinal organs from the accidental insertion of the needle and injection into a vein; infection from faulty asepsis; gangrene and sloughing from the introduction of too much paraffin, as a result of which obliteration of the blood-vessels has occurred.

FIG. 4022.

The method is applicable to cases in which the normal contour of the body is lost. It has been used with distinct benefit in saddle nose following caries of nasal bones. In one case treated at von Bergmann's Klinik, the result was striking. Several injections were made at different places and the nose was thus gradually built up. The injection should be made with care so that none of the paraffin shall find its way into the orbit. Cleft palate may be treated by this method, which is chiefly applicable to those cases in which a small foramen has remained after staphylorrhaphy. The contour of the cheek might be re-established after removal of the superior maxillary bone. The scrotum may be filled up after castration. The method is applicable to another class of cases, namely, those of urinary incontinence, especially in the female, in which condition a ring of paraffin is injected about the neck of the urethra so as to replace the sphincter. A cystocele has also been treated, with distinct benefit, by injections between the vagina and bladder wall. By establishing a paraffin depot around the rectum fecal incontinence has been cured. The method is still new and sufficient time has not yet elapsed to establish the permanency of cure in many of the brilliantly successful cases; nor have there been many opportunities to examine the changes produced in the tissues, beyond those produced experimentally on animals in the laboratory. The method promises much in the future, and certainly is a valuable aid to our surgical technique.

REPRODUCTION.—The various processes by which new organisms are produced are included in the general term, *reproduction.*

It was thought by the ancients that many organisms of complicated structure, such as worms, insects, plants, etc., could be formed from mud, decaying material, and other dead matter by a process of spontaneous generation, or *abiogenesis.* It was proved by Redi in 1688 that abiogenesis does not occur in insects, but it remained for Pasteur and his colleagues in the latter half of the nineteenth century to show that even the minute and simply

Digitized by Microsoft®

organized bacteria are always produced by division of the living substance of pre-existing individuals of the same species; that is, reproduction in the present condition of the world is always a process of *biogenesis*. Not only is every organism produced by a pre-existing organism, but every cell arises by division of a pre-existing cell, and every nucleus by division of a pre-existing nucleus. (See *Cell.*) Moreover, there is good evidence for the belief that the minute but apparently important elements of the nucleus, known as *chromosomes* (*q. v.*), are also produced only by division of pre-existing chromosomes. So reproduction, like all other vital functions in health and disease, must be regarded as essentially a cellular phenomenon.

Reproduction may be either sexual or asexual. The essential feature of *sexual* reproduction is the development of an embryo from a *fertilized* egg, that is, a germ produced by the union of an *ovum* and a *spermatozoon*, or their equivalents (see articles *Ovum*, *Spermatozoa*, and *Impregnation*). The capacity to produce one or the other of the reproductive elements, together with the associated peculiarities, constitutes the quality of *sex* (*q. v.*). Both of the reproductive elements are cells derived from apparently indifferent germ cells by an interesting process of development, which is discussed under the heading *Reduction-Division*. This process takes place in certain special organs, for which the general name is *gonad*, the female gonad being called the *ovary* and the male gonad, the *testis*. When the eggs or spermatozoa are ripe they are discharged from the gonad, and fertilization may take place outside of the body, as in most fishes, or within the oviduct (Fallopian tube, uterus, etc.), as in man. In man and other mammals the discharge of the ova is associated with certain peculiar physiological phenomena described in the article on *Menstruation*.

Fertilization having taken place, the egg proceeds to divide by the usual process of cell division, and by repeated divisions forms a mass of cells which becomes the embryo. The details of this process vary in different animals, as will be seen by reference to the article on the *Segmentation of the Ovum*. Sooner or later the cells of the embryo begin to differ among themselves in accordance with their destiny in the formation of organs. The causes of these changes are discussed under the title *Differentiation*, and the development of the embryo in form and structure is described in detail in the articles *Fœtus* (in THE APPENDIX), *Area Embryonalis*, etc.

Both during development and in the adult condition there is a noticeable similarity between parent and offspring at corresponding stages. This is a fact of great importance, and is fully treated in another place (see articles *Heredity* and *Reversion*).

When reproduction takes place by some method without the aid of a fertilized egg, it is said to be *asexual*. In the bacteria and some of the lower animals the reproducing individual divides into two or more nearly equal parts. This is called *fission* (*q. v.*). In the yeasts, the higher plants, and some animals, a small part of the parent grows more rapidly and becomes differentiated into a new individual. This is *budding* (*q. v.*). A third form of reproduction occurring normally in some species is known as *parthenogenesis* (*q. v.*), which may be regarded either as an asexual or as a degenerate sexual process. In such cases the offspring is produced by the development of an egg without fertilization. *Robert Payne Bigelow.*

RESALDOL is a light-brown powder prepared by the action of chlormethyl-salicyl on resorcin by means of acetylization. It is insoluble in water, ether, chloroform, benzol, and acids, and soluble in alcohol, acetic ether, and alkalies. Its taste is insipid and astringent. On account of its insolubility in acid media it causes no derangement of the stomach (Hermann), but in the intestines sets free the diresorcyl radical and acts as an astringent and antiseptic. Hermann recommends it in acute and chronic diarrhœa, colitis, the early diarrhœa of typhoid fever, intestinal putrefaction, and infantile diarrhœa, and he finds it useless in nervous diarrhœa or that due to mechanical irritation. Brochocki employed it in twelve cases of tuberculous enteritis, four of acute gastro-enteritis, three of catarrhal dysentery, and three of typhoid. All except the typhoid cases improved, though xeroform, bismuth, and opium had failed. The dose is 1-1.5 gm. (gr. xv.-xxiv.) three times a day. *W. A. Bastedo.*

RESECTION OF THE JOINTS.—The history of this operation dates from the year 1783, when Henry Park formally proposed the operation for the removal of disease. In 1786 Moreau first performed it, and became its stanch advocate as a method of treatment. Little was done, however, until Syms in 1831 in the elbow, and Ferguson in the hip, knee, and wrist, made use of this operation as a conservative method of treatment ("Excision of Joints," R. M. Hodges, Boston, 1861). Since this time this method of treatment has been wonderfully advanced and has been adopted by the ablest surgeons.

A resection is the removal of a portion of the skeleton without great sacrifice of the soft parts. Applied to joints it has for its object the more or less complete removal of the bones forming the joint, the preservation of the sensibility, contractility, and vitality of the soft parts influencing the joint, and the ultimate restoration of motion or the production of ankylosis.

When motion is desired—the ideal object of articular resections—the ends of the bones left in contact must be adapted to one another, and so fashioned in shape as to reproduce the joint surfaces removed. The muscles which move the joint must be left undisturbed in their attachment; or, if disturbed, restored so that their functional action is not compromised.

The ligaments and fibrous bands which subsequently develop and unite the bones must be analogous to those present before operation. To obtain this end, all ligaments must be preserved with their bony or periosteal attachments.

To attempt a nearthrosis with a sacrifice of the muscular and ligamentous attachments often results in a useless pseudarthrosis, inferior in every respect to a useful ankylosis.

To obtain mobility with steadiness and strength in action the preservation of the muscular and ligamentous attachments to the periosteum and the continuity of the articular capsule with the periosteum must be made the main object of the operation. Such a method of operating is known as the subperiosteal or subcapsulo-periosteal resection. Its object is motion with strength and steadiness in action.

In case a solid union—ankylosis—is desired, two conditions arise which influence the result. The first is seen when the divided ends of the bones can be brought into apposition and their fusion takes place directly. In this case ankylosis is assured, provided the disease is removed. The second condition exists when the divided ends of the bones cannot be brought into apposition, but are separated by an appreciable distance from one another. The union here takes place principally through the agency of the periosteum, and ankylosis, more or less doubtful and dependent upon the osteogenic power of the periosteum, results. It is in this latter variety that the pseudarthrosis and flail joints occur.

When ankylosis is desired and is reasonably attainable, the preservation of the muscular, ligamentous, and capsular attachments to the periosteum are of secondary importance.

When bone or a bony prominence is separated and replaced *in situ* in order that diseased tissue can be more thoroughly removed, the resection becomes an osteoplastic one.*

Again, resections are either complete or partial: complete when the component bony surfaces are removed; partial when one or more, but not all the articulating surfaces are removed.

Resections may therefore be partial or complete, par-

* This term is sometimes used and applied to operations in which bones not normally apposed are brought together after removal of the intervening bone or bones.

www.libtool.com.cn

Digitized by Microsoft®

osteal or subcapsulo-periosteal. They may also be osteoplastic.

The Incision.—They should avoid nerves and vessels. When possible, tendons and muscles should be spared. This is attained by using the intermuscular septa in approaching the joints.

Fig. 4024.

Incisions should be made to expose the joints without forcible retraction. They should be so situated that the entrance through the capsule and into the joint is the most direct one. Gentleness should be exercised by all throughout the operation. Maltreatment of the soft tissues not only interferes with the process of repair, but destroys an otherwise successful result. Care should be used in protecting the soft parts from the saw. The tendons, if possible, should be left undisturbed within their sheaths. Their insertions should be left in continuity with the periosteum, or a small piece of bone (Vogt) may be removed with the insertion. If it is necessary to divide tendons, they should be carefully sutured.

If muscles must be divided, they should be cut in the direction of their fibres, the nerve being avoided. If this is impossible, they may be divided transversely or obliquely as near their origin or insertion as possible.

The management of the periosteum is still in dispute. Some advocate the subperiosteal, others the parosteal method.

It must be remembered in any given case that the value of the periosteum in procuring bone is very variable, and is dependent mainly: (*a*) Upon age. The healthy physiological periosteum has but little osteogenic power except in youth. (*b*) Its power to develop new bone depends upon the thickness of the different bones. (*c*) Pathological processes involving the periosteum and causing a thickening of the osteogenic layer will increase its osteogenic power. In but few cases can a comparison be made between these methods in reference to these three points; and since many subperiosteal operations are very imperfectly performed, it is not surprising that a division of opinion should exist.

Ollier, Langenbeck, Sayre, and others have long insisted that the traumatism produced by the subperiosteal (*i.e.*, subcapsulo-periosteal) method was less than by the parosteal method, and have maintained that the reparative process itself was less impaired because of the protection to the soft parts afforded by the capsule and periosteum.

Fig. 4025.

My own opinion favors the subperiosteal method, both for the protection to the tissues, for the production of new bone, and for the aid to the reparative process.

Time is not sacrificed in the subperiosteal method, for the separation of the periosteum can be rapidly accomplished by a to-and-fro motion of the rugine. When one approaches a prominence of bone or a tendinous insertion is met, a small piece of bone may be separated with the periosteum by the chisel or the rugine; such a piece may act as a centre of bone growth. During the separation the rugine is to be pressed against the bone, separating the periosteum entire and not injuring its connection with the overlying tissues.

In the management of the bones, we strive to remove the smallest amount of bone which will remove the disease or correct the deformity. Where the bones can be protruded through the incision and the soft parts sufficiently protected, the butcher, the Emmerich, or the broad flat-bladed saw (carpenter) may be used. When the bones cannot be displaced and the protection of the soft parts can be secured by gentle traction, the Gigli saw can be used. Other varieties of saw seem scarcely necessary in resections.

The sawing is usually done in plane surfaces at right angles to the line of pressure. In some instances, especially where an attempt to obtain motion is made, mortises and tenons are fashioned, which tend to favor retention of the fragments and to preserve the shape of the joint ends of the bones.

Fig. 4026.

Fig. 4027.

In pathologically involved joints after removal of the articular ends, further removal of foci may be required with the gouge or spoon. After removal of the disease from the bones their fixation is necessary, either in the attempt to obtain motion or in that to secure ankylosis. For this purpose, silver, copper, aluminum bronze, wire, steel and steel-plated nails, bone pins (Marsh, *Brit. Med. Journal*, 1887, i., p. 389), and steel drills (Wyeth's) have been used. My own experience teaches me that fixation is not necessary for a longer period than ten to fourteen days, and that in the majority of cases in which good appliances are obtainable the fixation is not required, in aseptic cases, for a longer period than that during which the first dressing must be kept applied. I have therefore relied completely upon chromicized catgut, which is prepared to resist absorption for from two to three weeks. This has been my practice for fifteen years, and I see no need of subjecting the tissues to the presence of a foreign body, which, if pathological deposits exist in the bone, only offers a *locus resistentiæ minoris* for infection from within or without. I must add, however, that in some instances, as in the hip-joint, it is not always feasible to produce fixation by the catgut suture. In these instances the steel nails, drills, or bone pins may be used. The bone pins are absorbable.

The management of the synovial membrane, capsule, and ligament requires the removal of all pathological deposits affecting them, even if it include the entire removal of these parts. When possible, the synovial membrane, the capsule, and the ligaments should be saved in part or entire, since the perfection of motion in nearthrosis depends in no small degree upon the presence of these structures.

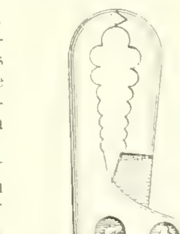

Fig. 4028.

The instruments which are specially used in resections are: 1. Those which divide the soft tissues immediately investing the bone, or joint-knives. These should have strong handles and short-cutting blades to insure precision and force in action (Figs. 4024 and 4025). 2. Those intended to detach the periosteum from the bones—rugines (Figs. 4026 and 4027). 3. Those intended to fix the bones while the soft parts are being detached and the bones sawed (Fig. 4028). 4. Those intended to divide the bones. When the bones can be displaced and a straight saw can be applied, either a bow saw with a rotating blade (Fig. 4029), or a solid straight back saw (Fig. 4030) may be used. When the bones cannot be displaced so that a straight saw can be used without injuring the soft parts, the chain saw (Fig. 4031), or the Gigli saw should be used. The former is used when the surface to be cut is in one plane; the latter when the cut surface is to be concave or convex. Electrically

Resection of Joints

propelled saws seem to have no advantages in resections. 5. Those intended to cut away spicula or prominences of bone with the periosteum attached: (*a*) Bone forceps (Figs. 4032 and 4033); (*b*) chisels (Fig. 4034). 6. Those intended to remove diseased foci in the bone after the sections are made: (*a*) Gouges (Fig. 4035); (*b*) spoons (Fig. 4036). 7. Those intended for drilling the holes required for the wire nails or catgut suture (Fig. 4037).

www.libtool.com.cn

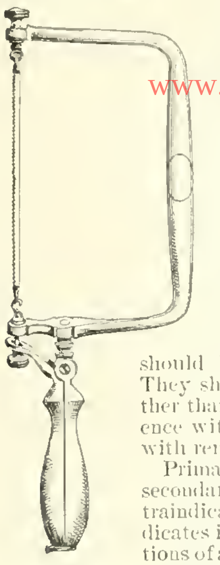

FIG. 4029.

The Indications for the Resections of the Joints.—In tuberculosis resections are usually looked upon as a sequel to rather than as a substitute for the conservative treatment. In the young, resections should be partial rather than complete. They should be subcapsulo-periosteal rather than parosteal, with as little interference with the epiphysis as is consistent with removal of the disease.

Primary tuberculosis of the lung with secondary joint involvement usually contraindicates operation, while the reverse indicates it. The mortality following resections of all varieties performed upon 117 patients was 21.3 per cent., with 15.3 per cent. of this number from tuberculosis (König). Whether early resection or the expectant treatment gives better results as regards mortality, function and a cure, must remain in doubt until similar cases are treated by each method and are compared. Undoubtedly many

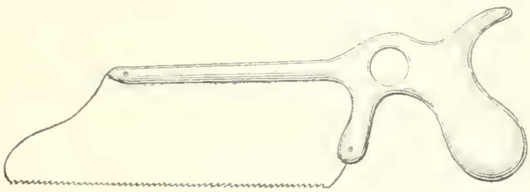

FIG. 4030.

cases treated expectantly and regarded as tuberculous are not so. The same cannot be said of resections, since the cases resected are proven before or after operation by microscopical or bacteriological examination as tuberculous in almost all instances. My own experience leads me to the expectant as the initial treatment, while resection is reserved as a secondary method.

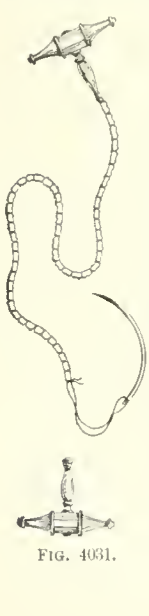

FIG. 4031.

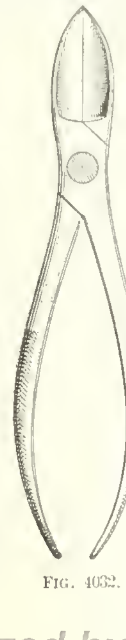

FIG. 4032.

In acute suppurative arthritis and synovitis, arthrotomy, not resection, is indicated. In chronic suppurative arthritis, resection is indicated for the removal of the disease and the relief of the deformity. In arthritis deformans, resection may be indicated for the flail joint. The rarefying osteitis must here run its course, however, in order to give a solid ankylosis. In chronic rheumatoid arthritis, resection is indicated in appropriate cases. In syphilitic arthritis, resection is indicated for the removal of gummatous foci, which have not given way to medicinal treatment. In gunshot and other injuries, resection is preferable to amputation. With the present weapons, the expectant treatment is the initial method, to be followed, in case of failure, by the partial or the complete resection. In malum senile, arthritis nodosa, urica, or neuropathica, resections are practised only in exceptional instances.

The functional results of resections are usually classed as: (1) Bad. This includes cases in which the bones remain at a distance from one another and are held together by fibrous bands only. The limb is without muscular control and cannot be used. (2) Mediocre. This includes cases in which there is also a pseudarthrosis, but the fibrous union is short and strong. The joint is flail, but nevertheless it obeys the muscles in many ways and can be made useful by apparatus. (3) Good. This includes those cases in which there is a nearthrosis and a sufficiently perfect one to differ from a normal joint only in the extent of the motions.

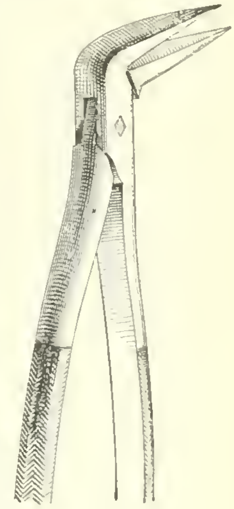

FIG. 4033.

In most resections ankylosis is the common result and is in some joints to be preferred to any other result than the ideal one (3). Flail joints are rare. Mediocre results are common.

During the operation the Esmarch bandage is a great help in exsanguinating the field of operation. It allows a complete inspection and renders possible careful dissection of the tissues. It must be used with discretion, and must not be employed in those whose arteries are diseased. Again, the exsanguination of the tissues should not be extended over a great length of time. This can be avoided in a measure by the more rapid work which it renders possible. After removal of the bandage there is some vaso-motor paralysis, but it soon yields or is corrected by elevation of the limb. In applying the bandage, care must be used to avoid direct compression of the motor and sensory nerves between the bone and the bandage.

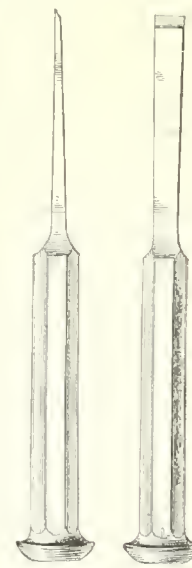

FIG. 4034.

The limb should be completely exsanguinated as regards both the arteries and the veins.

RESECTION OF THE INTERPHALANGEAL JOINTS OF THE FINGERS (Fig. 4038).—The most important of these joints is that of the thumb.

Indications.—Complete destruction; chronic tuberculous arthritis; chronic suppurative arthritis; chronic non-suppurative arthritis.

The preferable situation for the incision is the dorso-lateral aspect of the joint, somewhat nearer the dorsal than the palmar surface. The incision may be a single one upon the internal surface of the thumb and forefinger and upon the external surface of the little finger. Wherever fistulæ are present the incision may best be made so as to include them. The preferable method, however, is that of two incisions placed dorso-laterally, one upon each side of the extensor tendons. By means of these two the denudation of the bones and the

Digitized by Microsoft®

exposure of the joint are easily accomplished. Each incision is carried through the capsule and the periosteum for the full length of the skin incision, which should extend above and below the joint sufficiently to expose and to dislocate the articular ends of the bones. With a straight and curved rugine, the denudation of the bones is made from both incisions. Fine blunt retractors are used to expose the bone and to protect the separated periosteum and capsule and the tissues covered by them. When the capsule and periosteum have been freed sufficiently (subcapsulo-periosteal method), the ends of the bones are luxated without force through the more convenient of these incisions. The articular ends are now removed by the saw or cut away piecemeal by the bone-cutting scissors or rongeur forceps. After this is accomplished, the synovial membrane of the joint and the pathological foci in the soft parts about the joint are removed, preferably by dissection. The ends of the bones are now drilled, and one or two ten-day chromic-acid catgut sutures are inserted, bringing them in close apposition if ankylosis is desired. They are only loosely tied if an attempt at pseudarthrosis is made. In case a nearthrosis is desired, no sutures are necessary, as the suture of the divided periosteum and capsule will sufficiently hold the bones in their normal layer of tissue.

www.libtool.com.cn

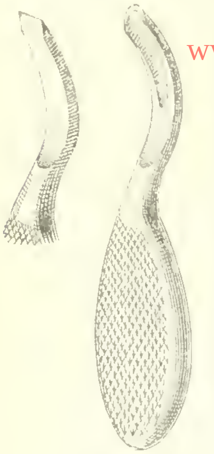

FIG. 4035.

If an Esmarch bandage has been used, it is now removed. The larger vessels are secured. The periosteum and capsule are sutured with catgut or silk. The remainder of the wound is closed, with catgut for the subcutaneous tissue and silk for the cutaneous. Drainage is not employed unless suppuration is already present. An aseptic dressing is applied. A fixation splint is applied over the dressing. The splint dressing is removed in ten days. At the end of two weeks all splints are removed. At the end of three weeks gentle passive motion is employed, unless ankylosis is desired.

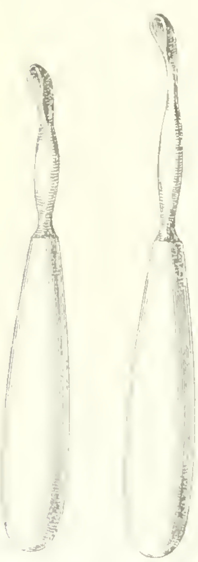

FIG. 4036.

RESECTION OF THE METACARPO-PHALANGEAL JOINTS (Fig. 4038).—Here also a single or two incisions may be used. When one is used it is placed upon the external dorso-lateral aspect of the thumb and index finger, upon the internal for the little finger, and upon either side for the other fingers. If two incisions are used, they are made as in the interphalangeal joints, on each side of the extensor tendons. For the metacarpo-phalangeal joints a single incision will often suffice. If feasible the operation should be the subcapsulo-periosteal one. The incision is carried directly through the skin and subcutaneous tissue to the periosteum and capsule of sufficient length to expose the joint well above and below. The digital nerves are avoided if seen. The short muscles passing between the metacarpal bone of the thumb and its phalanx, as well as the aponeurotic canal for the extensor and flexor tendons in the fingers and thumb, are also avoided. The capsule and periosteum are now exposed and are incised. The denudation of the periosteum and the elevation of the capsular attachments are carefully made, especially at the metacarpo-phalangeal joint of the thumb, in order that the muscular insertions may be preserved.

When this is accomplished, the bones are dislocated through the incision and are divided with the saw or by the rongeur forceps. In some instances the Gigli saw can be used without dislocation of the bone. If the operation has been a subcapsulo-periosteal one, no sutures in the bones are needed, provided a nearthrosis is attempted. If not, and a pseudarthrosis is desired, a retention bone suture is used, with a small interval between the fragments. When ankylosis is desired, the bones are held in apposition by the bone sutures.

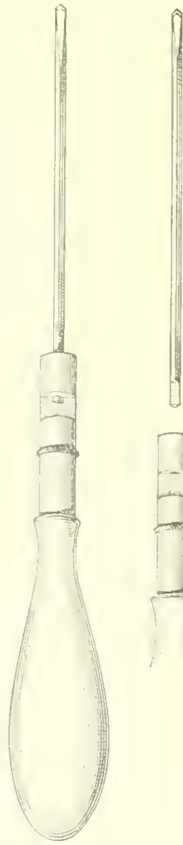

FIG. 4037.

RESECTION OF THE WRIST.—The history of this operation dates back as far as 1750, when Cooper, of Bungay, removed the lower end of the radius and ulna for injury. In 1762 Bagien excised the joint for a gunshot wound. In 1794 Moreau excised the joint for disease. Lister in 1865, Boeckel in 1867, Langenbeck in 1874, and others gave a great incentive to this operation by admirable papers; yet in spite of these papers the operation has never been a popular one. Its unpopularity was not due to its mortality, for this, according to Culbertson, amounts only to from one to 1.73 per cent. for all cases (Prize Essay, p. 628), and, according to Gurlt's "Military Surgery," to sixteen per cent. It was due to the failure to arrest the disease or because of the utter worthlessness of the hand after recovery. At the present time, with an improved technique and the aseptic treatment, these bad effects are to an extent avoided, and as a result the operation is again being strongly advocated.

Anatomy of the Wrist (Fig. 4039).—The anterior or palmar surface of the wrist is so well covered with tendons, arteries, and nerves that an approach from this side is not feasible. Upon the dorsal or lateral surfaces the bones are more easily exposed. Upon the back one can enter between the tendons without coming in contact with arteries, unless upon the external and posterior surfaces of the trapezium. The usual places selected are those between the extensor indicis and the extensor secundi internodii pollicis upon the outer side, and between the extensor carpi ulnaris and extensor minimi digiti upon the inner. In this interval one encounters only the extensor carpi radialis brevior before entering the joint. None of the tendons to the fingers passing over the dorsum of the wrist is attached to the wrist, so that they can be easily retracted to either side without injury.

FIG. 4038.

Upon the outer side of the dorsum the extensor carpi radialis longior and brevior and the flexor carpi radialis are intimately connected with the joint and bones to

Digitized by Microsoft®

Resection of Joints.

be removed. Upon the inner side the extensor and flexor carpi ulnaris are inserted into the base of the fifth metacarpal bone, and are intimately associated with the capsule and ligaments.

The bone which plays the most important part in this operation is the trapezium, which conceals and retains upon its anterior surface the flexor carpi radialis, and is covered by the radial artery upon its dorsal surface. From its crest it gives origin to the annular ligament, and by its articulation with the metacarpal bone of the thumb it becomes very necessary for the function of the thumb.

Provided the tendons are not incised, any incision which will enter the joint upon the dorsum, either to the inner or to the outer side of the mass of tendons made up of the extensor communis digitorum, extensor proprius pollicis, and extensor minimi digiti, will be found sufficient.

The bones of the carpus are united by a capsular ligament, of which the anterior is the strongest portion. The carpus itself may be regarded as one short and wide bone, articulating above and below with the bones of the forearm and those of the hand. The lower epiphyses of the radius and ulna join their shafts at twenty years. The radial epiphysis is entirely within the joint. The ulnar epiphysis reaches as high as the top of the radio-ulnar articulation.

A total resection of this joint includes the removal of the articular ends of the bones of the forearm and those of the metacarpal bones besides the bones of the wrist. Any resection short of this is a partial one.

Indications.—In both civil and military practice partial rather than complete resections are indicated. This holds good in most gunshot wounds, in compound and complicated fractures and dislocations. For tuberculosis, chronic suppurative arthritis, syphilitic arthritis, resection is indicated after medicinal and expectant treatment fails. Such is the case in other forms of joint disease where resection, partial or complete, is used to relieve deformity or increase motion.

Resection, especially the complete, is not permissible before the fifth year of life. It is rarely demanded before puberty. When it is demanded, the epiphyses of the bones of the forearm are not interfered with, and the operation is an informal or incomplete one. The object is to remove the diseased tissue and nothing else. After puberty the operation has its best results, and it is here that complete resections are made with good chances for functional results.

When, in an adult, tuberculosis exists in the carpus, with tuberculosis elsewhere in the body, the question to be decided is between amputation and complete resection. The general rule is that amputation should be selected if the local process succeeds the pulmonary, and that resection should be preferred if the local antedates the pulmonary. This must be taken with reserve, however, as many such cases of primary wrist involvement do best with amputation.

The older the subject the more we must consider amputation in preference to resection.

The methods of incision for entering this joint are:

1. The radio-dorsal incision, which, commencing at the centre of the ulnar border of the metacarpal bone of the index finger, is carried upward to the middle of the dorsal surface of the radial epiphysis between the tendon of the extensor indicis and that of the extensor carpi radialis brevior, and thence between the tendons of the extensor indicis and the extensor secundi internodii pollicis. The length of this incision varies between 8 and 12 cm., of which one-third should be above the articulation (Boeckel, *Gazette Médicale de Strasbourg*, 1867, and Langenbeck, *Archiv für klin. Chir.*, No. xvi.).

2. The dorso-ulnar incision. In abduction and slight flexion an incision of 7 to 8 cm. is made from the lower third of the fifth metacarpal over the ulna and vertically upward. In the lower part the incision passes between the tendons of the extensor carpi ulnaris and the extensor minimi digiti; over the ulna it passes in the interstice between the extensor carpi ulnaris and the extensor indicis muscles (Kocher, *Archiv für klin. Chir.*, No. 37).

3. Both radial and ulnar incisions. Both are upon the dorsum (Ollier, "Mètral Thèse," 1882, p. 45). One is dorso-radial and the other ulnar (Lister, *Lancet*, 1865).

Where two dorsal incisions are used: The radial commences opposite the centre of the shaft of the second metacarpal bone, and is continued upward along the extensor indicis tendon until it meets a line joining the two

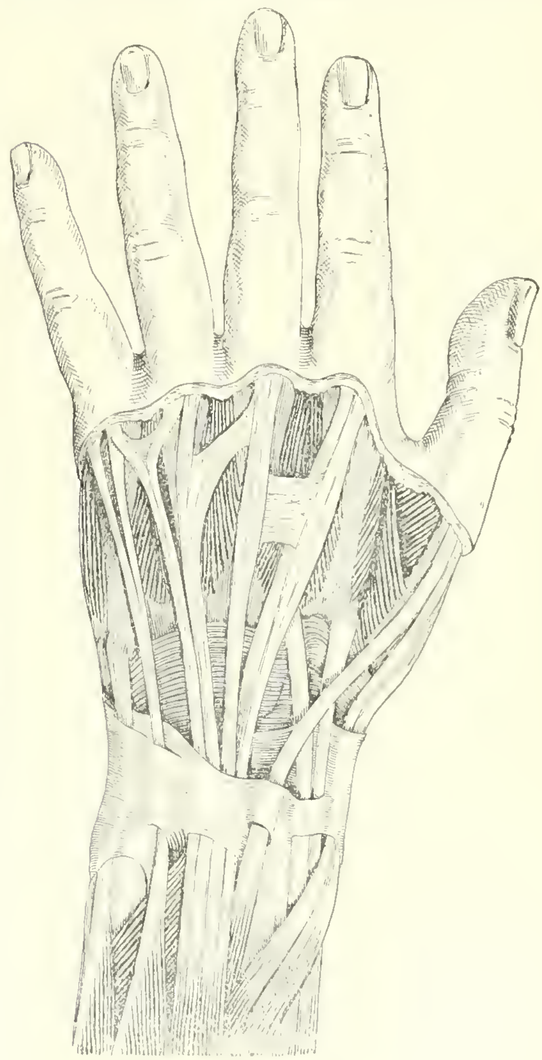

FIG. 4039.

styloid processes. From this point it passes upward in the axis of the forearm. The ulnar incision extends from the centre of the fifth metacarpal bone along the radial side of the extensor carpi ulnaris and the ulnar side of the extensor minimi digiti until it reaches the ulna. From this point it passes between the muscular bellies of the extensor carpi ulnaris and the extensor indicis. One third of both incisions is above the radio-carpal articulation; two-thirds below it.

Where one dorsal and one lateral incision is used: The radio dorsal commences at the middle of the dorsal aspect of the radius at a level of the styloid process, and is carried toward the inner aspect of the metacarpo phalangeal joint of the thumb, running parallel to the tendons of the secundi internodii pollicis. When the radial border of the second metacarpal bone is reached, the incision is carried along this border for one half its length. The ulnar incision commences 5 cm. above the extremity

www.libtool.com.cn
Digitized by Microsoft ®

of the ulna, and passes behind but parallel to the flexor carpi ulnaris as far as the middle of the fifth metacarpal bone.

Which of these incisions is the best depends largely upon the position of the fistulæ or the degree of development of the disease. When the disease is mainly upon the ulnar side, Kocher's incision is the best to commence with (Fig. 4040); if the disease is upon the radial side, Langenbeck's incision (Fig. 4041). If the disease is extensive and requires a complete arthrectomy, no method makes so perfect an exposure as the Ollier, *i.e.*, the two dorsal incisions. We will therefore describe first the Langenbeck and then the Kocher method, and will expect the reader, from these two descriptions, to imagine that of the double dorsal incisions.

www.libtool.com.cn

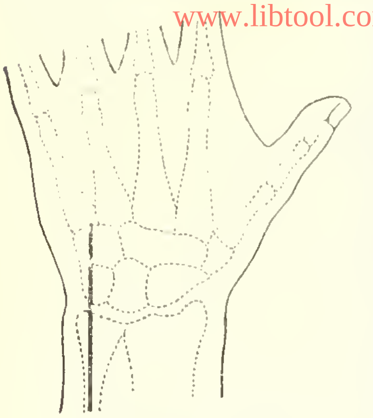

FIG. 4040. – Kocher's Incision.

Method by the radio-dorsal incision (Boeckel-Langenbeck): An Esmarch bandage is applied. The hand and wrist are placed upon a cushion with the thumb abducted and extended. The radio-carpal interspace is noticed by the position of the styloid processes. The tendons of the extensor indicis and the extensor secundi internodii pollicis are also seen.

The incision usually begins above the wrist between these tendons and descends along the tendon of the index finger to the middle of the second metacarpal bone. One-third of this incision is above the radio-carpal articulation; two-thirds is below it.

This incision is made through the skin and exposes the cutaneous terminal branches of the radial nerve, which are often cut. The external border of the tendon of the extensor indicis is recognized and is retracted with the inner flap out of the way. Incise toward the capsule of the wrist-joint and recognize the tendons of the extensor carpi radialis brevior attached to the third metacarpal bone. Above the joint carry the incision between the tendons of the extensor secundi internodii pollicis and the extensor indicis, separating them without entering their sheaths. The periosteum of the radius is now incised and the capsule of the wrist-joint is divided along the inner side of the extensor secundi internodii pollicis. Avoid cutting the tendons of the radio-carpal extensors. With the rugine (curved or straight), the periosteum of the radius and the capsular fibres of the wrist-joint (including the radio-carpal extensors) are respectively separated from the outer half of the posterior surface of the radius and from the bases of the second and third metacarpal bones.

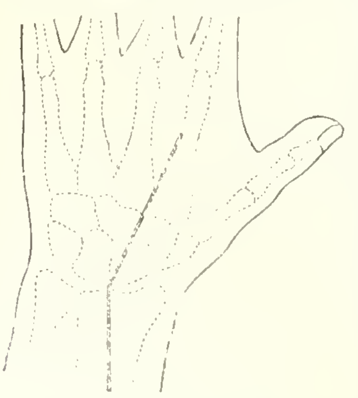

FIG. 4041. Langenbeck's Incision.

The capsule is now retracted outward and the scaphoid and trapezoid are separated from their attachments to the capsule on their posterior surfaces. The trapezium is not detached until a later stage. The capsule is now retracted inward and the periosteum and capsule are separated from the inner half of the posterior surface of the radius, the triangular cartilage, and the posterior surface of the ulna. It is detached also from the posterior surfaces of the semilunar, cuneiform, os magnum, unciform, and the bases of the remaining metacarpal bones.

If the soft parts are not extensively infiltrated and the movements of flexion and extension can be made, the radius and ulna may be luxated and sawn at this time and before the carpal bones are removed.

If this can be done, the hand is flexed and pronated and the external flap is retracted. The rugine now separates the periosteum upon the anterior surface of the radius. The hand is now flexed and supinated and the remaining portion of the radius and the ulna are denuded upon their anterior surfaces. The hand is now forcibly flexed, the flaps are retracted, and the radius and ulna project through the wound. These can then be sawn transversely. This section should be as narrow as possible, usually within 2 cm. of the cartilage (Fig. 4042). A retractor is now placed in the external wound, the wrist is flexed, the scaphoid bone is seized with the forceps, and its anterior and external surfaces are freed from the periosteum and ligaments.

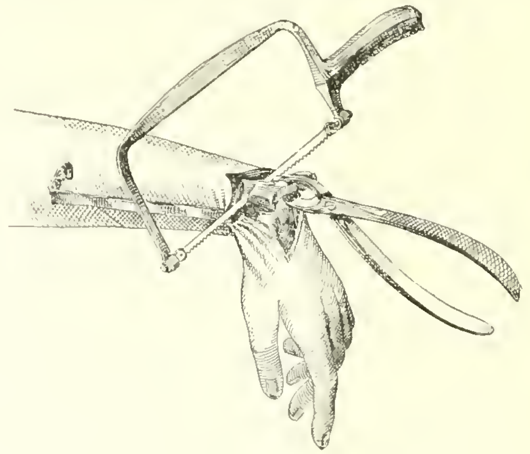

FIG. 4042.

The bone is next separated from the semilunar and is torn away easily. The internal flap is then retracted to the inner side and the semilunar and cuneiform bones are separated and removed in the same way, leaving the pisiform. The os magnum is now seized with the forceps, its anterior surface is denuded with the rugine, and its connections with the unciform, trapezoid, and metacarpal bones are severed. The trapezoid is finally removed in the same manner.

With more extensive wound retraction, the unciform may be seized and its anterior surface denuded until the base of its process is reached. This process is now separated with the cutting forceps, and a freeing of the bone upon its internal surface allows its removal.

If the trapezium is to be removed, a retractor draws outward the external flap, the left hand seizes the thumb, and the rugine clears the posterior and then the anterior surfaces of periosteum. The trapezium is now seized with the bone forceps, its external border is denuded, and the bone is removed.

Provided the pisiform and the hook of the unciform are to remain, and provided also the synovial membrane has been removed, the Esmarch bandage should be loosened and the larger arteries tied. In many instances, where one is certain of not injuring the larger vessels, the bandage is not removed until after the first part of the permanent dressing is applied.

Digitized by Microsoft®

Sutures between the ends of the bones have always been used by me, because I have always believed that a mobile pseudarthrosis with mobility of the fingers was the best obtainable result. Two chromicized catgut sutures

www.libtool.com.cn

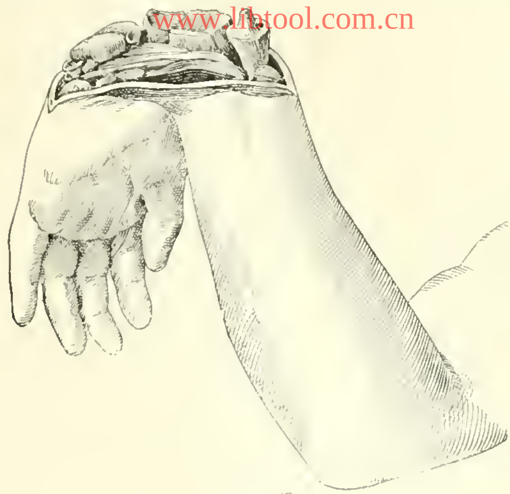

FIG. 4043.

are inserted, bringing the bones within one-fourth to one-half inch, or 0.6 to 1.25 cm., of one another. If the tendons of the extensor secundi internodii pollicis or the extensor carpi radialis longior and brevior have been divided, they are to be carefully resutured or reinserted if separated from their insertions.

The capsule is sutured with catgut. The skin is sutured with silk or catgut.

Provided the operative field is an aseptic one, catgut is employed for the skin. No drainage is used except that which occurs at the lower portion of the wound, near the index finger, where the skin and capsule are not sutured in order that any undue tension in the wound may be relieved. If the process is infective, drainage is employed through the incision by gauze packing.

The method by the dorso-ulnar incision (Kocher): The disadvantage of the preceding method, in Kocher's opinion, is the necessary separation of the radio-carpal extensors and the imperfect dorsal flexion, and possibly the volar subluxation resulting. The advantages of the dorso-ulnar incision are seen in the less important action of the extensor carpi ulnaris as a dorsal flexor and its greater importance as an adductor. Hence when it is separated its loss of action is favorable to the better position and action of the hand. Though the extensor tendon of the little finger is liable to be negative in action, this danger is not so great nor is its loss of function so important as that of the proprius pollicis in the preceding method. Hence he selects an ulnar and dorsal incision.

The incision is made as described above. It avoids the dorsal cutaneous branch of the ulnar nerve. The fascia and the dorsal annular ligament are divided and the sheath of the extensor minimi digiti is incised. This tendon is drawn outward, and, following its ulnar border, the capsule of the joint is divided, and with the insertion of the extensor carpi ulnaris it is loosened from the base of the fifth metacarpal bone. Along this latter tendon the incision is carried upward upon the ulna in the interstice between the extensor carpi ulnaris and the extensor proprius pollicis. The tendon of the extensor carpi ulnaris is now retracted inward and the capsule surrounding the ulna is separated by the rugine subcapsulo-periosteally, if possible and if indicated; but, if not indicated, it should be divided by the knife, which should sever the attachments of the capsule to the ulna and to the base of the fifth metacarpal bone, leaving the flexor carpi ulnaris attached. The joint is now entered and the articulation of the pisiform and cuneiform and the process of the unciform come into view.

The tendons upon the volar surface are retracted and the attachments of the capsule to the fifth, fourth, and third metacarpal bones are divided. The attachment of the flexor carpi radialis to the base of the second metacarpal bone is preserved. In like manner the attachment of the capsule to the radius is separated.

Upon the dorsum, the extensors of the fingers are easily exposed and the capsule beneath the radio-carpal extensors and the extensors of the thumb is loosened from the radius. The two radio-carpal extensors attached to the bases of the second and third metacarpal bones are not separated from their insertions.

The hand is now carried outward and in slight flexion until the thumb touches the radial side of the forearm. The lower ends of the radius and ulna appear in the wound to the inner side, while externally is seen the first row of carpal bones (Fig. 4043). The removal of the carpal bones and a removal of thin sections from the radius and ulna and metacarpal bones are now easily carried out. It is only in the region of the trapezium and the trapezoid that the field is restricted when the bones of the forearm and the third metacarpal bones are being removed. When the bones have been removed and the capsule extirpated, the bones of the forearm and the metacarpal bones are placed in apposition if a nearthrosis is wished. If a pseudarthrosis is desired, the bones are held in apposition more or less closely by chromic-acid catgut. The capsule and skin are now sutured. Drainage in aseptic cases is secured by leaving a small portion (1 to 2 cm.) of the incision open; or, if the wound be septic or hemorrhage be imperfectly stopped, by gauze packing through some portion of the incision.

When the disease is upon the radial side of the carpal or metacarpal bones, or when the radial side of the joint is exclusively the seat of the disease, the radio-dorsal incision is the incision of choice. When the disease is confined to the ulnar side or the joint as a whole is involved but not greatly infiltrated and swollen, the dorso-ulnar incision is the incision to be selected. When the whole joint is involved and the tissues are greatly infiltrated in front and behind the joint, both dorsal incisions are preferable to either singly. Hence we would select for these cases the incisions recommended by Ollier. These incisions are the same as those already mentioned as Langenbeck's and Kocher's. The direction of the skin incision varies somewhat, but the route to the joint is between the same structures. Excellent results have been obtained by Drs. Mynter and Taylor by means of a method suggested by Professor Stuckgaard, of Copenhagen, in 1891. This method consists in splitting the hand between the second and third fingers. The incision is both palmar and dorsal. The incision upon the dorsum begins at the radius and extends to the interdigital fold between the second and third fingers. The palmar incision extends from the interdigital fold not farther than the superficial palmar arch.

The dorsal incision divides the skin and the subcutaneous tissue, but no tendons. It avoids, in passing between

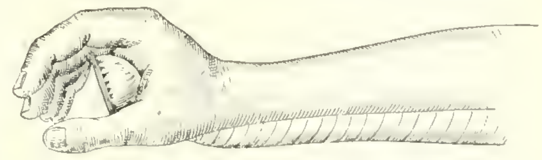

FIG. 4044.

the metacarpals the annular volar ligament, the flexor tendons and the superficial arterial arch. The wrist is now split between the trapezoid and os magnum in the second row and between the scaphoid and semilunar in the first row. Retraction of each side now allows of a complete exposure of the wrist-joint (*Annals of Surgery*, September, 1900). This operation has never been performed by the author upon the living. Upon the cadaver it is feasible and gives an excellent exposure without

Digitized by Microsoft®

injury to the dorsal tendons. It is here mentioned because of its apparent value.

No matter which method of resection may be chosen, (1) the trapezium should be saved if possible, so that the motions in the metacarpo-carpal joint of the thumb may be preserved; (2) the section of the bones of the forearm should be made within 2 cm. of their articular cartilages; (3) in so far as is feasible the operation should be a subperiosteo-capsular one.

www.libtool.com.cn

The After-Treatment.—The limb is to be placed upon a properly padded splint in such a manner that the hand shall be sustained in the position of dorsal flexion (Figs. 4044 and 4045). These splints fix the wrist-joint but allow

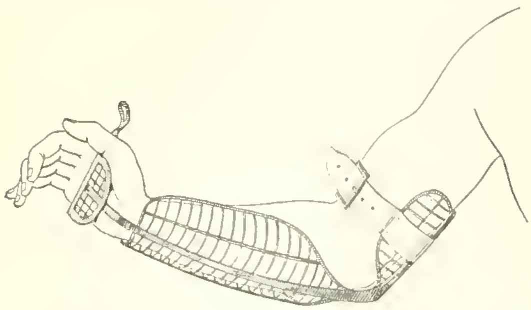

Fig. 4045.

passive motion of the fingers. They pass from above the elbow to the fingers and thumb. The latter pass beyond the splint and can be easily grasped for passive motion.

Where the wounds are aseptic and no drainage is required, as in a case of simple injury, the wound usually heals in from ten days to two weeks.

Where the operation is done for disease, the cavity is often packed with gauze, and, as it requires often two or three revisions with the curette, the healing of the wound may be delayed for from four to six weeks.

As soon, however, as the tissues are solid, though the splint is to be continued for a long period to prevent palmar dislocation and adduction, passive motion at the wrist must be assiduously practised if we desire a nearthrosis or a mobile pseudarthrosis (Ollier, "Traité des Résections," 1888). If we desire an ankylosis at the wrist, passive motion may be interdicted.

Passive and active motion of the fingers is practised as early as possible, in some instances at the third to fifth day after operation. After removal of the splint, a prothetic apparatus must be worn. This apparatus should allow flexion and extension at the wrist if desired.

From this time on, the patient's aim must be to increase the range of motion in his fingers and in the wrist. Much depends upon his own exertions in securing a good result.

The functional results after this operation vary. Culbertson, in 58 cases of gunshot wounds, reports the following results: Good, 1.7 per cent.; indifferent, 27.5 per cent.; bad, 13.7 per cent.; amputated, 3.4 per cent.; not stated, 53.4 per cent. In 11 cases of injury the results were as follows: Good, 28.5 per cent.; indifferent, 57+ per cent.; not stated, 14+ per cent. In 79 cases in which resection was performed for disease the results were: Good, 7.5 per cent.; indifferent, 45.5 per cent.; bad, 13.9 per cent.; amputated, 12.6 per cent.; not stated, 20.2 per cent. In our own civil war ("Med. and Surgical History of the War of the Rebellion," part ii., vol. ii., Otis), 6 cases of complete resection gave an indifferent result in 83.3 per cent.; amputation and death in 16.6 per cent. Gurlt's statistics of military surgery give ideal results in 6.25 per cent.; good results in 50 per cent.; indifferent results in 37.5 per cent.; bad results in 6.25 per cent. Nepveu (*Revue de Chirurgie*, 1883, p. 291) gives a collection of 36 cases. The results were satisfactory in 41.6 per cent.; indifferent in 36.1 per cent.; bad in 22.2 per cent. Ollier (*Gaz. méd. de Paris*, 1882, "Traité des Résections," 1888) believes, and has shown in two cases following a traumatism (partial resection), that ideal results may be obtained by carefully performed operations and long-continued after-treatment. The mortality statistics are about ten per cent. for all cases of resection. For gunshot wounds the mortality is about fifteen per cent. For disease, a death following operation is a rarity.

Resection of the Elbow-Joint.—Wainman in 1759 and Filkin in 1762 excised portions of this joint for injury or disease, but the first methodical operation is ascribed to Moreau in 1794. This method was enthusiastically accepted in England by Syme, and has since been established by numerous surgeons both in civil and in military practice. Resection of the elbow consists in removing the inferior extremity of the humerus and the upper extremities of the radius and ulna. In all cases the insertions of the brachialis anticus and of the biceps must be preserved, or if detached they must be replaced in order to insure the function of the joint.

Usually less than 2 cm. should be removed from the radius and ulna. More can be removed from the humerus without destroying its function. Usually the line of section is at the upper border of the epitrochlea, *i.e.*, the section is made well above the articular surface (Ollier, "Traité des Résections," t. ii., p. 203). When more is removed than is here recommended, one must expect a flail joint, unless special precautions against it are taken. When the section is below the epitrochlea—*i.e.*, just above the articular cartilage—one can expect a nearthrosis, a pseudarthrosis, or an ankylosis. If ankylosis results, the bones must be placed at a right angle with the radius in semipronation. This will give a very useful and serviceable extremity. If a nearthrosis follows, then the following condition most frequently occurs: The bones become fashioned so as to fit one another. They become smooth, polished, and shaped so as to allow flexion and extension. The lateral ligaments prevent any lateral displacement at the new articulation, and the movements of supination and pronation, though limited, are sufficiently supplemented by rotation at the shoulder-joint. The movement of the elbow, hand, and fingers is sufficiently strong for all ordinary work. Such a condition is the best result attainable, and should be considered ideal.

If pseudarthrosis exists, the union of the bones is by means of connective tissue. Such a union, if the bond is not too long, gives a good result. Where the union is short and where no lateral displacement at the point of union occurs, if the muscular power is sufficient, quite as useful a limb can be obtained as by the development of a nearthrosis.

The Indications.—For *gunshot injuries* in young and healthy persons in whom the articular cartilages are intact and in whom the tissues about the joint are not extensively damaged, the conservative treatment or at the most restricted operation should be made use of.

In *severe* bone injuries of the elbow-joint, including the articular cartilages with slight or no injury to the vessels and nerves, a partial or a complete resection is indicated, provided the age of the patient or his general condition does not demand an immediate amputation.

In *severe injuries* of the articular cartilages and of the bones, with severe injury to the vessels and nerves, amputation is required, especially in the aged.

In old *injuries* to the joint, resulting in ankylosis or pressure upon the main vessels or nerve trunks, a complete rather than a partial resection is indicated, because the tendency to secondary ankylosis is great by reason of the marked reparative power in all the tissues set up by previous injury. In old dislocations it has been my practice to reduce the dislocation by operative means, unless the contracture of the soft tissues demands a resection rather than a reduction. The earlier the old dislocation comes into the surgeon's hands the more successful will be the reduction by operative interference.

Ankylosis in a faulty position, resulting from injury or disease, is curable by complete resection only when the age

Digitized by Microsoft®

Resection of Joints.

of the patient (from twenty to thirty-five), the condition of the muscles, the presence of cicatricial bands about the joint, or the new bone production in and around the joint, will not interfere with the after-result.

In cases in which these conditions exist and the tendency to new bone production is a marked one a partial operation with a correction of the faulty position is alone indicated.

Tuberculosis.—After conservative treatment has failed, a complete resection is usually indicated. During the first three or four years of life resection is not recommended. At this time curetting is sufficient. After three years, make partial operation, if possible, or a complete one if necessary. In either case, however, we must remove the disease. Resection is indicated in some cases of *suppurative arthritis* (chronic), in *arthritis deformans* in a single joint, and in *tumors* involving the bones of the joint (exostoses).

It must be remembered that only one-tenth of the total growth of the arm and forearm is contributed by the epiphysis at the elbow (Ollier), so that earlier resections may be attempted here than elsewhere. In general we say that in injury and gunshot wounds, partial rather than complete operations are indicated. For disease, complete rather than partial operations are indicated. For ankylosis, complete rather than partial operations are indicated.

In youth much can be expected in the production of pseudo- or nearthroses. In the adult, unless some chronic irritation (inflammation) is present or the amount removed is small, the joint is liable to be a flail one.

Anatomy.—The elbow is a pure hinge-joint. The re-establishment of its function demands that the bones be so shaped as to flex and extend easily while in contact, that the lateral ligament holding the joint be short and not yielding, and that the attachment of the muscles which move the joint in flexion and extension, as well as in supination and pronation, be preserved.

As the anterior portion of this joint is not used for entrance into the joint, we will consider only its lateral and posterior aspects.

The posterior branch of the radial nerve, which is a motor nerve for she extension of the hand and fingers and for extension and abduction of the thumb, enters the supinator brevis muscle about 2 cm. below the articular surface of the head of the radius and passes obliquely through its fibres around the radius until it emerges 3 to 4 cm. below the interarticular line in the posterior interosseous space. Upon the inner side the ulnar nerve passes behind the internal condyle between the extensor carpi ulnaris and the periosteum covering the internal lateral surface of the ulnar. These two nerves are to be avoided. Both the brachialis anticus and the biceps are attached at points sufficiently removed to be saved in the more typical and complete operations. The supinator longus, because of its attachment to the external intermuscular ridge, can be preserved in its attachment even when a large extent of the humerus is removed.

The short supinator, which is so necessary for supination, is rarely injured because of its ready separation from the humerus with the periosteum. Such is the case with the muscles attached to the internal and external condyles of the humerus, which can with care always be separated from the bone and kept in relation with the periosteum of the humerus and the fascia, forming the intermuscular septa and the lateral ligaments of the joint. The triceps, however, is an important muscle. The major part of its tendon is inserted into the olecranon process of the ulna. It has, however, lateral attachments connecting it with the deep fascia of the posterior surface of the forearm. Of these connections, that with the fascia covering the anconeus and the posterior surface of the forearm is very strong, while that with the fascia covering the internal surface is thin and not strong. It is necessary, therefore, to maintain this connection with the deep fascia of the forearm when the attachment to the olecranon is removed, if we wish to obtain after resection the full power of extension.

The arterial supply of this joint is carried on by the circle formed by the radial and ulnar recurrents, the interosseous recurrent, and the anastomotica magna. These may be avoided by the subperiosteal method.

The interarticular line of the elbow-joint is represented by the middle two-thirds of a line joining the tips of the two condyles.

The humero-radial articulation is represented by a horizontal line; the humero-ulnar, by an oblique line, passing from without inward and above downward.

The external condyle of the humerus is less than 2 cm. above the articular line. The internal condyle is more than 2.5 cm. above it.

The lower epiphysis of the humerus joins the shaft at the seventeenth or eighteenth year.

The epiphysis of the radius joins the shaft at the sixteenth or seventeenth year.

The epiphysis of the ulnar (olecranon) joins the shaft at the seventeenth year.

These epiphyseal cartilages have finished their growth by the seventeenth year, and resections of large portions may be made at this age, although the muscles mentioned as important must be preserved to obtain the best results. When they are sacrificed, prothetic apparatus must be used to supply the deficiency.

THE METHODS OF INCISIONS.

The incisions used in resections of the elbow joint may be divided into: (1) those which enter the joint upon the ulnar side; (2) those which enter upon the radial side; (3) those which enter upon both sides or from behind. To the first belong the incisions of Liston, Langenbeck, Gurlt, and Jaeger ("Manuel Opératoire," Farabœuf, p. 715). To the second belong those of Ollier ("Traité des Résections"), Stimson ("Operative Surgery"), Roux and Nélaton ("Manuel Opératoire," Farabœuf), Kocher (*Archiv für klin. Chir.*, No. 37, p. 787), and Cavazzani (*Centralblatt für Chir.*, 1889, pp. 708 and 1121). To the last belong the H-shaped incisions of Moreau and Dupuytren ("Manuel Opératoire," Farabœuf), the lateral incisions of C. Hueter ("Gelenksresectionen") and of Vogt (Löbker: "Operationslehre"), and the posterior triangular flap of Textor ("Manuel Opératoire," Farabœuf).

Of all these incisions we find that four are sufficient for all resections, complete or partial. In ankylosed joints and in old dislocations a combination of the Kocher's radial incision and the ulna incision of C. Hueter will be found in the severer cases to be most satisfactory. In injury and in disease other than the above the Langenbeck, the Cavazzani, and the Kocher incisions are preferred.

These latter incisions are superior to the rest because they do the least injury to the fibrous expansion of the triceps insertion and no injury to the nerves supplying the triceps or the anconeus muscles.

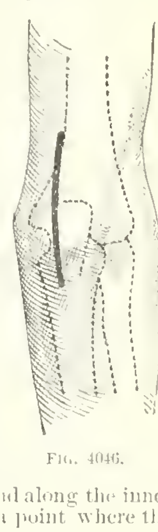

FIG. 4046.

The Langenbeck or dorso-internal incision is recommended when the disease involves particularly the internal segment of the joint.

The Kocher, or dorso-radial, incision is especially useful when the disease involves more especially the radio-humeral in addition to the humero-ulnar articulations.

The bilateral incisions above recommended are useful in old dislocations and in severe ankylosis following disease, injury, or operation. I will describe these methods.

1. *Langenbeck's Method.*—The Esmarch bandage is to be applied, if not contraindicated. The top and crest of the olecranon process having been determined, an incision is commenced 4 to 5 cm. above the olecranon, passing through the tendon of the triceps and along the inner border of the crest of the olecranon to a point where the

Digitized by Microsoft®

process disappears in the shaft of the ulna (Fig. 4046). Usually this point is 4 to 5 cm. from the tip of the olecranon. This incision is carried down to the bones throughout. A retractor is placed in the external flap, and, with

www.libtool.com.cn

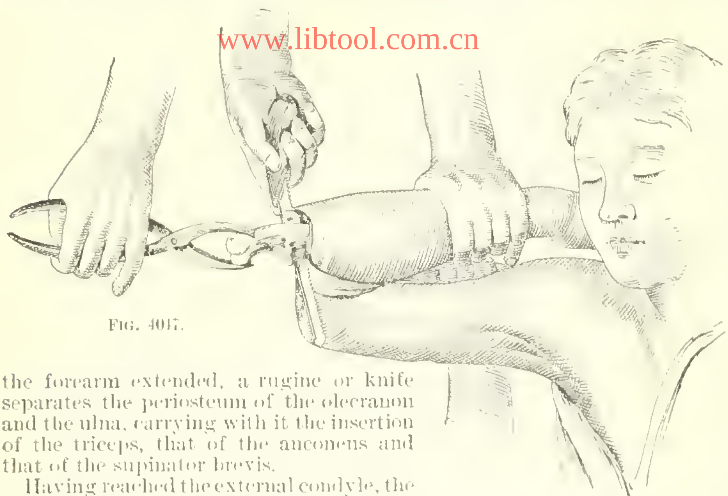

Fig. 4047.

the forearm extended, a rugine or knife separates the periosteum of the olecranon and the ulna, carrying with it the insertion of the triceps, that of the anconeus and that of the supinator brevis.

Having reached the external condyle, the surgeon should separate the external lateral ligament and the common origin of the extensors and supinators from the condyle subperiosteally or by removing with these structures a part of the epicondyle (P. Vogt). When this is sufficiently free and the humero-radial joint is exposed, the forearm may be flexed to complete the subperiosteal separation upon the anterior surface of the humerus. This completed, the internal flap is detached with the periosteum, while the forearm is extended until the internal surface of the olecranon is free and the coronoid process below and the internal condyle above are fully exposed. With the retraction of the periosteum of the humerus and olecranon, the ulnar nerve and the lateral ligament are carried away and are free from all danger. When the lower part of the humerus is sufficiently free, the forearm is again flexed and the ulna and radius are separated from it. The periosteum and capsule of the joint are separated from the anterior surface of the humerus as far as is necessary. The latter is then seized with the lion-toothed forceps and the bone is sawn transversely, just above the articular cartilage or, better, in a line joining the epicondyle and upper part of epitrochlea (Ollier, "Traité des Résections," t. ii., p. 203). The olecranon process is seized with the forceps and the periosteum and capsule are separated from the coronoid process to its base, as much of the insertion of the brachialis anticus as possible being saved. The anterior fibres of the annular ligament are separated with the periosteum of the ulna and are displaced downward so that the head of the radius can be removed close to the shaft if desired. The olecranon and coronoid process are now removed together from the shaft, if desired and if thought necessary (Fig. 4047). Otherwise, if sufficient bone can be left to form a new olecranon process, the bone is sawn as in Fig. 4048. This will give a projecting portion representing the former olecranon, which is very useful in preventing forward dislocation of the ulna during the after-treatment. After removal of the extremities of the bones the synovial membrane is dissected out completely, and such sinuses as appear are excised or curetted.

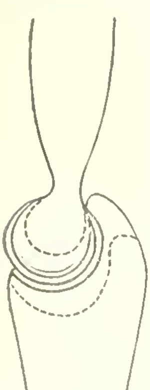

Fig. 4048.

The sawn surfaces of the radius, ulna, and humerus are placed in apposition and at an angle of 135°—*i.e.*, in nearly complete extension. In this position the tendency to forward dislocation of the radius and ulna through contraction of the flexors is avoided. If firm ankylosis is desired, the humerus and ulna are drilled and sutured with two-weeks chromicized catgut sutures. If a mobile pseudarthrosis or a nearthrosis is desired, chromicized catgut sutures are used only for the purpose of retaining the position of the bones during the application of the primary dressing. Such sutures should not last longer than a few days. The Esmarch bandage is removed and the larger arteries are ligated.

The capsule and the periosteum are sutured with catgut in position over the ends of the bones. The skin is sutured with catgut, providing the case is an aseptic one, and a small portion of the wound (2 cm.) at its highest point is not sutured, in order that leakage of blood may take place easily during the next few hours. If one so desires, a small piece of rubber tissue may be inserted through this opening to prevent its closure. What I prefer is to hold apart this small opening in the wound by two catgut sutures, one upon each side of the wound. These sutures will be absorbed within a few days (Maas' method) and will allow the wound to close before the first dressing is changed. The forearm is slightly flexed and semipronated. It is retained in this position by a splint, either plaster of Paris reinforced by sterilized basswood strips or the Esmarch's wire splint (Fig. 4049). With either of these the arm and forearm are elevated and retained in this position by suspension.

Kocher's Method.—By the Langenbeck incision, disease in the radio-humeral articulation is not so easily attacked as by the Ollier bayonet incision. Ollier's incision, which passes in the interstice between the external head of the triceps and the anconeus, must divide the nerve supplying the anconeus, since it is a branch of the division of the radius supplying this portion of the triceps. Hence Kocher planned an incision which avoids this nerve division and does not negative this portion of the triceps.

The forearm is flexed at an angle of one hundred and fifty degrees, and a stirrup-shaped incision is made, which begins 3 to 5 cm. above the epicondyle and over the external border of the humerus, and descends to the head of the radius. From this

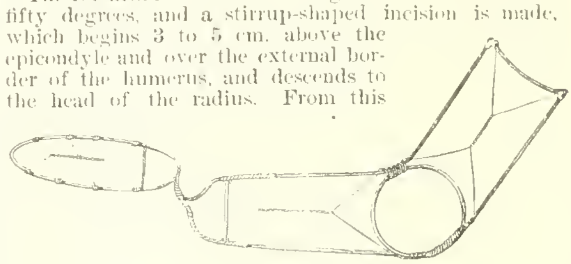

Fig. 4049.

point it descends downward and slightly inward, following the external border of the anconeus until it reaches the ulna at a point from 4 to 6 cm. from the tip of the olecranon. From this latter point it curves over the posterior surface of the ulna inward and upward for a distance of from 1 to 2 cm. (Fig. 4050). This incision above the epicondyle passes in the interstice between the supinator longus, extensor carpi radialis longior, and the common tendon for the supinators and extensors of the hand and wrist and fingers in front and the triceps and anconeus behind. From the epicondyle to the lateral surface of the ulna, the incision passes in the interstice between the anconeus and the extensor carpi ulnaris until it reaches the ulna at a point 6 cm. below the tip

Digitized by Microsoft®

www.libtool.com.cn

of the olecranon. The latter part of the incision usually divides the lowest fibres of the anconeus, as they often extend a longer distance up on the shaft of the ulna. This incision passes in the interval between those muscles innervated by the posterior muscular branch of the musculo-spiral and those supplied by the external muscular and posterior interosseus branches of the same nerve. The external ridge of the humerus, the epicondyle, the radio-humeral joint, and the supinator brevis muscles are now exposed, and the capsule of the radio-humeral and humero-ulnar joints are in view.

If the olecranon is diseased, the chisel may be placed upon its base and the process be removed from the shaft together with the attached triceps and anconeus muscles. This flap is retracted inward and the joint is exposed to its full extent. If the olecranon is not diseased, the periosteum beneath the external head of the triceps and the capsule are separated from the posterior surface of the humerus. In like manner the anconeus is separated from the epicondyle and the outer surface of the ulna, including with it the posterior humero-ulnar ligament. This dissection is continued over the ulna and olecranon, separating the triceps from the olecranon and a small part of the flexor carpi ulnaris from the internal surface of the ulna. The epicondyle is now fully exposed by separating the common tendon of the supinators and extensors subperiosteally and retracting the flap inward. This exposes the external lateral and the anterior ligaments passing from the condyle to the annular ligament of the superior radio-humeral joint. These are divided. The forearm is now extended and adducted. The joint is then brought into full view and the internal lateral ligament can be loosened from the inner surface of the ulna and of the trochlea (Fig. 4051). With this separation, the humerus is easily cleared of all muscles anteriorly and posteriorly and the bone section made as recommended in the preceding operation.

The annular ligament is now divided and the head of the radius is removed separately from the ulna. If possible, the section of the ulna should be such as will leave a process simulating in slight degree the olecranon. Such a method is useful in preventing the anterior subluxation of the ulna. The section is the same as is shown in the former operation.

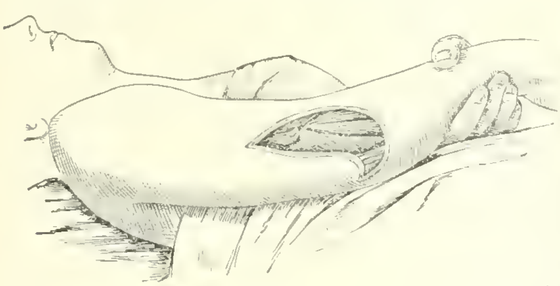

FIG. 4050.

When the disease is tuberculous, it is best not to incise the synovial membrane until the dissection of the soft parts is completed and the dislocation of the radius and ulna from the humerus is ready to be made. When the synovial membrane has been completely removed and the sinuses, if any, are excised or curetted, the parts are brought into apposition and sutured. Drainage, if necessary, is made with gauze at the lower angle of the wound beneath the anconeus. If drainage is necessary for only a few days, the Maas method is the preferable one (see Langenbeck's operation).

Sutures, both deep and superficial, are made with catgut if the wound is to be an aseptic one and if it is to heal under one dressing; if not, silk is used for the skin. If ankylosis is desired, suture the bone with two-weeks chromicized catgut. If a nearthrosis or a mobile pseudoarthrosis is desired, suture with catgut, which will last but a few days and will simply retain the bones in position during the application of the primary dressing. The extremity is placed in such a splint as has been previously recommended and is suspended and elevated.

These two methods are undoubtedly the methods of choice for both injury and disease in the vast majority of cases.

There is a method very similar to Kocher's, except in the skin incision and in some of the minor details, which may be used for it in cases of exploration, partial resection, and synovial extirpation. This is the method of Cavazzani. In two of my cases of synovial arthrectomy this method was found to be exceedingly valuable.

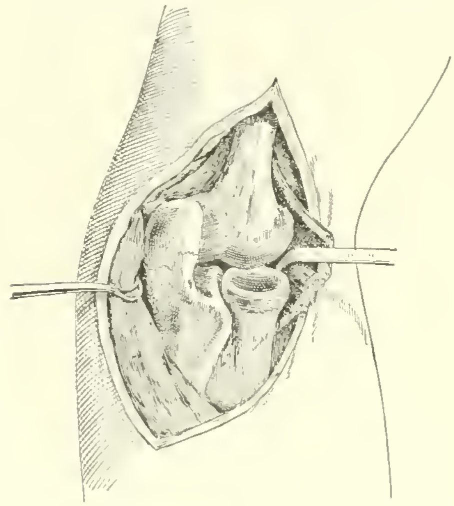

FIG. 4051.

Method of Cavazzani.—Three landmarks are taken—one the tendon of the biceps, one the head of the radius, and the third the olecranon process. Two centimetres below the epicondyle upon the outer border of the tendo bicipitis an incision through the skin and subcutaneous tissue begins and passes transversely outward parallel to the interarticular line of the joint. At the outer side of the forearm it passes obliquely from behind upward and ends at the inner border of the ulna near the tip of the olecranon (Fig. 4052). During the first half of this incision the forearm is extended. During the last half it is in half-flexion. This stretches the skin and prevents slipping. The upper flap is dissected up sufficiently to expose the interval between the anconeus and the muscles arising from the epicondyle, *i.e.*, the interstice between the anconeus and the extensor carpi ulnaris.

The epicondyle being exposed, the aponeurosis covering this interstice is divided over the neck of the radius and above the epicondyle. The epicondylar muscles are now loosened subperiosteally and are retracted inward. The capsule is thus exposed as far as the coronoid process. Upon the posterior surface the anconeus is also separated subperiosteally from the humerus and the ulna together; the tendon of the triceps is separated over the external half of the olecranon process. If one wishes to disregard the anconeus nerve supply, one may cut transversely in the interstice of the triceps and anconeus from the epicondyles to the outer surface of the ulna. The posterior capsule is now exposed. The joint is next opened by dividing the external lateral

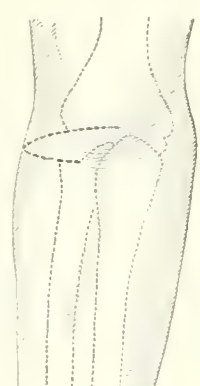

FIG. 4052.

Digitized by Microsoft®

ligament from the coronoid process anteriorly to the tip of the olecranon posteriorly. A movement of adduction will now dislocate the forearm from the arm.

After the operation is finished, the forearm is replaced, the lateral ligaments are sewed, and the muscles about the epicondyle sutured in place. No vessels or nerves are injured. The rad[illegible] www.libtool.com.cn The tendon of the triceps is preserved in half its detachment. The epicondylar muscles are preserved.

For exploration and synovial extirpation, Cavazzani's method is very satisfactory, for the reasons above stated.

For *ankylosis* and for the reduction of *old dislocations*, the method of Jeffrey, which has been more precisely described by Marangos (Thèse de Lyon, 1883), and that of Hueter ("Gelenkskrankheiten," vol. ii., p. 552) are undoubtedly the best. This is especially so in fractures with dislocation, where the reduction requires the removal of the callus with or without a partial resection; in old dislocations which require the removal of the callus and the adhesions in order to effect reduction; in all impractical ankyloses following disease, injury, or operation, which are to be made practical ankyloses or in which arthrolysis is to be attempted; and, lastly, in cases in which redislocation has followed the operative reduction of an old dislocation (Bunge, *loc. cit.*).

With the posterior incision or the single lateral incision, one comes upon the joint at a disadvantageous side for the correction of an ankylosis or for the removal of callus.

In ankyloses it is not possible to dislocate the bones, and the removal of the necessary wedge or piece of bone must be done without displacement. For this reason, Hueter and others accepted the bilateral incisions which Jeffrey formerly used in all resections. These incisions have been greatly modified by subsequent operators, but the method here described will, I think, be found to approach the ideal method. It consists of the radio-humeral incision of Kocher and the ulnar incision of the bilateral methods. The incision upon the radial side commences 5 or 6 cm. above the external condyle, and penetrates between the triceps and the supinator longus and extensor carpi radialis longior, until it reaches the external humeral border and descends to just behind the epicondyle. It here passes obliquely downward and inward in the interstice between the anconeus and external carpi ulnaris for a distance of from 2 to 3 cm. Unless the radius is involved, the annular ligament is avoided. Now clear the anconeus and the triceps from the capsule or tissues beneath them and retract them inward. Clear the supinator and extensor group from the epicondyle and retract them inward.

An ulnar incision is next made upon the internal border of the epitrochlea or at the place where it had been broken off or displaced. This incision is from 8 to 10 cm. in length. The ulnar nerve is freed and displaced backward. The pronator and flexor groups of muscles are displaced outward and in front after being freed from the internal border of the humerus and the epitrochlea. These incisions descend to the bone, and one separates subperiosteally with the rugine, or supraperiosteally with the knife, the soft parts from the bone upon both surfaces of the humerus. In the reduction of old dislocations the method pursued must be extraperiosteal (Bunge, *Archiv für klin. Chir.*, No. 60, p. 557). A blunt retractor is now inserted in front of and behind the humerus, for the purpose of guarding and lifting the soft tissues from the bone. If one desires, the bone section may now be made with the saw. If it is thought better, the adhesions between the humerus, olecranon, ulna, and radius may be divided and the humeral extremity first and the radius and ulna afterward displaced through the external incision. They may then be sawn and replaced. If the case be an old dislocation, the fibrous bands between the internal condyle and olecranon must be divided. The epitrochlea, if torn off and displaced, must be loosened and returned. The trochlea of the humerus and the sigmoid cavity of the olecranon must be cleared of all fibrous or bony tissue. When this is accomplished, a movement of adduction of the forearm will expose the humeral extremity in the external wound and allow the removal of the new formation in the olecranon fossa. When this is finished the radius and ulna may be exposed in the same manner and the process of clearing their articular surfaces completed. With the completion of the work upon the bones the extremities are apposed, sutured if desired, and immobilized at an angle sufficient to prevent dislocation. In the reduction of old dislocations, this is usually a right angle, with the forearm in full pronation to prevent redislocation. In resections in which motion is desired, the position is one of nearly complete extension, with semipronation. In cases in which an ankylosis is desired, the forearm is left at an angle a little less than a right angle.

The After-Treatment.—It is to be borne in mind that there is always a tendency to displacement of the fragments, that too wide a distance between the extremities of the bone tends to a flail joint, and that too close a distance tends to ankylosis. The usual distance for obtaining a false joint is between 1 and 2 cm. In children ankylosis is to be especially feared; consequently, as soon as possible passive motion must be enforced. Usually upon the third day passive motion is begun, and is repeated daily in the wrist and fingers. On the twenty-first day the forearm is moved in flexion every second day, and returned to the original position of extension. In from four to five weeks the forearm can be easily moved to ninety degrees and returned to the original position of extension.

The movements of supination and pronation are made at the same time as those of flexion and extension.

At the end of from six to eight weeks a splint can be dispensed with, when massage and electricity are used. The daily use of the arm must be secured. At four months the movement in the new joint should be sufficient to allow the patient to feed and dress himself and to carry quite heavy weights. It will require one year before one can see the best results in motion and stability.

If large quantities of bone have been removed and the operation has been subperiosteal and subcapsular, it is best to be satisfied with an ankylosis at a right angle and in semipronation rather than run the risk of a flail joint.

If ankylosis is attempted, passive motion in the wrist, fingers, and shoulder is daily practised, in order to preserve their full power.

If the amount of bone removed has not been great, say enough to allow from 1 to 2 cm. between the bones of the arm and forearm, and if the operation was subcapsulo-periosteal or partly so, it is best to attempt a nearthrosis or a pseudarthrosis. After the third week, when the wound is healed and passive motion at the elbow is begun, an angular hinged splint should be applied, which will prevent, during the exercises of flexion, extension, supination, and pronation, any lateral displacement of the bones. Very great care must be given by the patient and the surgeon to obtain the ideal result.

One factor must not be lost sight of during the after-treatment, and that is that an angular ankylosis with movement at the fingers, wrist, and shoulder is more useful to a laborious occupation than the excessive mobility often resulting from these resections. Another fact to be borne in mind is that in the young motion is to be begun early. In the adult, in whom there is less danger of ankylosis than there is of a flail joint, passive motion need not be begun until some firmness is present in the joint.

The mortality, according to Culbertson, is as follows: *Gunshot wounds:* Partial resection, 27.02 per cent.; complete resection, 25.30 per cent. *Injury:* Partial resections, 7.4 per cent.; complete resections, 21.05 per cent. *Disease:* Partial resections, 11.11 per cent.; complete resections, 9.94 per cent.

In the Franco-German war (1870–71), resections for gunshot injuries gave a mortality of 27.41 per cent. (Gurlt). In our own civil war, gunshot injuries, when resected, gave a mortality of 23.70 per cent. Salzman, quoted by Ollier, gives the mortality of resections for

Digitized by Microsoft®

ankylosis as 1.47 per cent. Functional results are in the main good, especially in civil practice.

For disease, Culbertson gives 6 perfect and 32 useful joints in 40 cases of partial resection, and 32 perfect and 196 useful joints in 290 complete resections.

Gurlt's statistics, obtained from the German wars (1848–77), gives 5.63 per cent. as very good, 23.66 per cent. as good, 53.24 per cent. as moderate, 14.37 per cent. as bad, 3.09 per cent. as very bad.

www.libtool.com.cn

Nepveu ("Bulletin et Mémoire de la Société de Chirurgie," 1883, p. 591) presents 21 cases with extensive restoration of the parts. The general form of restoration is brought about by the osteophytic growth of the condyles of the humerus.

In Kocher's Klinik, 1872–97 (Oschmann, "Über die operative Behandlung des tuberculösen Ellenbogengelenks und ihre Endresultate," Berlin, 1897), where a large number of good functionating joints were obtained, it was noticed that rotation at this joint was better than flexion and extension. It was observed that much value is to be placed upon the preservation of the anconeus for obtaining full power in extension of the forearm. It was also observed in three cases that repeated resections were necessary to secure good function. Hence the importance of a thorough removal at the first operation is plainly seen in these cases. After healing had taken place, the most frequent impediment to flexion seemed to be enlargement of the internal condyle or of the coronoid process. For these cases secondary resections, removing the impediment to motion, are properly indicated.

The functional results of resection for old, unreduced dislocations show that 70 per cent. have good results, 30 per cent. have bad (Culhorst, *Beit. zur klin. Chir.*, Bd. xx.), while the bloody reposition of these old dislocations gave 76.9 per cent. of excellent results, with 23 per cent. of bad results, no one of which can be considered due to the method of operation (Bunge, *loc. cit.*, p. 594).

Resection of the Superior Radio-humeral Articulation.—This operation is occasionally made use of in old dislocations, in fracture of the head of the radius, impeding the motions of rotation, of flexion, or of extension.

Operation.—An incision of from 5 to 7 cm. is made in the same manner as the Kocher incision for the resection of the elbow-joint. This incision passes in the interval between the anconeus postero-internally and the extensor carpi ulnaris antero-externally. After their attachments to the epicondyle have been loosened, the tissues are retracted and the capsule is exposed. This is incised and the head of the bone is removed as close to the shaft as possible. The section should be at the point where the annular ligament is closely applied to the neck of the radius. With this incision there is no danger to the musculospiral nerve anteriorly. The posterior interosseous nerve, as it crosses within the fibres of the supinator brevis muscle, is distant from the epicondyle of the humerus 4 cm. on the external surface of the forearm. On the posterior surface, where it meets the interosseous artery in the interval between the supinator brevis and the extensor ossei metacarpi pollicis, the distance from the epicondyle is usually 6 cm. or over. Hence it is difficult to injure it unless the incisions are prolonged further than recommended. After the head is removed, the capsule and ligaments are sutured and a nearthrosis or pseudarthrosis is attempted.

At ten or fourteen days passive motion is begun and continued for several weeks. It has usually required three months to obtain the best results, and great assistance has been derived, as I believe, from the daily use of the hot air by means of the Sprague apparatus. In three cases of fracture of the head of the radius with abolition of supination and pronation in marked degree, removal of the head and conservative after-treatment have given almost perfect results.

Resection of the Shoulder-Joint.—*History.*—James Bent, England, 1774, probably did the first excision; the elder Moreau probably the first complete excision, 1786.

In the Schleswig-Holstein campaign (1848), in the Crimean War (1855), and in our own civil war (1861–65) the operation gained greatly in prominence and has since then become fully established.

To obtain a nearthrosis or a good pseudarthrosis, the line of section in the humerus must be below the tuberosities to which are attached the rotators and above the adductors. In all cases as little is sacrificed as is possible, in order that the functions of the forearm and hand may be preserved in their entirety. In children, in whom the growth is almost finished, operations with sacrifice of the muscular attachments and with little loss of the humerus give good functional results with either a nearthrosis or a pseudarthrosis. In adults, especially if the periosteum is not saved and the muscular attachments have been sacrificed, ankylosis or a flail joint will result, for the periosteal activity in adults is often wanting and no reproduction takes place.

In all cases the constant tendency to forward displacement of the humerus must be avoided. In all cases the humerus must be held in contact with the scapular border or the glenoid cavity in order to obtain a fixed but movable joint upon which the muscles may move the humerus. The mobility of the scapula compensates in great measure for immobility at the gleno-humeral union.

Indications for Resection of the Shoulder-Joint for Injury.—In slight injuries and in gunshot wounds, expectant treatment and at the most a partial resection are indicated. In severe injuries to the head of the humerus, and in comminuted fractures from gunshot wounds with the nerves and vessels intact, a primary resection is indicated. In severe injury to the head of the humerus and to the acromion process and the scapula, the operation is not necessarily contraindicated, provided the nerves and vessels are intact. In case the latter are involved, amputation is in all probability the only successful issue. In case the nerves are injured, the main vessels escaping, and provided the injured nerves can be sutured, amputation should give way to resection of the joint and suture of the nerves.

In some cases of compound dislocation or of old unreduced dislocations, with or without fracture through the surgical neck of the humerus, resection has been made necessary; yet these cases are becoming more and more infrequent, owing to the aseptic treatment and to the earlier reductions by incisions (confer here Dollinger, *Deut. Zeitschrift für Chirurgie*, No. 66).

1. I can quote no better authority on the unreduced dislocation of the shoulder-joint than Souchon (Trans. Amer. Surg. Association, 1896, p. 409). He maintains: I. That operation is justifiable only in recent cases in full-grown subjects of sufficient age to insure no great shortening from want of growth in the bone. II. That resection should be performed in all instances except when the head and glenoid cavity are in good condition; when reduction can be accomplished without great effort or extensive dissection; and when the head, once reduced, readily remains in place.

2. In fracture of the upper part of the surgical neck of the humerus and dislocation of the head reduction of the dislocated head and suture of the fracture will be preferable to resection in a recent case (McBurney, *Annals of Surgery*, 1894, vol. i., p. 399); but when union fails and the joint becomes useless, or if the dislocated head cannot be reduced without too extensive interference with its nutrition, it must be removed.

3. In recurrent dislocations resection has been performed not infrequently, yet attempts at more conservative methods are recommended (Burrell and Lovett, Trans. Amer. Surg. Association, 1897, p. 293). Such a conservative method is described in the above paper.

For Disease.—Here partial and complete resections are indicated, although the functional results are not much better than in cases of ankylosis following expectant treatment. 1. In tuberculosis and in the destruction of a joint following epiphysitis and suppuration, gonorrhœal infection, injury and infection, or from suppurative subdeltoid bursitis, partial or complete resection is indicated

Digitized by Microsoft®

as soon as conservative surgical treatment fails to cure. 2. In ankylosis following acute rheumatic arthritis and acute traumatic arthritis with suppuration, resection is indicated in some instances.

For tumors involving the bones of the joint. A few (four) instances exist in which a part of the humerus has been removed for sarcomatous growths involving the joint.

www.libtool.com.cn

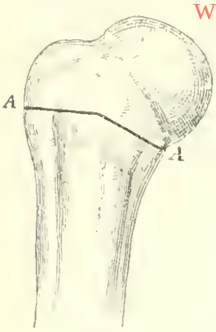

FIG. 4053.

Anatomy.—The anatomy of the shoulder joint is very simple. All the bony prominences in its vicinity can be easily felt. The groove between the pectoralis major and the deltoid, in which lie the cephalic vein and the acromiothoracic artery, are easily made out. The circumflex nerve and the posterior circumflex artery cross the humerus in a horizontal line one finger's breadth below the centre of a line drawn from the acromion to the deltoid insertion. These two structures usually pass just below the capsular attachment upon the internal surface of the anatomical neck, which point is opposite the so-called surgical neck of the humerus—the point above mentioned. The upper epiphysis becomes united to the shaft at twenty years. The deltoid muscle is so situated that the only place where it can be divided without injuring a portion of the nerve supply is close to the margin of the acromion process and of the spine of the scapula. This method of incision, recommended formerly by Nélaton, Neudörfer, Perrin, and Gurlt, avoids injury to the circumflex nerve and at the same time permits union of the muscle to the bones without atrophy of the muscular bundles. As a result, the humeral end is held in contact with the glenoid cavity or the border of the scapula in a firmer and stronger manner than can be obtained when atrophy of muscular fibres follows operation.

This method of entering the joint is not convenient for observation of all parts of the articulation, especially of the anterior portion.

Another method of entering the joint is by means of incisions which traverse the deltoid muscle anteriorly. There are two of these incisions. One (Baudens, Malgaigne, and Langenbeck, "Esmarch's Handbuch" and *Archiv fur klin. Chir.*, xvi.) divides the anterior fibres of the deltoid muscle and necessarily paralyzes the anterior fibres of this muscle. Its field of observation and manipulation is a direct and extensive one. The other anterior incision (Ollier, "Traité des Résections") passes nearer the interval between the pectoralis major and the deltoid muscles, paralyzes less of the deltoid muscle, and gives an operative field quite as good as that obtained by the Langenbeck incision. The posterior incision is anatomically the better one, but incisions must be made to expose diseased areas and to render possible a full inspection of other portions of a joint than those thought to be alone involved. For this reason incisions which traverse the anterior portion of the deltoid muscle have been selected by most surgeons as the best.

We will describe two methods of operation, one by the anterior incision, the other by the posterior incision. Both methods should be performed subperiosteally if possible, since the partial reproduction of bone greatly aids the function of the joint by giving a more perfect fulcrum for the muscles of the shoulder (von Langenbeck, *Archiv fur klin. Chir.*, 1874, xvi., and Ollier, "Traité des Résections," t. i. and ii.).

Operation by the Anterior Incision.—The patient is placed upon the back with the elbow slightly raised from the side and the hand resting upon the iliac spine of the same side. An incision is begun at the outer extremity of the coracoid process, and descends over the deltoid muscle parallel to its fibres (*i.e.*, slightly outward) for a distance of from 6 to 10 cm. (Ollier, *loc. cit.*; Hueter, "Gelenkskrankheiten," vol. ii., 587). The muscle is exposed in this incision. The muscle is incised parallel to its fibres, and the capsule, the humerus, and the coraco-acromial ligament are exposed. The borders of the wound are now retracted and the bicipital groove in the humerus is noted. The capsule is divided longitudinally and externally to the sheath containing the biceps tendon. This division of the capsule extends above as far as the glenoid ligament. Below, the capsule and the periosteum are divided close to but external to the commencement of the bicipital groove in the humerus. With the rugine when one can, and with the knife when necessary, the periosteo-capsular attachment of the internal flap is separated along the external ridge of the bicipital groove, across the groove, and beyond the lesser tuberosity. To facilitate this work the arm is rotated outward, and as one approaches this tuberosity the head is made prominent in the wound by lowering the elbow during the act of rotation. In this manner, with good retraction, the capsule and the periosteum, or the capsule alone, may be separated beyond the insertion of the subscapularis muscle. After this is accomplished the arm is returned to its original position and the separation of the periosteum and capsule of the external flap is commenced.

With a retractor beneath the capsule, the flap is raised and the separation of the capsule and the periosteum over the tuberosities and below upon the shaft is commenced. This is facilitated by rotating the arm inward while it is slightly adducted and the elbow is lowered. This manœuvre is continued until the attachments of the supra- and infraspinatus and teres minor muscles are passed.

The arm is now allowed to hang to the side of the table in a vertical position, and when the retractors separate the flaps and the biceps tendon is drawn aside the head is pushed upward through the wound and presents itself to view. The capsule and the periosteum are now cleared from the internal surface of the shaft, and when they are sufficiently so the saw is applied. During the section of the bone the head is held firmly with the long-toothed forceps while an assistant grasps the arm and steadies it.

Gigli's saw or a bow saw (Helferich's) is usually preferred in making the section. The line of section is from within outward and from below upward for one-half the diameter of the bone. For the rest the section is more horizontal (Fig. 4053, *A A*). As much of the shaft of the bone must be saved as is compatible with removal of the disease. The section should be made just below the articular surface if possible. In such a section, the whole length of the humerus will act as a fulcrum for the deltoid muscle in elevating the arm, and a greater power will be retained than when the section is nearer or through the surgical neck.

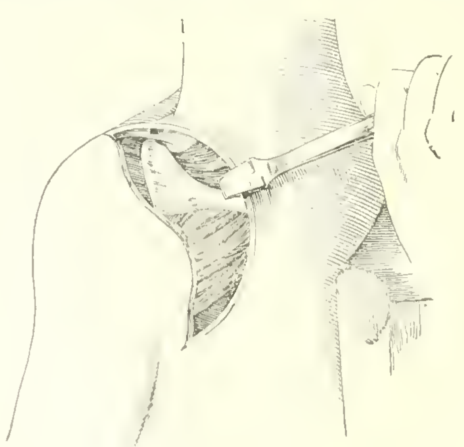

FIG. 4054.

The glenoid cavity is now examined and is curetted or

Digitized by Microsoft®

cut away with the chisel or cutting forceps. If this is necessary, the capsule and the insertions of the triceps and biceps muscles should be freed from the bone before its removal.

In cases of bony ankylosis, the line of union may be divided, and when the humerus is movable the resection may be completed as already described, or one may saw through the humerus first and subsequently extirpate the head from its capsular and muscular attachments.

www.libtool.com.cn

In tuberculous diseases, much time must be spent in removing the synovial membrane and clearing up the sinuses and the bursæ involved. When oozing is present, these cases are best partially sewed and tamponed for several days, but when hemorrhage is fully stopped they should be sewed up completely. The same holds true for other infections and for tumors. When the hemorrhage has been checked, the capsule and the periosteum are sutured with catgut. The deltoid is held together by catgut sutures involving a few of its fibres, but sufficiently to close the opening. Drainage when required may be obtained by an opening through the capsule posteriorly. The skin is sutured with silk.

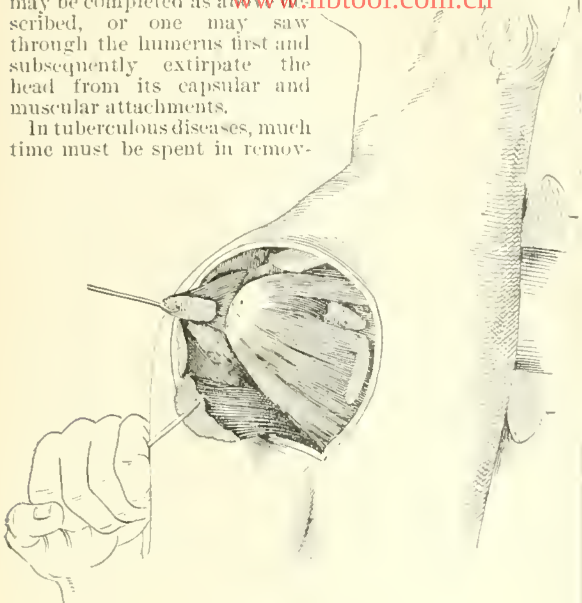

FIG. 4055.

The position of the arm should be one of slight abduction, with the humerus pushed upward and backward and in contact with the glenoid cavity or the border of the scapula, where it is retained during the dressing by chromicized catgut sutures inserted before closing the capsule.

The Method by the Posterior Incision.—This method of incision is recommended at the present time by McCormac and Kocher. McCormac ("Surgical Operations," Vol. ii.) recommends it when the site of section in the humerus is to be above the tuberosities. Kocher believes that this method is advantageous in allowing perfect drainage and in preventing a forward dislocation so frequent after resection by leaving intact all that part of the joint and muscle attachment between the biceps tendon and the lower border of the subscapularis muscle. His method of incision, he believes, overcomes the interference with the exposure of the joint produced by the prominent acromion, and likewise avoids the danger of injury to the circumflex nerve, as it passes close to the humeral attachment of the capsule and the teres minor muscle. His method leaves the deltoid practically uninjured, so that its action in elevation of the arm suffers in no degree (Fig. 4054).

An incision is made, passing from the acromio-clavicular articulation over the prominence of the shoulder, along the spine of the scapula to its middle. From here the incision inclines in a curve downward toward the posterior axillary fold, ending about two fingers' breadth before reaching it. The upper limb of this incision divides the tissue over the acromio-clavicular joint and the spine of the scapula, exposing each. The lower limb divides the tense fascia close to the posterior border of the deltoid muscle and exposes the muscle for a distance of from 2 to 3 cm. from the spine of the scapula. The muscular fibres of the deltoid muscle which are inserted into the spine behind this incision must now be divided. This is the only portion of the muscle which is divided and is deprived of action. The trapezius muscle is next separated subperiosteally as far as the acromio-clavicular articulation from the upper border of the spine of the scapula. Likewise, upon the lower border of the spine of the scapula, the deltoid insertion is separated subperiosteally as far forward as the spot marked by the junction of the acromion process and the spine of the scapula. At this point the spine is separated from the acromion process either with the chisel or, better, with the Gigli saw. (Fig. 4055). Care must be exercised not to injure the suprascapular nerve as it passes from the supra- to the infraspinous fossa. It is well also to make two drill holes before dividing the spine from the acromion process, so that they can be more easily sutured at a later date.

When this separation is completed, the acromion process with the attached deltoid muscle is luxated forward. The deltoid muscle is thus raised from the teres minor, the infraspinatus, and the supraspinatus muscles, to which it is but loosely attached by connective tissue. After the dislocation of the acromio-deltoid flap, the insertion and the muscular bellies of these three muscles which cover the humeral head are exposed (Fig. 4056). The elbow is now brought forward and the arm is rotated outward. Along the upper border of the supraspinatus muscle an incision is made from the margin of the glenoid cavity to the spine of the greater tuberosity, exposing the tendon of the biceps muscle in its whole length within the joint. The outward rotators are next loosened subperiosteally from the greater tuberosity, and, while still attached to the periosteum of the shaft, are retracted posteriorly. If one wishes, a small part of the tuberosity

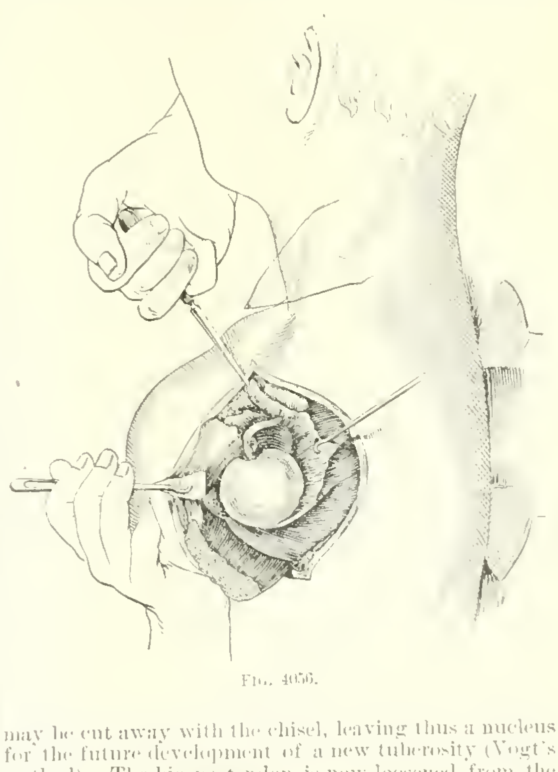

FIG. 4056.

may be cut away with the chisel, leaving thus a nucleus for the future development of a new tuberosity (Vogt's method). The biceps tendon is now loosened from the bicipital groove and is drawn forward. The insertion

Digitized by Microsoft®

of the subscapular muscle is seen at its attachment to the lesser tuberosity and to the spine of this tuberosity. It should be separated subperiosteally and drawn forward and inward. The circumflex artery and nerve are to be avoided at the lower border of this muscle. As soon as the head is thus freed, it can be easily protruded through the wound (Fig. 4056). After it has been removed, the glenoid cavity should be freely exposed and to an extent which is unattainable by any anterior incision. This exposure is best accomplished, after the head has been removed, by exerting traction upon the elbow while it is held in the position of adduction. The importance of the exposure of the glenoid cavity in tuberculosis of this joint cannot be questioned, and therefore this method has its specific application.

After the synovial membrane, the bursæ, and the bones are removed, the capsule and the periosteum are sutured, and the wound is closed. If drainage is necessary, the capsule should be incised below the border of the teres minor, and care taken to avoid the circumflex nerve and artery as it emerges beneath the muscle. These are easily recognized, however, since the field is so well exposed. After this is accomplished, the spine of the scapula and the acromion should be sutured. The trapezius and the deltoid are sutured over the acromion or spine of the scapula if necessary; if it is not thought necessary, they are left unsutured. The skin should be sutured separately.

Sir William MacCormac prefers entering the joint between the teres minor and the infraspinatus muscles, clearing the infraspinatus, supraspinatus, and the subscapularis muscles and the biceps tendon forward, until the bone is free, and subsequently clearing the teres minor muscle with the capsule posteriorly. In some instances this is undoubtedly a good method of approach after the deltoid has been retracted forward ("Surgical Operations," part ii.).

After-Treatment.—The main point in the after-treatment seems to be the retention of the head in contact with the glenoid cavity or with the border of the scapula. This contact may be secured by the use of chromicized catgut, which lasts long enough to insure no slipping during the primary dressing. A large pad made like the Stromeyer's cushion is now placed in the axilla, and the arm resting upon this pad is secured to the side, while the forearm is supported by a sling. This pad supports the humerus, fixes it, and prevents the tendency which the pectoralis major and the latissimus dorsi have, to displace the upper end of the humerus in an inward direction, beneath the coracoid process. This tendency will be more difficult to counteract if the external rotators have been divided.

The first dressing is not changed for from six to ten days if possible. The movements of the fingers, wrist, and elbow are gently exercised daily from the very first. It is useless to begin moving the shoulder until the deep parts of the wound are sufficiently healed, *i.e.*, usually in the second or third week. In this manipulation abduction must be made with care, for fear of dislodging the head and forcing it beneath the coracoid process. Daily application of massage, electricity, and superheated air (Sprague apparatus) to the muscles of the shoulder is very useful in preventing too extensive ankylosis.

The deltoid and the rotator muscles should be daily exercised by appropriate manipulations. This should be continued for from four to six weeks, after which the patient must carry out his own exercises, such as bringing a gun to the shoulder, lifting weights with the arm abducted, and appropriate exercises upon the various kinds of gymnastic weights and pulleys.

The after-treatment must be maintained for a long time in order to obtain the best results. Langenbeck refers to a case (*Archiv für Klin. Chir.*, xvi., p. 393) in which the arm increased in strength for two years following the operation.

Results.—According to Culbertson, the mortality was as follows: For gunshot wounds (855 cases), 31.44 per cent.; for disease (116 cases), 15.84 per cent. According to Otis, the results were as follows: Out of 2,369 cases of gunshot wounds, 577 of which were treated by the expectant method, there were 951 cases which were treated by excision, with a mortality of 36.6 per cent., and 841 cases which were treated by amputation, with a mortality of 29.1 per cent. The mortality for the 2,369 cases was 25.1 per cent. According to Souchon, the results, in cases of old irreducible dislocations, with or without fracture of the humerus, were as follows: In those treated by reduction, the mortality was 10 per cent., and in those treated by resection it was 12 per cent.

The Functional Result.—Usually flexion and extension are good; adduction is also usually good. Rotation and abduction are usually feeble. The tendency in this joint is toward ankylosis rather than toward a flail joint. The subperiosteal method (Ollier) gives the most perfect functional result, and should be practised whenever feasible. According to Gurlt ("Ueber Gelenksresectionen nach Schusswunden," Berlin), the results in 213 cases were as follows: Very good, almost perfect, in 1.87 per cent.; good, not perfect, but useful, in 42.25 per cent.; moderate, of limited use, in 47.88 per cent.; bad, useless, in 7.98 per cent. In the German wars (Langenbeck, *Archiv für Klin. Chir.*, xvi.), conservative treatment gave at least as good results as the resections which were then performed. Thus, in 44 cases of resection of the head of the humerus, the results were good in 2 instances, while in 31 cases the shoulder hung like a flail, and the elbow, hand, and fingers were more or less useless. On the other hand, in 54 cases treated conservatively, there was ankylosis in 43 instances, but the elbow, hand, and fingers continued to be useful. "When the subperiosteal method is employed and the supraspinatus, the infraspinatus, the teres minor, and the subscapularis muscles remain in connection with the periosteum of the shaft of the humerus, a flail joint will not result." "The good results are obtained when the subperiosteal method is carried out." He reports 8 cases with excellent results. Wegner (*Charité Annalen*, 1901, Bd. xxv.) also reports an excellent result following resection of this joint for caries sicca (tuberculosis).

THE RESECTION OF THE LOWER EXTREMITY.—The small joints of the foot occasionally require resection. Corresponding joints in the toes are removed in the same manner as those in the fingers. As a matter of fact, resection of the toes is seldom done, since their deformations do not demand it.

Resections of the metatarso-phalangeal joints are performed in the same manner as in the hand. The incisions are placed to either side of the extensor tendon in the second, third, and fourth metatarso-phalangeal joints, to the inner side of the tendon in the first metatarso-phalangeal articulation, and to the outer side of the tendon in the fifth metatarso-phalangeal joint.

Of these joints, the metatarso-phalangeal articulation of the great toe is not infrequently resected for hallux valgus. As these cases are quite often complicated with a bunion which requires removal at the same time, this incision is a semilunar one. It extends from a point on the metatarsal bone, 2.5 to 3.5 cm. above the joint. It descends in a curve over the lower quadrant of the bunion until it reaches its mid point, whence it ascends in a curve to the centre of the outer border of the first phalanx. This flap with the deep connective tissue is dissected from the bunion until its base is reached. The adventitious tissue and the bunion are now removed, after which the subperiosteo-capsular method is pursued in freeing the ends of the bones. When the periosteum and the capsule are loosened to beyond the centre of the articular surfaces, the ends of the bones may be made to protrude through the wound. (Fig. 4057.)

They may now be removed completely or partially as desired. Since it is very necessary to retain the sesamoid bones the separation of the periosteum and of the capsule upon the inferior surface of the joint must be done with care. After removal of the articular ends of the bones they are placed in apposition and sutured with catgut if one desires an ankylosis. If a pseudarthrosis or nearthrosis is desired, no suture of the bones is made.

Digitized by Microsoft®

Resection of Joints.

Ankylosis is obtained by maintaining the bones in apposition. Pseudarthrosis or nearthrosis is obtained when the ends of the bones are left within the capsule which is closed over them. Many deformities in hallux valgus, where the bunion and the deformity are not great, may be

www.libtool.com.cn

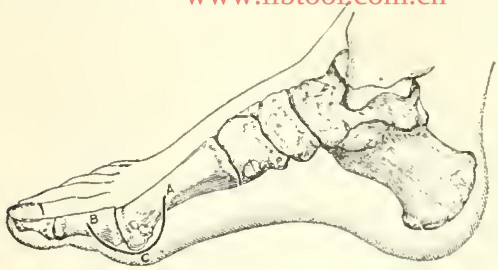

FIG. 4057.

corrected by a cuneiform osteotomy of the lower third of the metatarsal bone, and such an operation is to be advised in the minor cases of this condition.

Resections involving either the metatarso-tarsal, the tarsal, or the talo-tarsal joints, are rarely performed, because disease is scarcely ever confined to any one of these several joints. It is rare to have only one of the seven* articular synovial cavities of the foot involved.

Disease or infection from injury commencing in any one of these seven cavities soon spreads through the cancellous tissue of the bone to the neighboring synovial cavities, so that the process rapidly becomes a diffuse synovial, parasynovial, and periosteal one (Fig. 4058).

For this reason resections of single joints are rarely made on account of disease. In injuries to these joints and in deformities congenital or acquired, resections of single joints can rarely be performed in even minor grades of the injury or deformity. We must look upon the foot as a whole and operate without regard to the joints, with the sole idea of removing the condition for which we operate.

FIG. 4058.

There are several procedures which are applicable to injury or disease of this region: (1) Those of Bardenheuer and P. Bruns; (2) those of Wladimiroff-Mikulicz and Kümmell. For disease or injury situated between the bases of the metatarsal bones and the calcaneus and talus, Bardenheuer's method is especially applicable. In the majority of cases the involvement of the tarsal bones and the periosteal tissues is so great that an extensive exposure must be made in order to remove the diseased tissues completely. Where the disease involves the metatarso-tarsal, the talo-calcaneo-navicular, and the calcaneo-cuboid articulations, the method of H. P. Watson (Jacobson's "Surgery," vol. ii., p. 707) is not satisfactory and a more extensive exposure is required. It is here that Bardenheuer's method is most applicable.

Anterior Tarsectomy (Bardenheuer, "Mittheilungen aus dem Kölner Bürger-Hospital," 1-4).—An Esmarch bandage is applied. An incision is made through the skin, subcutaneous tissue, tendons of the extensor communis longus and brevis and proprius pollicis, and the cutaneous nerves, down to the bones from the first to the fifth metatarsal bones at their bases (Fig. 4059). From the extremities of this incision, two incisions are curved upward along the internal and external borders of the foot to beyond the medio tarsal joint. These incisions also extend through to the bone, dividing the tendons of the peroneus tertius and of the tibialis anticus. If necessary, these lateral incisions may be prolonged upon the metatarsal bones, the U-shaped incision being converted into an H-shaped one. This flap as marked out is dissected from the periosteum and the ligaments of the bones until it can be reflected above the level of the medio-tarsal joints. Here it is best to enter the joint, dividing the ligaments upon the anterior and lateral surfaces, when, if the forefoot is firmly held and depressed, the plantar ligaments holding the calcaneus and scaphoid and the calcaneus and cuboid can be divided. This division frees the tarsus, and allows, as in Lisfranc's amputation, an easy separation of the tendons of the tibialis posticus, the peroneus longus, and the less important muscles from the tarsus as far as the bases of the metatarsal bones. At this point a blunt retractor is passed between the bones and subjacent tissues, and the bases of the metatarsal bones are sawn at the distal side of their articular surfaces. The articular surfaces of the calcaneus and of the talus are now sawn off (Fig. 4060). The disease involving the muscles and the sheaths of the tendons is next removed. The vessels are ligated, the Esmarch bandage is removed, and the sawn extremities of the bones are apposed and sutured with chromicized catgut. If the disease is not thoroughly removed, or if

one so desires for any other reason, the wound may be packed until granulation appears, when a secondary suturing is done.

In this operation the tendons are rarely sutured. It has been found that in healing by granulation the fibrous tissue unites the tendons so that motion in the toes is often good. It is, however, advisable that the tendons be sutured whenever the wound treatment allows it. If possible,

www.libtool.com.cn

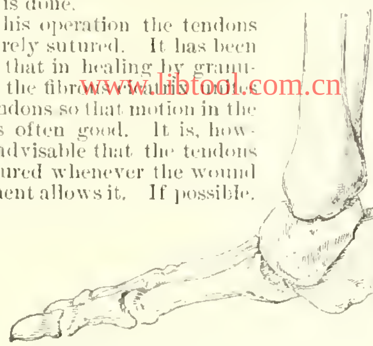

Fig. 4061.—Lateral View of the Bones after Bardenheuer's Resection of the Tarsus.

the tendons to the first toe should be sutured in all cases. In some cases sensation has returned though no suture of the nerves was attempted.

O. Wolff (Verh. d. deut. Ges. f. Chir., 1896) has presented 53 cases operated on by this method, in which the anterior tibial artery was cut. In 5 cases the posterior tibial artery was also cut. In 3 of these cases gangrene followed and required amputation. Of these cases, 42 were tuberculous in character, for which 9 complete tarsectomies, 7 partial with subsequent complete tarsectomies, and 13 partial tarsectomies were performed, with 29 complete cures. Two cases escaped subsequent observation. Three cases were amputated for gangrene and 8 cases remained under treatment at the time. In all the cured cases the foot remained a "flat" one, but the functional results were good.

Fig. 4062.—Anterior View of the Bones after Bardenheuer's Resection.

The after-treatment is mainly devoted to maintaining the forefoot in position and in apposition with talus and calcaneus.

Bardenheuer ("Mittheilungen aus dem Kölner Bürger-Spital," 1886) reported 17 cases of tuberculosis, in which none died as the result of operation. Twelve cases were cured with one operation, and of these 3 died subsequently of tuberculous meningitis; 3 required subsequent revisions before a cure was effected; 1 required amputation. One case of resection was due to loss of substance from injury; a cure resulted. (Figs. 4061, 4062, and 4063.)

Fig. 4063.—View of Cicatrix after Bardenheuer's Resection of the Tarsus.

Tibio-Calcanean Resection.—The statistics of Audry ("Sur les tuberculoses au pied," *Revue de Chirurgie*, 1890) show that tuberculous disease involves the ankle, the talo-calcanean, and the talo-calcaneo-navicular joints in fourteen per cent. of the tuberculoses in the foot, and that unless amputation be performed at the ankle (Syme's or Pirogoff's) some method must be found by which all of these joints can be opened and resected. Such a method has been elaborated by P. Bruns in 1890 (*Beiträge zur klin. Chir.*, No. 7, p. 223). This operation, made a typical one by Bruns, was previously done in an atypical fashion by Textor, 1852, and Mulvaney, 1866, and has subsequently been elaborated by Heidenhain, Helferich, Cramer, Küttner, and Kummer.

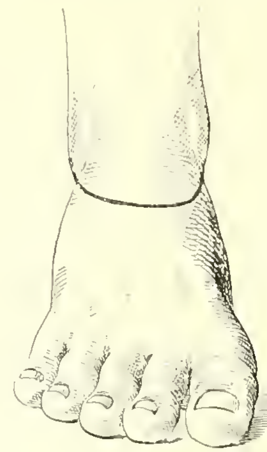

Fig. 4064.

The indications for this operation are the same as those for Pirogoff's amputation; namely, disease involving the talo-calcanean, talo-navicular, and talo-crural joints, with foci within the bones. Its advantage rests in the fact that it preserves the forefoot and gives a more useful member than is obtained by an amputation.

The method is as follows: An Esmarch bandage is applied. In order to obtain sufficient exposure an incision is made from one malleolus to the other in a broad curve over the dorsum of the foot in the neighborhood of the metatarso-tarsal joints (Fig. 4064). This curved dorsal incision, first made by Houssey (Heyfelder, "Resectionen," 1861) and subsequently used by Bardenheuer in his excision of the tarsus, is no disadvantage because of the division of the tendons and nerves. The flap thus marked out is deepened, passing above the peroneal tendons on the outer side and dividing upon the dorsal and internal surfaces the peroneus tertius, extensor longus digitorum, proprius pollicis, and tibialis anticus tendons, together with the branches of the anterior tibial and musculocutaneus nerves and the dorsalis pedis artery. This flap is dissected from the bones until the anterior tibial margin is reached. The talo-crural joint is opened by a transverse incision which divides the anterior fasciculi of the lateral ligaments. The foot is pulled forward and depressed, when the middle and posterior fasciculi of the lateral ligament are divided as close to the astragalus and os calcis as possible. With further depression, the posterior ligament of the ankle-joint is divided transversely, exposing the flexor longus pollicis tendon. The talo-navicular and the calcaneo-cuboid articulations are next entered and the superior and lateral capsular bands divided. If the astragalus

Resection of Joints.

is now cleared upon its lateral surfaces and the knife is passed into the sinus tarsi and carried from before backward and toward the sustentaculum tali, the interosseous ligament will be divided. The astragalus is now held only by a few undivided capsular fibres of the posterior talo-calcanean articulation and can be easily removed. The navicular, calcaneus, and cuboid bones, the tibia and the fibula, are now inspected for disease, and if they

www.libtool.com.cn

FIG. 4066.

are involved they should be treated as follows: The tibia and fibula are sawn so as to preserve their mortise shape. This is usually accomplished by cutting away the articular end of the tibia with the chisel or gouge, preserving its hollow shape, and by sawing the malleoli obliquely, leaving a small projecting edge beyond the surface of the tibia (Fig. 4065). The superior surface of the calcaneus is made to fit accurately the space between the malleoli. This will not infrequently require a removal of the sustentaculum tali. The calcaneo-navicular and the inferior calcaneo-cuboid ligaments are now divided or separated from the interior surfaces of the cuboid and scaphoid bones, so as to allow a vertical section with the saw. After this section, the anterior surface of the calcaneus is sawn in the same plane. The tendons, their sheaths, the ligaments and the muscles are next inspected, and if involved by disease they should be removed, after which the calcaneus is apposed to the tibia and fibula and to the cuboid bone. These bones are held in apposition by catgut sutures. The scaphoid bone will be seen to rest against the anterior margin of the tibia. The Esmarch bandage is now removed. The hemorrhage is controlled. The tendons, the nerves, and the deeper tissues are sutured to one another as far as is possible. As regards this point it may be said that most surgeons do not suture the several tissues to one another, but while no bad results may follow the adoption of this course, yet the time required for healing is undoubtedly lessened by a perfect apposition of like tissues. In the face of severe infections, the wound is left open and is packed until granulation appears, when secondary suture is made.

The after-treatment consists in absolute rest and elevation of the foot for from three to five days in an immovable splint, which holds the foot at right angle to the leg. At the end of ten days any deviation of the foot can be corrected with ease.

This operation can also be performed by a posterior curved incision which exposes the malleoli. The incision is deepened and is carried through the tendo Achillis, after which the joint is opened, the malleoli are sawn, and the talus is extirpated. The operation is completed as in the operation by the anterior incision.

The time required to obtain healing by first intention (5 cases) was from 28 to 48 days; for cases healing by second intention, 35 to 60 days (2 cases). If recurrences take place (2 cases) the time is naturally more extended, *i.e.*, 81 to 397 days—an average of 210 days (Küttner, *Beiträge zur klin. Chir.*, ii., p. 749). The mortality from the operation is nil.

The Final Result of Operation.—The shortening in the leg is usually from 1 cm. to 1.5 cm., and that of the foot about 1 cm. The appearance of the foot after operation is seen here (Figs. 4066 and 4067).

The function of the foot is good It allows use all day and requires only an ordinary shoe.

The pseudarthrosis between the calcaneus and the forefoot gives elasticity to the gait, which is wanting in artificial limbs.

The talo-calcaneus resection is to be preferred to amputation, either Pirogoff's or Syme's, because it preserves the foot. It is preferable to the Wladimiroff-Mikulicz resection because it is easier of execution and requires no subsequent prothetic apparatus.

Posterior Tarsectomy.—(Kümmell, *Centralblatt f. Chir.*, 1893, No. 47; Verhandl. der deuts. Ges. f. Chir., 1889, i., 57.) When disease involves not only the ankle-joint but the medio-tarsal and tarsal joints as well, one of three things must be done: either an extensive atypical resection (Kümmell and Cramer), or a Wladimiroff-Mikulicz resection, or an amputation at or just above the ankle-joint.

A priori, it may be thought that a removal of the calcaneus, talus, tarsal bones, the malleoli, and the articular surface of the tibia would give a bad functional result. This is not the case, however (Cramer, Verhandl. der deutschen Gesellschaft f. Chir., 1895, i., 16). The extensive removal of these bones, leaving a foot formed of a part of the tarsus, the metatarsus, and phalanges, gives a better result than the equinus position of the foot seen in the Wladimiroff-Mikulicz resection. It is true that the foot is shortened, but a foot with a sole is better than the equinus of the Mikulicz operation, because a movable foot is obtained and because the pressure-bearing surface is a natural one and greater in area than is obtained by the Mikulicz resection.

Indications.—Tuberculosis involving the ankle-joint, the calcaneus, talus, and tarsal bones, with fistulæ. In children and in young adults the operation is indicated. In adults who have tuberculosis elsewhere and are not holding their own against the disease, and in the old and anæmic, amputation is preferable. No matter whether the fistulæ are upon the dorsum or upon the plantar surface of the foot, the operation with the dorsal incision is equally indicated.

The incision for exposure of the bones is similar to that used in the P. Bruns method. The removal of the talus is similarly carried out; after which the bones of the tarsus are removed *en masse*, as is recommended in the Bruns method. This removal of the tarsus is often complete, so

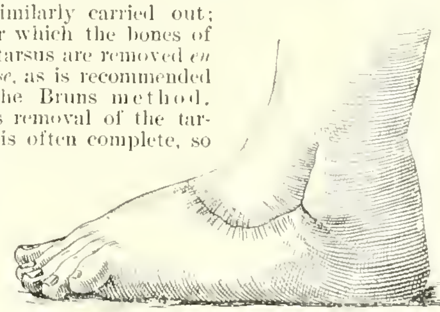

FIG. 4067.

that the section of the bones includes the bases of the metatarsal bones. The lower ends of the tibia and fibula are removed with a transverse section, unless the calcaneus can be partly saved, when the section is similar in shape to that recommended in the preceding resection. No matter how little of the calcaneus is saved, the resulting shortening and the functional result are much improved. After removal of the diseased bone the bases of the metatarsal or tarsal bones are apposed to the anterior sur-

Digitized by Microsoft®

face of the lower end of the tibia, where they are fastened with sutures if possible. In Kümmell's first case, in which 2.5 cm. of the tibia and fibula and all the tarsal bones were removed, the resulting shortening was about 3 cm. In two of Cramer's cases the resulting shortening was less.

www.libtool.com.cn

After-Treatment.—Frequently the large cavity left after extensive removal of the bones cannot be closed, and must be packed with gauze and treated as an open wound because of the presence of fistulæ. The cavity left between the tarsus and the tibia and fibula closes rather quickly. The soft parts of the planta pedis draw up between these bones and a pillow is formed under the tibia. The time required for this is usually two months. During this time the wound is dressed as required, and the proper position of the forefoot in its relation to the tibia is maintained by appropriate right-angled splints.

FIG. 4068.

The results of this operation show that the gait is elastic and not "hobbling," as is the case with the equinus position of the foot after a Wladimiroff-Mikulicz resection or the amputations or disarticulations. This elastic gait is due to the pseudarthrosis between the tibia and fibula, or the calcaneus, and the forefoot. Another advantage claimed for this procedure is to be found in the fact that prothetic apparatus will not be needed after the cure. Six cases reported by Cramer gave two cures in children of three and four years of age. Two cases of adults of ten and twenty years of age were still under treatment at three and four months. Two cases died of generalized tuberculosis following operation. A view of a foot following such an operation is seen here (Figs. 4068 and 4069).

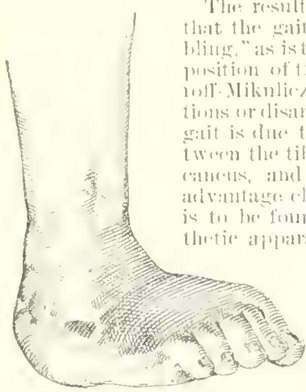

FIG. 4069.

When the disease is of the same extent as would lead one to perform the foregoing operation, while at the same time the greater part of the heel is the seat of destructive disease and of fistulæ, the resectio tarsea totalis of Wladimiroff-Mikulicz may be considered.

The indications for this procedure are: (1) Caries of the talus, calcaneus, and tarsus (Mikulicz); (2) extensive loss of the tissues of the heel (Mikulicz); (3) injuries destroying the heel (Mikulicz); (4) new growths involving the bone (calcaneus) or tissues of the heel (Schliffosowsky and Wahle); (5) to increase the length of the extremity, as occurs in infantile paralysis (Caselli); (6) for paralytic equino-varus (Bruns).

The object of the operation is to secure an artificial pes equinus. The toes and metatarsus are preserved and are apposed, in a vertical plane, to the tibia and fibula. The patient walks upon the heads of the metatarsal bones with the toes bent at right angles to the leg. The operation was first performed by Wladimiroff in 1871 and by Mikulicz in 1880 (*Archiv für klin. Chir.*, xxvi., p. 497).

Complete Tarsectomy (Resectio Tarsea Totalis).—An Esmarch bandage is applied. The patient is placed upon the abdomen with the foot extended. Just in front of the tuberosity of the scaphoid bone, upon the inner side of the foot, there is made an incision which passes transversely across the planta pedis to a point just behind the tuberosity of the fifth metatarsal bone. From each extremity of this incision, upon each side, an incision is carried upward and backward to the malleolus. The extremities of the latter incision upon the malleoli are now united by a transverse incision across the posterior surface of the leg. When the bones of the leg must be denuded at a higher level than is usual, the lateral incisions must be carried beyond the malleoli (Fig. 4070).

All incisions pass directly down to the bones, dividing the muscles, tendons, nerves, and arteries. The posterior capsule of the ankle-joint is divided, together with the posterior, middle, and anterior fasciculi of its lateral ligaments.

The foot is now thrown in dorsal flexion and the talus and calcaneus are carefully separated from the soft parts

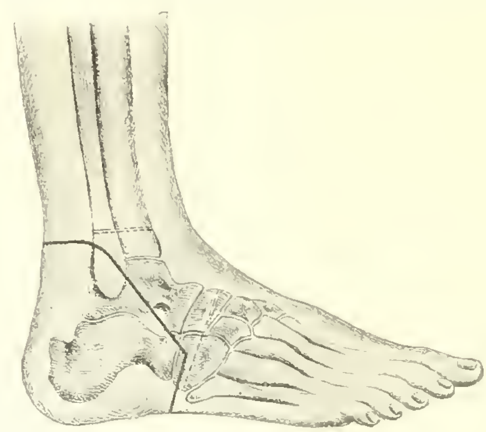

FIG. 4070.

of the dorsum of the foot until the medio-tarsal joints are reached. Here these bones are separated from the cuboid and navicular, and are removed with the heel flap. The lower ends of the tibia and fibula are now sawn across. The cuboid and navicular bones are likewise sawn transversely (Fig. 4071).

The Esmarch bandage is removed and the arteries are tied. When hemorrhage is completely stopped, the cuboid and navicular bones are apposed to the tibia and fibula and are retained in position by chromicized catgut sutures (Fig. 4072). The wound is now closed with deep catgut sutures and over the aseptic dressing is placed an immovable plaster dressing holding the parts firmly.

Sometimes in placing the bones in apposition the folding of the anterior bridge of soft tissues displaces the forefoot. When this occurs, the bridge of tissue must be folded and retained by a few mattress sutures.

The after-treatment consists in elevating the foot and retaining

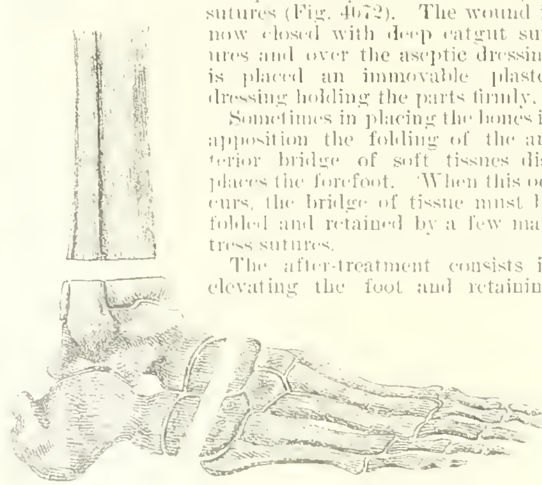

FIG. 4071.

this position for from three to five days; after this it may be lowered. In from six weeks to two months the union is complete. The lengthening of the limb is usu-

Digitized by Microsoft ®

Resection of Joints.

ally 1.5 cm., which can be easily overcome by a heel upon the opposite foot. Fig. 4073 shows the foot healed.

Kohlhaas (*Beiträge zur klin. Chir.*, viii.) has collected seventy-three cases of this operation with one death from

www.libtool.com.cn

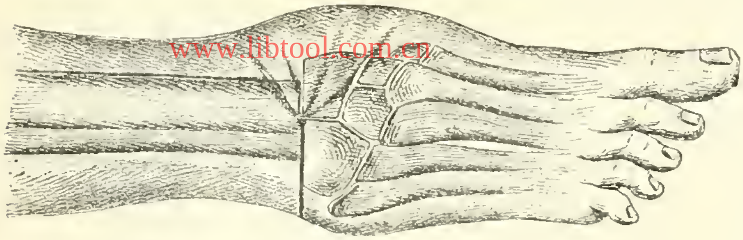

FIG. 4072.

pyæmia and one requiring amputation for gangrene. Several cases presented localized areas of gangrene, but did not require other than simple treatment. Three cases failed to have a firm union between the bones of the leg and foot and required subsequent operations. Fifty-six cases gave good results and required no extra prothetic apparatus or shoe. Nine cases gave moderate results and required special prothetic shoes.

To avoid the division of the posterior tibial artery and nerve, and the disturbances in nutrition and the gangrene which may result therefrom, Lotheisen (*Beiträge zur klin. Chir.*, xviii.), P. Bruns (*ibid.*), and Ollier ("Traité des Résections") have devised various modifications in the incisions. Lotheisen's incision is as follows: The patient lies upon the back. The extremity is raised and the foot is dorsally flexed. Upon the other surface an incision, commencing 1.5 cm. above the attachment of the tendo Achillis and between the fibula and the tendon, is carried obliquely forward and downward below the malleolus, ending 2 cm. behind the tuberosity of the fifth metatarsal bone (Fig. 4074). Upon the inner side a similarly placed incision is made, beginning above upon the same level and to the inner side of the tendo Achillis, descending forward behind the internal malleolus, and ending just in front of the tuber calcanei (Fig. 4075). The extremities of these lateral incisions are united across the sole by an oblique incision (Fig. 4076) and across the leg by a horizontal one. The enucleation of the talus and the sawing across the tarsus and the bones of the leg are accomplished as in the former method. A very similar method was described by Jaboulay and Lagaite ("Nouveau procédé pour pratiquer l'amputation ostéoplastique de l'arrière-pied,"

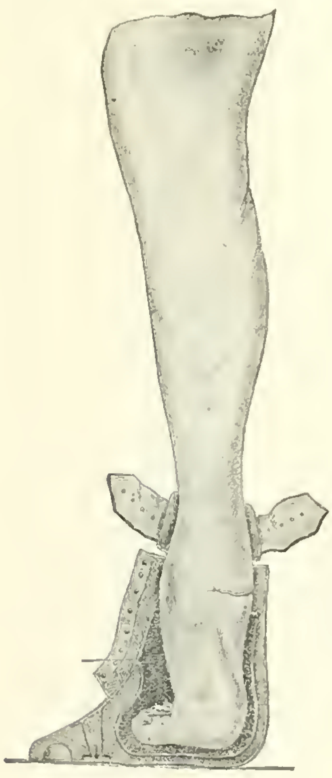

FIG. 4073.

Lyon médical, 1889, No. 11), but it offers no advantages over the above. The result of Lotheisen's method is seen in Fig. 4077.

To avoid the same result, P. Bruns has recommended strongly the simple median posterior incision, especially in cases in which the heel is intact and free from ulceration. Bruns' incision begins on the posterior surface of the leg, four fingers' breadth above the tubercles of the calcaneus, passes downward over the centre of the heel and to the centre of the sole of the foot. This incision extends immediately down to the bones. The talus and the calcaneus are removed subperiosteally after opening the ankle-joint. The bones are sawn and apposed and held by suture. Bruns meets the objection made by Lotheisen and by Ollier to the enormous mass of tissue left in the heel, which forms an ugly, thick, projecting hump on the posterior surface, by showing the photograph of his case of paralytic talipes equino-varus operated upon by his method (Figs. 4078 and 4079).

Ollier ("Traité des Résections," iii., p. 691) has described a similar incision, but he had not performed it upon the living subject at the time when Bruns used his incision.

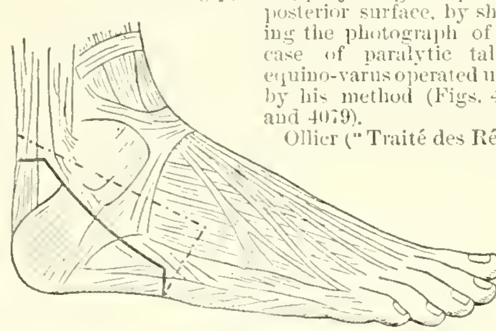

FIG. 4074.

Of the incisions used for the total tarsectomy, none seems to meet the surgical requirement so well as Lotheisen's, which avoids injury to the posterior tibial artery and nerve and allows the tissues of the leg and sole of the foot to be easily apposed and sutured one to another. In cases of paralytic equinus or equino-varus with extreme shortening, the posterior incision of Bruns or Ollier has given as good results as the methods of Lotheisen and Mikulicz. In this particular class of cases the objections to be raised

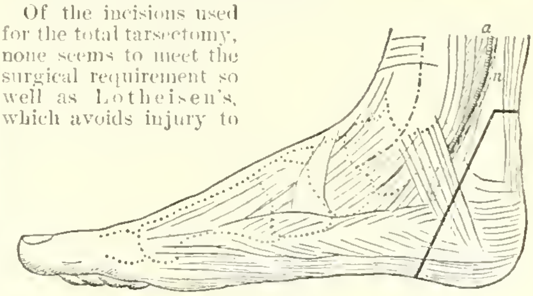

FIG. 4075.

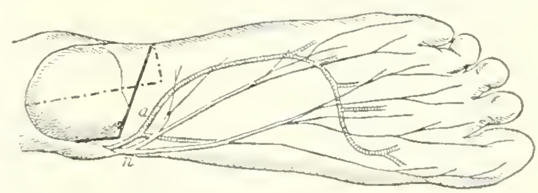

FIG. 4076.

Digitized by Microsoft®

against the incision, the subperiosteal enucleation of the bones, and the projecting mass of the heel when the parts are apposed, do not hold as they do in disease or injury.

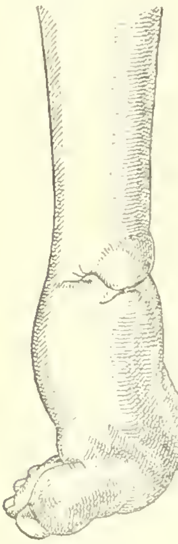

FIG. 4077.

It may be said with truth that the total tarsectomy (Wladimiroff-Mikulicz) and the extensive resections of Kümmell will rarely appeal to many surgeons, when they compare the time spent in obtaining these results, the extent of the procedure, and the drain upon an already worn-out subject. An amputation (Syme's, Pirogoff's, Guyon's) with the rapid healing and the practical prothetic appliances made in this country will, I doubt not, cause most surgeons to advise amputation whenever the patient can obtain an artificial limb. Only in the very poor and in those of moderate age and good health (especially such as have congenital and paralytic deformities or injuries) will the extensive procedures of Kümmell and Mikulicz be adopted. On the contrary, the anterior and posterior tarsectomies of Bardenheuer and Bruns give such excellent feet after operation that no question can be raised as to their advisability in suitable cases and their superiority to amputations.

www.libtool.com.cn

RESECTION OF THE ANKLE-JOINT. This operation was first performed by Moreau in 1792. Subsequently, owing to the complicated character of the joint, the presence of tendons and sheaths in the immediate neighborhood, and the relapses following operation, surgeons gave up the method and resorted to amputations.

Better methods of approach, more complete removal of the disease, and the aseptic treatment of the wound have so lowered the mortality that amputation now presents no advantage in this respect. At the same time the patient is left with a foot which is more useful and æsthetically better than the stump of an amputation. (See Fig. 4080.)

Partial resections are those which remove the whole or a part of the articular surfaces of the tibia, the fibula, or the talus. Complete resections do remove all of these surfaces.

FIG. 4078.

The talo-crural articulation is best approachable from the sides. In front, it is covered by the tibialis anticus, the extensor longus digitorum and proprius pollicis and the peroneus tertius, the nerves, and the anterior tibial artery. Behind, it is covered by the tendo Achillis in the centre, and upon either side of this by the peroneal tendons or the tibialis posticus, flexor longus digitorum, longus pollicis, together with the nerve and the posterior tibial artery. For this reason the lateral surfaces are much used for incisions. The ankle-joint is a powerful joint because of its bony construction as well as by reason of its strong ligaments.

The ligaments uniting the malleoli to the tarsus are strong. Those for the internal surface are three: the deltoid uniting the malleolus with the sustentaculum tali, the anterior uniting it with the scaphoid, and the posterior uniting it with the talus. Those for the external surface are: the anterior, uniting the external malleolus with the talus; the middle, uniting it with the calcaneus; the posterior, uniting it with the talus. The anterior and posterior ligaments are thin and insignificant. The synovial membrane lines the capsule, and extends beyond the limits of the articulation both in front and behind. At the sides it is delimited by the articular surfaces.

FIG. 4079.

The epiphysis of the tibia includes the lower end and the internal malleolus. It unites with the diaphysis at about the nineteenth year. The epiphysis of the fibula unites with the diaphysis at about the twenty-first year. The outlines of the malleolus are easily felt and seen.

The head of the astragulus is felt in full extension of the foot. The ankle-joint lies opposite a transverse horizontal line 1.25 cm. above the tip of the internal malleolus.

The Indications.—Partial resections are indicated in gunshot wounds; in compound fractures and in dislocations when the nerves and vessels are intact; and in suppuration following injury and infection when this resec-

FIG. 4080.

tion removes and drains the focus of infection. For tuberculosis in childhood, expectant treatment and iodoform injections may precede the partial resections, *i.e.*, the erosions or the arthrectomies, but delay must not be too long before resorting to the resection. In adults formal

Digitized by Microsoft®

resections are used. In older people, with other tuberculous foci, amputation is preferable to resections. As a general rule, when tuberculosis is apparently primary in the joint, resection is to be preferred. When the ankle-joint is involved, secondarily to other well-defined deposits in the lungs and elsewhere, amputation is preferable.

There are about thirty

www.libtool.com.cn

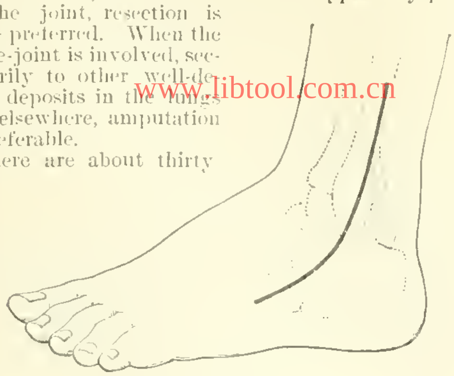

FIG. 4081.

six incisions (Farabœuf, "Manuel Opératoire"; Ollier, "Traité des Résections"; Karewski, "Chirurgische Krankheiten des Kindesalters"; Kocher, *Archiv für klinische Chirurgie*, No. 37) which have been recommended for entering this joint. All surfaces of the joint have been made use of to gain an entrance. Even the sole of the foot, *i.e.*, the heel, has been included in the incisions. No incision has so many advantages as that of Lauenstein. This incision resembles Kocher's incision (*Langenbeck's Archiv*, 1887 and 1888), but it gives a better exposure of the posterior angle of the ankle-joint and of the neighborhood of the internal malleolus. Kocher's incision was an improvement upon Reverdin's (*Revue Médicale de la Suisse romande*, 1883, Mars). Lauenstein's (Verhandl. der deutsch. Gesellsch. für Chir., 1890, ii. 71) is an improvement upon Kocher's.

The method is as follows: An Esmarch's bandage is applied. The foot is placed upon its inner side. An incision is begun upon the fibula at the point where the fibula appears between the peroneus brevis and the peroneus tertius muscles. This incision is carried through the skin to the tip of the malleolus, where it bends forward in a broad curve to the talo-navicular joint, passing over the heads of the extensor brevis digitorum and exposing the tendons of the peroneus tertius (Fig. 4081). It is now deepened, exposing the periosteum of the fibula, the anterior fasciculus of the lateral ligament, and the capsule of the ankle-joint. Upon the posterior border of the fibula the sheath of the peroneal tendons is opened, and the tendons are retracted posteriorly. The knife now separates from the periosteum of the tibia and fibula, the muscular fibres of the peronei and the flexor longus pollicis until one-half the transverse diameter of the tibia is freed.

The retractors used in retracting these structures are now removed and are inserted into the anterior flap. The ankle-joint is opened in front of the external malleolus and the blunt retractor is inserted, lifting and protecting the capsule and the superjacent tissues. The upper and lower attachments of the capsule to the talus and to the tibia are severed until the median line of the tibia and the talus are both of them reached. The foot is now supinated and the three fasciculi of the external lateral ligament are divided. When they have been divided, if the foot be placed in the equinus position and be gently thrown into supination, it will turn upon the internal malleolus as an axis, provided the tissues in front and behind the joint have been freed to a point beyond the median line of the joint. With a little force the foot can be completely inverted, so that the planta pedis looks upward and the articular surfaces of the talus and tibia are upon the same plane, separated by the internal malleolus (Fig. 4082). By means of blunt hooks every part of the articular surfaces of the talus, tibia, and fibula can be reached: every pocket of the synovial cavity, including the inferior tibio-fibular prolongation and the posterior surface of the synovial membrane; the sheaths of the tendons of the tibialis posticus, flexor longus digitorum and pollicis, as well as the bursa and fat in front of the tendo Achillis. When these are inspected and all foci of disease have been removed by curettage or excision, the foot is easily pronated and thrown into proper position. The only structures injured are the vena saphena parva and the arteria perforans peronea. The advantage of the incision over Kocher's is that it allows a greater stretching of the borders of the incision and an easier dislocation of the foot. It moreover parallels the sheaths of the tendons and permits a surgical treatment of them when involved. If in operating by this method it becomes necessary to remove the talus, it can be accomplished easily by dividing its ligaments which are exposed to view. Indeed, the method renders the extirpation of the talus a very easy matter.

If disease involves the medio-tarsal and the talo-crural joints together with the neighboring bones, or if this is only recognized by the operator after he has entered the talo-crural joint by the Lauenstein incision, the suggestion of Heidenhain (Verhandl. der deutschen Gesell. f. Chir., 1894, ii., p. 137) may be adopted for the treatment of the case. This suggestion consists in continuing the lower end of the Lauenstein incision across the dorsum of the foot below the medio-tarsal joint and dividing the tendons

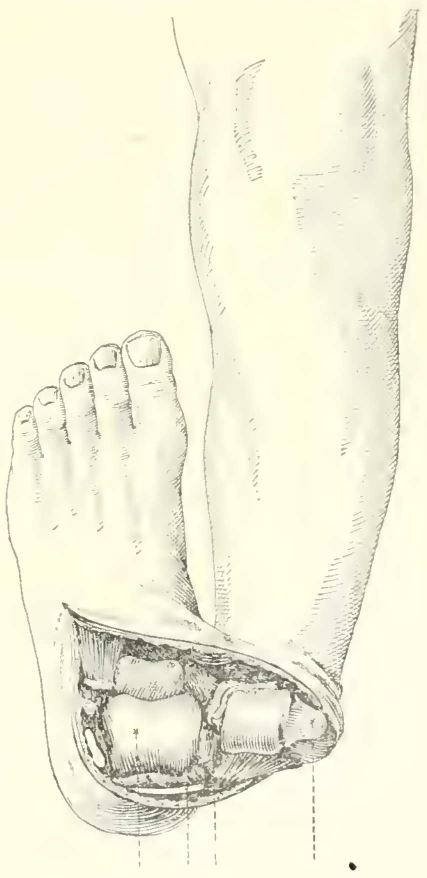

FIG. 4082. Lauenstein's Method. Parts exposed ready for resection. *t.*, Talus; *p. t.*, peroneal tendons; *e. m.*, external malleolus.

of the peroneus tertius and longus digitorum but preserving if possible the tibialis anticus and proprius pollicis. This incision gives all the advantages of the Lauenstein

Digitized by Microsoft®

and P. Bruns resections, and opens to view for easy attack the medio-tarsal articulation.

Again, if the talo-calcanean or the talo-navicular joint is alone involved, we can adopt the following suggestion of Lauenstein and approach these parts with the same skin incision: Instead of opening the talo-crural articulation, we divide the calcaneo-tibular division of the external lateral ligament, and then, passing a thin knife into the sinus tarsi, carry it backward and inward to the sustentaculum tali, dividing the interosseous ligament. After this division the anterior talo-calcanean capsular ligament is made tense by everting the calcaneus and is divided. This is followed by division of the muscular fibres of the extensor brevis digitorum and the talo-navicular ligaments upon the outer and superior surfaces of this joint. If strong supination is now made upon the foot, the calcaneus will be luxated or rotated upon its inner side over the malleolus internus. In this manner the talo-calcanean and the talo-navicular joints may be exposed without opening the ankle-joint. During the luxation of the calcaneus the peroneus tendons are retracted posteriorly and do not obstruct the field. From this position of the foot the talus may be easily removed by division of its lateral ligaments. In extensive disease in this region the Lauenstein incision permits an entrance into the talo-crural articulation, and if desired allows an exposure of the medio-tarsal and talo calcanean joints with removal of the talus. The medio-tarsal and talo-calcanean articulations may be entered first, and if suspicion exists as to an involvement of the talo-crural articulation this may be exposed by removal of the talus. This incision gives the best approach to the ankle-joint. It allows of such modifications as will insure successful results in spite of unsuspected foci of disease, since through one incision the talo-crural, the talo calcanean, and the medio-tarsal joints can be approached and the talus removed. In a pure resection of the ankle-joint the synovial membranes and the articular surfaces of the talus and of the tibia and fibula are removed, their shape being preserved as far as possible. For this reason the section of the tibia and fibula is usually made concave from side to side, while that of the talus is made convex. If the talus is removed on account of disease, this concavity in the tibia and fibula is made so as to fit the calcaneus, while the scaphoid rests upon the anterior border of the tibia. When but little of the articular surfaces of the tibia and fibula is removed, it is best to shorten the malleolus so that the tibia may rest upon the calcaneus directly. It has been my custom to suture the scaphoid, tibia, fibula, and calcaneus together with two or three chromicized catgut sutures. It is rare that a single artery requires ligature, and if any bleed excessively they will stop upon elevation of the limb. I usually blood-clot these cases, excepting where it is impossible to remove all tuberculous material. In the latter instance the wound is packed until healthy granulation tissue appears.

The after-treatment is a matter of importance. When the wound is sewed up and blood-clotted the foot is elevated at an angle of forty-five degrees for from three to five days, after which it is lowered. In this method the first dressing is made about the tenth day. Where wounds are packed, the foot is usually elevated for twenty-four to forty-eight hours, after which it is lowered. The dressings should be changed every two or three days.

A suitable splint is difficult to find. A splint which will maintain the foot at a right angle with the leg and will prevent lateral deviation of the foot is the one desired. Upon the whole, a plaster-of-Paris dressing properly and carefully applied is the best. This plaster-of-Paris dressing may be used alone or in conjunction with the McCormac splint (Jacobson's "Operative Surgery," vol. ii., p. 699). If it is applied alone, it is well to place this dressing within a Volkmann's posterior splint, where it will be held firmly. After two weeks' treatment the other splints may be discarded and a splint plaster-of-Paris dressing will be sufficient until union is complete.

Results.—The mortality, in the different classes of cases, was as follows: *For gunshot wounds* (45 cases) it was, according to Culbertson, 26 per cent.; according to Otis (33 cases in the civil war), 29 per cent.; and, according to the same authority (150 cases from all sources) 33 per cent. *For injuries in civil practice* (152 cases) it was, according to Culbertson, 12.5 per cent. *For disease* (124 cases) it was, according to Culbertson, 8.06 per cent. for complete resection, and 6.55 per cent. for partial resection; while, according to Isler and Kappeler, it was almost nothing in cases of tuberculous disease.

Functional Results.—Some say that a flail joint is very rare, some that it is unknown. Ankylosis is often obtained, and when it occurs the medio-tarsal joint compensates in great measure for the stiffness in the ankle. In seventy-five per cent. of the cases recovery takes place with a useful limb, and in many instances, especially in the subperiosteal method, the nearthrosis is a remarkable one, giving a most useful joint (Langenbeck).

According to Isler, the results of resection functionally are divided as follows: Very good, 40.8 per cent.; good, 26.8 per cent.; moderate, 7.6 per cent.; indefinite, 8 per cent.; bad, 6.2 per cent. In children the good results are more frequent than in adults, since the disease is usually less extensive.

Schmidt Monnard gives the good results as 74 per cent. for the first fifteen years of life. In Bardeleben's clinic good results were obtained in 81.2 per cent. of the cases. Karewski in 30 cases had 25 good results, 2 deaths from scarlet fever and tuberculosis respectively, and 3 cases with recurrences ("Chirurgische Krankheiten des Kindesalters").

Resection of the Knee-Joint.—In 1762 Felken attempted a partial resection of this joint. Park in 1781, and Moreau and Roux before 1820, operated, performing a complete resection, but the unfortunate results obtained by their imitators deterred many surgeons until W. Fergusson in 1850 restored the operation. From this time the operation has been practised extensively and remarkably good results are now obtained in every country (Hodges, "Excisions of Joints," Boston, 1861).

The cases operated upon are divided into those which are typically resected and those which are atypically treated. The typical operation consists in the extirpation of the synovial membrane and the removal of the bones intra- or extra-epiphyseally. The atypical one consists in the extirpation of the synovial membrane without removal of the bone except where diseased. This is the arthrectomy of Volkmann (Verhandl. d. deut. Ges. f. Chir., xiii.) and the erasion of Wright (*Lancet*, 1881, vol. ii., p. 992).

The atypical operation is undoubtedly the operation for children, since in eighteen per cent. of the cases in which the bones were not at all or only very slightly involved, movable joints have been obtained. In the second place, no shortening, at least no more than follows conservative methods, takes place (Maudry, *Beiträge zur klin. Chir.*, iii., p. 235).

A comparison of these atypical cases with the intra-epiphyseal resections (Hoffa, *Archiv für klin. Chir.*, 1885, xxxii., p. 795) shows that the only real advantage is the possibility of obtaining in the most favorable cases a movable joint, and since this occurred in nearly eighteen per cent. of the seventy cases collected (Maudry), it offers a substantial advantage in favor of the atypical operation. The disadvantages of the atypical method consist (1) in the liability of leaving beneath the articular cartilages foci of disease, (2) in the greater tendency to contracture of the flexor muscles. The first disadvantage is more apparent than real in the cases of children, because in making an intra-epiphyseal section one must cut the bone below the level of the articular cartilage. "Every bone section in children must be surrounded by a line of articular cartilage to be certainly intra-epiphyseal" (König). This section is so thin that foci may not be revealed by it, just as when the articular cartilage is present. The advantage which belongs to the typical intra-epiphyseal method, and which does not belong to the atypical method, is the firmer union which takes place

Digitized by Microsoft®

between the bones and the slighter tendency to deformity. The lack of this advantage in the atypical method is compensated for by prolonged mechanical after-treatment.

When the bones are slightly involved and the synovial membrane is the principal seat of disease, the atypical operation is indicated because of the eighteen per cent. of movable joints which have been secured by its employment. If in addition to the synovial membrane the bones are involved, the intra- or extra-epiphyseal resection is indicated, according to the extent of disease in the bones. This is because of the firmer ankylosis in the extended position which is obtained by the section of the bones, and also because it is not possible to obtain motion on account of the destruction of the articular cartilages. It is to be remembered that in resections shortening is greater if done before than after the fourteenth year.

www.libtool.com.cn

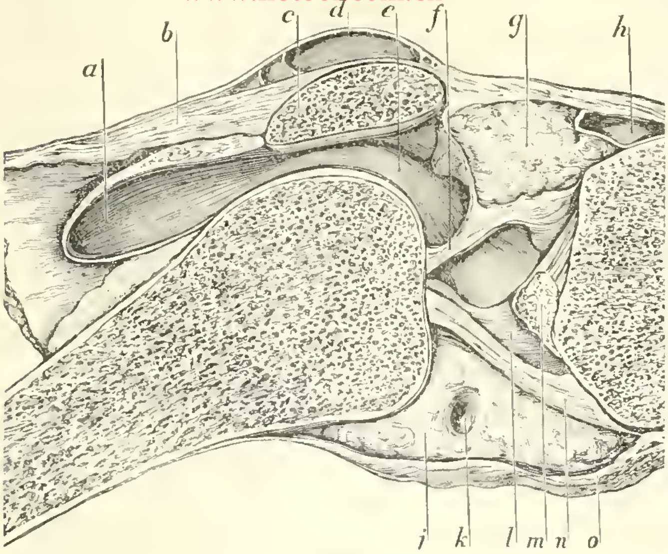

FIG. 4083.

Indications.—For disease: 1. Tuberculosis. Excision in these cases should be performed (*a*) in all cases in which the articular cartilage is found eroded, whether suppuration is present or not; (*b*) in cases with backward dislocation of the tibia; (*c*) in cases that have lasted over six months, in which the expectant treatment has been tried and has failed and in which the disease is in all probability an epiphyseal osteitis; (*d*) in cases of synovial tuberculosis which has extended over the articular cartilages. In the child before fifteen years, this operation affects the growth of the limb. In adults of twenty years and over, the length of the limb need not be considered, but the conditions of the viscera and the general health become important considerations. In all cases the presence of amyloid degeneration; tuberculous disease of the lungs and other viscera; great emaciation and extensive involvement of the soft parts about a joint demand amputation rather than resection. 2. Chronic arthritis, with caries of the bones. 3. Chronic osteo-arthritis in a single joint in middle life. 4. Ankylosis of the knee in a bad position after osteotomy has failed. 5. In infantile paralysis for the production of ankylosis. In these cases the resection is usually a complete one.

For injury: Gunshot wounds and other compound and complicated wounds. In these cases the resection is usually partial rather than complete.

Anatomy.—The axis of the femur is directed inward at the knee. That of the tibia is straight, *i.e.*, in the axis of the body. The joint obtains no strength from the shape of the bones. It derives its strength from its crucial and posterior ligaments rather than from its lateral and anterior ligaments. The cavity of the synovial membrane is extensive and the bursæ about the joint are numerous. Of these bursæ, that between the inner condyle, the semimembranosus, and the inner head of the gastrocnemius communicates with the joint. The bursa beneath the tendon of the poplitens communicates with both the knee-joint and the superior tibio-fibular articulation. In like manner, the bursa beneath the vasti and the rectus communicates in eighty per cent. of the cases with the joint (Fig. 4083). The popliteal artery and vein are quite closely associated with the ligament of Winslow, and care must be given in dissecting out diseased tissue in this region in order to avoid injuring them (Fig. 4083). The articular arteries should if possible be avoided, but, if they cannot be avoided, they should be tied before closing the wound, even when the blood-clot method is used. The superior articular arteries are situated just above the condyles, while the inferior pass beneath their respective lateral ligaments, the internal below the tibial tuberosity, the external above the head of the fibula. It is to be remembered that the upper limit of the femoral epiphysis is represented by a line passing across the femur at the tubercle of the adductor magnus. This epiphyseal line is intracapsular. The tibial epiphysis is marked at the sides by a line just including the fibular articular surface, and the depression for the semimembranosus tendon behind this line just includes the tuberosities. In front the epiphysis descends to the lower margin of the tubercle. This epiphyseal line is extracapsular. The femoral epiphysis joins the shaft at twenty, the tibial at twenty-one years (Fig. 4084, *a* and *b*). In a child, scarcely more than 1 cm. of the tibia and

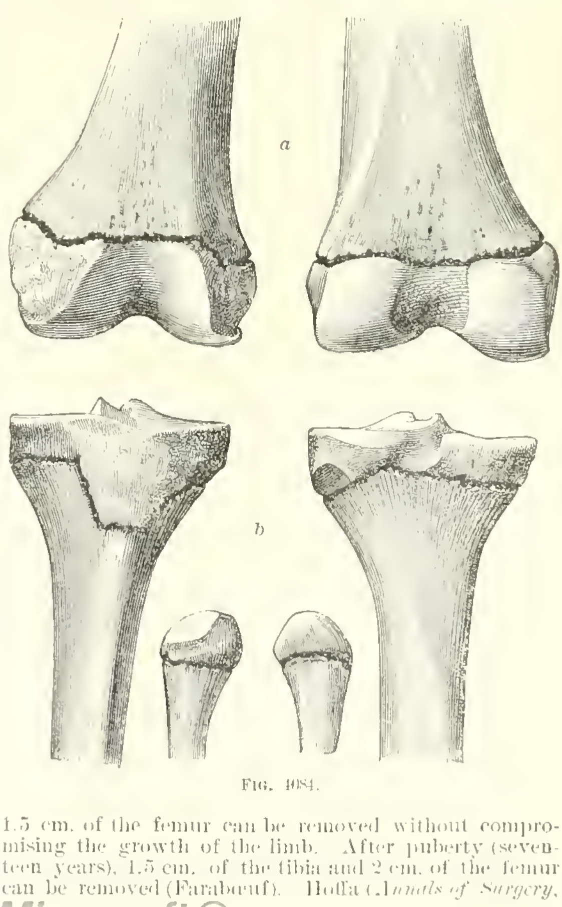

FIG. 4084.

1.5 cm. of the femur can be removed without compromising the growth of the limb. After puberty (seventeen years), 1.5 cm. of the tibia and 2 cm. of the femur can be removed (Farabeuf). Hoffa (*Annals of Surgery*,

Digitized by Microsoft®

Resection of Joints.

March, 1886) says that (1) in one case the removal of both epiphyses at the end of ten years gave 25.5 cm. shortening; (2) in one case at the end of two years there was 10 cm. shortening; (3) the loss of the femoral epiphysis alone in one case gave 17 cm. shortening at the expiration of six years; (4) the loss of the tibial epiphysis alone in two cases gave respectively 15.5 and 6 cm. shortening in six years; *i.e.*, an average of 10.7 cm. Petersen (*Archiv f. klin. Chir.*, xxxiv., p. 445), in a child of six years of age, at six years from the time of the resection, found a shortening in the femur of 10.2 cm., of which 8.5 cm. was due to the loss of the lower femoral epiphysis. In the tibia, there was 5 cm. shortening, of which 3 cm. was due to the loss of the upper tibial epiphysis.

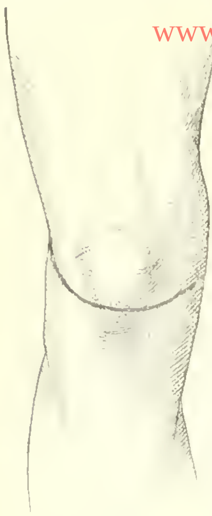

Fig. 4085.

It is to be remembered that when the knee is flexed the extension of the synovial membrane above the femur and beneath the quadriceps femoris tendon scarcely reaches above the articular cartilage of the femur; when the leg is extended, the same rises to a much greater distance.

Incisions.—Many incisions have been recommended for this operation, and of the great number variously used by Park, Moreau, Fergusson, Mackensie, Bird, Volkmann, Langenbeck, Ollier, Textor, Sanson, and Bégin, no one seems to me to be as advantageous as that recommended by Mackensie, Farabeuf, Erichsen, and Kocher, *i.e.*, the transverse curved incisions of Textor.

The object of this resection is usually to produce ankylosis without considerable shortening, *i.e.*, without shortening over 10 cm., which can be corrected by a high shoe and by the inclination of the pelvis. For this reason only such incisions are useful which will expose all parts of the joint and enable one accurately to remove only the diseased tissue. To obtain this exposure, the transverse incision is preferable to the longitudinal. The longitudinal incisions were designed to save the patella and to aid in producing mobile joints, but the best results are usually those in which ankylosis exists, and in these the patella is not necessary.

The operation by the longitudinal incision is difficult and tedious and in disease fails to expose all parts of the synovial membrane. For this reason alone, in disease, the transverse is to be preferred to the longitudinal incision. In some few cases of injury with partial resection of the bones, the longitudinal incision is indicated, but in the vast majority of cases no incision is so satisfactory as the transverse.

Method of Operation.—Typical resection. The patient lies upon the back, with the leg at the end of the table, so that in flexion at the knee the foot may rest on the table. The surgeon stands upon the side to be operated. One assistant, opposite the surgeon, manages the thigh, another manages the leg. A third manages the sponging, etc. During the skin incision, the leg is held firmly flexed upon the thigh. The incision, at first involving the skin and subcutaneous tissue, passes from the epicondyle of one side to that of the other in a broad curve, which crosses the ligamentum patellæ midway between the tubercle of the tibia and the lower margin of the patella (Fig. 4085). This incision avoids, as it approaches the internal epicondyle, injuring the saphena magna vein and the internal saphenous nerve. The flap marked out is dissected from the capsule and the patella and is reflected above the upper border of the patella. An oval-shaped piece of the anterior capsule, including the patella and the synovial membrane, is now excised by two incisions passing from the posterior borders of each lateral ligament across the upper and lower extremities of the patella (Fig. 4086). With the removal of this piece the joint is fully exposed. This is the method of procedure in non-tuberculous processes, in injuries, and in deformities, where the ultimate aim is ankylosis. In tuberculosis Kocher's suggestion is the proper one. After reflection of the skin and subcutaneous tissue as above, an incision is carried through the lateral ligaments, the fascia of the vasti muscles, and the quadriceps tendon in a curve above the patella down to but not through the synovial membrane. The flap above is cleared from the synovial membrane until the attachment of the latter to the femoral articular cartilage is reached. In like manner, the flap below is separated from the synovial membrane as far as the latter's attachment to the tibia, the ligamentum patellæ being divided at its attachment to the patella. In this manner the tuberculous synovial membrane, together with the patella, is removed in one piece. Whichever way one has proceeded the joint is now open and the crucial ligaments are seen. With increased flexion by the assistant, the crucial ligaments are rendered more evident and the division of the anterior and then the posterior close to the femur is made. The leg now hangs loosely upon the femur. It is flexed to a right angle, with the foot resting upon the table and the femur raised. In this position the femur is cleared of its soft parts—including the periosteum if desired and if indicated by the local condition—up to the line of intended section. The popliteal space is protected by a broad retractor and the bone is sawn with a solid-bladed saw. The plane of section is sagittally at right angles to the axis of the femur. Frontally it is parallel to the plane of the articular surfaces of the condyles.

The tibia is now pulled forward while the foot still rests upon the table. The popliteal tissues are put upon the stretch and brought into a lower plane than the articular surface of the tibia. This is exaggerated by freeing the tibia posteriorly where the ligament of Winslow is attached. The tibia is now held firmly in this position and is cleared of all tissues to the line of bone section. It is sawn at right angles to the axis of its shaft. The section in the bones is in the young always within the epiphyseal line; in the adult, the section is made as often extra-epiphyseally.

The tissues in the popliteal space are in no danger, since they are placed at a lower level than the bone section, owing to the traction upon the leg held in the vertical position. In non-tuberculous cases and in cases of deformity, the synovial membrane is now dissected from the bones and the capsule. It is usual to begin with that above the femur and beneath the quadriceps tendon. This with the bursa is removed as a continuous membrane and can in almost all instances, except where disease has advanced beyond its limits, be removed without further incisions. In the more extensive cases a vertical incision must be added to the transverse one. So infrequently is this the case and so thoroughly can one, by means of this additional incision, approach without excessive injury the space beneath the vasti and quadriceps muscles, that I have rejected entirely all incisions with their curve upward (Hahn, Verhandl. der deutschen Gesell. f. Chir., No. xi.) which are designed more fully to expose this region.

Fig. 4086.

The advantages obtained by this method of procedure are, taken all in all, more than those derived from inci-

www.libtool.com.cn

Resection of Joints.

sions destined to expose the space beneath the quadriceps muscle at the expense of the rest. The areas next in importance are the immediate neighborhood of the tibia and the popliteal space. The synovial membrane about the sides and front of the tibia and the adjacent synovial membrane are now removed, including the bursa beneath the ligamentum patellæ. At this stage an assistant places his hand in the angle formed by the tibia and femur, and by pushing apart these bones puts the tissues in the popliteal space upon the stretch, which renders the removal of the bursæ already referred to an easier matter than when their tissue is not firmly stretched. If removal of the disease in the rest of this region is now undertaken and if sinuses exist here, it is best to locate first the position of the artery and vein and then to proceed to the removal of the diseased parts. Providing the resection has been an extensive one, it is my custom at this time to remove the Esmarch bandage and to tie the articular, the anastomotica magna, and the recurrent tibial arteries. All hemorrhage from the bones stops when they are apposed. If the operation has not been so extensive, then in all probability these vessels have not been cut or at most only one or two of them; under these circumstances I do not remove the Esmarch bandage, but rely entirely upon the firm dressing and the elevation of the limb for controlling the hemorrhage. Two openings are now drilled in the femur and in the tibia, and through them are passed large-sized chromicized catgut sutures, which, after the popliteal tissues are held away from the bones and after the bones are apposed, are tied tightly. These stitches are not for the purpose of holding the bones after the operation is completed but rather at the time of applying the primary dressing. They enable the assistants to feel that the bones remain *in situ* and have not slipped from their original position. Complete reliance is placed upon the dressing for holding the bones in position.

If large sections of the femur and tibia have been removed a piece of the circumference of the femur may be sawn out and transplanted to the space between the tibia and femur, as in a flap operation upon the soft parts. Sykow was successful in one case in preventing shortening and in having the consolidation of the limb perfect in three months. His success may well be imitated in suitable cases (*Centralblatt für Chir.*, 1902, No. 15).

After the suture of the bones the capsule, the ligamentum patellæ, and the tendon of the quadriceps femoris are united with catgut. For the tendon and the ligament I use the chromicized catgut, which lasts for from fourteen to twenty days. For the capsule, I use simple catgut. The skin is sutured also with catgut.

Drainage is established only to give exit to the excess of blood, so that the employment of Maas' method or the insertion of rubber tissue into the incision wound is quite sufficient.

In operating upon joints which are flexed, it is best to straighten them as much as possible before operating. In this way one avoids removing too much bone and at the same time removes enough, so that the tissues in the popliteal space are not too much stretched. This stretching tends to displace the fragments, and by closing the vessels tends to produce gangrene of the foot and leg.

The author's method of dressing these cases has been most satisfactory. It consists in applying an even and not lumpy dressing of gauze from the ankle to the upper third of the thigh. Upon the outer side of this gauze dressing eight to twelve thin bass or white wood splints, cut in strips 2 to 3 cm. wide and boiled until they are not only aseptic but perfectly pliable, are applied over the joint and are bandaged quite loosely in position. Over this is placed a sufficient cotton dressing which is fixed with plaster-of-Paris bandages. This plaster of Paris is not thick; it is scarcely more than two bandages thick, except where it covers the knee. It extends from the toes to the upper third of the thigh. The limb is now placed in a Volkmann's splint, which can be suspended or raised in bed to the required height. No dressing nor splint which I have seen used holds the knee so firmly and without undue pressure as does this combination. The wood splints or strips, applied directly over an evenly applied gauze dressing, can be trusted, when they harden, to render slipping of the bone surfaces impossible. The plaster of Paris applied outside of the cotton and from the toes to the middle of the thigh holds the foot, leg, and thigh immovable, and exerts an even pressure upon all these parts. The Volkmann's splint protects and sustains the plaster-of-Paris dressing, which on this account need not consist of more than two thicknesses of bandage. This suffices for the immediate dressing, but fixation must be continued for a varying period after operation. Some have placed the period when ankylosis becomes complete at two months (Riedel, *Deut. Zeits. für Chir.*, Bd. xv.), others at from six to eight months (Volkmann's klin. Vorträge, 51), and still others at one year (Hoffa, *Arch. für klin. Chir.*, Bd. xxxii.). During this period the limb must be kept perfectly straight, and for this purpose plaster-of-Paris dressing is still used with perfect satisfaction. Windows can be made where necessary and the wound kept clean and healthy. There seem to me to be no advantages in the Howse or Hodgson splints which are not found in the above plaster-of-Paris dressing. Almost all the splints employed have the disadvantage of being complex and difficult to adjust. After splints have been removed, a leather support is usually applied. In children a support should be worn for from two to three years.

Results.—The age of the patient is important. The results are best, for either injury or disease, between five and fourteen years. Esmarch ("Beiträge zur Statistik der Kniegelenksresectionen," Kiel, 1883) had no deaths in 30 cases, Volkmann (Verhandl. der deutschen Gesell f. Chir., xiii.) no deaths in 20 cases. Hahn, Maas, and Schede have had similar results. In 1898 Napalkow reported 26 cases operated upon between seventeen and twenty-five years old, with no deaths ("Chirurgie," 1898, p. 345). These statistics for tuberculosis bring the mortality very low. The general mortality for all cases and under all conditions is at present about ten per cent. (Bothe, *Beitr. z. klin. Chir.*, vi., p. 282). The former high mortality of 7 per cent. for gunshot wounds, 40 per cent. for injury, and 30 per cent. for disease is being gradually reduced by a better selection of cases and an improved technique.

The final results of resections in children up to the fourteenth year show (Hoffa, *Archiv f. klin. Chir.*, xxxii., p. 763) that 6 per cent. of failures occur, most of which require amputation; that 7 per cent. die of tuberculosis in other organs at a subsequent period; that 58.47 per cent. have an ankylosis in the straight position, with neither genu valgum nor genu varum; that 41.53 per cent. have a flexion contracture due (1) to a faulty position of the leg and thigh at the time of operation, (2) to contracture of the flexors and atrophy of the quadriceps femoris, and (3) to the weight transmitted through the limb in faulty position. All of these conditions are avoided by obtaining a bony ankylosis in the extended position before the limb is used. Eighty-seven per cent. of the cases were permanent cures (54 per cent. without subsequent fistulæ, 33 per cent. with fistulæ requiring from one to twenty-one months to cure). One hundred per cent. of the cases show some interference in the growth of the limb, yet in 92 per cent. this is not greater in the intra-epiphyseal resections than in the conservatively treated cases (*loc. cit.*, p. 791). In 8 per cent. of the cases measured by Bothe (*Beiträge zur klin. Chir.*, vi., p. 208) lengthening had taken place. The final results in resections in which the subjects are older and in which the operation is either intra- or extra-epiphyseal, in so far as the bone section is concerned, are as follows:

In operations for tuberculous disease (443 cases) (Bothe, *l. c.*). Healed and useful limbs, 67.4 per cent.; incompletely healed, 13.7 per cent.; amputated, 8.8 per cent.; useless, 17 per cent.; mortality, 10.1 per cent.

In operations for gunshot wounds. Useful, 60 per cent.; required amputation, 24 per cent.; unknown, 16 per cent.

In operations for relief of deformity. Perfect, 19.5 per cent.; useful, 68 per cent.; unknown, 13.5 per cent.

The Atypical Resection.—By this is meant the method

Digitized by Microsoft®

employed by Wright under the name of erasion and by Volkmann under the name of arthrectomy. It is an operation in which the synovial membrane and bursæ are removed entire and in which the bone foci are gouged out, scraped out, or chiselled out, while all that is healthy is left intact. An operation of this kind in more favorable cases consists of a synovial extirpation with the goug-

www.libtool.com.cn

FIG. 4087.

ing out of one or more small osseous foci; in the more extensive cases it consists of a nearly complete removal of the articular cartilage, *i.e.*, of an almost typical resection.

The operative technique is usually carried out by a transverse incision through the skin, subcutaneous tissue, lateral ligaments and fibrous capsule, down to the synovial membrane; reflection of this flap upward; and extirpation of the synovial membrane as recommended by Kocher for typical resections. It is now my custom, after the crucial ligaments are divided and the menisci removed, to examine the bones carefully, in order to determine from the beginning whether I can be content with a limited destruction of the articular cartilage, or whether this must be removed in greater part. It is at this stage that I determine whether my operation is to be the erasion or the intra-epiphyseal resection. Provided the former is the selection, the foci in the bones are removed by a gouge or chisel, and as much of the articular cartilage is saved as is possible. If two-thirds of the articular surface is intact, I then attempt to obtain a movable joint (eighteen per cent. in seventy cases, Maudry), and after dissecting away the posterior synovial membrane and the bursæ I suture carefully the capsule, the ligamentum patellæ, and the skin. I treat the joint subsequently as in fractured patella, with absolute rest for from four to six weeks. If one-half to two-thirds is removed by the gouge or chisel I remove the remaining articular cartilage by sawing intra-epiphyseally and I attempt to obtain an immediate bony union in the extended position. In my opinion the atypical and the typical intra-epiphyseal operations should be combined in this manner to obtain the best possible result of each method. Kocher, in order to avoid the cutting of the quadriceps tendon, makes the usual curved anterior incision, dividing the skin, subcutaneous tissue, and the fasciæ of the vasti muscles. He then makes upon each side of the quadriceps tendon two vertical incisions, which, meeting the incision in the fasciæ of the vasti, form two right-angled flaps which are retracted outward (Fig. 4087). The capsule and synovial membrane are now cleared as in the typical resection, and are removed together with the menisci and ligamenta alaria (Kocher). The crucial ligaments having been previously separated at the tibial eminence, the femur is dislocated outward or inward in order that the posterior and postero-lateral portions of the capsule be rendered accessible for removal. The condyles are now examined, and if necessary foci are removed. The patella is at last turned completely upon itself and cleared of all tuberculous or diseased tissue.

Either of these methods of exposure may be selected. For myself, I prefer the former method, dissecting out the synovial membrane in the manner recommended by Kocher for the typical resection.

RESECTION OF THE HIP-JOINT.—This operation was first performed by Whyte for deformity in 1818, for disease by Hewson in 1822 or by Brodie in 1836, and for gunshot injury by Oppenheim in 1829. The resections are classed as complete when the acetabulum is partially removed together with the femur, as partial when only the femur or the acetabulum is removed. They are typical or atypical, according to the modifications in the method of approach and the manner of attacking osseous tissue.

The indications for the operation are:

1. Gunshot wounds, where partial and atypical resections rather than typical and complete methods are undoubtedly indicated. With the new projectiles, conservative methods rather than operative should be employed unless the operative interference is confined to a correction tending to production of better wound healing.
2. Tuberculosis, where operative procedure is not to be delayed, but earlier interference recommended.
3. Deformities from injury or disease. Here partial or complete resections are alone indicated when osteotomy cannot correct.
4. Old dislocations from disease or traumatism, where partial operations are quite sufficient.
5. Intracapsular fracture of the neck of the femur followed by disability and pain. Here the partial resection confined to the femur is beneficial.
6. In dislocation of the head and fracture of the neck of the femur. Here removal of the dislocated head is sufficient.
7. Congenital dislocation in adults which have failed of reduction by manipulation. (Lorenz and Hoffa.)
8. In acute infectious arthritis. Here arthrotomy rather than resection will be found to be more beneficial.

Results.—The mortality of resections for gunshot wounds is, according to Culbertson, 89.07 per cent., while according to Gurlt it is 88.23 per cent. Gurlt classifies this mortality as follows: 92.68 per cent. for primary resections; 94 per cent. for intermediary resections; 89.39 per cent. for secondary resections; 60 per cent. for late resections. Otis gives a mortality of 90.9 per cent. in the primary resections, while similar cases treated conservatively give 98.8 per cent., and by exarticulation 83.3 per cent.

The mortality for disease is low. Culbertson gives 44.8 per cent., of which 6.93 per cent. represented deaths from operation directly, leaving 37.89 per cent. for deaths from the disease and its complications. Grosch (*Centralblatt für Chir.*, 1882, p. 228) gives a mortality, in 120 cases of tuberculosis treated antiseptically and observed to the end, of 36.7 per cent., which, compared with the results of Culbertson in pre-antiseptic times, shows that the cases dying from operation have been excluded by the present methods of operation, but that the deaths from the disease have not been diminished. Nor can it be said that the time of after-treatment is shortened, nor is the functional result better. These statistics include only cases operated upon late in the disease. The results of the operative treatment are better in proportion as the operation is early performed, and better in children than in adults. The mortality in the first stage, *i.e.*, in the

Digitized by Microsoft®

Resection of Joints.

stage in which the changes in the joint are slight and in which sinuses have not formed, is 0 per cent. The mortality in the second stage, *i.e.*, in the stage in which fistulæ have formed and pus is present, is 24.1 per cent. The mortality in the third stage, *i.e.*, in the stage in which the patients are already debilitated by long-standing suppuration and fistulæ, is 67.5 per cent. Two-thirds of the deaths following operation are due to general tuberculosis or tuberculosis of other organs; one-third is due to septic infection, suppuration, and amyloid degeneration (Bruns, *Beiträge zur klin. Chir.*, xxii., 1894). The mortality at present is in the neighborhood of five per cent. (Wright, 3 : 100).

Functional Results.—Baehr reports 44 cases of resection which were able to walk: 8 with perfect motion = 18 per cent.; 23 with restricted motion = 52 per cent.; 11 with ankylosis = 25 per cent.; 1 with a flail joint = 2.5 per cent. Baehr also found that resection of the head alone gave 0.9 cm. shortening; of the head and neck, 1.5 cm. Subtrochanteric section gave a shortening of 4 cm. His views substantiate Riedel's: namely, that the early resections give less shortening than the continuance of the disease will give, and that motion in the joint is equally good or better (*Deut. Zeits. f. Chir.*, No. 30, p. 349). Mauninger (*Deut. Zeits. f. Chir.*, No. 65, p. 1) gives the statistics of 41 cases carefully observed. The shortest time during which a patient was kept under observation after operation was one year and six months. The following are the classified results: 41.02 per cent. were healed without fistulæ; 17.07 per cent. were healed after treatment for fistulæ or after subsequent operations; 9.75 per cent. were healed, but now and then a fistula would open and close. The general health of these patients was good. In 67.84 per cent. the results were good. In 11.195 per cent. of the cases the health was bad, and the wounds suppurated profusely; 21.95 per cent. of the patients died. The results were bad in 33.145 per cent. of the cases. Of the deaths (21.95 per cent.), 1 was due to fat emboli in the lungs. In about 10 per cent. the cause was miliary tuberculosis, which followed the operation in from one to five months, and the development of which was probably hastened by the operation. In another 10 per cent. of the cases death was due to tuberculosis of internal organs, the disease developing from one to ten years after the operation.

Functional results in these cases must be considered in reference to the condition of the extremity at the time of operation. In no case had the disease in the hip lasted less than two and three-fourths years, so that the operation had to do with (1) the shortening of the extremity due to an atrophy from inaction—4 to 8 cm.; (2) slipping upward of the head of the femur upon the ilium—2 to 3 cm.; (3) contracture of the soft parts (muscles, etc.), usually a flexion-contracture of thirty degrees and an adduction-contracture of twenty degrees; (4) atrophy of the musculature of the pelvis and femur. Yet, in spite of this condition of affairs, in 50 per cent. of the cases in which good results were obtained good motion was present; in 50 per cent. of these cases a cane with or without a high shoe was used in walking. With the exception of one case, all limped more or less; *i.e.*, most patients walked from two to four hours without pain or special fatigue. All followed their vocations. In 50 per cent. their general health was good; in 50 per cent. it was very good. With the exception of one case in which multiple caries existed, no case was suspected of having tuberculosis in other organs. Mauninger collected, in addition to these cases, 304 cases which were operated in the aseptic period of surgery. Permanent healing took place in 65.8 per cent. The mortality was 17.4 per cent. The question to-day is whether conservative treatment will give as good or better results than the operation.

The statistics of Gibney, Waterman, and Reynolds, of 114 cases examined five years and upward after leaving the hospital, show that 107 were cured and able to follow an occupation without trouble; 7 cases were cured, but with considerable deformity, for which osteotomy or excision was done. About 14 per cent. showed perfect motion, 20.5 per cent. good motion, 38 per cent. limited motion, and no motion in about 8 per cent. Shortening of the limb averaged 1.75 in. (*i.e.*, 4 cm.) in all the cases except in 21 in which it was absent, *i.e.*, 19.5 per cent. (*Annals of Surgery*, 1897, vol. ii.).

The statistics of Mauninger (*loc. cit.*), obtained for the conservatively treated cases, give the following results as regards the cures and deaths: purulent cases, 27.1 per cent. healed, 48.8 per cent. mortality; non-purulent cases, 74.2 per cent. healed, 16.5 per cent. mortality.

The results of conservative treatment are therefore, in reference to mortality, no better than those obtained by the operative method, for even if the cases of death due to operation alone or induced by the operation be included, still the operative cures present a mortality of only 17.4 per cent. as against 16.5 per cent. in the non-suppurative cases and 48.8 per cent. in the suppurative cases treated conservatively. If in this comparison cases be deducted in which the disease is attacked early before suppuration exists, the mortality ranges from 0 (Bruns) to 3 per cent. (Wright)—a result far superior to that shown by the statistics of the cases treated conservatively, and even better than the results obtained by Gibney—8.8 per cent.—or by Marsh—6 to 8 per cent.—("Diseases of Children") for the conservative treatment.

The functional results are quite as good—perfect motion being obtained in 18 per cent. of the operative cases (Baehr), in 14 per cent. of the conservative (Gibney, *et al.*). Even in the cases reported by Mauninger, operated after two and three-fourths years of the disease, 67 per cent. were good results; one-half of these patients had motion and one-half walked with a cane. All could follow their vocations. These excellent results obtained by both methods of treatment depend much upon two factors. In the first place, in the conservatively treated, some cases of *restitutio ad integrum* are due to the fact that the disease was non-tuberculous (Karewski). Again, in the cases treated by operation much will depend upon the time at which the operation is performed. Operations are not to be performed because conservative treatment has failed, but at an early stage when fistulæ and suppuration are not present, or, if they are present, only to a small extent (Wright, "Diseases of Children"; Barker, *Lancet*, 1900, vol. i., 1099).

The shortening in the limb is less by the operative treatment than by the conservative treatment. In the older cases the average shortening from operative procedures is not increased over that which is present at the time of operation and which is due to the atrophy of inaction, the slipping upward of the head of the femur, and the contracture of the limb. In the early cases, the statistics of Baehr show that shortening for any section made on a line situated higher up than below the trochanter is very slight (0.9 to 1.5 cm.), while average shortening in the conservative treatment is 4 cm., with 19 per cent. of the cases showing practically no shortening (Gibney), *i.e.*, less than ½ in. or 1.25 cm. Our view is that operation should be carried out as soon as it is clear that conservative measures cannot prevent suppuration. A resection is indicated so soon as suppuration exists in the joint and before fistulæ are present (König, "Das Hüftgelenk," Berlin, 1902).

In the wealthy class, where long-continued mechanical treatment can be carried out and where iodoform injections can be made as indicated, suppuration can oftentimes be prevented and a result obtained which, as we have seen, gives perfect motion in fourteen per cent. of the cases. In the poorer class, who cannot afford or will not carry out this long-continued mechanical treatment, suppuration is more frequent, the deformity is greater, and the destruction of the bones is more marked than is the case in those who have been able to command mechanical treatment and have followed it faithfully. In these latter cases operative treatment is frequently indicated and will give results superior to those offered by the conservative treatment both in respect to function and in respect to mortality, when like degrees of disease are compared.

Anatomy.—The hip-joint is deeply placed and is immediately surrounded by the psoas and iliacus muscles; by the quadratus femoris, the obturator internus, the gemelli, and the pyriformis behind; by the gluteus medius, gluteus minimus, and rectus femoris externally; and finally by the pectineus and obturator externus internally. Beneath these muscles is the thick capsule, the auxiliary bands of which are the ilio-femoral, the pectineo-femoral, and the ischio-femoral, the border of which latter is known as the zona orbicularis. Between the ilio- and ischio-femoral bands the capsule is strong; opposite the lower and back part of the femoral neck and opposite the cotyloid notch it is thin. Within the joint is the ligamentum teres, a flat band extending from the acetabular notch to the depression in the head of the femur. The marginal fibro-cartilage and the transverse ligament complete the ligamentous structures. The synovial membrane lines the capsule and passes over the border of the acetabulum to cover the round ligament. The bursæ are numerous and of frequent occurrence; upon the outer and anterior surfaces there are five, while upon the posterior surface there are four.

www.libtool.com.cn

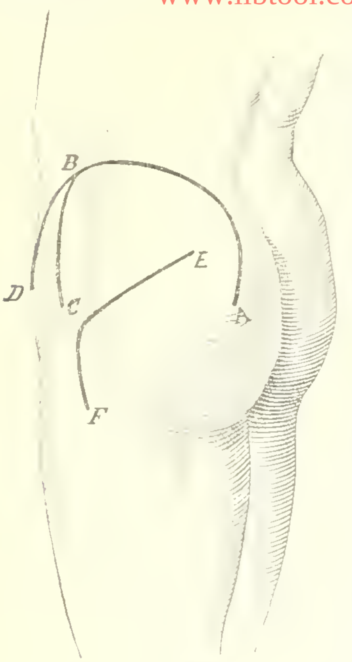

Fig. 4088.

The bones consist of the innominate and the femur. The former contains the acetabulum, a hemispherical cavity which receives the femur. The latter consists of a rounded head and a neck, which latter is long and joins the shaft obliquely, *i.e.*, at an angle of one hundred and twenty-five degrees.

Ossification occurs in the head of the femur and in the greater and lesser trochanters, respectively, at the first, fourth, and thirteenth years. They join the shaft in the reverse order at the eighteenth, eighteenth and a half, and nineteenth years.

The acetabulum ossifies at the sixth year from the Y shaped cartilage occupying its centre. At the fourteenth the ilium and ischium unite with the acetabulum. The pubis does so at the fifteenth year. Ossification is completed in the acetabulum at the seventeenth year.

Owing to the obliquity and the length of the neck of the femur, the muscular attachments to the bony prominences have great leverage and a wide range of motion is possible. When the head is removed these muscles tend to draw the femur upward unless the neck is engaged in the cotyloid cavity. If the neck is also removed, the abduction and rotation of the femur are lost. The pelvi trochanteric and all muscles passing between the pelvis and the femur cause the femur to ascend, which ascension is limited only by the tension of the capsule. The shortening, then, in any resection will depend upon: (1) The loss of the epiphyseal cartilage. This is slight. (2) The amount of bone removed. (3) The muscular displacement of the femur. (4) The atrophy of the limb from disuse.

This shortening is partly corrected by the inclination of the pelvis on the side operated. The object to be acquired in a resection is a nearthrosis or a tight pseudarthrosis. They give the best results in walking. To obtain either, the neck must be retained in the acetabulum or in apposition with the bone at this level, and not allowed to ascend. Owing to the inclination of the pelvis after shortening, the femur must be retained slightly flexed and abducted upon the pelvis. The main points, then, are to preserve the greatest possible length, to obtain a solid, slightly mobile union with the acetabulum, and, lastly, to preserve the proper position in the limb.

Methods.—The hip-joint has been removed by several methods of incision.

1. By the external incision. First proposed by Charles White in 1769, and modified by Langenbeck in 1867 (*Langenbeck's Archiv*, No. 16, p. 24), by Sayre in 1874 (personal communication from son), and still later by Ollier ("Regénération des Os," t. ii., p. 384) and Kocher (*Correspondenzblatt f. Schweizer Aerzte*, 1887, Dumont).

2. By the anterior incisions. (*a*) The longitudinal (Schede, Verhandl. der deut. Gesell. f. Chir., i., p. 68, 1878; Lücke, *Centralblatt für Chir.*, 1878, p. 681; Hüter, 1878, "Chirurgische Operationslehre," Löbker; Parker, Transactions of the Clinical Society, vol. xiii., 1880; Barker, *British Med. Journal*, vol. i., p. 1326, 1888). (*b*) The transverse (Roser, "Chirurgisch-anatomisches Vademecum," 1870).

3. Posterior incisions, Hueter ("Die Gelenkserkrankungen," 1877); Guérin ("Manuel Opératoire" of Farabœuf); Bidder (*Langenbeck's Archiv*, No. 39).

4. Superior incisions, Bardenheuer (*Langenbeck's Archiv*, No. 41), H. Schmid (Verhandl. der deut. Gesell. f. Chir., 1891); Sprengel (*Festschrift Braunschweiger Aerzte*, 1898).

In addition to these, there are from fifteen to eighteen other modifications of these methods of approaching the joint ("Manuel Opératoire," Farabœuf). They are of little value. Of these methods of entering the joint three are selected: 1. The external incision. 2. The anterior longitudinal incision. 3. The superior incision.

1. *Operation by the External Incision.*—The patient lies upon his sound side with the thigh flexed upon the pelvis at an angle of forty-five degrees. It is also rotated inward. One assistant holds the limb with one hand upon the knee and the other upon the foot and produces the required positions during the operation. The operator stands behind the thigh and is usually aided by two assistants.

An incision is made which may correspond to that of Langenbeck, Sayre, Ollier, or Kocher. If Langenbeck's is selected, it passes from the posterior superior iliac spine over the great trochanter behind its centre and follows the axis of the femur. Two-thirds of this incision is above the trochanter one-third is below it. If Sayre's incision is selected, it passes from a point mid-

Fig. 4089.

Digitized by Microsoft®

Resection of Joints.

way between the anterior inferior spine and the trochanter across the top of the great trochanter behind the centre, and curves thence forward and inward. If Ollier's incision is selected, we flex the thigh on the pelvis at one hundred and thirty-five degrees. From a point four fingers' breadth behind the anterior superior spine

www.libtool.com.cn

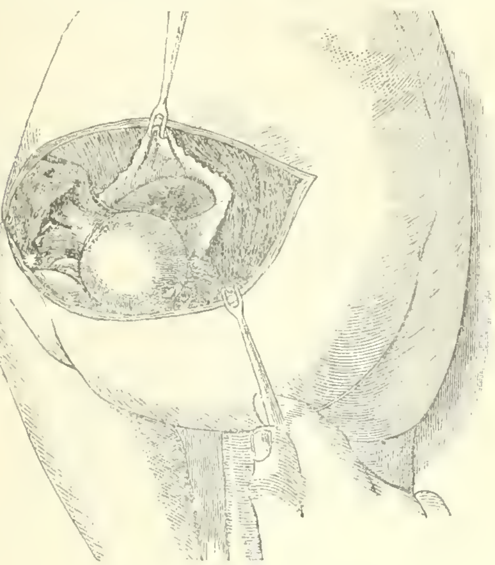

FIG. 4090.

and the same distance below the crest of the ilium, the incision passes downward and forward in the direction of the fibres of the gluteus medius to the trochanter, thence forward and downward in the axis of the femur. If Kocher's incision is selected, it commences at a point opposite the upper border of the great sciatic notch in a line connecting the posterior superior spine of the ilium and the centre of the trochanter major, and descends parallel to the fibres of the gluteus maximus to the trochanter major on its external surface. From this point it bends backward and downward. The upper limb of this curve is usually 8 cm. in length, the lower 6 to 8 cm. (Dumont, *Correspondenzblatt f. Schweizer Aerzte*, 1887).

Of these incisions I prefer Kocher's, because of the ready exposure of the parts which it affords, and the easy access which it gives to the joint through the muscular interstices, thereby avoiding the arterial and nerve supply of the muscles (Fig. 4088, *E F*).

Having selected the latter incision, the surgeon should divide the skin and deep fascia and thus expose the fibres of the gluteus maximus in the upper two-thirds of the cut. These are divided parallel to their length and in the line of the skin incision. Two or three branches of the gluteal artery are usually cut here in their middle. Two retractors are introduced, the gluteus medius and pyriformis are exposed beneath this muscle internally, while externally the trochanter is felt. The knife now divides the strong fascial attachment of the gluteus maximus, passing over the trochanter and descending in the interstice between the vastus externus and the quadratus femoris (Fig. 4089). In this incision the tendon of the gluteus maximus is in part divided, and this division, by reason of the resulting retraction, exposes the muscles covering the joint behind and the trochanter in front. It is here that the external circumflex artery is sometimes cut. The interstice between the pyriformis behind and below, and the gluteus medius above and in front, is seen in the anterior part of the exposed area. Below this is seen the interstice between the pyriformis above and the gemelli and obturator internus below. It is between the latter muscles that the incision is deepened, since in the upper retracted flap will be the gluteus medius and pyriformis supplied by the superior gluteal nerve, while in the lower retracted flap will be the obturator internus and gemelli supplied by the inferior gluteal artery. The joint capsule is now exposed throughout its length and should be divided by an incision which runs parallel to the axis of the neck of the femur, and at the same time divides the periosteum of the neck, the orbicular zone of the ischiofemoral band, the capsule and the circumferential fibrocartilage of the acetabulum. This incision is usually sufficient to allow dislocation of the head of the femur, but, if it does not suffice, a transverse incision may be added near the acetabular margin. The internal circumflex artery is usually cut here as it passes over the capsule. The incision in the periosteum of the neck is now continued over the trochanter major upon its posterior border, and the periosteum, together with the attachment of the gluteus medius above, the pyriformis internally, the gluteus minimus, the vastus externus, and the Y-ligament anteriorly, is separated with the rugine. This separation is greatly facilitated by flexion and rotation outward of the thigh. It is here that the external circumflex artery is often cut a second time. This flap can now be pulled forward over the trochanter. It contains within, if we exclude the small portion of the vastus externus, only those muscles which are supplied by the superior gluteal nerve. The thigh is now less flexed, adducted, and rotated inward. The tendons and the periosteum are separated with the rugine from the apex and posterior half of the trochanter as far as the origin of the quadratus femoris from the linea quadrati. These tendons, namely, the gemelli, the obturator internus and externus, and as much as is necessary of the quadratus femoris, are now retracted backward and downward with the capsule. These muscles are all supplied from the inferior gluteal or sciatic, whose branches are uninjured.

When these capsulo-periosteal flaps are freely retracted, the posterior surface of the head of the femur, its neck, and the trochanter are in view. The sciatic nerve is free from danger, being carried away from the joint when the obturator internus, the obturator externus, and the quadratus femoris are divided and retracted.

The thigh is now strongly flexed, adducted, and rotated inward. The round ligament is divided if intact and the head is luxated (Fig. 4090). The remaining periosteum and capsule upon the neck is separated with the rugine. The head is now held firmly with the lion-toothed forceps, the soft parts are protected by the retractors, and the bone is sawn with the Gigli saw just below the level of disease or injury.

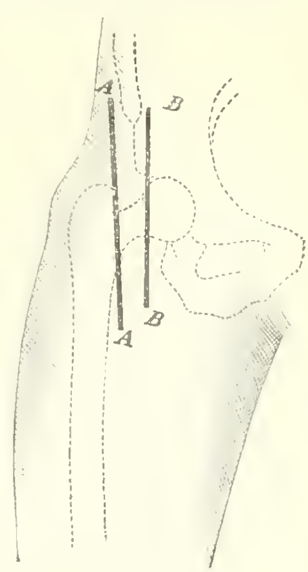

FIG. 4091.

The acetabulum is next removed with the gouge, chisel, or Volkmann's spoon, according to the indications. The synovial membrane and parts of the capsule are removed after the bones are cleared of disease. If sinuses are present they must be excised or curetted. Hemorrhage usually consists of oozing, and can be stopped by hot saline solution; if it is very troublesome the wound may be packed with gauze. Where no oozing is present and no sinuses exist the wound may be closed directly. If, however, abscesses, sinuses, or great oozing is present, it is best to pack with gauze, for a time at least.

The section in the bone should be made in the neck if

Digitized by Microsoft®

possible, if not, through or beneath the trochanter major, because of the shortening which is liable to ensue.

A nearthrosis is best secured when the section passes through the neck near the head, yet subtrochanteric sections have given as good results in the restoration of the joint. Such cases are seen in the autopsy shown by J. Israel (German Surgical Congress, 1883) and in the collection made by Sach (*Deutsche Zeitschrift für Chir.*, xxxii.). In some of these cases a newly formed head covered with fibro-cartilage, a new trochanter, and synovial membrane were reproduced to a considerable extent. To obtain the best results, one must operate early in the disease, early in life (three to fifteen years), and subperiosteally, and must preserve as much of the bones as possible, so as to diminish the shortening.

www.libtool.com.cn

FIG. 4092.—Löbker's Spoon-Elevator. (About ½ natural size.)

When a nearthrosis is not attainable or is inadvisable, the after-treatment should secure the retention of the limb in abduction with the slightest flexion. This gives a very good and useful limb.

2. *Operation by the Anterior Incision.*—The only incisions here considered are those which are longitudinal. The transverse are too destructive of the soft parts.

According to Lücke and Schede, the incision commences one finger's breadth below and to the inner side

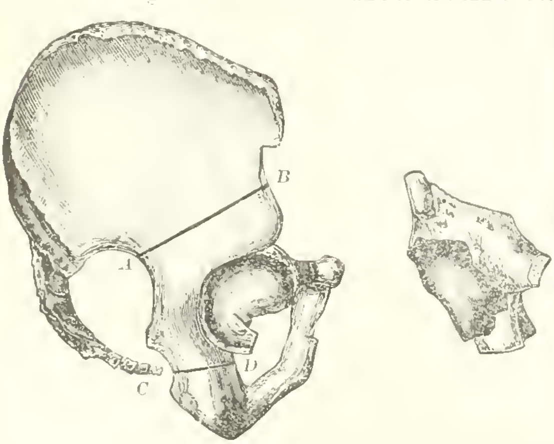

FIG. 4093.

of the anterior spine and descends in the long axis of the femur for a distance of 10 to 12 cm. (Fig. 4091, *BB*). As it is deepened it passes to the inner side of the sartorius and the rectus muscles and to the outer side of the ilio-psoas muscle. The crural nerve and the external circumflex artery are avoided. The assistant flexes, abducts, and rotates outward the thigh. The sartorius and rectus muscles are drawn outward, the ilio-psoas muscle and the crural nerve inward. The capsule of the joint is exposed and is divided by a crossed incision, the transverse portion parallel to the neck passing from the acetabulum over to the anterior intertrochanteric line, while the vertical portion crosses this line at a right angle. The neck is now sawn with a Gigli saw and the head is extracted after dividing the ligamentum teres by Löbker's spoon-elevator (Fig. 4092) or by a lion-toothed forceps. For the extraction of the head alone this incision may suffice, but if we wish

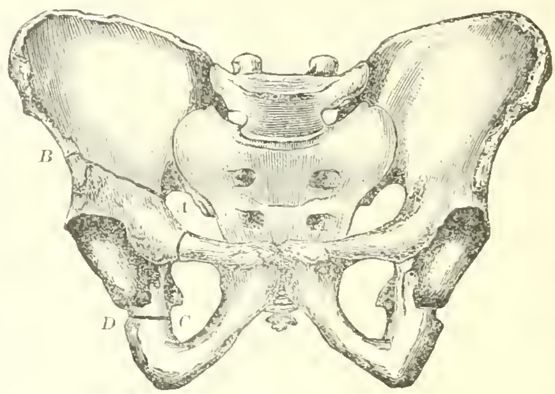

FIG. 4094.

to reach the trochanter in addition we must advocate the incision of Hueter which has been much used and strongly advocated by Barker. In this latter method, the patient rests supine with the thighs extended; the surgeon makes an incision which, according to Hueter, passes from the middle of a line drawn from the anterior superior iliac spine to the trochanter major, downward and slightly inward along the outer border of the sartorius. In children the incision is 6 to 8 cm., in adults 10 to 15 cm. in length. According to Barker, the incision commences in the anterior surface of the thigh, one-half inch below the anterior superior spine of the ilium, and runs downward and inward for three inches (Fig. 4091, *AA*). With either incision, the dissection is carried in the space between the sartorius, anteriorly, and the tensor vaginæ femoris and the gluteus medius behind. The incision is deepened to the bone and some fibres of the vastus externus are divided. In the lower angle of the wound is seen the external circumflex artery, which may be divided. These muscles are retracted, the joint capsule is seen and is incised by the same cross incision mentioned in the Schede-Lücke method. After this exposure of the head and neck, the spoon-elevator may be used and the trochanter freed of its muscles sufficiently to allow an easy exposure of the joint. The diseased head is now removed after encircling the neck and dividing it with the Gigli saw. The removal of the head is often difficult unless it be much diseased. With the lion-toothed forceps the removal is often very difficult and the soft parts and the head are often crushed. The easier method is to pry the head out of the acetabulum by introducing a strong, gently curved elevator or Löbker's spoon in the space between the head and the acetabulum, and after the ligamentum teres has been divided the head is then easily removed.

The bleeding by this anterior incision is small in amount if one avoids the anterior circumflex artery. Drainage of the wound will require not infrequently a posterior opening, but in many cases operated early all necessary drainage can be secured through the anterior incision.

In neither of these methods by the anterior incision are muscles cut. Neither nerves nor vessels are injured. In both methods the route to the joint is a direct one. The advantage of the Hueter incision over the Lücke-Schede

Digitized by Microsoft®

incision is that the trochanter, as well as the head and neck, can be reached.

When the acetabulum is primarily involved, or the x-ray and the clinical symptoms show that the disease which affects it must be especially attacked, the methods introduced by Bardenheuer (*loc. cit.*) and Schmid (*loc. cit.*) give the best chances for radical cure. As usual methods, these procedures are considered at present too extensive. In Bardenheuer's hands, the mortality due to the operation alone was 4.3 per cent. In Schmid's hands, the recurrences were not lessened by the procedure, two of the four cases dying of continued tuberculosis. In the large majority of cases the Kocher incision will give sufficient exposure to enable us to chisel or gouge away the diseased acetabulum; and as this method is less extensive and more easily accomplished it should be preferred.

Operation by the Superior Incision.—In a few cases, Kocher's operation is not sufficient, and we recommend for these the suggestion of Sprengel ("Zur operativen Nachbehandlung alter Hüftresectionen," *Festschrift*, 1898), which consists in making an extensive incision along the crest of the ilium from the posterior superior spine of the ilium to the anterior superior spine of the same. This incision divides the muscles and the periosteum. At the border of the gluteus medius and the tensor vaginæ femoris this incision descends to the trochanter major. (Fig. 4088, *ABC*.) This quadrilateral flap is removed subperiosteally from the ilium until the joint is opened and the head and neck of the femur are exposed. As the nerves and vessels are avoided by this, the muscular paralysis and hemorrhage are practically nil. If the disease is well forward in the acetabulum and pubis, especially if a flexion-contracture exists, the incision is made in front of the tensor vaginæ femoris, sartorius and rectus, and these muscles are separated with the rest (Fig. 4088, *ABD*). After exposing the head of the femur, it is rotated inward or outward, as occasion demands, and adducted strongly. If the acetabulum alone is to be removed, this can be easily accomplished with the chisel or gouge through the incision first recommended (*ABC*). If the disease requires a resection of the acetabulum and the surrounding bone, the second incision is used (*ABD*). In this latter case the outer surfaces of the ilium, the acetabulum, and the outer margin of the great sciatic notch are bared of their periosteum. In like manner the internal surface of the ilium, the iliac fossa, is freed from the pelvic fascia and muscles until the great sciatic notch is reached. A Gigli saw is then inserted through the sciatic notch beneath the iliac muscles and over the anterior inferior spine of the ilium and the bone is sawn (Figs. 4093 and 4094, *AB*). The horizontal ramus of the pubis is next cleared of its periosteum, carrying with it the vessels, which are displaced from 1 to 2 cm. internally. An aneurism needle now carries a Gigli saw around the ramus and out of the obturator foramen (Fig. 4091, *CD*). The bone is sawn. As the bone is now cut upon two sides, it can be displaced outward somewhat. The periosteum is next removed from the descending ramus of the ischium from above downward with great care to avoid injuring the vessels and nerves as they pass out of the pelvis. The Gigli saw is again passed around this ramus at a point one finger's breadth beneath the acetabulum (Figs. 4093 and 4094, *EF*). The bone is sawn. The acetabulum and surrounding bone can now be quite easily removed with the heavy lion-toothed forceps. If the head of the femur is to be removed with the acetabulum, it is best removed before we attempt the resection of the acetabulum.

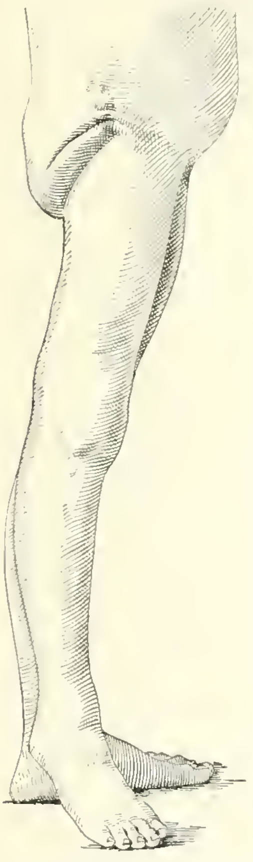

FIG. 4095. A Patient Three and a Half Years After Removal of One-Half the Pelvis and the Head of the Femur. (Kocher.)

After the hemorrhage has been controlled the wound is closed with sutures except in some portion where the packing emerges. It is best in all cases to pack the large wounds for from twenty-four to forty-eight hours, in order to control hemorrhage completely. After this, that portion from which the gauze emerges can be left for drainage or it may be sutured at this time.

After-Treatment.—The after-treatment in resection of the hip is important. An aseptic dressing, equable compression and rest for the wound are the first desiderata. The position to be maintained is that of extension and abduction of the thigh, with the neck or the trochanter closely applied to the acetabulum or ilium. During the first three weeks, since these wounds are packed with gauze and require secondary suture or dressings, a Buck's or Volkmann's extension apparatus with plaster-of-Paris spica passing to the knee is most frequently used. After this period, when the packing is removed or the wound is healed in great part, a Thomas splint or the plaster-of-Paris dressing may be used for the next three weeks. If the patient is up and about upon crutches (children), a Thomas splint is very inexpensive and satisfactory. If the patient is confined to bed, a plaster-of-Paris splint which can be readily removed for the active exercise of the joint is the more useful form of splint. During this period of three weeks, active exercise in the new joint is made every two or three days.

During the following three to six weeks patients are allowed to walk with their splints, and during this time the Taylor hip splint or some modification of it is substituted for the former apparatus. These splints allow flexion, extension, and abduction when applied, and the surgeon must continue the extension and abduction of the limb for a long time to overcome the constant tendency to flexion and adduction. It is only by this careful after-treatment that a good functional result can be obtained. *Frank Hartley.*

RESECTION OF THE SUPERIOR MAXILLA.—HISTORY.—Partial removal of the superior maxilla for alveolar growths, necrosis, disease of the antrum of Highmore, etc., has probably been practised for a very long time, but the complete, formal resection of this bone appears to have been first proposed by Lizars in 1826.

In the following year Gensoul, quite independently of Lizars' suggestion, performed the operation, and therefore seems entitled to the credit of having first executed this procedure.

The indication for resection of the upper jaw is almost invariably the presence of a new growth. Hueter states that the jaws are more frequently the seat of tumors than any other bones of the skeleton. Almost every variety of neoplasm is found in connection with these bones.

Benign tumors such as cysts, epulis, adenomas, fibromas, chondromas, osteomas, etc., require partial resections only; merely enough of the bone being removed to give access to the tumor or to effect the complete removal of the latter.

Complete resection of the superior maxilla is usually done for malignant growths, *i.e.*, carcinomas and sarcomas, affecting the bone. They occur with about equal frequency. The majority of the former begin in the alveolus.

Digitized by Microsoft®

www.libtool.com.cn

Anatomy.—The superior maxilla is the largest bone of the face, the lower jaw (mandible) excepted, and with its fellow forms the whole of the upper jaw. Each bone forms a part of the wall of three cavities: the mouth, the nasal fossæ, and the orbit. It is hollow, its cavity being known as the antrum of Highmore, which communicates by an aperture with the middle meatus of the nasal fossa. Either of these cavities may be the seat of new growths which involve the maxilla; the mouth and the antrum being most frequently affected. The mucous membrane of the antrum is frequently the seat of a catarrhal or purulent inflammation, giving rise to an excessive discharge through the nose, or if the fluid is prevented from escaping, the thin walls of the bone yield, and protrude toward the cheek, toward the mouth, or in both directions, the appearances then simulating those observed in solid growths of the bone.

Instruments Required.—Mouth gag, sponge holders, scalpels, toothed dissecting forceps, hæmostatic forceps, scissors, keyhole saw, Hey's saw, tooth forceps, bone-cutting forceps of different angles, chisels and mallet, lion-jaw forceps, sequestrum forceps, Paquelin cautery, tracheotomy tube, needles, straight and curved, ligatures, sutures, marine sponges.

Partial resection for alveolar tumors and necrosis may be carried out through the mouth in most instances, without making any external incisions. The removal of other benign growths must be carried out on general surgical principles. The affected part is approached by incisions designed to avoid important structures and to give the best exposure with the minimum resulting deformity, and the neoplasm, together with the bone to which it is attached, is then removed.

If the tumor is open to the suspicion of being malignant, a generous portion of the adjacent bone in all directions should be removed, or the complete resection may be advisable.

The dangers of resection of the superior maxilla are: hemorrhage, the entrance of blood into the air passages, and septic pneumonia.

Various means have been adopted by different operators with the view of controlling the hemorrhage. The internal maxillary and temporal arteries, and the external carotid artery have been ligated as a preliminary step in the resection. The common carotid has been compressed and subjected to temporary and permanent ligation. Crile has devised a clamp to be applied to one or both common carotids, as may be necessary, for the temporary control of bleeding during operations on the head and face if serious hemorrhage is probable.

With the view of preventing the blood from flowing into the air passages, Rose advises that the patient's head be allowed to project beyond the end of the table, and to drop well down so that the vertex points vertically to the floor. In this position the mouth and nose are on a lower level than the larynx and the blood would escape from them before it would enter the latter.

The objection to this position is that the surgeon is obliged to work at a great disadvantage, and the hemorrhage is greater when the head is dependent than when it is elevated.

Some surgeons perform a preliminary tracheotomy, introducing a tube, and continue the anæsthesia through this, so that the pharynx may be packed with marine sponges to which stout strings have been attached to assist in their withdrawal. The sponges absorb the blood that finds its way to the pharynx and prevent any from flowing into the trachea.

Of this procedure it may be said that while a carefully performed tracheotomy that is well cared for afterward does not add much to the dangers of the operation, it is an additional complication, and is usually unnecessary.

The use of Trendelenburg's tampon cannula for the trachea answers the same purpose as the tracheotomy, and is open to none of its objections.

The methods which are employed in preventing the entrance of blood into the lungs do not diminish in the least the amount of blood lost. By having the patient only partially anæsthetized, he will be able to spit out the blood and thus keep his air passages free. In this way the necessity for adopting the measures spoken of will be avoided, and if the operation be expeditiously performed, the amount of blood lost will not be great.

To summarize, it may be said: (1) That Rose's position is not to be recommended. (2) If no complications are to be expected, the operation may be done with the patient but partially anæsthetized. If this plan be adopted, everything that may be needed should be at hand, and there should be an ample number of assistants, so that not an unnecessary moment shall be lost after the operation has actually begun. (3) In performing the operation for vascular tumors affecting the bone, or when for any other reason unusually free bleeding may be expected, it will be advisable to pass a loop of silk about the external or common carotid, traction upon which will occlude the vessel, or, if at hand, one of Crile's clamps may be applied. In either case, especial care must be exercised to prevent infection of the wound exposing the artery, as such an occurrence may readily be more serious than the resection of the bone. (4) If there is no reason to expect serious hemorrhage, these precautions become unnecessary. On the other hand, if a more deliberate operation is required, as in cases in which tumors have passed the limits of the maxilla and must be followed in whatever direction they have taken, the advantage of having a dry wound, so that every portion may be inspected without being obscured by blood, cannot be overestimated. In these instances some method of controlling the circulation is of inestimable value.

Septic pneumonia is best prevented by having the nasopharynx treated before the operation by cleansing sprays, douches, and gargles, and by keeping the cavity sweet and clean after the operation.

Operation.—A number of methods have been devised for resecting the superior maxilla, and many of them have been named after the operator who devised them. The chief variation is in the skin incisions employed to expose the bone, the mode of actually removing the latter being essentially the same in all.

In the classical resection the incision variously known as the median, Fergusson's, Nélaton's, Liston's, Weber's, etc., is beyond question the best. It gives ample exposure and is followed by less disfigurement than is any other incision. For partial resections and special cases some of the other incisions may be more suitable.

The incision from the angle of the mouth to the malar bone has been ascribed to Lizars and to Velpeau. Langenbeck exposed the bone by a U-shaped flap, beginning at the side of the nose, at the point of junction of the nasal cartilage and bone, and carried downward, outward, and upward, terminating at the middle of the malar bone. Liston's incision extended from the angle of the mouth to the external angular process of the frontal bone. Gensoul made three incisions: the first from just below the inner canthus, down the side of the nose, and through the upper lip; a second at right angles to this, on a level with the floor of the nose, as far out as a line perpendicular to the external angular process of the frontal bone; and a third, from the termination of the second to the external angular process.

The anæsthetic may be either ether or chloroform, according to the custom of the surgeon. If the thermocautery is to be employed to control bleeding, chloroform should be administered on account of the inflammable character of the vapor of ether.

The patient should be placed on his back, with the head and shoulders raised on pillows, the affected side being uppermost. His face should have been cleanly shaven.

The median incision is made in the following manner: The knife should enter the skin about half an inch below the inner canthus, and the incision should then be carried downward in the line of junction of the nose and cheek to the ala nasi, around and close to the latter, and it should stop just short of the middle line of the lip, from which point it should be extended vertically through the lip to its free border. The incision should be carried down to

Digitized by Microsoft®

the bone at once, all bleeding points being caught by pressure forceps. Finally, a second incision is to be carried along the lower border of the orbit from the beginning of the first to the malar bone.

www.libtool.com.cn

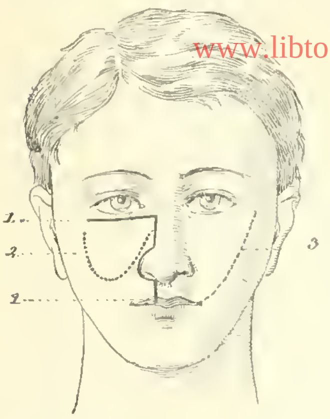

FIG. 4096.—Resection of the Superior Maxilla. 1, The median incision (also called Fergusson's, Nélaton's, Liston's, and Weber's); 2, Langenbeck's incision; 3, Lizars' or Velpeau's incision.

The flap thus outlined should be rapidly dissected from the bone, all bleeding points being secured by forceps or by sponge pressure.

At this stage it is well to tie off such forceps as interfere with the subsequent steps, and to arrest all bleeding as far as possible. The malar bone is next divided at about its middle by Hey's saw. If it is proper to leave the orbital plate a second saw cut is made in the line of the second incision, beneath the orbit as far as the nasal process. If the orbital plate is to be removed, the periosteum is incised along the lower border of the orbit and carefully separated from the bone as far back as necessary, and the floor of the orbit divided at the proper line with a chisel and mallet; or if it is necessary to remove the orbital plate entire, the periosteum is fully separated and it is wrenched from its connections at the time of removing the maxilla.

The nasal bone and nasal cartilage are next separated from the maxilla by means of a saw or chisel. The upper central incisor tooth in the affected maxilla must now be extracted and the mucoperiosteum covering the hard palate divided near the middle line from before backward; the soft palate should also be separated by a transverse incision along the posterior border of the hard palate on the diseased side. By means of a keyhole saw introduced into the nostril the hard palate is divided in the line of the incision in the mucoperiosteum as rapidly as possible. The bone is then grasped by lion-jaw forceps and wrenched from its remaining attachments, the principal one being the pterygoid process. At this stage the use of the bone-cutting forceps bent at an angle may be required to sever any firm connections. Sponges should be instantly thrust into the cavity and pressure exerted to check the bleeding, and the patient's throat should be cleared of any collection of blood. The sponges may now be removed one by one, and the bleeding points dealt with by ligation or by the thermo-cautery. Usually the hemorrhage will cease after a few moments' pressure.

It will be necessary to pack the wound with gauze which will effectually arrest oozing, but it must not be depended upon to control spurting vessels. Each piece of gauze introduced should have firmly attached a strong thread to assist in its removal. After the operator has assured himself that the hemorrhage is controlled, he should replace the flap and should suture it in position by means of silkworm gut. Especial care should be observed in adjusting the free margin of the lip.

If the bone is much diseased it is apt to break, and must then be removed in fragments. In such cases every portion should be examined for evidences of remaining disease and all such tissue removed.

The advantage in leaving the floor of the orbit when possible is that the eye is not disturbed. When it is removed, the eye drops somewhat, and the lower lid is apt to remain red, swollen, and distorted.

The removal of both superior maxillæ becomes necessary in rare instances. The technique is the same as that described above save that it is duplicated on the opposite side.

After-Treatment.—The gauze tampon should be removed on the day following the operation unless there is reason to expect free hemorrhage, when it may be allowed to remain another twenty-four hours. The mouth must be kept as clean as possible by the frequent use of washes, douches, and sprays. These should consist of mild antiseptics like solutions of boric acid, salicylic acid, etc.

Nourishment during the first few days is maintained preferably by nutrient enemata, and later by milk, broths, and other liquid foods given by the mouth.

Mortality.—This varies in different collections of cases. Butlin in 1887 found the mortality to be about 30 per cent. Bryant's collection (1890) showed 14 per cent. of deaths. Of 66 more or less complete unilateral and 5 bilateral resections, collected by White and Wood (1896), but 6 per cent. died as a result of the operation. The records of St. Bartholomew's, St. Thomas', and University Hospitals, London, have been examined by Butlin (1900), who found 127 cases of resection for malignant disease with 16 deaths (12.6 per cent.). Martens (quoted by Butlin) reports from the Clinic of König, in Göttingen, 74 total resections, from 1875 to 1896, with nearly 30 per cent. mortality.

Osteoplastic resection of the superior maxilla is occasionally performed for the purpose of removing nasopharyngeal tumors. Nélaton's method consists in the division of the soft palate antero-posteriorly, and the removal of the posterior half of the hard palate after the mucous membrane and periosteum have been separated from the middle line toward the alveolus on either side. After the removal of the polyp the palate is closed by sutures.

Chalot separated the upper lip from the superior maxilla until the nasal fossæ were opened, then extracted the two upper canine teeth and made an incision through the mucoperiosteum of the hard palate from the point occupied by the extracted teeth, along the alveoli, to the posterior border of the hard palate. The alveolus and palate were next divided by a mallet and chisel and the fragment was separated from the vomer and turned down into the mouth, being attached only to the soft palate. After the removal of the tumor the bone should be replaced and held by sutures.

Several methods have been proposed by different surgeons for reaching these tumors by temporary resection of portions or all of the nose, the most useful perhaps being that of Rouge. This consists in separating the upper lip from the maxillæ by dividing the mucous membrane close to the bone; the septum and the alæ are also detached from their attachments to the bone and turned upward by inverting the upper lip and making traction. After the removal of the tumor the parts fall naturally into place.

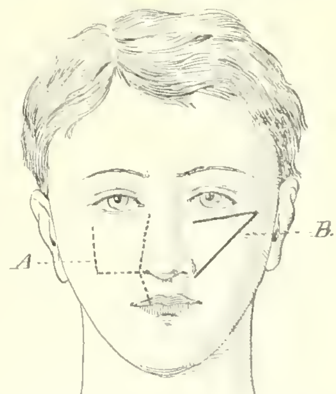

FIG. 4097.—Resection of the Superior Maxilla. A, Gensoul's incision; B, Langenbeck's incision for osteoplastic resection.

This procedure is suitable for tumors situated anteriorly chiefly. Some means must be adopted for preventing the blood from getting into the larynx. Langenbeck makes two incisions: one from below the inner canthus to the malar bone, and another from the nostril to join the outer extremity of the first. The bone is sawn through in the lines of the incisions. The bone still attached to the soft parts is then raised

Digitized by Microsoft®

and thrown over on the opposite cheek. The parts are restored and sutured in place after the tumor is removed.

Alfred C. Wood.

RESINS. See *Active Principles.*

RESOPYRIN. See *Antipyrin.* www.fbtool.com.cn

RESORBIN is a readily absorbable ointment base made by emulsifying expressed oil of almond with yellow wax, soap, gelatin, and water, and adding lanolin to give it a proper consistency. It was introduced by Lebermann, who used it as a vehicle for mercury, as more readily absorbed and less greasy than blue ointment. He also employed it in various skin diseases. In course of time it tends to become rancid. *W. A. Bastedo.*

RESORCIN: RESORCINOL.—Resorcin, chemically *metadioxybenzene*, $C_6H_4(OH)_2$, is one of a trio of isomeric diatomic phenols, of which pyrocatechin and hydroquinone are the other two members. It is official in the United States Pharmacopœia under the title *Resorcinum*, Resorcin.

Resorcin occurs in colorless, needle-shaped crystals, having a peculiar smell, resembling that of carbolic acid, and a bitter-sweetish taste. Resorcin dissolves readily in water, and still more readily in alcohol and in ether. In its effects resorcin resembles its congener, carbolic acid, but is, in general, less active than that substance, and, in particular, very much indeed less poisonous, constitutionally. Resorcin inhibits bacterial growth, but probably less potently than carbolic acid. Locally, the drug is without effect upon the sound skin, but applied, undiluted, to a moist mucous membrane, it is mildly caustic, while at the same time anæsthetic and healing. By reason of the anæsthesia it produces, resorcin may be applied even to such sensitive parts as the mucous membrane of the larynx (Andeer). Internally, resorcin may be given in very considerable doses, as compared with carbolic acid, and such doses, administered to a fevered subject, will show to a marked degree the peculiar antipyretic effect so characteristic of the phenols. After a dosage of from 2 to 3 gm. (from gr. xxx. to gr. xlv.) there set in, in a few minutes, quickening of heart action and of breathing, reddening of the face, and buzzing in the ears, with giddiness. Within fifteen minutes sweating begins, speedily becoming active, whereupon the antecedent derangements abate, and at the same time the pyrexial temperature rapidly falls—so rapidly as perhaps to reach the normal point within an hour. The sweating does not last long, so that after the lapse of an hour from the time of dosing, the fever patient may have a naturally moist skin only, with temperature and pulse rate reduced to the normal. But while defervescence by resorcin is quick to occur, it is also quick to give way to the natural tendency of the fever to regain its former height. Within from two to four hours, therefore, the temperature often begins its succeeding rise, and within a single additional hour may have attained its original height. Such rapid after-risings of temperature may be attended by a chill. Resorcin is variable in its action; sometimes the fall of temperature is slight, and sometimes the by-effects are excessive and even alarming. Thus, after medicinal doses, there have been observed delirium and illusions, with muttering speech and convulsive trembling of the hands, and, in one case at least, a deep comatose sleep. In overdosage resorcin is competent to induce constitutional poisoning after the general type of poisoning by the phenols—producing giddiness, insensibility, profuse sweating, great reduction of temperature, and general collapse, with olive-green coloration of the urine. Such alarming condition has followed a succession of doses increased from half a drachm to two drachms. Therapeutically, resorcin has been used for both local and constitutional medication. Locally, resorcin is possibly available for a simple "antiseptic" effect, but is surpassed in this therapeusis by so many other agents as to be little used for the purpose. But for a combined antizymotic and *healing* effect the local application of resorcin may be quite serviceable. Thus injections of a five-per-cent. aqueous solution have been made into the bladder, in cystitis, and into suppurating cavities, with good effect, and salves of resorcin have abated malignant and syphilitic ulcerations. A spray of a two-per-cent. solution has been used in whooping-cough; and a ten-per-cent. solution has been praised for local application to the throat in diphtheria. Internally, resorcin has been used for its antipyretic action, in which application the medicine presents the feature of a fair degree of safety and efficiency combined; but the action is evanescent and attended by disagreeable excitement and sweating. The dose of resorcin for an antipyretic effect ranges from 2 to 4 gm. (from gr. xxx. to xlv.), best given in divided doses and administered, dry, in a wafer or capsule, or in solution in water, sweetened and aromatized. Constitutional effects are also asserted (Andeer) to be procurable, in diseases attended by an affection of the skin, by inunction of resorcin in admixture with vaseline, in proportion of from five to eighty per cent., such effects being the abatement of symptoms in so-called zymotic diseases. Andeer claims thus to have produced striking amelioration in such diseases as smallpox, scarlet fever, measles, and leprosy, by inunctions, over the whole body, of resorcin vaseline. Resorcin has been used as an intestinal antiseptic, under a variety of conditions, in doses of one or two grains every two hours. *Edward Curtis.*

RESPIRATION, PHYSIOLOGY OF.—Respiration is the function by which living cells obtain oxygen and get rid of carbonic-acid gas. It is an essential factor in the existence of both animals and plants, being a necessary accompaniment of the chemical processes underlying life. In the higher animals respiration is a very complicated process, consisting of many stages, but in lower forms it is comparatively simple and may be studied to advantage.

COMPARATIVE.—*Protozoa.*—Simple one-celled organisms like the amœba, live in a fluid medium, water, which surrounds them on all sides. From this surrounding medium the dissolved oxygen is absorbed by the general surface of the body, and distributed to all parts by diffusion or by currents set up by the contracting vacuoles, or by some unknown form of cell activity. The carbon dioxide is got rid of by a reverse process. This simple form of respiration is probably very similar to the process by which the cells of the higher animals obtain their supply of oxygen and return their carbon dioxide to the surrounding lymph, constituting the so-called "internal or tissue respiration."

Cœlenterata.—In this group each animal consists of a central cavity surrounded by two layers of cells (see Fig. 4098). Oxygen is taken in to some extent by the external surface, but also by the central body cavity, which serves the double purpose of food absorption and respiration. This prepares us to find the lungs of higher animals having a common embryological origin with the organs of digestion, and suggests the close relationship of the two processes. The currents set up to and from the central cavity by the movements of the body wall and of the tentacles facilitate the respiratory processes by bringing fresh fluid with a new supply of oxygen within reach of the absorbing cells.

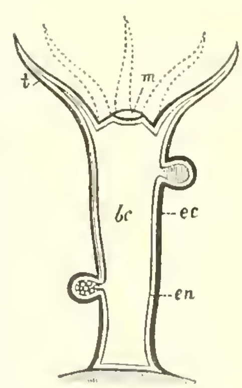

FIG. 4098.—Hydra, diagrammatic, showing Body Cavity *bc*, body wall in two layers *en* and *ec*, tentacles *t*, and mouth *m*. (After Bell.)

Worms.—In this heterogeneous division of the animal kingdom we find a circulating fluid or blood capable of

Digitized by Microsoft®

carrying the oxygen from the surface of the body where it is absorbed, to the cells in the interior which have need of it. In some cases the blood contains a special substance, hæmoglobin, with which the oxygen can enter

www.libtool.com.cn

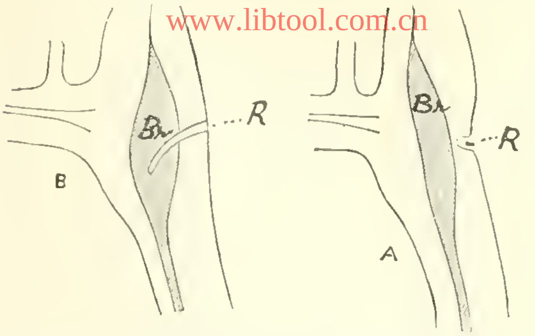

FIG. 4099.—Two Types of Nemertinea showing Rudimentary Respiratory Organs, *R*, Leading in toward the Brain, *Br*. In *A*, *R* is a simple pit and in *B* it is a duct ending blindly among the cells of the brain. (After Bell.)

into loose combination while being carried about. In the worms we find for the first time special organs of respiration. Sometimes these are little more than grooves or pits supplied with cilia to favor the renewal of the oxygen-containing medium. In other cases we find these pits becoming deeper so as to form ciliated ducts (Fig. 4099).

Insects.—In insects we find a system of tubes (tracheæ) adapted for air breathing. These are distributed through the body, and the renewal of the air within them is favored by movements of the legs and wings.

Higher Animals.—As we ascend the scale we find further developments of the organs of respiration, such as to offer the greatest respiratory surface in the smallest possible space. This is seen both in the gills of fishes and the lungs of air-breathing animals. The arrangements for the renewal of the oxygen-containing medium are elaborated and reach their highest development in the bony thorax of the higher vertebrates with their costal and diaphragmatic breathing. The blood-vascular system also becomes better adapted for taking up oxygen and carrying it rapidly all over the body.

The human embryo in its respiratory function, as in other things, passes through many of the stages represented in lower forms. The one-celled ovum, like the amœba, takes in oxygen by its general surface from the fluids which surround it in the uterus. As growth proceeds it develops a blood-vascular system, but for a time continues to take in its oxygen by the general surface of the surrounding membranes. When the placenta is formed, the fœtus has a special organ of respiration, but obtains its supply like a fish from a fluid medium, the mother's blood. At birth the tying of the cord shuts off the placenta, and the consequent deficiency of oxygen stimulates the centre in the medulla to initiate the first respiratory movements. The opening up of the lungs diminishes the pressure in the pulmonary vessels, and thus determines an increased blood supply to these organs. The foramen ovale closes and the adult condition is rapidly established.

THE ORGANS OF RESPIRATION.—These include the *air passages* leading into the lungs from outside and comprising the nose, pharynx, larynx, trachea, and bronchi; the *lungs* which contain the respiratory surfaces (air sacs or alveoli) in which the interchange of gases takes place, the divisions and ramifications of the bronchi leading down to the alveoli, and the supporting connective tissue in which run the blood and lymph vessels and the nerves; the *pleuræ* which cover the lungs and line the thoracic walls with a smooth slippery membrane facilitating movement; the *thoracic walls* which enclose the lungs and which are strong enough to protect them and yet mobile enough to be the medium through which the expansion of the lungs is effected; the *muscles of respiration*, including the diaphragm and the muscles acting upon the ribs; the *nervous mechanism* through which all the respiratory processes are initiated and regulated.

The *nose* serves a useful purpose in warming the inspired air and thus protecting the other air passages from too sudden changes of temperature. The *larynx* is especially concerned in speech and voice production. It also plays an important part in preventing dust particles and noxious gases from entering the lungs by the cough and spasm which these substances excite when they come in contact with its mucous membrane. The *trachea* and *bronchi* consist of tubes of fibrous and elastic tissue supported at regular intervals by incomplete rings of cartilage. The portion behind, where the cartilage is absent, is supplied with plain muscle tissue by which the tubes can be somewhat constricted. The mucous membrane consists of loose lymphoid tissue. It is supplied with mucous glands, which keep the surface moist, and is lined with ciliated columnar epithelium. The cilia carry the mucous secretion and inhaled dust particles up toward the larynx. The *lungs.* As the bronchi enter the lungs they divide and subdivide, forming the bronchial tubes, to the smallest of which the name bronchioles is applied. The structure of the trachea and bronchi is continued into the bronchial tubes with certain modifications. The cartilaginous rings are replaced by irregular plates of cartilage distributed at intervals around the tubes, and even these are not found in the very smallest bronchioles. The unstriped muscle becomes relatively more abundant as the size of the tubes diminishes and it forms a continuous layer of circular fibres. The epithelium changes from columnar to cubical, and in the smallest tubes mucous glands are not found. The lungs may be seen to be divided into innumerable tiny sections known as lobules, of which each has a diameter of 1–3 cm. They are of pyramidal shape, and are divided from one another by a little fibrous tissue. A bronchial tube entering such a lobule divides several times, forming tiny bronchioles. If we follow the bronchiole along we will find the epithelium changing from cubical to pavement, and we will see an occasional air sac or alveolus opening out from the side. These tubes supplied with alveoli are known as respiratory bronchioles. Each respiratory bronchiole ends in a dilated passage called an alveolar duct, into which open a number of infundibula. An infundibulum is a cone-shaped expansion with the apex toward the duct. Extending out from it are numerous hemispherical expansions known as air sacs or alveoli which very greatly increase the total surface (see Fig. 4100).

The wall of an infundibulum consists of a thin basement membrane lined by epithelium, the so-called "respiratory epithelium." The cells composing this epithelium are of two kinds: non-nucleated platelets resting upon the blood capillaries and smaller nucleated cells between. Around the infundibula is spread out a network of capillaries so dense that the meshes are narrower than the vessels themselves. Between the air in the air sacs and the blood in the capillaries nothing intervenes but the two layers of epithelium belonging to the alveoli and the capillaries respectively. In some cases the capillary may be in contact with the epithelium of two contiguous alveoli (see Fig. 4101).

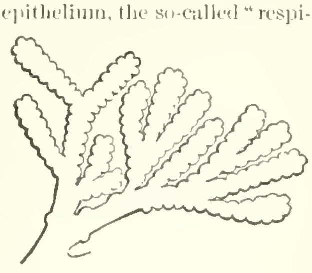

FIG. 4100.—Diagrammatic Representation of the Ending of a Bronchial Tube in Sacculated Infundibula. (After Schaefer.)

The capillaries distributed to the air sacs are from branches of the pulmonary artery. The walls of the bronchial tubes and the connective tissue of the lungs are supplied by the bronchial arteries belonging to the systemic circulation. The connective tissue which inter-

Digitized by Microsoft®

venes everywhere between the infundibula and under the pleura is rich in elastic tissue. The nerves of the lung come from the anterior and posterior pulmonary plexuses, which are formed by branches from the pneumogastric and sympathetic. The sympathetic fibres come off from the inferior cervical ganglion, annulus of Vieussens and stellate ganglion, and can be traced back to the upper thoracic nerves. See also *Nasal Cavities, Larynx*, etc.

www.ibtool.com.cn

Physical Relations of the Lungs to the Chest Wall and the External Atmosphere.—Before birth the lungs are solid organs; that is to say, the opposite walls of the alveoli and bronchial tubes are in contact, and form merely potential spaces communicating through the respiratory passages with the outside. At birth the thoracic cavity is enlarged by the action of the muscles of respiration. The additional space which results must be filled up as it is formed, for "nature abhors a vacuum." The only avenue through which anything can enter the thorax to fill it is through the respiratory passages, and so air enters, expanding the lungs and keeping them in contact with the receding chest wall. Throughout life the lungs continue to follow the movements of the chest wall. If the chest is enlarged, air enters the lungs, expanding them sufficiently to fill it up. In doing this the air has to overcome the elasticity of the lungs. During rest the air exerts upon the inside of the lungs the same pressure as upon the external surface of the body, 760 mm. of mercury or fifteen pounds to the square inch. When the chest is suddenly expanded, as in inspiration, the air within the lungs is rarefied and the pressure within the lungs, *the intrapulmonary pressure*, is diminished. During expiration the thorax diminishes in size, compressing the air in the lungs, and the intrapulmonary pressure rises. In either case movement of air in or out of the lungs takes place till the intrapulmonary pressure is again equal to atmospheric when equilibrium is established.

The pressure in the pleural cavity and in the mediastinum is known as the *intrathoracic pressure*. It is always less than atmospheric because the elasticity of the lungs tends to pull them away from the chest wall, and protects the latter from part of the intrapulmonary pressure. The more the chest is expanded the more is the elasticity of the lungs brought into play, and the more does intrathoracic pressure fall below atmospheric. The intrathoracic pressure is often spoken of as *negative*, meaning that it is less than atmospheric. The fact that it is so may be seen when an opening is made in the chest, as in this case air is drawn into the pleural sac and the lungs collapse. During ordinary breathing intrathoracic pressure varies from 758 to 752 mm. of mercury, which is 2–10 mm. below atmospheric. This is expressed by saying that there is a negative intrathoracic pressure of 2–10 mm. During forced inspiration, when the lungs are very much on the stretch, there may be a negative intrathoracic pressure of 30 or 40 mm.

Renewal of the Air in the Alveoli is effected by the movements of respiration supplemented by diffusion. The respiratory movements are primarily movements of the thoracic walls, which lead to changes in the capacity of the thorax and indirectly to expansion and contraction of the lungs. The size of the thorax can be increased or diminished in three directions—vertical, antero-posterior, and transverse. The vertical diameter can be increased by the descent of the arched diaphragm and by the backward and downward movement of the lower ribs. It can be diminished by the passive return of the diaphragm to its arched position of rest, assisted by the contraction of the abdominal muscles, which force the viscera up against the diaphragm and increase its arch.

The antero-posterior diameter is increased by the raising of the ribs from the resting position, in which they slant downward, to one in which they extend more directly forward, carrying the sternum with them. In quiet breathing the upper end of the sternum acts as a fulcrum and the lower end is pushed out; but in very deep inspiration the upper end is also raised and extended forward. The antero-posterior diameter is diminished by the thorax returning to a position of rest as a result of gravity and elastic recoil.

The transverse diameter is increased by the outward and upward rotation of the ribs. Any tendency of the contracting diaphragm to draw in the lower ribs is overcome by the fact that the abdominal viscera are compressed by its descent and tend to press the ribs outward.

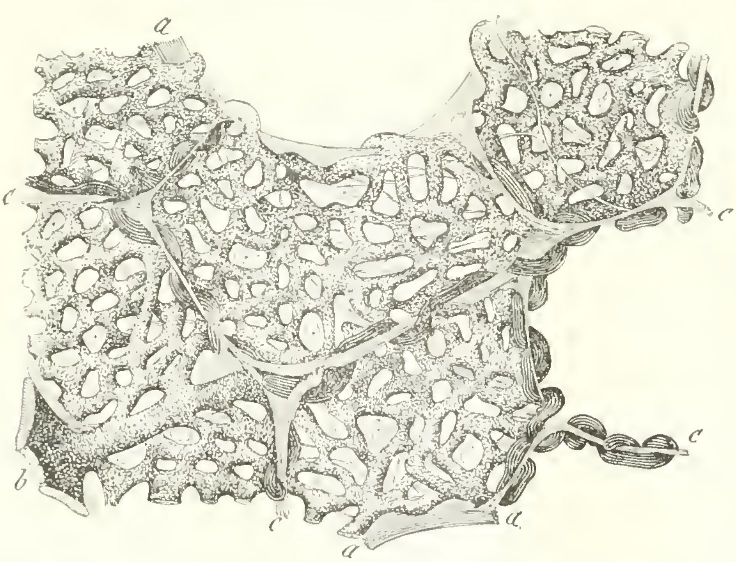

Fig. 4101.—Section of Injected Lung, Including Several Contiguous Alveoli. (F. E. Schultze.) (Highly magnified.) *a*, *a*, Free edges of alveoli; *c*, *c*, partitions between neighboring alveoli, seen in section; *b*, small arterial branch giving off capillaries to the alveoli. The looping of the vessels to either side of the partitions is well exhibited. Between the capillaries is seen the homogeneous alveolar wall with nuclei of connective-tissue corpuscles and elastic fibres. (Schaefer.)

Muscles of Respiration.—In ordinary inspiration the vertical diameter is increased by the descent of the *diaphragm*, assisted by the *quadratus lumborum* and *serrati postici inferiores*, which fix the lower ribs. The antero-posterior and transverse diameters are increased by the *scaleni*, *levatores costarum*, and *serrati postici superiores*, which fix the two upper ribs and assist the elevation and eversion of the others, and by the *external intercostals* which raise the lower ribs. Both the *external and internal intercostals* by their contraction give strength to the intercostal spaces and enable them to withstand the atmospheric pressure. Expiration is largely passive, being brought about by the influence of gravity and the elastic recoil of the thorax, and by the relaxation of the diaphragm which allows it to be forced up again by the pressure of the abdominal viscera. Some claim that the descent of the ribs is assisted by the contraction of the interosseous portion of the *internal intercostals*.

In forced inspiration a great number of additional muscles are called into play, first those having attachments to the ribs or sternum, and later a very great number which indirectly assist the enlargement of the chest or the opening up of the respiratory passages. Forced expiration is assisted by the action of the abdominal muscles, which press on the viscera and so push up the diaphragm, and also by those muscles

Digitized by Microsoft®

of the abdomen and back which pull down the lower ribs.

Types of Respiration.—An infant breathes mostly with its diaphragm. Such breathing is spoken of as the *diaphragmatic* or *abdominal type.* In adults we find a

www.libtool.com.cn

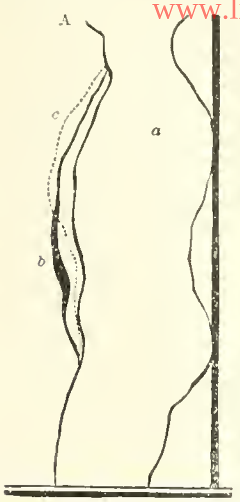

Fig. 4102.—*A*, Inferior Costal and *B*, superior Costal Type of Breathing. *a*, *a*, Outline of body in forced expiration; *b*, *b*, heavy continuous line. The outer margin indicates the contour of the body in ordinary inspiration and the inner margin that of ordinary expiration. The relative thickness of this line in the two sexes shows that in the male the greater movement takes place in the abdomen and lower thorax (inferior costal) and in the female in the upper thorax (superior costal). *c*, *c*, Contour of forced inspiration. Note that forced inspiration is of the superior costal type in both sexes. (After Hutchinson.)

difference in the manner of breathing between the male and female. In the male the movements of the abdomen and lower part of the thorax are more pronounced, forming the so-called *inferior costal type*, while in the female movements of the upper chest predominate, and we speak of the *superior costal type*. This difference in the sexes is not found in all races, and so is ascribed by some to the influence of dress, but others see in it an adaptation of woman for her sexual life, pregnancy, through natural selection (see Fig. 4102).

The Quantity of Air Breathed.—During ordinary quiet breathing about 300 c.c. of air is taken into the lungs with each inspiration and expelled with each expiration. This is called the *tidal air*. By a forced inspiration an additional quantity, known as the *complemental air*, may be taken in. Its volume is about 1,700 c.c. The air that can be expelled by an effort after an ordinary expiration is the *supplemental air*, and measures about 1,500 c.c. The air remaining in the chest after the most powerful expiration is the *residual air*, amounting to about 1,000 c.c. The total quantity that can be taken in after a complete expiration or breathed out after the fullest inspiration is called the *vital capacity*, and includes the complemental, tidal, and supplemental air. It measures therefore in a typical case about 3,500 c.c. *Lung capacity* is the total quantity of air in the lungs after a forced inspiration, and is equal to the vital capacity plus the residual air, or about 4,500 c.c. All these quantities naturally vary very much in different individuals and under different conditions, but the above numbers may be taken as more or less typical.

The quantity of air breathed in any given case can be estimated by means of an instrument known as a spirometer (see Fig. 4103).

The Changes that Take Place in the Air.—In the lungs certain things are taken from the air and others added, as shown in the following table, in which the quantities are given in volumes per cent.:

	Inspired air.	Expired air.
Nitrogen	79	79
Oxygen	20.96	16.03
Carbonic acid	.04	4.4
Aqueous vapor	Variable.	Saturated.
Argon, etc.	Traces.	Traces.

It is to be noted that the volume of oxygen lost, 4.93, is slightly greater than the volume of CO_2 added, 4.36, so that the total volume of the expired air is slightly less than that of the inspired air.

The expired air is warmed to the temperature of the body and is also fouled by organic emanations given off from the lungs and respiratory passages. The principles on which the analysis of expired air is carried out may be conveniently studied in the apparatus designed by Waller, which is one of the simplest and yet sufficiently accurate for most purposes (see Fig. 4104).

In other methods the carbon dioxide is absorbed by soda lime or by baryta water instead of by sodium hydrate, and arrangements may be made for passing the air through a chamber containing sulphuric acid for the arrest and estimation of the aqueous vapor.

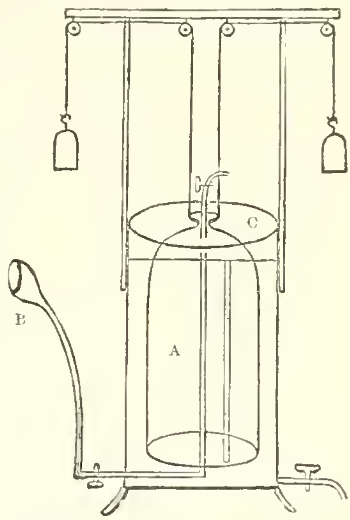

Fig. 4103.—Diagram of Hutchinson's Spirometer. (Landois.) *A*, Graduated cylinder serving as a receiver for the breath; it is supplied with a stopcock at the top for the ready expulsion of air, and is balanced by weights passing over pulleys. *B*, Mouthpiece with tube reaching nearly to the top of the graduated receiver (*A*), when the latter is sunk in the reservoir ready for an experiment; there is a stopcock in this tube near the first angle to prevent regurgitation of air. *C*, Reservoir for the graduated receiver. In using the spirometer the reservoir and graduated receiver are filled with water, or, to prevent the absorption of carbon dioxide, with a saturated aqueous solution of common salt (NaCl). When ready for an experiment, the stopcock at the top of the receiver is closed and that in the tube of the mouthpiece opened, and the breath forced into the receiver. The receiver rises as fast as the breath displaces the water. After the breath is forced into the receiver the stopcock in the tube of the mouthpiece is closed, and the water outside and inside the receiver brought to the same level, so that the air within the receiver shall be at the atmospheric pressure. The amount of breath within the receiver is then read directly from the scale attached to the receiver. For accurate measurement the breath should stand a few minutes to acquire the temperature of the liquid over which it is collected, then the various corrections for aqueous vapor tension, and the variations from the standard temperature and pressure, should be made.

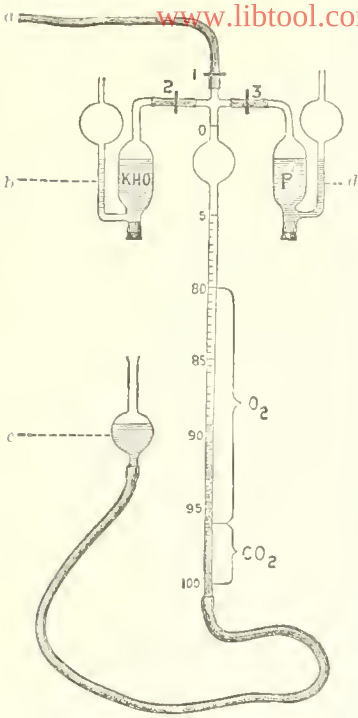
Respiratory Quotient or Respiratory Coefficient.—As is shown in the table given above, the volume of oxygen absorbed is greater than the volume of carbon dioxide excreted. The relation of one to the other is expressed as $\frac{CO_2}{O_2}$ and is known as the respiratory quotient. If all the oxygen taken into the body reappeared in the expired air as CO_2, the volumes would be equal and the respiratory quotient $\frac{CO_2}{O_2}$ would be 1. Some of the oxygen, however, combines with hydrogen to form water, and is excreted as aqueous vapor by the lungs, or as water by the skin and kidneys, and thus does not leave the body as CO_2 at all, but as H_2O. The respiratory quotient varies with the relative proportions of carbon, hydrogen, and oxygen in the food. Carbohydrates contain in themselves just enough oxygen to sat-

Digitized by Microsoft®

isfy all the hydrogen present, so that only the oxidation of the carbon has to be provided for by the oxygen taken in by the lungs. Thus the presence of a large amount of carbohydrate in the diet tends to make the respiratory quotient approach 1. Fats and proteids, on the other hand, contain a relative excess of hydrogen, and require oxygen for combination with it, so that the CO_2 excreted represents only part of the oxygen absorbed and the respiratory quotient falls below 1.



www.libtool.com.cn

Fig. 4104.—Estimation of O_2 and of CO_2 in Expired Air. (Waller.) A 100 c.c. measuring tube graduated in tenths of 1 c.c. between 75 and 100. A filling bulb. Two gas pipettes. The measuring tube communicates by three tubes guarded by simple taps 1, 2, 3, with the inlet and with the gas pipettes. It is first charged with acidulated water up to the zero mark by raising the filling bulb, tap 1 being open; it is then filled with 100 c.c. of expired air, the filling bulb being lowered until the fluid in the burette has fallen to the 100 mark. Tap 1 is now closed, the measuring tube containing 100 c.c. of expired air with unknown quantities of CO_2 and of O_2. The amount of CO_2 is ascertained as follows: Tap 2 being opened, the air is expelled into a gas pipette containing KHO by raising the filling bulb until the fluid has risen to the zero mark of the measuring tube. Tap 2 is now closed, and the air left in the gas pipette for about a minute, during which the CO_2 present is entirely absorbed. The air is then drawn back into the measuring tube by lowering the filling bulb while tap 2 is open. The volume of air (minus the CO_2, which is being absorbed) is read, the filling bulb being adjusted so that its contents are at the same level as the fluid in the burette. The amount of O_2 is next ascertained in a precisely similar manner by sending the air into a second gas pipette containing sticks of phosphorus in water, and measuring the loss of volume (due to absorption of O_2) in the air when drawn back into the tube. A gas pipette works thus: fluid in its lower half is displaced into its upper half, when air is driven in from the measuring tube, and returns to its original place, when air is drawn back. If desired, the apparatus can be connected with a vessel in which a frog or mouse or excised muscle has been placed and the consequent alterations of the gases O_2 and CO_2 measured in a similar manner. *a*, Inlet or outlet; *b*, gas pipette for absorption of CO_2; *c*, filling bulb; *d*, gas pipette for absorption of O_2.

Temporary variations in the respiratory quotient may be due on the one hand to oxygen being absorbed in excess and stored up as tissue oxygen, or on the other hand to tissue oxygen taken in long before being made use of for oxidizing some of the carbon. The former tends to lower the respiratory quotient and is seen during rest; the latter raises it and is seen in conditions of activity and quickened metabolism.

Ventilation.—The withdrawal of oxygen from the air and the addition of CO_2 and organic matters that takes place during respiration renders it vitiated or unfit to be breathed again. When a room has been breathed in until the amount of CO_2 has risen to 0.07 volume per cent., the air becomes more or less stuffy, although in very badly ventilated rooms the proportion may reach ten times this figure. The closeness or stuffiness is due principally to the organic emanations, of which some are of an odorous nature. This is shown by the fact that much larger quantities of CO_2 can be added to the air of a room in other ways without causing any inconvenience to the inmates. Air containing even as much as twenty-five per cent. of CO_2 can be breathed safely for a short time if there are no other impurities in it, and if it contain plenty of oxygen. An ordinary individual requires about 2,000 cubic feet of air per hour if the proportion of CO_2 is not to rise above 0.07 volume per cent. This may be supplied by allotting 1,000 cubic feet of space to each individual, and providing ventilating arrangements for renewing the air twice every hour. The smaller the space allotted to each individual the more frequently must the air be changed by ventilation.

The following table may be useful for ready reference on some of the points discussed above, although the exact numbers vary very much in different people. The proportions given in cubic centimetres and litres are somewhat less than those usually given, but are probably more correct than the larger quantities given in inches and feet.

Amount of	One Breath.		Twenty-Four Hours.	
	Cu. in.	C.c.	Cu. ft.	Litres.
Air breathed	30	300	350	7,000
Oxygen absorbed	1.5	15	17.5	350
CO_2 excreted	1.3	13	15	300
Air rendered close (Proportion of CO_2 raised to 0.07 volume per cent.)	5,000	50,000	50,000	1,000,000

The Blood and Its Gases.—While the air on one side of the respiratory epithelium is being constantly changed by the movements of the chest and by diffusion, the blood on the other side is being changed by virtue of the circulation. The blood is brought in a venous condition by the pulmonary artery and its branches, and is carried away in an arterial condition by the pulmonary veins. The gases of the blood are the same qualitatively as those of the atmosphere, but are not present in the same proportions. The proportions naturally vary somewhat, but the following are approximate in volumes per cent. of blood:

Blood.	O.	CO_2.	N.
Arterial	20	40	1-2
Venous	10	46	1-2

In considering the nature of the connection between the blood and its gases it is necessary for us to keep in mind the various constituents of blood and their power of taking in gases. The *plasma* may for our present purpose be considered as made up of water, salts, and proteids. *Water* is capable of holding a certain quantity of gas in solution, the exact amount depending on the nature and tension of the gases surrounding it, and on the temperature. If water be exposed to a mixture of gases it will absorb and hold in solution a quantity of each, which will depend on the quantity of that particular gas in the mixture. Each gas present in a mixture exists at a certain tension, and exerts what is called a *partial pressure*. This partial pressure is not affected by the amount of any other gas that may be present. Thus if a jar were half full of water and the rest of it occupied by air, the water would take up from the air a certain amount of nitrogen and a certain amount of oxygen. If now pure nitrogen were pumped into the jar without allowing any of the air already there to escape, the tension or partial pressure of the nitrogen in it would be increased and the water would take a proportionately larger amount into solution. The tension or partial pressure of the oxygen would remain, however, what it was before, and the water would not absorb any more. If now pure oxygen were pumped in, the partial pressure of oxygen in the jar would be increased and the water would take a proportionately larger amount of this gas into solution.

The nitrogen of the blood is held chiefly in simple solu

Digitized by Microsoft®

tion in the water of the plasma. The oxygen and carbon dioxide, however, are present in much larger proportions than water could take into solution at the tension or partial pressure of these gases prevailing in either the lungs or the tissues. These gases must therefore be attached to the other constituents of the plasma or to the corpuscles. *The salts of plasma* include among others considerable quantities of sodium carbonate. This salt is capable of combining with carbonic acid gas to form sodium bicarbonate. There is reason to believe that the carbonic acid is principally held in the blood in this chemical combination. Sodium phosphate, another constituent of the plasma, may combine with carbonic acid too, forming sodium bicarbonate and sodium biphosphate. *The proteids* of the plasma, especially the globulins, are also claimed to have some power of combining with carbonic acid gas. *The corpuscles*, both red and white, may similarly carry a certain amount of CO_2 in combination with their salts and proteids.

www.libtool.com.cn

The chief interest of the corpuscles for respiratory purposes, however, is connected with the colored proteid hæmoglobin of the red corpuscles.

Hæmoglobin makes up about ninety per cent. of the solids of the red corpuscles. It is a substance possessing a remarkable property of forming loose chemical combinations with various gases. As it exists in the blood it is combined with oxygen to form oxyhæmoglobin. One molecule of hæmoglobin can combine with one molecule of oxygen or 1 gm. of hæmoglobin can attach to itself 1.34 c.c. of oxygen. In arterial blood the hæmoglobin is nearly saturated with oxygen, and in venous blood it still has some oxygen associated with it. Oxygen-free hæmoglobin or reduced hæmoglobin is not usually present in the body, but can be demonstrated in parts where the circulation has been stopped for from forty to three hundred seconds (Vierordt).

There are a number of compounds and derivatives of hæmoglobin which can be most readily distinguished by the absorption bands in their spectra. In the article on *Blood* in another volume of this HANDBOOK, they are described in some detail, and their spectra are figured.

Oxyhæmoglobin is the bright red substance which gives the color to arterial blood. In this compound the oxygen is present in a very loose chemical combination, and may be readily taken up by the tissues of the body or by reducing agents.

Methæmoglobin is a brown substance formed by the action of oxidizing agents on oxyhæmoglobin. It is found in the blood in cases of poisoning by chlorate of potash and similar substances. Methæmoglobin is of no use for respiratory purposes, as the oxygen is too firmly united to be abstracted by the tissues, although it is readily taken up by strong reducing agents, such as ammonium sulphide, with the formation of hæmoglobin (reduced).

Carbonic-Oxide Hæmoglobin.—If illuminating gas be inhaled the carbonic oxide which it contains unites with the hæmoglobin of the blood in place of the oxygen by virtue of the fact that CO possesses the stronger affinity of the two for hæmoglobin. This quite destroys the oxygen-carrying properties of the blood and results in death.

Other gases, such as NO, H_2S, etc., may also destroy the oxygen-carrying power of the blood by replacing the oxygen, or by otherwise changing the hæmoglobin molecule.

Hæmatin.—Hæmoglobin may be decomposed under the action of heat and acid or alkali into two parts, a proteid of unknown nature, usually referred to as globin, and a brown coloring matter rich in iron and designated hæmatin.

Hæmochromogen, or reduced alkaline hæmatin, may be formed by the action of reducing agents on hæmatin, or by breaking up hæmoglobin in the absence of oxygen. Hæmochromogen has the same power of uniting with gases as hæmoglobin has, and in fact has been shown to be able to attach to itself the same quantity (of CO) as the corresponding amount of hæmoglobin. Hoppe-Seyler taught that hæmochromogen existed as such in hæmoglobin, and lent it its gas-carrying property. This is disputed, however, by Gamgee (Schaefer's "Textbook").

The proteid part of the hæmoglobin molecule is believed by many to be of the nature of a globulin. It is probable that the small quantity of CO_2 that can be carried by hæmoglobin is attached to this proteid part.

The Mercurial Pump.—The gases of the blood are obtained for analysis by subjecting the blood to the vacuum of a mercurial pump. One of the simplest and best is that of Leonard Hill (see Fig. 4105).

A is a reservoir filled with mercury which may be raised or lowered. By raising it and manipulating the various taps the whole apparatus is filled with mercury. By lowering it the blood chamber *F* is made a vacuum. *F* is separated from the apparatus, weighed, and partly filled with blood. It is then reattached and the gases are drawn off from the blood into the reservoir *B*. By raising and lowering *A* repeatedly with manipulation of the taps, the gases are all drawn off from the blood in *F* into the reservoir *B* and then forced over into the eudiometer tube *H*, where they are collected over mercury and measured. The amount of CO_2 is measured by inserting potassium hydrate which takes up the CO_2 to form a carbonate. The diminution which takes place in the total volume of gas is the amount of CO_2 which was present. The amount of oxygen can similarly be measured by using a solution of pyrogallic acid, which unites with it. The gas remaining unabsorbed is nitrogen.

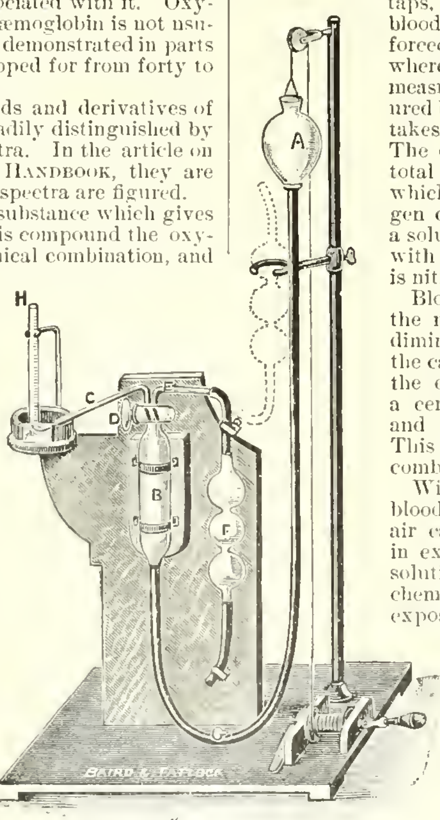


FIG. 4105.—Hill's Mercurial Gas Pump.

Blood does not give off its oxygen in the mercurial pump in proportion to the diminution in the pressure as would be the case if it were in simple solution. On the contrary, very little comes off until a certain degree of vacuum is reached, and then large quantities are given off. This points to its being in loose chemical combination.

With regard to the CO_2, the fact that blood even when exposed freely to the air can retain an amount of CO_2 greatly in excess of what it could hold in simple solution proves that this gas too exists in chemical combination. Now if plasma be exposed to the mercury pump and the pressure sufficiently lowered, much of the CO_2 is given off, and must therefore be quite loosely combined. Another portion is not given off without the addition of an acid or hæmoglobin (red corpuscles), which seem able to liberate it from some more stable compound.

The nitrogen is given off in proportion to the diminution in the pressure, and the view generally held is that it is in simple solution in the plasma.

THE INTERCHANGE OF GASES BETWEEN THE BLOOD AND AIR.—Here we find ourselves face to face with the fundamental question of the relation of epithelial cells to the processes taking place through them. Does the

Digitized by Microsoft®

interchange of gases between the blood on the one side of the respiratory epithelium and the alveolar air on the other side take place by a mere process of diffusion, or does the functional activity of the epithelial cells exert some controlling or modifying influence? Our answer to this question must be determined by a consideration of what we know of the properties of epithelium elsewhere, and by the possibility of explaining the interchange on a purely physical basis.

There is an increasing tendency to attribute more importance to lining epithelium in the absorption and secretion of liquids and solids. This is seen in the change that has recently taken place in the teaching of the text-books with regard to intestinal absorption and the process of secretion. The fact that epithelium may also play an active part in the secretion of gases has been amply demonstrated by a number of investigators in connection with the secretion of gases in the swim bladder of fishes. Bohr has shown that this process is under nervous control.

With regard to the possibility of explaining the interchange of gases in the mammalian lung on a purely physical basis, it might be explained by the laws of simple diffusion and osmosis if the partial pressures on the two sides of the epithelium were always such as to favor the exchange that takes place. This question has been investigated as follows: First air is drawn off from the alveoli by one of the instruments devised for the purpose, of which *Pflüger's lung catheter* is the best known. Then this air is analyzed and the partial pressure of each gas in the alveoli can be calculated. Next the partial pressures of the gases in arterial and venous blood are estimated by some form of *aerotonometer* or *hæmataerometer*, and a comparison of the results obtained from the alveolar air and the arterial and venous blood in any given case will show whether the partial pressures are favorable to the interchange or not. The principle of the *aerotonometer* is as follows: It is an apparatus in which blood is brought into close relation with two gaseous mixtures, in one of which the CO_2 tension is above, while in the other it is below the anticipated tension of the blood. As blood flows through the apparatus an interchange of gases takes place between it and the gaseous mixtures contained. By analyzing the latter before and after, the tension of gases in the blood can be approximately determined.

Fredericq gives the following as a typical result of such an investigation in a dog:

	External air.		Alveoli.		Arterial blood.		Tissues.
Tension of oxygen..	20.95	>	18	>	14	>	0
	External air.		Alveoli.		Venous blood.		Tissues.
Tension of carbon dioxide..........	.03	<	2.8	<	3.81-5.4	<	5-9

In this case the tensions or partial pressures of the gases are such that oxygen would tend by mere diffusion to pass in from the air to the blood and CO_2 in the reverse direction.

Other workers, however, notably Bohr, and Haldane and Lorraine Smith, employing somewhat different methods, have obtained results which seem to show that oxygen may be taken in and CO_2 excreted even when the partial pressures are such as to oppose the process. If these experiments are reliable, as seems probable, we must look to some active secretory power of the respiratory epithelium for the explanation.

Dr. Wesley Mills has maintained this view for many years, and his text-book, published in 1889, was one of the first to recognize it in the following terms: "The view expressed by some physiologists to the effect that diffusion explains the whole matter so far at least as carbonic anhydride is concerned, and that the epithelial cells of the lung have no share in the respiratory process, does not seem to be in harmony either with the facts of respiration, or with the laws of biology in general."

The Seat of the Oxidation which Occurs in the Body.—At the beginning of the last century physiologists were divided in opinion as to the principal seat of oxidative processes in the body. Some, who followed Black, believed that these processes took place exclusively in the lungs, while others, led by Le Grange, regarded the blood as the seat of these changes. During the past fifty years Pflüger and others have shown that neither of the old views was correct, but that oxidation is continually taking place in all the tissues, and that it varies to a great extent with their functional activity. It has been shown, moreover, that the taking up of oxygen and giving off of CO_2 do not necessarily run parallel, but that the former may be stored up in excess during rest as tissue oxygen, and may remain in some more or less stable combination until a time of functional activity, when a dissolution of the molecule occurs with the setting free of CO_2. Some of the facts on which these views are founded are the following: If the blood of a frog be replaced by saline solution, the animal may live for hours or days, and continue to take up oxygen and excrete CO_2 (Oertman). Bleeding, although diminishing the quantity of blood in the body, has no effect on the amount of gaseous interchange (Pembrey and Gürber). If a muscle be made to contract *in vacuo*, it will give off CO_2, derived from its tissue oxygen, in sufficient quantity to be determined (Hermann). If a solution of fresh blood be supplied to a frog's heart, the oxyhæmoglobin will be reduced more quickly during activity than during rest (Yeo).

"The avidity of the different tissues for oxygen varies greatly, and the differences are doubtless expressions, broadly speaking, of the relative intensities of their respiratory processes" (Reichert).

Quinquaud records the following absorption capacities for 100 gm. of different tissues submitted for three hours to a temperature of 38° C.:

	C.c.		C.c.
Muscle	23	Spleen	8.0
Heart	21	Lungs	7.2
Brain	12	Adipose tissue	6.0
Liver	10	Bone	5.0
Kidney	10	Blood	0.8

Internal or Tissue Respiration is the term applied to the interchange of gases between the blood and the tissues. The partial pressures of the gases in the tissues, lymph, and blood are said to be such as to favor the taking up of oxygen by the tissues, and the giving off of CO_2 in accordance with well-known physical laws, but this fact does not necessarily exclude some participation of the endothelial and tissue cells in the process.

Graphic Record of Respiratory Movements.—Innumerable devices have been employed for this purpose. Some, either because they require a cutting operation or

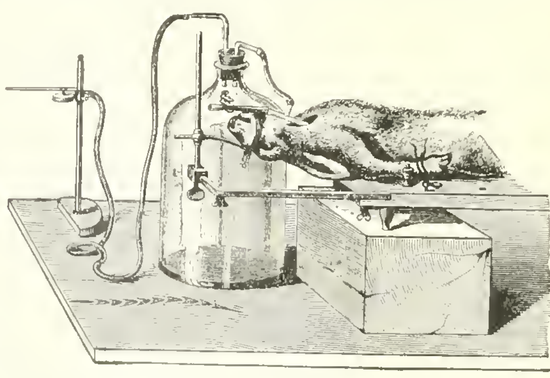

FIG. 4106.—Arrangement of Tracheal Cannula and Marey's Tambour for Recording Changes in Intrapulmonary Pressure. (Langendorff.)

for other reasons, are employed only on animals; and others may be used clinically on man. To the former category belong the *phrenograph*, by which the movements of the diaphragm are recorded by the use of a lever or rubber bag passed up between the liver and dia-

phragm and connected with a recording lever; various forms of sounds and cannulas, which can be passed into the pleural cavity or the œsophagus and connected with a recording tambour to register the variations in intrathoracic pressure; a tracheal cannula or a nose cap from either of which the volume of air breathed can be recorded

www.libtool.com.cn

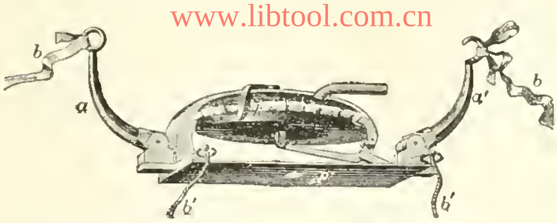

Fig. 4107.—Receiving Tambour of Marey's Pneumograph, New Form. (Langendorff.) *b, b*, Belt to go around chest; *b', b'*, strings to suspend the instrument from the neck.

by the *aërophthysmograph* of Gad, or the changes in intrapulmonary pressure can be registered by a Marey's tambour. In either case it is usual to have an air chamber between the animal and the recording apparatus, so that the same air will not be breathed over and over again (see Fig. 4106).

Among the methods which may be employed in man are the *pneumograph* or *stethograph*, in which a belt surrounding the chest is attached to some form of receiving tambour from which a rubber tube leads off to a recording tambour, and indicates the changes in the girth of the thorax (see Fig. 4107). In the *stethometer* of Burdon Sanderson the changes in the antero-posterior diameter of the chest are recorded.

Perhaps the simplest method of all is to connect a recording tambour through a piece of rubber tubing with a small funnel, and to press the latter into the episternal notch. A fair record of the respiration may be obtained in this way.

The curves obtained in these various ways differ in their details, but the tracing shown in Fig. 4108, and obtained with Marey's pneumograph, may be taken as a type.

As the figure shows, inspiration begins somewhat suddenly and advances rapidly, being followed immediately by expiration, which is carried out at first rapidly, but afterward more and more slowly.

Nervous Mechanism of Respiration.—The muscles of respiration act rhythmically under the influence of nervous impulses, which originate in the medulla oblongata and pass out by the motor nerves. The respiratory centre in the medulla sends out these impulses as the result of a constant stimulus imparted to it by the blood. The explanation of the rhythmic action of the centre under the constant stimulus of the blood is to be sought for in the fundamental properties of protoplasm. The action of the centre is modified by impulses reaching it by afferent nerves, of which some are constantly in operation and others only act occasionally.

The Respiratory Centre.—All the brain above the medulla may be removed without serious interference with the breathing. If the spinal cord be separated from the medulla all respiratory movements of the trunk cease, but some of the facial muscles, still in connection with the medulla through the cranial nerves, continue to exhibit movements of a respiratory character. Injury of the medulla in the lower part of the floor of the fourth ventricle (calamus scriptorius) is sufficient to cause cessation of respiration and death, all the rest of the nervous system being intact. These facts suffice to localize the respiratory centre in the floor of the fourth ventricle, but the exact nerve cells which constitute it cannot be pointed out. From the fact that cessation of respiration has followed injury to different parts in the hands of different investigators, the respiratory centre is probably made up of several separate groups of cells or nerve nuclei and bundles of connecting fibres.

If the medulla be carefully divided in the median line respiration continues; and if the pneumogastric nerve on one side be divided, the movements on that side will become slower than on the other, and we may have the two halves of the diaphragm contracting independently, each with its own rhythm. This shows that the respiratory centre consist of two halves, each more or less complete in itself. Normally, however, they act in harmony, being co-ordinated through commissural fibres, which cross the median line from one side to the other.

From the fact that certain influences affect especially inspiration and others expiration, it seems logical to assume that the respiratory centre is physiologically divided into an inspiratory and an expiratory centre, but we cannot separate these anatomically at present.

Subsidiary Centres.—Stimulation of various parts of the brain gives rise to modification of the respiratory movements. This fact has led to a number of structures, among which are parts of the cerebral cortex, the tuber cinereum, the optic thalamus, the pons Varolii, and the anterior and posterior corpora quadrigemina, being dignified with the name of "*subsidiary respiratory centres.*" As will be shown later, a tonic inhibitory influence seems to be exerted on the respiratory centre by the posterior corpora quadrigemina, but the other structures named are probably mere stations through which afferent impulses from the various sensory nerves may affect the respiratory centre in the medulla. Brown-Séquard, Langendorff, Wertheimer, and others lay great stress on the fact that after separation of the spinal cord from the medulla in young animals a kind of respiration is carried on by the cord alone. It is very different in its character, however, from normal breathing, being "rapid and irregular" (Wertheimer), and in many cases it does not occur at all. One, therefore, feels disposed to look upon these so-called spinal centres for respiration as rather coordinating centres for the respiratory muscles, which usually perform their functions under the control of the respiratory centre in the medulla. In some cases they seem to have retained a vestige of their original protoplasmic power of rhythmic activity.

The Influence of the Blood on the Respiratory Centre.—If the amount of oxygen in the blood be diminished or the proportion of carbonic oxide become higher, there follows increased activity of the respiratory centre. The respirations become deeper and often quicker, constituting the condition known as *hyperpnœa*. If the change in the blood be greater the respiratory movements become still more pronounced, additional muscles are called into play, and expiration, which is normally largely passive, becomes an active muscular act like inspiration; this condition is known as *dyspnœa*. Dyspnœa may pass into the condition known as *asphyxia*. The form of asphyxia caused by occlusion of the trachea and deprivation of oxygen is characterized by convulsions, followed by exhaustion and death. In asphyxia due to breathing an atmosphere in which carbonic acid gas is in excess, but where oxygen is not greatly deficient, the animal passes from dyspnœa into a state of stupor, and dies without passing through the stage of convulsions. The condition of the blood affects the centre directly, and not through

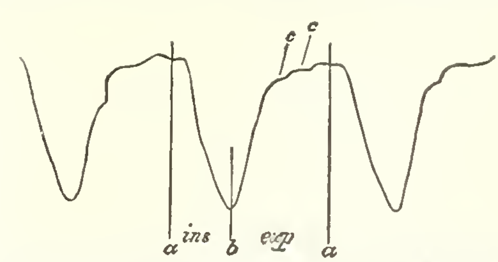

Fig. 4108.—Tracing of Thoracic Respiratory Movements obtained by means of Marey's Pneumograph. (Foster.) the afferent nerves, as is shown by the so-called "cross circulation" experiment. In this experiment the neck vessels of two dogs are joined in such a way that the head of each is supplied from the carotid arteries of the

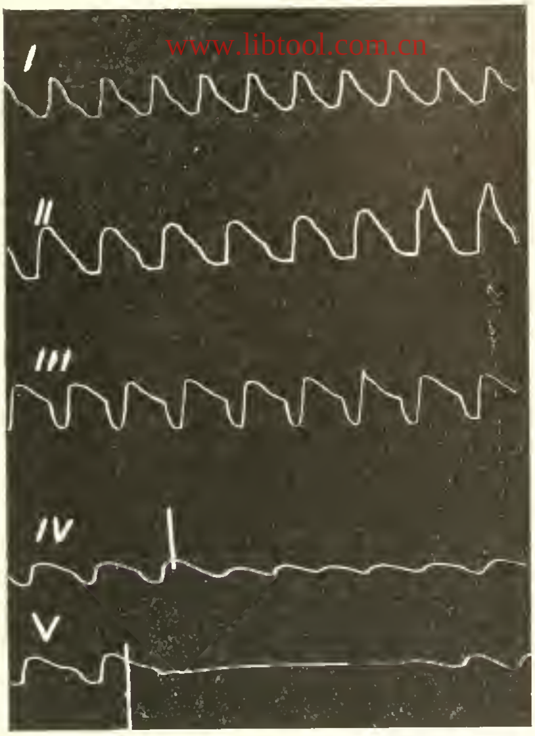

FIG. 4109.—Illustrates the Action of the Vagus on Respiration. Taken by the writer with an apparatus like that shown in Fig. 4107. *I*, Normal breathing of rabbit under ether; *II*, both vagi cut, respiration deeper and slower; *III*, cerebral hemispheres removed also; *IV*, weak stimulation of vagus opposite vertical line showing shallowing and quickening; *V*, stronger stimulation showing complete inhibition. Note: Downstrokes, inspiration; upstrokes, expiration.

other. The result is that the body of No. 1 and the brain of No. 2 receive the same blood and *vice versa*. If now the respiratory interchange of No. 1 be interfered with, the blood supplying his body will become venous, but his brain will continue to receive arterial blood from the other dog and his breathing will be unaffected. Dog No. 2, however, whose brain receives venous blood, will become dyspnœic, although the rest of his body is receiving good arterial blood.

Certain substances, other than carbonic acid, are produced in the muscles during activity, substances which also increase the activity of the respiratory centre. It has been shown that various acid substances have this effect, and the unknown substances formed in muscle are probably acid in nature.

The so-called automatic activity of the respiratory centre is believed to depend on a stimulus received from the blood, but it is yet undetermined whether the most important factor in this stimulus is a deficiency of oxygen, the presence of carbonic acid, or the action of the acid products of metabolism, although much can be said in favor of the last named.

The Influence of Afferent Nerves.—There is only one pair of nerves which have a tonic influence on the respiratory centre, as shown by a change in respiration when they are cut. These are the pneumogastrics.

On cutting one vagus (pneumogastric) the breathing becomes slightly deeper and slower for a time. Later the effect may pass off and the breathing become normal again. If both vagi are cut, the deepening and slowing of the breathing is more pronounced and the effect is more lasting.

The effects of stimulating the central end of one vagus are differently described by different writers. Nearly all agree that weak stimulation frequently produces shallowing and quickening, so that the breathing becomes more or less like what it was before the nerves were cut. With stronger stimulation various results are obtained according to the way in which the experiment is carried out, being influenced by the employment of anæsthetics and to some extent by the kind of stimulus used. This being the case, some writers believe that the pneumogastrics carry impulses which stimulate the respiratory centre to increased activity; and others, among whom is the writer, believe that it carries principally inhibitory impulses.

The impulses which normally ascend the vagus, exercising a constant inhibitory influence on the respiratory centre, are dependent upon the lung being distended, for Loewy has shown that opening the pleural cavity on one side so as to allow the lung to collapse has exactly the same effect on respiration as cutting the vagus on that side.

By rapidly inflating the lungs with a bellows the breathing may be entirely inhibited, the condition known as *apnœa* being produced. The result follows, no matter whether air be used for inflation, or some neutral gas, such as hydrogen. If air be drawn out of the lungs, diminishing their distention, very deep inspirations result. Hering and Breuer, who obtained these results, and also Head, who repeated their experiments, endeavor to explain them on the assumption that there are two kinds of fibres in the vagus, of which one set brought into action by distention of the lung favors expiration, and another set acting when the lung is collapsed favors inspiration. Their results are far more simply explained in the light of Loewy's work, by saying that the moderate distention of the lung normally present causes weak inhibitory impulses to ascend the vagus, which control the respiratory centre; increased distention gives rise to stronger impulses, which inhibit it altogether and produce a condition of apnœa; while during collapse of the lung the centre acts more powerfully in the absence of the usual inhibitory impulses.

In considering the effect of stimulating the fibres of the vagus directly we must remember that besides the respiratory fibres proper we can have passing up the vagus impulses of general sensibility and of pain, and these may cause changes in respiration through the sensorium like any other afferent nerve. The more completely we prevent the animal from feeling pain, the less likely are we to get pain effects and the more certain to see the direct action of the vagus on the respiratory centre. If an animal be experimented on without being completely narcotized, artificial stimulation of the vagus may produce almost any imaginable effect on the breathing, either inspiratory spasm (gasp), expiratory spasm (cry), or inhibition. If, on the contrary, the animal be well anæsthetized or decerebrated pain effects are eliminated and pure inhibition is nearly always seen, as shown by shallowing and quickening with weak stimulation, passing gradually, as the stimulus is increased in strength, into a state of complete inhibition or standstill in a position intermediate between inspiration and expiration (see Fig. 4109).

Even in unnarcotized animals the ascending constant current which stimulates without causing pain has almost always an inhibitory effect.

The other afferent nerves have no tonic action on the centre, for cutting any of them does not produce any change in the breathing. In special emergencies any afferent nerve may carry impulses that modify the action of the centre. If the nasal mucous membrane (fifth cranial nerve) be stimulated we get a *sneeze*, consisting of a gradual inspiration followed by a sudden spasmodic expiration through the nose. If the *glossopharyngeal* nerve be stimulated, as in swallowing, we get inhibition of respiration, which prevents food being drawn into the

Digitized by Microsoft®

www.libtool.com.cn

larynx. Certain kinds of stimuli applied to the mucous membrane of the pharynx and tonsils cause the complex act of vomiting in which the muscles of respiration play a part. Stimulation of the *laryngeal* nerves causes in some cases mere slowing of the breathing; but if the stimulus be strong, we see inhibition of inspiration and expiratory spasm or cough. Stimulation of the *splanchnics* inhibits respiration. Stimulation of the optic or auditory is said to increase inspiratory activity. Stimulation of other sensory nerves, such as the sciatic, produces in many cases one or more deep inspirations with weak stimulation, and a strong expiration or cry if the stimulation is strong; but the results are by no means uniform.

The Influence of the Posterior Corpora Quadrigemina.—Removal of the brain in front of the posterior corpora quadrigemina has little effect on the breathing; but separation of these from the medulla has an effect just like bilateral section of the vagi; that is, the respiration becomes deep and slow. If the vagi be cut as well and the animal has been protected from excessive hemorrhage the respiration becomes still deeper and very infrequent. Usually in this case inspiration and expiration are separated from each other by long pauses. Restoration of the respiration, to about its normal character, may be effected by a well-chosen stimulus applied either to one of the vagi or to the corpora quadrigemina.

Cheyne-Stokes Breathing.—If the upper part of the medulla itself be injured the breathing is sometimes seen to take on a periodic character; that is to say, the respirations occur in groups of three, four, five, or more, of which the first respiration in each group is the deepest (Markwald), and the groups are separated by intervals in which respiration is in abeyance. A similar kind of respiration is seen when a blood extravasation presses on the region of the alæ cinereæ near the respiratory centre. These facts are interesting in connection with the so-called Cheyne-Stokes breathing occurring in various diseases of the brain, heart, and kidneys, which bears certain resemblances to this experimentally induced periodic breathing (see article on *Dyspnœa*).

The Conditions under which the Centre Acts.—A rational interpretation of all the facts given above would seem to be as follows:

1. The respiratory centre is situated in the medulla, in the lower part of the floor of the fourth ventricle.
2. It receives a constant stimulus from the blood.
3. Acting alone it would expend all its energy by responding at long intervals with a very great respiratory effort.
4. It receives inhibitory impulses from the posterior corpora quadrigemina, and by the vagi nerves from the lungs which control its action and convert the deep infrequent respiratory acts into the shallower and consequently more frequent ones that we know as normal breathing.
5. In special cases the centre may be influenced by impulses reaching it by other nerves.

The Efferent Nerves are the phrenics to the diaphragm, the intercostals, and the motor nerves to the other muscles of respiration. If the spinal cord be injured above the first dorsal vertebra the intercostal nerves and muscles are cut off from the centre and thoracic respiration ceases. If the injury be as high as the fourth or fifth cervical vertebra the phrenic nerves and diaphragm are also cut off from the centre and death ensues.

For the effect of breathing air at various pressures and air containing impurities see articles on *Air*, *Aerotherapeutics*, and *Caisson Disease*. *William S. Morrow.*

REFERENCES.—In preparing this article use has been made of the books of Schaefer, Mills, Foster, "American Text-Book" (Reichert), Hall, Halliburton, Jeffrey Bell, Böhm and Davidoff, Quain's "Anatomy," Hermann's "Handbook" (Rosenthal), Langendorff's "Physiologische Graphik"; also of numerous journal articles and data from experiments performed by myself. Special acknowledgment must be made of assistance received from two papers by Max Lewandowsky in Du Bois-Reymond's Archives for 1896 on "Die Regulierung der Athmung."

RETINA, DISEASES OF.—The retina is seldom affected by disease which is limited to itself alone, or even to the eye alone, but most often lesions of the retina are part of a general disease and are frequently of assistance in the diagnosis of the latter. The diseases most apt to produce serious retinal complications are, diseases of the kidneys, syphilis, diabetes, septicæmia, and leukæmia. Among ocular affections choroiditis and optic neuritis almost always lead to retinal changes, the former because of the close anatomical relationship of the choroid and retina, and the latter on account of the interference of the retinal blood supply produced by the swelling of the disc. Both choroiditis and optic neuritis, however, are usually in turn dependent upon some general disease.

VASCULAR DISTURBANCES OF THE RETINA.—*Pulsation of the retinal veins* on the disc is frequently seen under normal conditions, and can readily be produced by a slight pressure of the finger upon the eye. It is particularly associated with increased intra-ocular tension from any cause, and hence is common in glaucoma. No better explanation of the phenomenon than that of Donders has been advanced. According to Donders it is due to the changes in arterial tension being communicated to the veins through the vitreous humor. True transmitted venous pulsation has been seen in valvular heart disease, arteriosclerosis, and anæmia, but never under normal conditions.

Pulsation of the retinal arteries is always pathological, and indicates either an increase in intra-ocular tension or decrease in the arterial pressure. It may occur in glaucoma, anæmia, syncope, senile arteriosclerosis, aneurism of the arch of the aorta, aortic insufficiency, and Basedow's disease. It may also result from compression of the central artery by tumors of the nerve or orbit.

Hyperæmia of the retina may be either arterial or venous in nature. The general redness of the fundus depends to such a great extent upon the degree of pigmentation of the choroid, and the tortuosity of the vessels varies so much under normal conditions, that it is impossible to diagnose retinal hyperæmia unless the disc is also reddened. *Arterial hyperæmia* manifests itself by distention and tortuosity of the arteries which sometimes lie in antero-posterior planes so that they project toward the observer. It may result from eye strain due to improper illumination or errors of refraction, irritation of the eye from any cause, such as the presence of a foreign body on the cornea, and from keratitis, choroiditis, and iritis. It is common in meningitis, and may be noted in Basedow's disease, plethora, and neurasthenia. Strangely enough, it may result from excessive loss of blood or from chlorosis, and in the former case it may be so intense as to give rise to retinal hemorrhages. *Venous hyperæmia* is characterized by dilatation and tortuosity of the veins, which appear darker than normal, and is always associated with hyperæmia of the disc. It is not infrequently accompanied by retinal hemorrhages. The arteries may show no change, or they may be narrowed owing to the same obstruction which is producing stasis in the veins. In general, venous hyperæmia is due to some hindrance to the outflow of venous blood from the eye, as, for instance, to compression of the central vein in optic neuritis or glaucoma. Sometimes the obstruction lies in the orbit, as in cases of tenonitis and orbital cellulitis, or even in the cranial cavity, as in intracranial tumors, thrombosis of the cavernous sinus, and meningitis. Rarely it is a part of a general venous stasis due to valvular heart disease. A few cases of particularly exaggerated venous congestion have been seen associated with congenital heart disease, the condition then being spoken of as *cyanosis retinæ*.

Thrombosis of the central vein of the retina, which produces the highest grade of venous hyperæmia, is very rare. It usually is monocular and occurs in patients affected with general arteriosclerosis, and hence most often between the ages of sixty to seventy, but sometimes it occurs as the result of orbital cellulitis. The affection comes on suddenly without prodromal symptoms, and though vision is much diminished, blindness

Digitized by Microsoft®

www.libtool.com.cn

is not produced at once. In marked cases the retinal veins are greatly distended and tortuous, the arteries are attenuated, and the fundus is covered with hemorrhages which are largest and most numerous around the disc. The disc itself is suffused with blood, and there is apt to be a small hemorrhage in the centre of the macula. In less marked cases the thrombosis may involve only a branch of the central vein, the disturbances then being confined to a limited portion of the retina. The intraocular tension is not increased. Ultimately the thrombus may break up, freeing the lumen, or organization may occur, producing permanent obstruction, though it would seem possible that even in the latter case canalization of the thrombus might take place so as to re-establish the circulation. Vision is not entirely destroyed for some time and may undergo marked temporary improvement, but relapses occur so that blindness is finally produced. If large extravasations of blood are poured into the vitreous body, as is sometimes the case, sight is early destroyed.

The *treatment* of hyperæmia of the retina must in every case be directed toward the cause, but the application of cold compresses to the eyes and the use of smoked glasses are often advisable. In thrombosis of the central vein treatment is of little avail, though strychnine has been advised, and potassium iodide and mercury may be given in the hope of hastening the absorption of the effused blood.

Anæmia of the Retina.—All degrees of this occur up to the complete cessation of the retinal circulation. Incomplete retinal anæmia may be either chronic or acute; in the former case it is usually dependent upon chronic general anæmia, either primary or secondary, and is not associated with any disturbance of vision, while in the latter it most often results from excessive loss of blood and frequently produces permanent blindness. It is rather remarkable that instead of anæmia, loss of blood may give rise to retinal hyperæmia and hemorrhages. Incomplete retinal anæmia is also an accompaniment and no doubt often the cause of retinal atrophy, and is constantly seen as the result of optic atrophy. The retinal changes seen in albuminuric retinitis are also in all probability dependent upon the anæmia resulting from sclerosis of the retinal vessels, and the impairment of vision in acute glaucoma is thought to be due to anæmia from pressure. Ophthalmoscopic examination in incomplete anæmia shows constricted arteries, dark veins, pallor of the disc, and sometimes arterial pulsation. As a matter of fact, however, unless the changes are quite marked, the condition is apt to be overlooked.

Ischæmia, or complete anæmia of the retina, is usually due to obstruction of the central artery, and may be the result of embolism, primary thrombosis, spasm of the muscle walls of the artery, hemorrhage into the optic sheath, direct injury to the artery within the nerve, or to pressure exerted upon the artery by a neoplasm. It was considered one of the earliest and most positive signs of death, but recent observations have shown that it cannot always be relied upon.

Embolism of the central artery is of very rare occurrence, probably more so than is generally believed, many cases diagnosed as such being due to some other cause. This view has recently been urged by H. H. Thompson, who states that the few anatomical examinations that have been made are unsatisfactory, and suggests that the majority of the cases of so called embolism are due to spasm of the central artery. Embolism is said to be more common in men than in women and to be almost always unilateral, occurring more frequently in the left eye. The diagnosis of embolism is practically always made when in addition to ischæmia of the retina there is reason to suspect the presence of emboli in the circulation, as in cases of endocarditis. The embolus may be carried to a branch of the central artery, the anæmia then involving only a portion of the retina. Sometimes the macular region alone escapes in this way. If the embolus is infected, suppurative panophthalmitis results. *Thrombosis of the central artery* has been diagnosed in a few cases, but usually upon insufficient evidence. In one case, however, Haab has recently demonstrated the process of thrombosis by means of serial sections. *Hemorrhage into the sheath of the optic nerve* has never been demonstrated by an anatomical examination to be a primary cause of obstruction in the central artery, but it occurs as a result of trauma to the eye or from a hemorrhage at the base of the brain, forcing its way along the nerve. (Plate L., Fig. 2.)

Spasm of the Muscle Walls of the Central Artery.—In migraine attacks of temporary blindness not infrequently occur, and naturally enough have been attributed to spasm of the central artery, especially so since the inhalation of amyl nitrite gives such prompt relief. Wagenmann observed one of these attacks ophthalmoscopically, and saw the retina become markedly anæmic and then return to its normal condition within an interval of about ten minutes. Six months later a similar attack occurred in this case, and resulted in permanent blindness with the ophthalmoscopic picture ordinarily considered characteristic of embolism. Quinine in large doses may also cause constriction of the retinal arteries, which may be seen with the ophthalmoscope. There is great impairment of vision together with contraction of the visual field. In some cases there is complete blindness, and a cherry-red spot has even been seen in the macula. Central vision is ultimately recovered, sometimes, however, only after many months, but the peripheral field is apt to remain contracted. Some recent investigators have maintained that the impairment of vision in such cases is due to the direct action of the drug upon the ganglion cells of the retina, but the ophthalmoscopic findings certainly point strongly to spasm of the arteries as the primary factor.

In ischæmia of the retina, no matter what the cause of the shutting off of the blood supply, the changes produced are always much the same. The disc is pale; the arteries are so much reduced in calibre that they can be followed only for a short distance, and interrupted columns of blood may be seen in them. If the case is seen early, a to-and-fro motion of the blood may be observed, such as is seen in the vessels of a frog's web when the circulation is beginning to stop. The veins are also contracted, but to a much less degree, and pulsation may still be brought out in them by pressure on the globe. The retina soon becomes opaque, first near the vessels, the opacity being most marked around the macular region. But the most striking as well as the most characteristic feature of retinal ischæmia is a cherry-red spot about one-third the diameter of the disc, which makes its appearance in the centre of the macula. This spot is not invariably present, however. The explanation usually given for its occurrence, which was first offered by von Graefe, is that it is due to the dark and congested choroid showing through the thin fovea, the general white opacity of the rest of the retina, especially the surrounding macula, rendering it unduly conspicuous. A later theory is that the spot is due to a hemorrhage, and a recent observation leads the writer to believe that this view is correct. A short time ago, at the Massachusetts Charitable Eye and Ear Infirmary, there was enucleated and submitted to the writer for examination an old glaucomatous eye upon which an optico-ciliary neurectomy had been performed ten days previously, the optic nerve and with it the artery and vein being severed close to the globe. It will readily be seen that such an eye presented an exceptional opportunity for the anatomical study of retinal ischæmia, since eyes affected by embolism, etc., ordinarily offer no indication for enucleation, or at least not sufficiently early to be of much value from the standpoint of pathological anatomy. The eye had undergone no outward change as the result of the first operation, but it was removed on account of an unsightly squint. On macroscopic examination there presented itself the typical sharply defined red spot in the centre of the macula, and on microscopic examination this proved to be a hemorrhage. The extravasation of blood was limited to the macula, and there was no hemorrhagic infiltration of the

choroid behind it, a fact which showed that the blood did not come from the choroidal vessels. The retina was almost completely necrotic, especially in its inner layers, and there were marked proliferation and migration of the cells of the pigment layer. In almost all of the retinal vessels the red blood corpuscles stained very feebly, but in the hemorrhage itself, and in a few of the vessels near the macula, the blood was well preserved, thus indicating that the source of the hemorrhage was the cilio-retinal vessels. The fact that the hemorrhage was comparatively fresh, and that there were no other retinal hemorrhages, went to show that it was not the result of the glaucoma but that it was dependent upon the cutting off of the circulation in the central artery.

www.libtool.com.cn

In a number of cases of supposed embolism the circulation after a time has been seen to return. This has possibly been due to the breaking up of an embolus, or more likely to the establishment of a collateral circulation through the cilio-retinal vessels, but on the other hand it certainly supports the view that the cases in which it occurred were really due to spasm. Sometimes the direction of the circulation is reversed. The return of the circulation gives rise to numerous hemorrhages, most of them in the macular region, and no doubt due to the injury to the vessels produced by the cessation of the flow of blood. The final picture is that of atrophy of the retina and optic nerve.

As a result of ischæmia of the retina, vision is almost instantaneously lost. Occasionally a part of the visual field may remain intact for a while, but later it also becomes blind. It is said that in some instances the macula is sufficiently well nourished by the cilio-retinal vessels to prevent impairment of central vision. If the circulation returns quickly, as in migraine, vision is completely restored, but in total embolism it is almost always permanently destroyed.

Treatment of Retinal Anæmia.—In the simple variety of retinal anæmia dependent upon general anæmia, treatment appropriate to the latter must be adopted. If the anæmia is very marked, lowering the head at intervals during the day may be practised. The acute retinal anæmia resulting from excessive loss of blood should be combated by saline infusions and general supportive treatment. Inhalations of amyl nitrite are of great value in spasm of the central artery associated with migraine. In embolism, paracentesis of the cornea, iridectomy, and massage of the cornea with the purpose of dislodging the embolus, have been recommended.

Retinal Hemorrhages.—Aside from trauma, which is of course a frequent cause, hemorrhages into the retina may occur as the result of a general disease, less commonly as the result of disease confined to the eye alone, or they may occur occasionally in young people without any assignable cause. As already noted, hyperæmia of the retina frequently gives rise to them, especially the venous hyperæmia resulting from thrombosis of the central vein, optic neuritis, or neuroretinitis. When they are the predominant feature in the latter, the condition is usually designated by the term *hemorrhagic retinitis.* Venous hyperæmia due to pressure on the central vein at the disc is also probably the cause of the retinal hemorrhages which sometimes occur in primary glaucoma, and the intense hyperæmia resulting from suffocation is also likely to produce them. Their occurrence as an after-effect of embolism has already been referred to. The retinal hemorrhages that occur as the result of general disease are dependent either upon alterations in the retinal vessels, associated in most cases also with high arterial pressure, or upon changes in the character of the blood itself. Thus they are seen with comparative frequency in general arteriosclerosis, Bright's disease, gout, diabetes, anæmia, leukæmia, purpura, and scurvy. When such predisposing factors are present the immediate cause is often violent exertion, such as coughing or straining at stool. In arteriosclerosis they may appear quite suddenly in great numbers, just as in cerebral apoplexy, and in such cases the condition is, in fact, often spoken of as retinal apoplexy. Retinal hemorrhages also occur as the result of menstrual disturbances, sometimes as one of the manifestations of vicarious menstruation. They frequently occur in new-born infants as the result of excessive pressure on the head during delivery, but they are quickly absorbed without leaving any macroscopic changes. In this way no doubt many obscure cases of congenital amblyopia are produced. Among other general causes may be mentioned poisons, especially lead and phosphorus, jaundice, pregnancy and parturition, malarial fever, septicæmia, and pyæmia. (Plate L., Fig. 1.)

Retinal hemorrhages vary greatly in regard to size, shape, number, and position. When few in number they are usually situated not far from the disc or near the macula. They occur in any of the retinal layers that contain blood-vessels, but most frequently in the nerve-fibre layer where they assume a characteristic striated "flame-like" shape, due to the fact that the blood insinuates itself in between the nerve fibres. Owing to the radial arrangement of the fibres around the disc, hemorrhages in its neighborhood tend to take the form of red radii. The extravasations of blood may break through the retina into the vitreous humor producing vitreous opacities, or they may force their way between the retina and choroid. Sometimes the blood collects beneath the hyaloid membrane, forming the *subhyaloid hemorrhage.* This most frequently occurs in the macular region, appearing as a sharply defined dark red disc. When recent, retinal hemorrhages are bright red in color, but they soon become darker, often almost black. The blood is absorbed rapidly, especially when the hemorrhage is small, but white spots in many cases are left to mark their sites. The white spots are due to necrosis of the retinal tissue and may contain fat globules and cholesterin crystals. They may finally disappear or they may remain permanently, not infrequently becoming more or less pigmented, owing to the migration of cells of the pigment layer into them. It is said that the pigment striæ, known from their resemblance to obliterated vessels as *angioid streaks in the retina,* are due to metamorphosis of retinal hemorrhages. Extravasations that have broken into the vitreous humor but that still remain attached to the retina, sometimes undergo organization and become converted into connective tissue. It is in this way that *retinitis proliferans* is thought to arise.

The disturbance of vision produced by retinal hemorrhages obviously depends upon their size and position, and of course is particularly great when one of the hemorrhages occupies the macula. Sometimes there is metamorphopsia, less often photopsiæ. Even small hemorrhages may produce a temporary clouding of vision if they break through the retina into the vitreous humor. The prognosis is favorable when they are small and the tendency to relapses can be successfully overcome. It is particularly unfavorable when they occur in connection with a general retinitis. The subhyaloid hemorrhages which occur at the macula are usually absorbed and vision is completely restored. When the hemorrhages are dependent upon a general disease the treatment must necessarily be directed chiefly toward the latter, but rest in bed, the application of cool compresses to the eyes, and the administration of mercurial inunctions or potassium iodide to favor the absorption of the effused blood, are usually indicated. Leeching, purging, and the production of diaphoresis by pilocarpine are also advised.

Phlebectasia retinæ is a name given to a rare condition in which the retinal veins show dilatations and constrictions, sometimes producing a decided beaded appearance. In some cases it is probably due to vaso-motor disturbances. Schöbl describes a case in which the condition was also present in the conjunctival veins and was evidently dependent upon suppression of the menses, the phenomenon disappearing when the menstrual flow was re-established.

Retinal aneurisms are of very rare occurrence, but they have been seen in the living subject and also in enucle-

Digitized by Microsoft®

ated eyes. Most frequently they are multiple, miliary in size, and situated on the smaller retinal arteries; but sometimes a single large aneurism may form on one of the large arteries. An arterio-venous aneurism has been known to occur as the result of an injury. Treatment is of no avail.

Sclerosis of the retinal vessels probably always occurs where there is general arteriosclerosis, but the alterations in the retinal vessels are rarely sufficiently obvious to attract attention on ophthalmoscopic examination, owing, no doubt, to the fact that the vessels are much smaller than those in which marked atheromatous changes are apt to occur. Both the veins and the arteries may show white borders, due to an increase of connective tissue in their walls, and sometimes constrictions and spindle-shaped thickenings. Often, however, the first evidence of disease of the retinal vessels is the occurrence of retinal hemorrhages. In syphilis changes are met with in the retinal arteries similar to those seen in cerebral syphilis, so that they are of diagnostic significance as regards the latter. Owing to obliterating endarteritis, the arteries appear as thin white bands, and there may be hemorrhagic infarcts. The veins are broad and dark colored. Vision is unaffected for a long time.

RETINITIS.—This term strictly should signify inflammation of the retina, but as a matter of fact most of the retinal conditions to which it is applied are not of an inflammatory nature, but are due either to degenerative or to atrophic changes, or they are dependent upon obstructive œdema and hemorrhage. In fact, there is probably only one condition, suppurative retinitis, in which the retina is actively inflamed. When retinitis occurs in association with neuritis the condition is spoken of as neuro-retinitis. In not a few cases retinitis is secondary to optic neuritis, the swelling of the disc interfering to such an extent with the venous outgo as to lead to œdema and hemorrhage. On the other hand, in many general diseases, neuritis and retinitis may be produced independently, either one or the other predominating. The chief varieties of retinitis are as follows:

Suppurative Retinitis.—This most commonly occurs as the result of penetrating wounds of the globe or following operations, particularly those for the removal of cataracts, and almost always results in or forms a part of a general panophthalmitis. It is usually due to micro-organisms which have been introduced into the eye, but a comparatively mild form of it can be produced by chemical irritation due to the disintegration of a foreign body, especially if the latter contains copper. The condition may also be metastatic in origin, particularly in puerperal septicæmia and in the acute infectious diseases of children. In these metastatic cases the inflammation may be confined throughout to the vitreous chamber, and thus, in children, it may result in one of the conditions which gives the clinical picture known as *pseudo-glioma*. Contrary to what has been generally believed, in panophthalmitis it is the retina, not the choroid, from which the purulent exudation mainly arises. In a large number of cases of panophthalmitis examined microscopically by the writer, the retina has invariably been found densely infiltrated with pus cells, while the choroid showed scarcely any purulent infiltration. It might be thought that the pus cells in the retina came there from the choroid, but they can be seen in the act of emigrating from the retinal vessels around which, too, they are most abundantly collected. The choroid seems to play the part of an abscess wall, and is congested, more or less œdematous, and infiltrated with lymphoid and plasma cells. The choroid also early gives rise to a formation of granulation tissue. In the cases diagnosed clinically as metastatic choroiditis the condition is usually that of metastatic retinitis, although the micro-organisms no doubt often reach the eye through the choroidal vessels. If seen sufficiently early, the retina in these cases is found to be hazy and covered with hemorrhages, but the vitreous humor soon becomes so cloudy that the later stages of the process cannot be followed by means of the ophthalmoscope. Suppurative retinitis from any cause may pursue either an acute or a chronic course, and ultimately results in phthisis bulbi. The treatment is that suitable for panophthalmitis, and is of little avail. Recently the introduction of powdered iodoform in the vitreous chamber has been tried, sometimes, it is claimed, with successful results.

Retinitis Septica (Roth).—In pyæmia and septicæmia the retina frequently shows hemorrhages and white spots not unlike those seen in albuminuric retinitis. There are no signs of active inflammation and no pain. Vision is not much affected and the prognosis is favorable so far as the eye is concerned. Roth believes the condition is not due to the presence of micro-organisms in the retina, but to toxic substances circulating in the blood produced by the septic processes elsewhere. Some observers claim that the hemorrhages are due to the lodgment of septic emboli in the retinal vessels, but the absence of inflammatory symptoms and the mild course pursued by the affection are decidedly against this view.

Retinitis Simplex, Serous Retinitis, Retinal Œdema.—Under certain conditions not understood, the retina becomes hyperæmic and shows a haziness evidently due to œdema, which either may be diffuse or may occur in circumscribed patches. This mild form of retinitis is supposed to result in some instances from eye strain. It is also said to be an early manifestation of sympathetic ophthalmia. Vision may be considerably reduced and there may be megalopsia, micropsia, and metamorphopsia. Under complete rest the condition entirely disappears. A special variety known as *commotio retinæ* is due to a blow upon the eye. This also clears up, usually in about three days, with complete restoration of vision. (Plate L., Fig. 3.)

Albuminuric Retinitis.—In some cases of Bright's disease the retina shows changes which are met with under almost no other conditions, and which therefore may be regarded as practically characteristic of renal disease. Such plainly marked cases of albuminuric retinitis, as they are named, occur in only a small per cent. (about seven per cent.) of patients suffering from Bright's disease. On the other hand, if carefully searched for, less characteristic retinal changes—such, for instance, as alterations in the vessels and hemorrhages—will be found sooner or later in probably one-fourth of these patients. Typical albuminuric retinitis may occur in any form of renal disease, whether acute or chronic, but it is met with by far the most frequently in chronic interstitial nephritis and least often in amyloid disease of the kidneys. It is rarely limited to one eye, though the retinal changes may differ considerably in the two eyes, both in extent and in character. While the retinal affection appears only in cases of renal disease which have lasted some time, yet not infrequently it is by means of the ophthalmoscope that the serious condition of the kidneys is first discovered. The most characteristic feature of the affection is the presence of a "star-shaped figure in the macula," consisting of a greater or less number of white striæ which radiate from the centre of the macula, frequently, however, without completely encircling it. The fovea is usually not involved and stands out as a clear red spot. Other changes almost always present are hemorrhages, œdema, and irregular white patches of various sizes. The latter have ill-defined edges and are situated in the inner layers of the retina, often obscuring the vessels that cross them. The arteries are narrowed and frequently show white borders, while the veins are broad and tortuous. The narrowing of the arteries is not uniform, so that the same artery may show variations in width along its course. The arteries are also somewhat tortuous, and the light streaks in their centres are much brighter than in the case of normal arteries. When an artery crosses a vein the latter sometimes appears pale for a short distance on each side of the artery, due no doubt to compression. Optic neuritis is commonly present, and in some cases is the most prominent feature. In other cases hemorrhages predominate, while in still others the most striking change is that due to œdema. As just noted, the appearances may be quite different in the two eyes. Thus in one eye the principal change may consist in the

Digitized by Microsoft®

star-shaped figure about the macula, while in the other this may be absent and the retina covered with hemorrhages. If at any time there has been severe optic neuritis the retina and optic nerve ultimately undergo atrophy. Rarely the retina shows folds or even complete separation, the latter especially in the albuminuria of pregnancy. (Plate L., Figs. 4 and 5.)

www.libtool.com.cn

The retinal condition most likely to be mistaken for albuminuric retinitis is that which results from a high grade of optic neuritis, especially that associated with brain tumor. In this the star-shaped figure may be present in a perfectly typical form, so that if at the same time there should be a trace of albumin in the urine and the general symptoms of brain tumor should not be plainly marked, the diagnosis might be difficult. In such cases, however, sight is almost always lost, whereas in albuminuric retinitis complete loss of vision rarely occurs. It should be remembered, too, that a high grade of optic neuritis does not occur in Bright's disease except in advanced cases in which the diagnosis is plain. Finally, renal disease could be excluded in most cases by a microscopic examination of the urine. In lead poisoning, too, the retina may present appearances identical with those seen in albuminuric retinitis (*saturnine retinitis*), but it is not certain that they are not due in reality to kidney lesions produced by the lead.

Anatomically the most important lesion in albuminuric retinitis, and one that gives the key to the other changes, is a widespread endarteritis and hyaline degeneration of the vessels. This is, of course, not limited to the retinal vessels, but it produces more serious damage in the retina than in the other structures of the eye. The atheromatous condition of the vessels associated with the general high arterial pressure results in numerous hemorrhages, while the insufficient blood supply leads to degenerative changes in the retinal tissue. Most of the white patches seen by the ophthalmoscope are produced in this way, but some of them are left by retinal hemorrhages that have undergone absorption. The degenerated areas show fatty degeneration of the retinal tissue, including the ganglion cells, nerve fibres, and fibres of Müller, and contain fibrin and granular detritus. Proliferation and migration of the cells of the pigment layer occur in the later stages. The degenerative changes make their first appearance at the macula because here the vessels are least numerous, but the fovea centralis ordinarily escapes, since it is well nourished by the choriocapillaris behind it. The star-shaped figure is said to owe its form to the radial arrangement of the fibres of Müller about the macula, though the degenerative changes are not limited to them. It seems to the writer more likely that its form is determined by the radial arrangement of the vessels in this region. The retina in general is apt to show marked œdema, usually in association with a high grade of optic neuritis, though the retinal œdema is sometimes quite marked where there is very little swelling of the disc. The cause of the optic neuritis is obscure; some observers attribute it to cerebral disturbances secondary to the renal disease. In addition to the other changes, the retina may show a certain amount of round-cell infiltration and hyperplasia of its connective tissue.

The disturbance of vision usually is slight when compared to the extensive retinal changes, and in the milder forms vision may be entirely unaffected. The fact that the fovea centralis is but seldom affected accounts for the almost constant preservation of central vision. Complete blindness is rare, and when it occurs it is usually the result of secondary atrophy of the optic nerve and retina or is due to separation of the latter. It should be remembered, however, that in Bright's disease, whether or not there is retinitis, attacks of blindness, *uræmic amaurosis*, may come on within a few hours as the result of uræmic poisoning, though they are more common in acute nephritis than in the chronic forms of renal disease. Here the blindness in all probability is due to the action of the uræmic poison upon the brain itself, the pupils in most cases still reacting to light. It is associated with other uræmic symptoms and disappears when the uræmia is overcome.

The prognosis of albuminuric retinitis depends chiefly upon that of the renal disease, and since the retinal affection occurs only in advanced stages of the latter, it is almost always bad. Conversely, the prognosis of the renal disease, and hence the prognosis in regard to life, is particularly bad when albuminuric retinitis has made its appearance. The prognosis in regard to sight is of little importance, because the patients seldom live long enough for the visual disturbance to become of serious moment, death usually occurring well within a year, rarely later than two years, after the discovery of the retinal disorder. The nephritis associated with pregnancy is an important exception to this rule, complete recovery being of frequent occurrence after it. Recovery also sometimes follows the nephritis which accompanies the acute infectious diseases. In these cases the retinal disease ceases to progress, and many of the retinal alterations disappear. The star figure at the macula, however, seldom entirely disappears.

Aside from the measures usually employed in severe cases of nephritis there is no treatment that will benefit the retinal disease in any way. It sometimes happens, however, that the retinitis may undergo decided improvement under treatment directed toward the kidneys and yet death ensue in the usual short time. In the albuminuric retinitis of pregnancy, especially if it appears early, the induction of abortion is often advisable.

Diabetic Retinitis, Glycosuric Retinitis.—This affection is certainly rare, though just how rare is not definitely known. It is a late manifestation of the general disease, and according to Hirschberg it is always present in diabetes which has existed for twelve years. In some instances the retinal changes are no doubt due, in part at least, to an accompanying interstitial nephritis; but it is generally believed that they may be entirely independent of kidney lesions, and there is no question but that in typical cases they differ decidedly from those seen in typical albuminuric retinitis. The affection is probably confined to diabetes mellitus, though it is claimed that diabetes insipidus has produced it. It is likely that the retinal changes that have been seen in supposed cases of diabetes insipidus have not been due to the latter disease, but that the polyuria and the retinitis have independently been due to a tumor of the brain. It is possible, too, that the polyuria of chronic Bright's disease may have been mistaken for that of diabetes insipidus.

In the form of retinitis most characteristic of diabetes, *central punctate retinitis of Hirschberg*, the retina shows great numbers of small bright shining spots, sometimes irregular in shape, which are most numerous near the disc and in the macular region, without, however, having a stellate arrangement. Scattered more generally over the fundus there are many punctate hemorrhages. Neither the retina nor the disc shows evidences of œdema, and the retinal vessels are apparently normal. Larger white spots are also occasionally seen. Sometimes in diabetes the white spots are entirely absent and the retina shows only various kinds of hemorrhages. This condition is the *hemorrhagic diabetic retinitis* of Hirschberg, though why it should receive the name retinitis is not evident. In diabetic albuminuric retinitis the changes characteristic of nephritis are associated with those of diabetic retinitis. Albuminuric retinitis may also occur alone in diabetic patients.

Diabetic retinitis is always sooner or later binocular. Vision is apt to be considerably impaired, especially central vision, and there may be contraction of the peripheral field. It is difficult to say in a given case, however, whether or not the disturbance of vision is due to the retinal changes, since amblyopia is common in diabetes even when the ophthalmoscopic examination is negative. In some cases the disturbance of vision is very slight. Not infrequently vitreous opacities due to hemorrhages occur and may produce total blindness, and glaucoma secondary to hemorrhage is also met with. Total blindness, however, is rare in diabetic retinitis.

Digitized by Microsoft®

The prognosis of the retinal affection is bad, the latter seldom showing improvement under treatment, and occurring as it does in the later stages of the general disease, diabetic retinitis is of evil significance in regard to the duration of life. This is particularly true of the hemorrhagic form, since a tendency toward hemorrhage on the part of the cerebral vessels is indicated. The treatment is that suitable for the general disease.

www.libtool.com.cn

Leukæmic Retinitis.—In all severe cases of leukæmia the retina presents an abnormal appearance, but actual retinitis is relatively uncommon. The fundus is apt to appear light yellow in color owing to the altered color of the blood in the choroidal vessels, but where the choroid is highly pigmented this may not be noted. The arteries are pale and sometimes small; the veins are dilated, frequently tortuous, and their walls may appear thickened owing to infiltration with white cells. Retinal hemorrhages are extremely common, in fact, they are the most constant ocular lesion met with in leukæmia. In addition to these changes other lesions sufficiently marked to warrant the name of retinitis sometimes occur. These are confined almost entirely to the spleno-myelogenous type of leukæmia, and consist of haziness of the retina and the presence of white spots with red borders. The latter are most numerous at the periphery and in the macular region, and are due to collections of white cells in the centres of hemorrhages. Though not often seen, they are highly characteristic of leukæmia. Other white spots, due to degeneration, also occur. The disc may be practically unaffected, or it may be greatly swollen owing to œdema and to infiltration with cells. Both eyes are almost always affected, though in different degrees. The impairment of vision depends upon the position and number of the white patches and hemorrhages; a hemorrhage in the macular region will of course cause loss of central vision. This may be of the subhyaloid variety, however, and afterward clear up. A large hemorrhage into the vitreous humor may cause permanent loss of sight and in some cases glaucoma. Albuminuric retinitis may occur as a complication. The prognosis is hopeless as regards both the general and the local affection.

Syphilitic Retinitis is far less common than syphilitic chorioretinitis (see Vol. III., p. 64), but still it does occur. It is met with in both acquired and congenital syphilis, though in the latter only the final stages are seen. In the acquired form it may develop four to six months after the primary infection. The retina shows a grayish-white opacity which is most marked near the vessels, and along the latter small white spots are frequently seen. The vessels themselves are apparently not much affected, the arteries are somewhat thinner, and the veins thicker than normal. Dust-like opacities are almost always present in the posterior part of the vitreous humor, and may persist after the retinal affection is cured. Hemorrhages are rare. Microscopically the important changes found have been diffuse round-cell infiltration of the retina, endarteritis of its vessels, and nodular collections of round cells in the choroid. No distinct gummatous formations have been observed in the retina, but the nodules in the choroid are said to resemble gummata. Proliferation and migration of the cells of the pigment epithelium have been noted. An early subjective symptom of the disease is a constant shimmering of light, due, according to Hirschberg, to insufficient blood supply to the retina. Visual acuity is much reduced and there is frequently night blindness. Ring scotomata are sometimes detected. The retina and with it the optic nerve ultimately may undergo atrophy. The prognosis and treatment are similar to those of syphilitic chorioretinitis.

Relapsing Syphilitic Central Retinitis.—This is an extremely rare affection, first described by von Graefe, characterized by repeated sudden attacks of marked impairment of vision. At first the vision returns to normal during the intervals, but finally it becomes permanently impaired. The retina shows slight dimness in the macula around which fine dots are frequently seen, and in the later stages of the disease pigmentary changes occur in the macular region. Reduction in central visual acuity usually persists even after prolonged antisyphilitic treatment, owing to the structural alterations in the retina.

Retinitis Proliferans (Manz).—In this disease masses of connective tissue arise from the retina and extend out into the vitreous humor. They are usually attached near the disc, rarely directly to the latter. There is little doubt that the condition is brought about through the organization of retinal hemorrhages. The progress of the disease is slow, but it usually leads to total blindness. Iridocyclitis or separation of the retina may occur, and the globe finally undergoes atrophic changes. It is said that mercurial inunctions and potassium iodide are of benefit.

Retinitis Punctata Albescens (Mooren).—As indicated by the name, in this affection the retina is studded over with numerous small white spots which are most numerous around the disc and in the macula; the fovea, however, usually escapes. Central vision is reduced and there are sometimes night blindness and contraction of the peripheral field. The disease is extremely rare and occurs in young persons.

Consanguinity in the parents seems to be an important factor in its occurrence and several members of the same family may be attacked. Aside from the ophthalmoscopic picture, it is thus very similar to retinitis pigmentosa.

Retinitis Circinata (Fuchs), a very rare disease of unknown etiology, always occurring in elderly persons, is characterized by the presence of a number of small white spots situated around the macula in the form of a more or less complete circle, with a diameter two or three times that of the disc. Within the circle, but not quite reaching its circumference, the macula shows a grayish opacity. The white spots lie deeper than the retinal vessels and sometimes are slightly pigmented. Small retinal hemorrhages occasionally occur, especially in cases of long standing. Along with these changes there are diminution in central vision, limitation of the visual field, and a small central scotoma. Vision gradually becomes more and more defective, but absolute blindness does not occur. The affection may be either monocular or binocular. According to Fuchs, the spots sometimes disappear, but the disease is not benefited by treatment.

Retinitis Striata (Nagel), another very rare affection of the retina, owes its name to the presence in the retina of gray stripes situated in front of the pigment layer, but behind the vessels. The stripes vary in width, but may be three or four times as wide as a vein. They may run from the disc like radii, or they may have no special arrangement. In addition to these striæ the retina may show pigmentary changes. The disease appears at an early age, runs a chronic course, and although there is some reduction in visual acuity, blindness does not generally result. The etiology and pathology of the affection are unknown, though some observers hold the view that the stripes are due to metamorphosis of hemorrhages, as in the case of angioid streaks in the retina. L. Caspar maintains that they are the result of a retinal separation that has undergone spontaneous cure. Treatment is of no avail.

Retinitis from exposure to bright light is sometimes met with, occurring most often as the result of exposure of the retina to sunlight during an eclipse (*solar retinitis*), or less frequently to exposure to an electric arc light. There is produced a central scotoma which may or may not persist, and, later on, pigmentary changes may be seen in the macula.

Snow blindness, which results from long exposure of the eyes to the brilliant light reflected from large expanses of snow, is not dependent, as might be thought, upon retinal changes, but it is due to the photophobia and blepharospasm resulting from a peculiar form of conjunctivitis. It is said, however, that sometimes the retina may be hyperæmic, and that there may be some actual diminution in visual acuity.

Amaurotic Family Idiocy (Tay).—In this very rare disease the retina presents an appearance as striking as it is

Digitized by Microsoft ®

characteristic. There is a grayish-white patch in the macular region, about twice the size of the disc, the centre of which is occupied by a small red spot similar to that seen in embolism of the central artery. Otherwise the fundus appears normal. The disease makes its appearance within the first year of life, both eyes being affected in the same way and the child showing marked symptoms of idiocy. It occurs almost exclusively in children of Hebrew parentage, usually attacking several children of the same family. Optic atrophy followed by blindness gradually ensues, and death inevitably occurs within a very short time, most often before the child reaches the age of two years. Anatomically the chief lesion found is an extensive degeneration of the cells of the cerebral cortex. According to Holden, there is a similar degeneration of the large ganglion cells of the retina, which, he thinks, gives the explanation of the ophthalmoscopic findings, since these cells are absent in the fovea and most numerous in the macula surrounding it.

Retinal atrophy is the final outcome of embolism of the central artery, thrombosis of the central vein, and of the severe form of retinitis. It also occurs as the result of separation of the retina and in the late stages of glaucoma. It is characterized particularly by marked thinning of the vessels, which sometimes become almost invisible, and by secondary atrophy of the disc, the latter taking on a pale dirty gray color and presenting an atrophic excavation. Pigmentary changes not infrequently take place in the retina. An apparently idiopathic form of retinal atrophy is that known as *chorioretinitis pigmentosa* (see Vol. III., p. 69), or more commonly as *retinitis pigmentosa*.

Separation of the Retina, Amotio Retinæ.—Normally the pigment epithelium of the retina is adherent to the choroid, but not to the rest of the retina, the latter simply being held in contact with it by the pressure of the vitreous humor. In so-called detachments of the retina the pigment layer is, in general, always left behind and the condition should therefore be spoken of as a separation, not as a detachment, although the latter is the term almost universally used. In enucleated eyes, these two portions of the retina separate with the greatest ease, and indeed it is a difficult matter to obtain histological specimens of the retina with the pigment layer *in situ*. Notwithstanding this fact, however, separation of the retina, though not rare, seldom occurs except under conditions which in themselves are of a most serious nature. Thus the most common conditions which lead to it are advanced myopia, severe injuries, especially if accompanied by loss of vitreous humor, iridocyclitis, choroiditis, intra-ocular tumors, and hemorrhage. Idiopathic separation (that is, separation of the retina without obvious cause) does occur, however, and is most common in youth and in old age. An important though uncommon cause for retinal separation is albuminuric retinitis, especially that associated with pregnancy. (Plate L., Fig. 6.)

The large majority of separations are found below, though in many cases they no doubt started elsewhere and sank downward, the retina becoming reapplied at the site of the original separation. Owing probably to the position of the disc, separations are less frequent on the nasal than on the temporal side. Localized separations at the macula are rare. The best ophthalmoscopic view of a retinal separation is to be obtained by the indirect method, though it is advisable also to make use of the direct method, holding the instrument some distance from the eye of the patient. In large separations that have come far forward the retina can often be seen by oblique illumination alone without the aid of an ophthalmoscope. The retina, if the separation is recent, projects forward into the vitreous humor as a tremulous, translucent, gray membrane, showing a greater or less number of folds over which the blood-vessels are seen to take a tortuous course. The latter lose their light streaks and appear smaller and also much darker than normal owing to the reflection of light from the choroid behind. Ordinarily if the media are clear the condition is readily recognized, but when the separation is flat and extensive the diagnosis is sometimes difficult. If the separation continues to increase, as is usually the case, it ultimately becomes total, the retina remaining attached at the disc and ora serrata only, and forming a plaited funnel behind the lens. Most often, however, it cannot be seen with the ophthalmoscope at this stage owing to lenticular or vitreous opacities. In the case of intra-ocular tumors, distinction should be made between an actual separation of the retina and the lifting up of the latter, due to the growth of the tumor beneath it. While the retina is attached to the tumor it is of course not tremulous, shows no folds, and the color of the tumor may be recognized through it. Even very small tumors, however, may early cause complete separation of the retina, and when this takes place the separated retina differs in no way from that which occurs under other conditions. The portion of the retina first to become separated is usually that covering the tumor, but not infrequently this portion of the retina never becomes separated and is overgrown and destroyed by the tumor cells. Even when this is the case, the remaining portion of the retina usually undergoes separation.

The apparent color of the separated retina depends upon that of the subretinal fluid; if the latter is tinged with blood, the retina takes on a greenish color. Owing to degenerative changes, the retina very soon becomes opaque, but it finally becomes translucent again when atrophy sets in. Quite frequently ruptures can be detected in separated retinæ.

The tension of the eye as a rule is diminished and the anterior chamber is deep, the iris frequently showing iridodonesis. Where the separation is due to an intra-ocular growth, the tension is almost always increased, or at least not diminished, a fact of great diagnostic importance. Liquefaction of the vitreous humor in association with vitreous opacities is common, and in old cases cataract and a low grade of iritis are apt to occur.

The separated retina frequently is œdematous and shows hyperplasia. Calcification, more rarely ossification, may occur, and cholesterin crystals may form in it. Pigmentary changes and hemorrhages are not often seen. Rarely cysts are formed. The blood-vessels remain pervious for a considerable length of time, but many of them finally show sclerosis and thrombosis. The nervous elements of the retina atrophy, and the layer of rods and cones soon undergoes maceration owing to the lack of the nourishment normally furnished by the choroid.

The manner in which separation of the retina is brought about is apparent in a large number of cases, but in an equally large number it is a matter of dispute. Cyclitis produces separation by the contraction of exudates that have been poured in the vitreous chamber. Choroiditis may produce it in a similar manner, or by giving rise to exudates which collect in front of the rods and cones. Traumatic separations are produced in several ways. When occurring immediately or soon after an injury or operation they are usually due to hemorrhage or to the loss of vitreous humor, which by lowering the intra-ocular tension allows serum to collect behind the retina. In other cases the retina is ruptured by the injury and the vitreous humor passes behind it through the rupture. The separations that occur some time after the injury are due to the traumatic cyclitis and choroiditis that have been set up. Foreign bodies in the vitreous chamber may cause separation of the retina if they produce a severe inflammatory reaction; but, on the other hand, they may remain attached to the retina for years without separation resulting. Finally, spontaneous subretinal hemorrhages from any cause, glaucoma for instance, may produce separation of the retina.

To explain other cases of separation a number of theories have been advanced. In myopia it seems clear that the elongation of the eyeball plays the chief rôle, but the exact way in which it does so is not certainly known. Iwanoff found that in myopic eyes the vitreous body became separated from the retina posteriorly, and that the preretinal space thus formed was filled with serum; but he failed to explain satisfactorily how this led

Digitized by Microsoft®

to retinal separation. De Wecker suggested that the latter was due to spontaneous rupture, permitting the serous fluid to find its way behind the retina. Leber and Nordensen maintain that in the large majority of cases retinal separation is due to a fibrillar condition of the vitreous body leading to its shrinkage and hence to traction upon the retina. The peculiar condition of the vitreous body is said to be dependent upon a chronic choroiditis. Suddenly developing separations, according to this theory, are due to rupture of the retina resulting from the traction. Rachlman, however, has called attention to the fact that the fibrillar condition of the vitreous body, noted by Leber and Nordensen, may be secondary to the separation, and that separations may occur when the vitreous body is perfectly fluid. He holds the view that a process of diffusion plays the most important part in the production of retinal separations. According to his diffusion theory, an albuminous exudate first collects behind the retina, and then fluid passes by diffusion from the vitreous body through the retina, gradually increasing the amount of fluid behind the latter, and separating the retina more and more from the choroid. It seems almost self evident that separation of the retina having once begun, the process of diffusion must play an important part in carrying it on to completion.

Among the early subjective symptoms of retinal separation are photopsiæ, chromatopsiæ, and metamorphopsia, followed by the appearance of a dark cloud which obscures part of the visual field and produces a positive scotoma. Vision at the macula is maintained so long as the separation has not involved this region, but it is apt to be impaired in any case. The separated retina may retain light perception for a short time, and if it soon becomes readapted, it may completely resume its function. Thus the macula may be separated at first and then become reapplied to the choroid and regain its function as the separation sinks lower down. But the prognosis in retinal separations is very unfavorable, though in rare instances a spontaneous cure has resulted. Small separations occurring after an injury or as the result of retinitis, such as albuminuric retinitis, offer the best prognosis so far as the separation itself is concerned. Usually the separation increases until it is complete and there is absolute blindness. The prognosis is particularly unfavorable in myopic cases because there is no way in which we may combat the myopia. Idiopathic separation also has a highly unfavorable prognosis.

Until recently the method of *treatment* considered most satisfactory was rest in bed and the administration of diuretics, diaphoretics, and purgatives, in the hope of causing absorption of the subretinal fluid; but of late much more brilliant results have been obtained by repeated subconjunctival injections of normal or physiological saline solutions. Unfortunately, however, even after this method of treatment recurrences are common. Many surgical measures have been tried, but with indifferent success; incising the retina, withdrawing the subretinal fluid by means of a syringe, and injecting iodine with the purpose of setting up an adhesive inflammation, have all been recommended, but it is likely that they will be generally replaced by the method of subconjunctival injections.

Subretinal Cysticercus.—The cysticercus has been found as a parasite within or beneath the retina, but the condition is an extremely rare one, especially in this country. At first the retinal separation produced is localized over the parasite, and the movements of the latter can sometimes be observed under it. The vitreous humor soon becomes cloudy and the retinal separation becomes total, producing complete blindness, and the eye finally undergoes atrophic changes. Sometimes the parasite works its way through the retina into the vitreous humor. Drugs given with the object of killing the parasite have always proved ineffectual. When the attempt is made sufficiently early, the entozoon may be successfully removed by operation with preservation of sight.

Tumors of the Retina. (See Vol. IV., p. 112.)

Frederick Herman Verhoeff.

RETROPERITONEAL TUMORS.—This subject has received its full share of attention during the past decade and with satisfactory results. That it is still at the present time a subject of much thought and earnest research cannot be denied. Thus far, investigations go to show that in the past there have been much confusion in the pathology of these growths, many errors in diagnosis, and not a very satisfactory record regarding operative interference. Like many other problems in this great field of surgery, an early, careful study of the case, a judicious weighing of all symptoms, subjective and objective, an experienced touch, no haste, are doing much to place on a more secure basis of classification these rare growths. Careful workers in the pathology of these tumors are doing much to clear up doubtful points, and establish on a more secure basis their true nature. Operating surgeons, when the tumor has obtained full size, have not found the work of removal at all encouraging, yet it is plainly to be observed that when the growth has been reached early, a fair percentage of recoveries has been secured.

A careful study of retroperitoneal tumors shows that many of them are of a mixed variety, containing the elements of both lipoma and myxoma, tissues which are, histologically, very closely associated.

Both of these tissues are found normally in the retroperitoneum, and doubtless many of these growths arise, under suitable conditions, from congenital neoplasms. These tumors are sometimes active in their growth, often become cystic, and at times reach immense proportions. Cases are reported of tumors of this kind weighing eighty pounds. The distribution of the elements is very diverse. The fat may be regularly distributed throughout the tumor or may occur as islands located here and there. These growths are very often œdematous, and by chemical analysis present a large percentage of mucin. The microscope, besides revealing the usual elements of lipoma and myxoma, very often reveals a numerous round-celled infiltration in the stroma of the growth, pointing to a sarcomatous element in their character. While not presenting all the features of active malignancy that carcinoma and sarcoma do, yet they often show a marked tendency to recur locally when removed.

Clinical histories and pathological research both show that tumors containing embryonal elements are very apt to be malignant; indeed, it may truly be said that they are always so.

The tumors found in the kidneys of young children are, for the most part, mixed tumors, chiefly myosarcomata. Many are surely congenital, and are an example of a new growth developing from embryonal tissue. They have, by Grawitz, recently been compared to a series of embryonal growths which spring from the suprarenal capsules, and have the appearance of adipose tissue, but are usually sarcomatous. (Orth, "Pathologische Diagnostik.")

Even though the tumor may not at first present the condition of true malignancy, yet the operative surgeon has learned to know that the semi-malignant growth is very apt to return either in the cicatrix or in the neighboring connective tissues, and to involve important structures, such as the large secreting glands or the lymphatics.

A careful investigation of the reported cases, together with an examination of all accessible works on pathology, impresses one with the belief that the most frequent origin of these growths is in the connective tissue of the capsular envelope of the kidney; the next most frequent seat being the suprarenal capsules.

Mr. Hulke, of Middlesex Hospital, reports a case of myxoma which enveloped the left kidney and upon which he operated. A median section was made through the tumor when it presented itself. The incision was continued through the posterior blade of the peritoneum, just beyond the descending colon. The tumor proved to be a myxoma, and, although the patient recovered from the operation, the growth returned locally. The kidney was not involved by the tumor, and could have been enucleated.

Digitized by Microsoft®

The growths embraced in this class are peculiar in several respects. None can be said to be absolutely benign, even those which are made up entirely of the histological elements of either lipoma, fibroma, or myxoma, and notwithstanding the fact that they do not tend to the formation of metastases or to the infiltration of immediately surrounding tissues. It is true that they show no great tendency to recurrence when completely removed, yet from the great size to which they develop, and from their tendency to undergo degenerative changes, they cannot be classed as innocent growths.

www.libtool.com.cn

The late Dr. John Homans, of Boston, has called attention in two papers to the reported cases of pure lipoma, among which were some on which he had himself operated.

Subserous lipomas rarely of themselves reach a large size. However, those going out from the peritoneum may be of sixty pounds' weight. Lipomas are usually slow-growing, the subserous particularly so. Subcutaneous lipomas sometimes grow rapidly after remaining stationary for years. Lipomas seldom change to other varieties, but they may primarily be mixed in character—myxolipomas.

The character of the latter group can never be determined with certainty without careful microscopical examination, as many growths having the appearance of lipomatous tissue often have the elements of myxoma and sarcoma as well. They may reach great size, but show no disposition to return after removal.

Sir Spencer Wells reports, in his first edition of "Abdominal Surgery," a case in which the removal of such a growth was undertaken, with fatal results.

Sarcomas, either in typical form or in combination with myxomatous, lymphomatous, or fibromatous tissue, also occur, and have been observed quite often. Many of the tumors which have been described as sarcomas of the mesentery were doubtless retroperitoneal sarcomas, arising at the root of the mesentery and presenting themselves anteriorly, after separating its folds.

Carcinomas are very rare, and present the strongest type of malignancy. They are of the hard, solid variety, soon forming deep and firm attachments, and offering little to be hoped for from an operation.

Varieties such as fibroma and cystoma have been observed. It may be said of the latter, for the most part, that they either spring from the walls of the pelvis, or from the subperitoneal connective tissue of that region. Virchow looks upon this series of growths as being analogous to those tumors which arise from the deep tissues of the neck.

A few remarks may be made in regard to the starting-point and relations of all these growths. Those which spring from the walls of the pelvis encroach upon or involve the bladder, uterus, and rectum, very often presenting features which are exceedingly perplexing in diagnosis. The origin of a smaller number is reported respectively as from the retroperitoneal lymphatics, the bodies of the vertebræ and bones of the pelvis, and the root of the mesentery. In by far the greater proportion of the cases no exact origin is given; indeed, from the subsequent changes in anatomical relations, it would seem quite impossible to determine the exact point of origin of many of the very large retroperitoneal new growths. They have almost uniformly presented themselves in the line of the least resistance, that is, anteriorly. In my case, reported in the *American Journal of the Medical Sciences*, January, 1892, the tumor presented itself in the back—a condition which can be attributed to its origin from the extreme upper border of the kidney, where it was less completely bound down by the lumbar muscles and fascia. When the growths have reached a sufficient size to attract the attention of the patient, they are found presenting themselves at either side of the umbilicus, somewhere in the region of the lateral lines drawn in the arbitrary divisions of the abdomen into regions, although they may appear centrally. As the growths increase in size the viscera are displaced, not infrequently completely to the opposite side, although those growths which spring from the left kidney may have the descending colon externally. Owing to circulatory disturbances within them, and to their liability to a subsequent malignant infiltration, as well as to the development of cachectic conditions, they present, clinically, features which suggest a condition almost immediately hazardous to life.

As with any large abdominal growth, there is always a certain degree of encroachment upon the thorax and pressure upon other organs. In my second case, the tumor pushed the inferior border of the liver up to the fourth intercostal space, while the cæcum and ascending colon were displaced toward the left side of the abdomen.

Diagnosis.—Notwithstanding our constantly increasing experience in abdominal surgery, we must admit that an exact diagnosis as to the true nature of these growths is not always possible. Nor can it be said to be absolutely necessary, especially in the lesser and more movable varieties.

I cannot well imagine a more severe task for a writer than to attempt to outline the symptoms and diagnosis of a condition which, until the present time, has baffled, quite without exception, the skill of all who have met with it. Yet, recognizing the importance of the factor of exact diagnosis, especially in abdominal surgery, I wish to call attention to all such symptoms as may be associated with these growths, and, after carefully weighing them, put together what seems useful.

In the first place, there is not a single symptom that is pathognomonic, and we are dependent for diagnosis upon the process by exclusion. Diseases and neoplasms of the uterus and its appendages, of the liver and the gall bladder, of the spleen, pancreas, and kidney, are to be excluded, as well as aneurism of the aorta, tumors of the mesentery, and of the abdominal walls.

The sex of the patient or the history of the case may enable one to exclude the organs of generation at once, and bimanual examination will rarely fail to locate the uterus and its appendages and determine any pathological changes in them. Pelvic congenital cysts from the spinal cord or membranes should not be lost sight of. Subperitoneal fibroids are the only ones likely to be confounded with this condition; but then uterine fibromas are more easily movable within the abdomen, and their attachment to the uterus can be made out. Solid tumors of the ovary and broad ligament present greater difficulties, which at times cannot be surmounted.

Diseases of the liver, together with new growths of that organ, have very often been mistaken for retroperitoneal neoplasms. Hypertrophic cirrhosis, amyloid degeneration, hepatic abscess, hydatids, obstruction of the cystic duct, and distention of the gall bladder, together with carcinoma and sarcoma, present physical signs which may be confounded with retroperitoneal tumors. The history of the case, together with a painstaking weighing of general symptoms, will naturally assist in clearing a doubtful diagnosis.

Disturbances of biliary excretion may occur from pressure on the common duct by the tumor. Again, tumors of the liver always move synchronously with the respiration. Retroperitoneal ones do not, as a rule. Very often a line of resonance is found between liver and tumor, which at once shows that the growth is not connected with the former organ.

My own experience teaches me that growths connected with the spleen make the case at times very embarrassing.

It has been said that the differentiation from hypertrophy and tumors of the spleen presents less difficulty than does the differentiation from tumors of the liver. Here palpation and percussion will be quite sufficient, if employed to locate the spleen in its normal position. Tumors of the omentum lack the fixed position of these growths. The absence of digestive disturbances, with fatty stools, will serve to exclude the rare new growths of the pancreas.

As stated, many of these tumors have their origin in the capsule of the kidney, or in the connective tissues

Digitized by Microsoft®

surrounding it. They present, at least in their earlier stages, physical signs differing in no respect from tumors of the nephritic parenchyma. An examination of the urine may give an exact clew to the diagnosis. In none of the cases reported had renal hemorrhage or albuminuria, with or without casts, occurred; conditions which are the rule with tumors of the parenchyma of the kidney.

www.libtool.com.cn

Regarding the use of the aspirator, while I must admit that up to the present time it has been of no special value in the diagnosis of my cases, yet I believe that in many instances the fluid withdrawn by this instrument and carefully examined, would enable us to make a diagnosis as to classification of the tumor. In a recent case of sarcoma of the kidney, by means of the medium-sized needle I was able to draw off sufficient fluid fully to demonstrate the nature of the growth, the diagnosis being confirmed later by the autopsy. All things considered, I believe that the instrument may of be value in the diagnosis of retroperitoneal tumors.

Dr. W. G. Macdonald's suggestion to insufflate hydrogen gas into the rectum, is, I believe worthy of trial, especially where a careful examination has been made before, and the percussion areas have been outlined with care upon the abdomen. The process of insufflation should be carefully watched, that the relation of the intestinal tube to the tumor may be established.

Treatment.—Without operative interference there is but one termination. The rapidity of the fatal termination varies somewhat with the character of the growth. Pure lipomas are slow growing until a certain volume is reached, when they proceed with great rapidity to a fatal termination. From a study of the clinical histories found in the literature, I am of the opinion that the mean duration of life, after the discovery of the tumor, is not more than nine months. Operative treatment offers to us much promise. Recovery has followed the removal of retroperitoneal tumors of great weight, even those weighing fifty pounds. The immediate mortality following operations is great, from necessity; yet from the hopelessness of the conditions an operation is to be urged with great earnestness upon the part of the surgeon. Incomplete operations have been immediately more fatal than those in which the tumor has been completely removed. Like all surgical lesions, these tumors illustrate the necessity of early diagnosis and prompt operation.

Czerny, in concluding a paper in which he had reported three cases, says: "In all cases operative interference can be safely undertaken; when the tumor is no longer encapsulated, the incision had better be closed, otherwise the growth should be enucleated."

Operations for the removal of retroperitoneal growths will, from necessity, be subjected to considerable modification in detail. The choice of incision will usually fall in the line of the linea semilunaris, on one side or the other; Langenbeck's incision for removal of the kidney may be made use of. Frequently, when the incision is at first exploratory it must be made in the median line. When the anatomical relations can be made out, and the operation continued by an extension of the cut, then the more favorable incision is in the linea semilunaris. By the separation of the peritoneum from the internal border of the tumor, it may be attached by sutures to the internal border of the abdominal wound, making the whole field of the operation extraperitoneal.

The incision of the posterior fold or blade of the peritoneum should be external to the attachment of the mesentery of the colon, although this is not absolutely necessary. The removal of the growth by enucleation must be accomplished with great care; particularly is it always desirable to determine the source of the blood supply and its relations to the great vessels. The vena cava has been wounded by accident in the enucleation of these growths. There are likely to be large, thin-walled veins located deeply in the wound, and requiring ligation. It will be found at times necessary to remove the kidney with the tumor, and here the danger of hemorrhage is very great. The supply vessels of the kidney will frequently be found very short and difficult to reach.

The length of time required for the performance of the operation will vary necessarily. As long a time as two and one-half hours has been consumed in a difficult operation. As in all strictly abdominal work, the operator must be prepared for any and every possible complication.

After enucleation, as well as when the kidney has been removed with the growth, the cavity must be thoroughly drained, either by full-sized drainage tubes or by tamponade with iodoform gauze.

The after-treatment presents no indications for management other than those of a severe case of abdominal section.

As in all other conditions in surgery, there is certainly at the present time a better understanding of these cases. A more correct and early diagnosis, as is the case in all that pertains to medicine and surgery, will surely bring a larger percentage of recoveries.

These are purely surgical cases; no medicines, no mineral waters, or baths, electricity, or other lines of therapeutics, have as yet been of any service.

A. Vander Veer.

REVERSION.—Reversion is a special case of heredity, and the term is usually applied somewhat loosely to include all cases in which the offspring does not resemble the immediate parents, but exhibits correlation with a more remote ancestor, or group of ancestors. Recently Pearson has sought to give greater precision to the use of the term. He distinguishes (1) regression, (2) reversion, and (3) atavism.

If we take any pair of characters, as, for example, the lengths of the thumbs of the right and left hands of the same person or the statures of father and son, and construct a correlation table from a sufficiently large number of cases, it will be found that for any given dimension in one group (the "subject," *e.g.*, length of right thumb or stature of father) the dimensions of the associated characters in the other group (the "relative," *e.g.*, length of left thumb or stature of son) will be on the average nearer the general average of the whole population. This is *regression*, and is a general phenomenon of correlation when the correlation is not perfect, as is almost always the case (see article *Heredity*, Table I. and Fig. 2606). But as every individual produced sexually has two parents, four grandparents, eight great grandparents, and 2^n grandparents of the nth degree, one need go back only a few generations, if there has not been much inbreeding, to find a group of ancestors sufficiently numerous to give a fair sample of the population as a whole. So, in cases of direct heredity, regression may be said to be a tendency of the offspring to depart from the peculiarity of the parent toward the general average of the ancestry.

Reversion, in the strict sense of Pearson, is a departure from the peculiarity of the parents toward the peculiarity of some particular ancestor. From the many recorded cases we may select for illustration two cases cited by Darwin. A pointer bitch produced seven puppies, four of which were marked with blue and white, a very unusual color for pointers. One of these puppies was preserved and it was found later that he was the great-great-grandson of Sappho, a pure bred pointer bitch, which he closely resembled. The other case is that of a black bull in Kincardinshire, the son of a black cow with white legs, white belly, and part of the tail white. In 1870 a calf was born which was the great-great-great-grandchild of the bull and had the same very peculiar markings as the bull's mother, all the intermediate ancestors of this calf having been black like the bull himself.

Atavism (Lat. *atavus*, an ancestor) in the strict sense, is a return to the peculiarity of the ancestral form of the species. As this ancestral form is generally unknown, the explanation of an unusual variation as due to atavism is in most cases merely conjectural. For example, the dark stripes that appear sometimes upon the back, shoulders, and legs of horses have been attributed to atavism by Darwin, Ewart, and others; the presence of these

Digitized by Microsoft®

stripes being regarded as evidence of a striped ancestry when considered in connection with the coloring of other species of the genus Equus, like the zebra, quagga, etc. Another example of atavism is the occasional appearance of supernumerary mammæ and teats in women and in men. In women they have been observed to produce milk. These are regarded as atavistic because in the Lemuroidea, the lowest group of Primates, there are, in addition to the well-developed functional mammæ on the pectoral region, rudimentary teats upon the abdomen and groin. They thus approach the condition found in dogs and pigs, while in the apes and man there is normally but a single pair of mammæ.

www.libtool.com.cn

Sometimes it is difficult to determine whether a given unusual variation is a case of atavism or a sport. For example, it is known that the ancestors of the horses had three toes, and it is probable that the ancestors of the modern cats and dogs had five digits on all four feet, but dissections in some cases have shown, and it is probably true in most cases, that when polydactylism occurs in these animals the phenomenon is similar to polydactylism in man, which is certainly a sport and not atavistic.

Darwin showed that the crossing of distinct breeds of animals may result in the appearance of atavistic characters. For example, in his experiments with pigeons he found that when he crossed two distinct breeds, even when they showed no trace of blue color or of bars on the wings, the mongrel offspring would frequently exhibit some of the blue color or traces of the wing bars of *Columba livia*, the wild rock pigeon, which species he regarded as the ancestral form of the domestic pigeon. More striking results were obtained by again crossing the mongrels, the best case was the result of pairing a mongrel female barb-fantail with a mongrel male barb spot, neither of which mongrels had the least blue about them. The offspring exhibited the general blue color and every characteristic mark of the wild rock pigeon.

When individuals of separate races or species are crossed, the mongrel or hybrid offspring of the first generation may be more or less intermediate in character between the two parents, or they may resemble one parent only in some respects. But in subsequent generations there is greater diversity among the offspring, and reversion to one or the other parental type is common. The facts were noted by Darwin, but the first one to study them by statistical methods was Gregor Mendel, abbot of Brünn in Austria. Mendel's work was published in 1866 and 1870, but it remained practically unnoticed until 1900, when De Vries, happening to find a reference to it, looked it up and was surprised to discover that Mendel had anticipated results which De Vries himself was then about to publish. Mendel worked with varieties of garden peas and studied one character at a time, first testing the varieties to make sure that they would breed true. He found that when the parents possessed certain contrasted characters one character of each pair would fail to appear in the first generation of offspring, but would reappear in subsequent generations. He called the character that appears exclusively in the first generation *dominant*, while the one that reappears only in later generations he termed *recessive*. In peas he found that the rounded form of the seed is dominant and the wrinkled form recessive, the yellow color of the cotyledons of the ripe seed is dominant, the green color recessive, and the same is true of a number of alternative characteristics. Now the point of Mendel's work is that he found the dominant and recessive characters to reappear in succeeding generations according to a definite and simple numerical law.

If a certain dominant character be represented by A and the corresponding recessive by a, then all the offspring of the first generation will have apparently only the character A. But if the flowers of this generation are fertilized with their own pollen, the next generation will contain $1a$ to $3A$. These plants being again self-fertilized, all of the recessives, a, are found to breed true and to continue to do so during succeeding generations. One-third of the dominants also breed true in the same way, but the other two-thirds give rise to both forms, as the hybrids did, in the same proportion of one to three.

These relations may be represented by the following diagram:

Parents				A	a			
Hybrids				A				
Second generation	1 A			2 A				1 a
Third generation	A	1 A		2 A			1 a	a
Fourth generation	A	A	1 A	2 A		1 a	a	a
Fifth generation	A	A	A			a	a	a

If we represent pure dominants by A and dominants capable of producing both kinds of offspring by Aa, and suppose each plant to produce only four seeds, the following ratios will be obtained:

	A	:	A a	:	a
Second generation	1	:	2	:	1
Third generation	3	:	2	:	3
Fourth generation	7	:	2	:	7
Fifth generation	15	:	2	:	15
Sixth generation	31	:	2	:	31
1 + *n*th generation	$2^n - 1$	:	2	:	$2^n - 1$

If we consider two or more characters at a time, the results become correspondingly complicated, for characters that are not mutually exclusive may appear in the offspring in any possible combination. Thus the seed may be dominant in shape and recessive in color, or *vice versa*, or it may be dominant in both or recessive in both.

Mendel offered as an explanation of these relations the supposition that in cases of this kind the alternative characters are not combined in the germ cells, but each carries the pure heritage of one parent only with respect to any one character, *e.g.*, the shape of the seed. That this view harmonizes with recent studies of the maturation divisions was pointed out in a previous article (see *Reduction Division*). If the chromosomes transmit the bases of separate groups of characters, as is indicated by Boveri's recent work, we may represent a pair of homologous chromosomes in the hybrid by the symbol Aa. In the maturation of the germ cells with a reducing division the chromosomes would be separated into four cells thus:

$$A + A + a + a\ ;$$

and when fertilization takes place by union with an equal number of germ cells of opposite sex containing $A' + A' + a' + a'$, the following combinations are possible:

$AA' + Aa' + aA' + aa'$, the most probable proportion being $1\,AA : 2\,Aa : 1\,aa$.

This would give one recessive to three dominants, but only one dominant out of three would breed true, for the other two would contain recessive chromosomes in their germ plasm.

The difficulty with Mendel's theory is that the statistical results obtained by other observers do not always show the exact proportions required, and that the dominant and recessive characters are variable and therefore sometimes difficult to distinguish. And also for this reason it is not easy to determine whether a race is breeding true or not. The theory has been criticised on these grounds by Pearson and Weldon; while it is defended, and its results are confirmed, by De Vries, Correns, Bateson, Castle, and others. *Robert Payne Bigelow.*

RHATANY.—(*Krameria*, U. S. P.; *Krameriæ Radix*, B. P.; *Radix Rhataniæ*, P. G.) The dried roots of several species of Krameria, especially of *K. triandra* R. et P., *K. Ixina* L., and *K. argentea* St. Hil. (fam. *Krameriaceæ*).

The last mentioned is not now official in the United States Pharmacopœia, but will doubtless be so in the forthcoming edition. The Kramerias are low or semiprostrate shrubs of tropical or warm temperate parts of America. They have very long, thick roots, noted for the thickness of their bark. Since the active constituent exists mostly in the cortex, the thicker-barked varieties are the better. The first-named grows in the higher Andes and yields Peruvian Krameria, the poorest variety. The second comes from the Santa Marta region of Colombia, and is about intermediate in quality between the first and the third, which latter comes from Northern Brazil. This is usually sold as Savanilla, the genuine Savanilla now reaching the market only occasionally. *K. lanceolata* Torr., of the Southwestern United States and Northern Mexico, yields a good Krameria, but it is scarcely a commercial article.

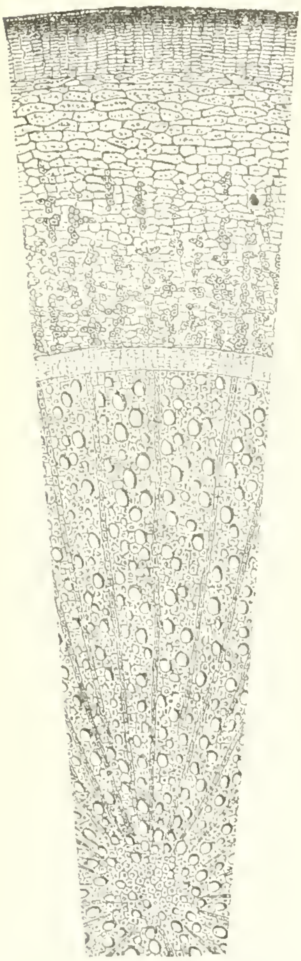

Fig. 4110.—Krameria Triandra; transverse section of root. (Baillon.)

Description.—*Peruvian Krameria*.—Root branches usually occurring with several or many attached to a short, hard, and woody tap root, which is 1.5–4 cm. (⅗–1⅗ in.) thick, roughly fissured and supports a knotty, several- to many-headed crown; of indefinite length, rarely exceeding 50 cm. (20 in.) and usually less than 1 cm. (⅖ in.) thick, cylindrical, flexuous or wavy, very flexible; externally light red brown, more or less marked with dark, scaly patches, especially upward, otherwise smoothish, devoid of transverse fissures; fracture tough and splintery, the pinkish-brown bark occupying less than one third of the radius, the wood yellowish or pinkish-white, finely radiate; inodorous and of a very astringent taste.

Brazilian Krameria.—Branches usually occurring detached from the tap root and crown, less flexuous than those last described, externally of a deep purple-brown or chocolate-brown and with numerous transverse cracks or fissures; fracture less tough than that of the last, the bark and wood both darker, the former occupying two-fifths, or even more, of the radius, the taste more astringent than that of the last.

The most important constituent is from eight to twenty per cent. of *krameria-tannic acid* or *rhatania-tannic acid*, a brilliant deep red amorphous mass, soluble in alcohol and, if pure, in water also. It is usually only partly water-soluble, owing to the change of a portion of it to phlobaphene by dehydration. Krameria-tannic acid gives a dull green color with diluted acids, and is flesh-colored with gelatin. It is decomposed by dilute mineral acids into sugar and rhatania red.

Published statements as to the relative percentages of tannin in the different varieties are not reliable, since it is the very commonest occurrence for the varieties to be confused in commerce and in experiments.

Rhatany is a reliable and useful astringent, owing to its tannin, and is applicable to all conditions in which gallic or tannic acid is useful. The crude drug may be given in powder, in doses of 1–2 gm. (gr. xv.–xxx.), though a liquid preparation is preferable. The pharmacopœia provides an extract, the dose of which is two to four grains, a fluid extract, dose fifteen to thirty minims, and a twenty-per-cent. tincture, the dose of which is from one to two fluidrachms. *Henry H. Rusby.*

RHEUMATIN is the salicylate of saloquinine, and represents a large percentage of the salicylic radical in combination with quinine. It occurs in tasteless white acicular crystals, which are but sparingly soluble in water. Overlach finds its action practically specific in acute rheumatism, without any digestive disturbances, and distinct from that of a mixture of quinine and salicylic acid. Pieper found it valuable in trigeminal neuralgia as well as in rheumatism. The dose is 1 gm. (gr. xv.) three or four times a day. *W. A. Bastedo.*

RHEUMATISM, ACUTE ARTICULAR.—Definition.—An infectious disease, caused by a germ or germs not yet identified, and characterized by (1) a general constitutional reaction; (2) an irregular febrile movement; and (3) non-suppurative inflammation of the connective-tissue structures of the joints, the muscles, and the heart.

History.—In former times articular rheumatism was confounded with gout. Sydenham, in the closing years of the eighteenth century, first made plain the difference between the two diseases.

Nature.—Rheumatism is now regarded almost universally as an infectious disease caused by germs from without. Two other theories were formerly held: first, that it is due to the presence of an excess of lactic acid in the blood; second, that it is of neurotrophic origin. These views are no longer held by the best men. With regard to the first, it need only be said that it offers no reasonable suggestion as to the cause of the excess of lactic acid. An excess of lactic acid is almost always present, but it is no more logical to say that the lactic acid causes the joint troubles than that the joint troubles cause the lactic acid, or that the fever causes both.

The second, or neurotrophic, theory is open to objection on the ground that it offers no cause for the neurotrophic disturbances. Furthermore, if so serious and acute a disease as rheumatism be neurotrophic in its origin, we ought to find in every case serious disturbance of the central nervous system, while as a matter of fact such disturbance is very uncommon. Again, all other diseases of proven neurotrophic origin are of slow progress and conspicuously slow recovery, which rheumatism, under proper treatment, is not. The neurotrophic theory is really founded upon a confusion between articular rheumatism and rheumatoid arthritis. The latter disease is now regarded as neurotrophic, but its morbid anatomy and clinical picture are so different from those of rheumatism that the two diseases may be said to have nothing in common except the fact that they both affect the joints.

In favor of the germ theory of rheumatism we may urge the following arguments: (1) All other acute diseases with fever and constitutional reaction are now believed to be infectious. Most of them have been proven so.

Digitized by Microsoft®

(2) All other acute inflammations of joints—*e.g.*, pyæmic, gonorrhœal, tuberculous, and syphilitic arthritis—are known to be infectious. (3) Acute rheumatism has several times been found to occur in epidemics. (4) There are two cases on record in which parturient women, suffering from rheumatism, have borne children who shortly after birth developed fever and polyarthritis.

www.libtool.com.cn

The bacteriology of rheumatism is still in doubt. In 1891 Achalme, of Paris, claimed to have identified the germ. He isolated from the blood and pericardial fluid of, in all, eight rheumatic patients, a bacillus which he regarded as characteristic. It was found, however, that cultures of this bacillus, injected into animals, produced not the ordinary lesions of articular rheumatism, but local congestion, destruction of tissue, and gas bubbles. Westphal, Wasserman, and Malkoff, in 1899, found in a fatal case of post-rheumatic chorea a very few diplococci which produced in animals fever and non-suppurative polyarthritis. Poynton and Paine, of London, in 1900 found a diplococcus which may prove to be this same germ. They isolated it from eight cases of severe acute rheumatism, finding it in the blood, the pericardial fluid, the vegetations from diseased heart valves, the tonsils, and the urine. They also demonstrated its presence in the joint exudations of inoculated rabbits. These rabbits showed multiple, non-suppurative arthritis, valvular endocarditis, pericarditis, and moderate pyrexia. Passed along from one animal to another, the germ showed great constancy in its effects. These results are very striking, but up to the time of writing no confirmatory reports have been published.

A view which has gained some support during the past year is that rheumatism is due to the presence in the body, not of bacteria, but of toxins. F. W. Packard, of Philadelphia, has declared in favor of this view, and has also stated that in a large number of cases the intoxication results from an infected tonsil. It is certain that tonsillitis is of very common occurrence at the beginning of an attack of rheumatism, and it may be imagined that the lymphoid tissue of the tonsil, by its power of filtration (Manfredi) allows the toxins to pass through and stops the bacteria. The emigration of the inflammation from joint to joint, so often seen during an attack of rheumatism, seems to suggest a local intoxication rather than infection, and so also does the rapid and complete recovery under proper treatment. And salicylic acid, while a very weak germicide, is known to have a powerful chemical action upon toxins, *e.g.*, diphtheria antitoxin. There is need for further investigation along this line.

Etiology.—Rheumatism is seen everywhere. It is most common in temperate climates. In New York it occurs most frequently during the early months of the year. A series of 514 consecutive cases from the records of the New York Hospital gave the following results:

Season of year: July 1st to January 1st, 140 cases; January 1st to July 1st, 374 cases.

Sex: Of all ages, 337 males, 177 females.

Of cases under 20, 43 males, 44 females.

Age: Under 10 years, 6 cases, or 1.17 per cent.; 10–20 years, 81 cases, or 15.8 per cent.; 20–30 years, 200 cases, or 38.9 per cent.; 30–40 years, 130 cases, or 25.3 per cent.; 40–50 years, 66 cases, or 12.8 per cent.; 50–60 years, 23 cases, or 4.47 per cent.; over 60 years, 8 cases, or 1.55 per cent.

These figures are in general agreement with those for the Montreal General Hospital, quoted by Osler. It will be seen that rheumatism is pre-eminently a disease of early adult life, nearly sixty-five per cent. of the cases occurring during the period of greatest bodily and mental strain, or between the ages of twenty and forty. The difference in susceptibility between men and women is hardly explainable except upon the ground of difference in occupation and women's freedom from the alcoholic and tobacco habits.

Many observers claim a distinct hereditary predisposition (Osler, Church and Cheadle, Lyman). But, as many different conditions have in the past been grouped together under the common name of rheumatism, the importance of an hereditary predisposition may have been exaggerated.

Exposure to cold, especially *damp* cold (Lyman), is the exciting cause in a certain number of cases. Men who lead outdoor lives, exposed to all kinds of weather, and who are—as this class often is—somewhat alcoholic, are very liable. Second and third attacks are common. Of the 514 cases quoted above, 64 had had one previous attack, and 43 more than one; so that one attack of rheumatism confers no immunity as regards subsequent attacks.

Morbid Anatomy.—Typical rheumatism always attacks more than one joint. A case of monarthritis without history of previous attacks should be viewed with doubt. The inflammation is exudative in type, with congestion and a fibrino-serous exudate, containing a few leucocytes, in all the tissues of the joint proper, and also in the cellular tissue and tendon sheaths around the joint. There are rarely, if ever, in an uncomplicated case enough leucocytes to make the exudate purulent. The synovial fluid, with which the joint cavity is distended, is sometimes of acid reaction and may be blood-stained. The cartilage cells in the joint cartilages proliferate, and the intercellular substance splits up, assuming a velvety appearance. All these changes are susceptible of rapid repair.

The blood shows increase of fibrin, fats, cholesterin, and extractive matter. The serum remains alkaline. Urea and uric acid are not increased. Red blood cells are much diminished. No disease produces pronounced anæmia quicker than acute rheumatism.

The urine is acid, high-colored, and of high specific gravity. It deposits, upon standing, a sediment of amorphous urates and sometimes uric-acid crystals.

There is an excessive excretion of sweat. This is of neutral reaction, but quickly becomes acid if the patient's skin be not kept scrupulously clean.

Clinical History.—In the majority of cases the first symptom noticed is lameness of one or more joints. This may be preceded, during a few days, by the symptoms of an ordinary coryza or acute pharyngitis or tonsillitis. The slight lameness and soreness are usually overlooked, and the patient continues to follow his ordinary occupations. After a few days more the symptoms grow worse, swelling and redness appear in the affected joints, the pain increases until the least motion causes agony, there is a febrile movement, with or without distinct chills, anorexia, constipation, and profuse sweating, and we have the full clinical picture developed. In a few cases the disease is ushered in by a rigor, with an immediate development of all the symptoms; or the case may begin in a mild way, and later develop suddenly the graver and more acute type.

When the disease is once established, it shows very little tendency to spontaneous termination. Under the older systems of treatment it would run for many weeks. The inflammation may move entirely in a few hours from one part of the body to another—from knee to wrist, from wrist to ankle, or from one leg or arm to the other. Of the location of the disease it is a noteworthy fact that it shows a marked tendency to attack the same joint on both sides of the body. In the above-quoted series both knees were involved in 213 cases, the left knee alone in 79, the right knee alone in 59. All the joints of the body showed at least a plurality of cases of symmetrical involvement. The knee is the most frequent seat of inflammation, 351 cases showing affection of one or both. The ankle came second in my series with 256 cases; next the wrist, 125 cases; shoulder, 116; foot, 109; hand, 97; elbow, 78; hip, 44; and lastly the sternoclavicular joint, 1 case. The fever is irregular, rarely very high except in cases of hyperpyrexia, and yields more readily to the salicylates than do the joint troubles.

Complications.—Of these the most important are those which affect the heart. Indeed, were it not for the cardiac complications, an attack of rheumatism would be little more than a disagreeable incident in a man's life.

Digitized by Microsoft®

Endocarditis ordinarily adds but little to the severity or immediate danger of the attack, but it leaves permanently damaged valves which, except in a very few cases, never regain their perfect function. As to the frequency of this complication www.libtool.com.cn the 514 cases quoted above, 152, or 29.57 per cent., showed murmurs distinctly valvular. Of these 104, or more than two-thirds, gave the signs of mitral insufficiency. Only two showed a pure mitral stenosis, while 24 showed a double mitral lesion. In 22 cases there were murmurs at the base of the heart, of which 8 were systolic, 6 diastolic, and 8 double.

Rheumatic endocarditis is usually an inflammation of the connective-tissue portion of the endocardium of the valves. The endothelial covering, according to MacLagan, is affected only secondarily as a result of friction caused by changes in the shape of the valve. By this means the endothelium is rubbed off, leaving a rough spot upon which the fibrinogenic elements of the blood coagulate, forming so-called "vegetations." Poynton and Paine report diplococci in the base of the valve, but not near the surface. Malignant ulcerative endocarditis is very rare in rheumatism. Where it occurs, it is probably always due to secondary infection.

Rheumatic endocarditis usually gives no symptoms. It is generally discovered by the attending physician, who must always be on the lookout for it. In bad cases there may be indefinite pain referred to the præcordium, or slight dyspnœa and palpitation. There may be embolic attacks, due to detachment of a vegetation.

Pericarditis, either dry or with effusion, often occurs. It shows the ordinary morbid anatomy of an exudative inflammation of a serous membrane. The symptoms vary according to the character of the exudate. In dry pericarditis there is great pain in the præcordium, with a violent and irregular pulse. The characteristic "see-saw" murmur may be present, or there may be only a systolic murmur, or a faint clicking sound, or even no murmur at all. With effusion we get muffling of the heart sounds, upward displacement or total disappearance of the apex beat, increase of the præcordial dulness, and the patient complains of great weakness and urgent dyspnœa on the slightest movement. Generally, but not always, there is increase in the fever, and there may be a distinct chill at the invasion of the pericarditis.

Myocarditis is rare in rheumatism. It is seen in middle-aged or older patients, whose aortæ and coronary arteries are not of the best. Fatal cases which come to autopsy show a slight degree of granular degeneration of the heart muscle, due to the systemic poisoning.

Respiratory Tract.—As stated above, coryza, pharyngitis, and tonsillitis are often seen early in the disease. Laryngitis and bronchitis occasionally occur. Pleurisy and pneumonia are sometimes found, usually in the cases with heart complications. Among the five hundred and fourteen cases mentioned there were fifteen pleurisies and five pneumonias. The pleurisy is generally accompanied by serous effusion. The pneumonia is patchy, and lobular in type. According to Osler, severe and fatal pulmonary congestion is sometimes seen.

Nervous System.—The peripheral nerves are sometimes affected by rheumatism. The sciatic nerve is the most common seat of trouble, but occasionally a part or the whole of the brachial plexus is involved. These complications are sometimes slow to yield to treatment. More severe are the *cerebral* complications. Rheumatic meningitis is certainly very rare, and probably in some cases salicylic acid poisoning has been mistaken for it. The cerebral symptoms most commonly seen are delirium, stupor and occasionally convulsions. These symptoms, in connection with excessively high temperature, constitute the condition known as *hyperpyrexia*, which is always grave and often fatal. The high temperature (sometimes reaching 110° F.) seems to be due to paralysis of the heat control centre in the medulla.

Chorea is sometimes, especially in children, seen in association with rheumatism, but more frequently combined with endocarditis than with polyarthritis. It is apt to occur late in the disease. The nature of the connection between the two diseases (rheumatism and chorea) is not known.

Eye.—Rheumatic iritis is certainly a genuine disease. It presents the ordinary appearance and symptoms of iritis, and yields to salicylates. It is usually mild. Iridocyclitis with destruction of the eyeball belongs rather to gonorrhœa than to rheumatism.

Skin.—Sudamina are common, as might be expected from the profuse perspiration. Erythema nodosum has been reported by Osler. Scarlatiniform erythema is seen from time to time. Purpuric spots occurred in three cases in my series.

Subcutaneous Tissues, Fascia, etc.—Occasionally, in severe cases, small lumps are noticed under the skin in the neighborhood of affected joints. These are called "rheumatic nodules." They consist of fibrous tissue with a number of small round cells. Poynton and Paine report having found diplococci in some of them.

Course and Prognosis.—As to whether or not rheumatism is a self-limited disease authorities differ. It is certain, however, that the disease without treatment runs a tedious and uncertain course, and is liable to relapse, and to develop a low form of chronic arthritis, the so-called chronic rheumatism. The prognosis is almost always good as to life. Only two deaths occurred in the five hundred and fourteen cases cited. This is a low ratio, less than 0.4 per cent. Probably the usual mortality is between 0.5 and 1 per cent. It would seem from the literature (and Lyman indorses this) that the disease runs a milder course in America than in England. The fatal cases are those with severe acute heart and lung complications, or hyperpyrexia. As regards complete recovery the prognosis must always be guarded on account of the heart complications. Most of these leave permanent damage, to give trouble perhaps many years later. Life insurance men say that second and third attacks are less likely to affect the heart than first attacks, perhaps because the second and third attacks come later in life. It is certain that the most serious rheumatic cardiac lesions are seen in young persons. The mitral valve, when not too extensively damaged, is able sometimes to adapt itself to new conditions, and regain perfect competency.

Diagnosis.—Articular rheumatism may be confounded with gouty, gonorrhœal, or septic arthritis, with tuberculosis and syphilis, with acute septic epiphysitis, and with arthritis deformans. *Gout* occurs late in life, in its acute form is monarticular, and the history of inherited tendency, of faulty hygiene, and possibly of previous attacks, helps to distinguish it. *Gonorrhœal arthritis* is also frequently monarticular, the joint has less of the appearance of an acute inflammation, is less painful, and an urethral discharge may be discovered on careful examination. *Tuberculosis* is also monarticular, and of subacute or chronic type. At the beginning of the second stage of *syphilis* there are sometimes joint pains with the slight febrile movement which precedes the roseola. Here the history usually serves, and the appearance of the rash dispels doubt. Septic arthritis and acute epiphysitis are always due to some septic focus elsewhere in the body, the course of the temperature is pyæmic, and the symptoms do not respond to salicylates. Some forms of rheumatoid arthritis are occasionally mistaken for rheumatism, but careful examination will almost always reveal the characteristic deformity of the affected joints. Rheumatism may, however, occur in a patient who is already the victim of rheumatoid arthritis. Here the diagnosis may be difficult, and one may have to rely upon the progress of the inflammation from joint to joint or upon the test of treatment. It may be repeated here that without the history of previous attacks, a certain diagnosis of rheumatism is impossible unless more than one joint is involved.

Treatment.—The patient must be put to bed and kept there. His pajamas or night gown should be of flannel, and he should lie between blankets whenever possible. The bowels must be opened freely at the out-

Digitized by Microsoft ®

set. The best purgative is one grain of calomel, given in quarter-grain doses every fifteen minutes, and followed, four hours later, by a Seidlitz powder, or a full dose of citrate of magnesia, or half an ounce of Rochelle salts. No more bed clothes should be allowed than just enough to give reasonable warmth. If their weight cause pain or discomfort, they must be supported upon some kind of a framework. The patient must be sponged off with warm water, often enough to keep his skin perfectly clean. The copious sweat rapidly undergoes acid fermentation, and if not removed causes itching and soreness. The diet should consist mainly of milk. This may be varied, from time to time, with small quantities of beef tea and clam broth. Plenty of water should be allowed, or vichy, or soda water, or lemonade. These drinks help to keep the urine bland, and ease the strain upon the kidneys. The drug of drugs to be used is salicylic acid in one of its forms. It may be given as the salicylate of soda, or as oil of wintergreen, or as salicin. Salicylate of soda is the cheapest, and most patients bear it well, but it sometimes upsets the stomach. Oil of wintergreen is said to be quicker in its action, but it has no advantage so far as the stomach is concerned, for patients quickly tire of its penetrating odor and taste. Salicin is less active than the other two, but delicate stomachs bear it better. Whichever of these drugs is chosen must be pushed to the limit of toleration. This, and only this, should be the limit of dosage. Salicylate of soda is usually given in watery solution, the other two usually in capsules. It is best to begin by giving twenty grains every two hours, and to continue this until deafness and tinnitus aurium begin to develop, when the dose should be lessened, or the intervals lengthened, or both. It is good practice to give ten or twenty grains of bromide of sodium when the tinnitus begins. Elderly people, whose arteries and kidneys are worn, do not bear salicylates well. Such patients must be carefully watched, and the dose regulated to suit them. Symptoms of poisoning sometimes develop quite rapidly. The writer has seen maniacal delirium, lasting two days, as the result of two and one-half drachms of oil of wintergreen, given in the course of twenty-four hours. Should poisoning occur the salicylates must be discontinued, bromides and chloral must be given, the heart being carefully watched, and in most cases no permanent harm results. As the pains subside, and the temperature comes down, the dose of salicylate may be reduced, but the medicine must be continued for several days after all pain has disappeared, otherwise the symptoms may return. Some authorities claim that relapses are more frequent under the salicylates than under the older systems of treatment. This does not seem to be the case, provided the medicine be continued long enough. The salicylates have no effect upon a cardiac lesion, once established, but by their action in shortening the disease and lessening its virulence and severity, they certainly protect the heart to some extent.

How the salicylates act is a question difficult to answer. They are not strongly antipyretic and analgesic, like acetanilid and phenacetin, and, according to Miquel, they are rather feebly antiseptic, salicylic acid being effective in preventing bacterial growth in a strength of 1 to 1,000, while salicylate of soda requires a strength of 1 to 100. Salicylate of soda has been found useful in relieving unpleasant symptoms due to diphtheria antitoxin, and if we suppose rheumatism to be due to intoxication rather than to infection, this may be the answer to the question. The efficacy of the salicylates is beyond question, but the reason for this efficacy needs further investigation.

There are some unfortunate patients who, on account of idiosyncrasy, cannot take salicylates at all. For these we must rely upon the old-fashioned alkaline treatment. Twenty grains each of citrate and bicarbonate of soda may be given every two or three hours. The results of this treatment are not brilliant.

Local treatment of the affected joints is advisable, with the idea rather of increasing the patient's comfort than of affecting the course of the disease. The joints must be kept at rest in the least uncomfortable position attainable. They should be protected by bandages of flannel, or lightly packed in cotton batting or wool. They may be dressed with a ten-per-cent. ointment of salicylic acid, or with pure oil of wintergreen, or with guaiacol, dissolved in olive oil, or incorporated with lanolin or lard. The joints must not be handled at all. The writer has seen most exquisite agony in a case under his care, caused by an ill advised friend of the patient, who insisted upon gently stroking her inflamed wrist. The manipulation gave momentary comfort, but within an hour the wrist swelled almost to twice its normal size, and throbbed until it was necessary to use iced cloths to relieve the pain. Ice has been commended as an application in rheumatism, also heat in various forms. In some cases hot or cold applications are of use, the choice lying with the one which gives the greater comfort, but in most cases protection and ointments will give all the comfort attainable. Occasionally after an obstinate case of rheumatism, one or more joints exhibit a low grade of chronic synovitis. These are best treated by blistering, followed by a tight bandage.

Of the complications of the disease, endocarditis calls for little or no direct treatment. The patient must be kept absolutely quiet, with the head low. If the heart be overacting, ice may be applied. Very rarely, if ever, does rheumatic endocarditis cause urgent cardiac weakness. Should this appear, the salicylates must be stopped, and a little strychnine may be very cautiously administered. No more than necessary should be given, for every extra heart beat may cause the endocarditis to spread. Pericarditis, on the other hand, calls for active treatment. An ice bag, or a cold coil, should be applied over the heart, aconite, in one-drop doses of the tincture, may be given under careful observation, and morphine or codeine may be needed to relieve the pain. If effusion appear, blisters and diuretics are required, and if these fail to cause absorption the pericardium may require tapping. Of the nervous complications, the neuralgic pains are best treated with local applications of pure oil of wintergreen, or of menthol, twenty-five per cent. in alcohol. Hyperpyrexia must be treated by cold baths. No other antipyretics are of the least use. Alcohol and strychnine are also needed. The treatment of this condition is quite similar to that of sunstroke, to which it is probably akin. The neurasthenic and melancholic conditions seen sometimes during convalescence require appropriate care, but these conditions have no peculiar features depending upon the rheumatism that caused them.

The skin complications require no treatment. The treatment of the respiratory complications is on general principles.

The after-treatment requires tonics, general hygienic regulation of the daily life, and avoidance of over-exertion. It is well to have the throat carefully examined and, if necessary, treated, for there is ample warrant for believing that future attacks may occur as the result of infection of a diseased tonsil. *Donald M. Barstow.*

RHEUMATISM, CHRONIC ARTICULAR.—DEFINITION.—A chronic affection, characterized by stiff and painful joints.

ETIOLOGY.—The impression is gaining ground that chronic, as well as acute, articular rheumatism is of bacterial origin, although the responsible micro-organisms have not as yet been identified. The disease, according to continental writers, is a frequent sequel of acute rheumatism, but in North America it is more commonly independent of antecedent acute or subacute attacks. It occurs most frequently after the middle period of life, especially among those who, in addition to contending with the hardships of poverty, must engage in occupations of a laborious character which involve exposure to cold and dampness, such as day laborers, farmers, hunters, washerwomen, and the like.

PATHOLOGY.—The cavity of the joint is not infrequently dry. The synovial membrane and its villi are

www.libtool.com.cn

Digitized by Microsoft®

www.libtool.com.cn

thickened and injected, and adhesions may form between the opposing surfaces. The articular cartilages are distorted, perhaps eroded and partly absorbed in cases of long duration. The capsule and ligaments of the joint and the tendon sheaths adjacent to the affected articulation are thickened. Atrophy of the muscles in the vicinity of a chronically rheumatic joint is by no means uncommon, especially when single large articulations (knee, shoulder, hip) are involved. Atrophy from disuse is likely to occur if the joint becomes ankylosed. Peripheral neuritis and pressure from exudation on the muscles themselves or their nutrient vessels have also been designated as factors in the muscular wasting.

SYMPTOMS.—The conspicuous symptoms are pain and stiffness in the affected joint. Most commonly the onset is slow and insidious. The pain usually becomes more severe during rainy weather, particularly in the variable climatic conditions of spring and autumn. The stiffness is most marked in the morning and after rest, and lessens after exercise. The pain is apt to be increased by movement, and is often very troublesome at night. The affected joints may be tender upon palpation, but swelling, if present, is usually slight. The inflammation is rarely of sufficient intensity to cause redness of the joint. The course of the disease is as a rule afebrile, but if many joints participate in an exacerbation there may be a slight and transient rise of temperature. The disease may be monarticular, involving a single large joint, the knee, shoulder, or hip in particular, but generally a number of joints, both large and small, are implicated. The joints, if the disease is of some duration, are likely to creak or grate when moved, because of the dryness and roughness of the articular surfaces. In cases of long standing the joints are enlarged and distorted, the mobility is decreased in varying degrees, and they may become completely ankylosed. Muscular atrophy takes place, and the patient may, in the severest cases, become bedridden. The joint changes when established are usually persistent, and do not shift from one articulation to another as in rheumatic fever. In mild cases the general health may remain wellnigh unimpaired, but in the severer and more painful cases gastric disturbances, emaciation, anæmia, and neuralgias may be present with varying intensity. Other complications are not common, but chronic endocarditis, with resultant valvular defects, may be associated with the joint changes.

DIAGNOSIS.—Chronic articular rheumatism may require to be differentiated from chronic articular gout and arthritis deformans, although in the majority of cases the diagnosis is easily made.

Gout is more apt to affect the smaller joints. There is usually a history of acute attacks involving the great toe-joint, tophi if found are distinctive, and the evidences of arteriosclerosis and granular kidney are much more common in gout than in chronic rheumatism.

It is difficult, and readily may be impossible to distinguish between arthritis deformans and chronic rheumatism in the early stages. In more advanced cases the former presents greater deformity of the joints, while rheumatism tends rather to ankylosis with comparatively slight alteration in shape, and moreover is likely to attack a larger number of articulations than arthritis deformans. It is proper to state that by some writers arthritis deformans is regarded as an advanced stage of chronic rheumatism.

PROGNOSIS.—The presence of chronic rheumatism is, as a rule, not incompatible with a long life, but it is essentially a chronic ailment, and the majority of cases are obstinately resistant to all therapeutic measures. In exceptional cases great improvement or apparent cure may take place; in many the disability and pain may be much relieved; in some the disease may seriously affect many joints and render the patient helpless.

TREATMENT.—If circumstances permit, the patient should live or at least spend the winter months in a warm, equable, dry climate, such as that of Southern California or the South of Europe. Otherwise the utmost care should be taken to shield the subject from dampness, cold, and bad weather by good shelter and warm clothing. The digestive functions should be maintained in good order, enemata and laxatives being employed when they are required. The diet should be regulated so that it is digestible and ample in order to keep the nutrition of the body at its best. Moderate exercise should be taken when possible. A daily cold sponge followed by a good towelling is usually helpful, and those who find that the sponging disagrees with them should employ the dry friction alone.

Local treatment is of prime importance. Counter-irritation should always be used, by means of stimulating liniments or by painting with tincture of iodine; by the application of a series of small blisters; or by "striping" the painful joint with the Paquelin cautery, or, what answers as well, with a glass rod, the end of which has been heated in an alcohol flame. The application of ichthyol and iodine, salicylic acid (gr. xxx. to ℥ i.) or belladonna ointments, is at times of much service. Systematic massage and passive movements are useful, especially for the prevention of ankylosis and atrophy, and for the lessening of swelling and stiffness. Electrical treatment may or may not be of service, but is always worth a trial.

Hydriatic measures of various kinds should not be omitted. At home a hot bath at night often mitigates pain and secures a more restful sleep; so also do hot fomentations of the painful joints. Or, finally, the affected joint may be wrapped in three or four thicknesses of linen wrung out of cold water and covered with flannel and oiled silk or, in lieu of the latter, thick brown paper.

Complete and systematic hydriatic measures, including also the hot-air treatment (baking the affected joints) generally require a daily visit to, or, if practicable, a stay of some duration in, an establishment provided with the necessary apparatus and trained attendants, particularly in the sanatoria which avail themselves of natural medicinal and thermal waters. Among the latter are the Hot Springs of Arkansas and Virginia, Richfield Springs of New York State, Banff on the Canadian Pacific Railway in the Rocky Mountains, Mt. Clemens in Michigan, and Santa Rosalia * in Mexico. Here and in Europe a variety of baths—Turkish, Roman, sand, mud, and peat—have been employed. Thorough and persistent hydrotherapeutic treatment usually secures great relief, and even in obstinate cases a permanent cure is sometimes obtained.

Medicinal treatment is not very satisfactory. As a rule the administration of iron, quinine, strychnine, arsenic, and other reconstructives is helpful; so also is a course of cod-liver oil, mixed fats, or extra butter and cream in the dietary. Iodides, guaiacum, colchicum, alkalies, and bichloride of mercury, are occasionally useful. The salicylates are unquestionably beneficial during marked or subacute exacerbations.

Glentworth R. Butler.

RHEUMATISM, MUSCULAR.

—(Synonyms: Myalgia, rheumatic myositis.)

DEFINITION.—A disease characterized by (1) stiffness and soreness on motion of certain muscles; (2) tenderness on deep pressure over certain points in their substance; and occasionally (3) a general constitutional reaction.

CAUSE.—Muscular rheumatism is probably, like the articular variety, a local manifestation of a general toxæmia. Of the primary causes little is known. Some cases are probably of infectious origin. Others seem to belong to the group of auto-intoxications whereof gout is the classic type.

MORBID ANATOMY.—Adler (New York *Medical Record*, vol. lvii., p. 529) describes the process as follows: In one or more places hyperæmia, sometimes accompanied by

* "Santa Rosalia, a city of Southern Chihuahua, Mexico, on the Mexican Central Railway, 325 miles south of El Paso. It is celebrated for its hot sulphur springs, long known to be curative by the natives, and much resorted to by invalids. They are especially useful in inflammatory rheumatism. Population estimated at 8,000." From "The Universal Cyclopaedia and Atlas." Newly revised edition. Appleton & Co. 1901.

Digitized by Microsoft®

small hemorrhages, takes place, followed by emigration of cells into the interstitial tissues, crowding between the bundles of muscle fibres and even between the single fibrils. Soon the interstitial tissue proliferates actively, bringing about an infiltration of the muscle, which varies in extent and density according to the intensity of the process. In the milder cases the process ends here, the infiltrating material is absorbed, and the muscle returns to practically the normal condition. In severe cases, however, there is more extensive formation of new connective tissue, which compresses the muscle fibres so that they degenerate and are absorbed. In cases of the severest type, there results a hard white mass of cicatricial tissue, in structure like a bit of tendon. Often the process is not confined to the muscles. The neighboring joints, fasciæ, tendons, and especially nerves, may be involved. The nodules are recognizable on palpation by a trained hand. They are not necessarily found in the spot where the pain is felt, for if a nerve be involved, the pain will usually be referred to the peripheral distribution of that nerve.

www.libtool.com.cn

Clinical History.—The disease most commonly affects one of four localities as follows: (1) The deltoid muscle; (2) the lumbar muscles (lumbago); (3) the intercostal muscles (pleurodynia); and (4) the sterno-mastoid muscle (torticollis, wry-neck). The relative frequency of these locations is hard to ascertain, for many patients are not sick enough to go to bed, and hence go to the dispensary rather than to the hospital. Less frequently we find the trouble located in the muscles of the head, especially the suboccipital region, and occasionally in the muscles of the jaw. Adler (*loc. cit.*) reports three cases of rheumatism in the abdominal muscles, one case simulating biliary colic, the other two suggesting appendicitis. No one of the voluntary muscles is altogether exempt.

The disease may be ushered in by a chill, a febrile movement, and all the signs of an acute infectious disease. This is uncommon. Most patients develop their symptoms gradually, and the disease runs a subacute course, although it is rarely without some fever. The pain is not usually excessive. It is increased by attempts to use the affected muscles, and also by lying upon the affected side. It is dull and aching in character, and very tiresome and wearing. In some cases, where nerves are involved, the pain is paroxysmal and radiates over a wide surface. Such cases are often puzzling.

Diagnosis.—In typical cases this is very easy. Lumbago and wry-neck are common enough, and not easily confused with anything else, although in the former case pyelitis, and in the latter, deep cervical cellulitis, must be thought of. Deltoid rheumatism has been confused with necrosis at the upper end of the humerus. Intercostal rheumatism may be mistaken for pleurisy. Suboccipital rheumatism may be confused with neuralgia, neurasthenic headache, or migraine. Abdominal rheumatism may simulate disease of the liver and gall bladder, the appendix, or the uterine adnexa. In doubtful cases the diagnosis must be made by palpation of all the muscles in the region where pain is felt. "The infiltration varies in size, shape, and consistency. After subsidence of the acute stage the infiltrations may be recognized by careful palpation. . . . They may be round, fusiform, or flat, hard and firm or soft and doughy, with surface smooth or uneven. . . . While normal muscles react upon a certain vigorous grip with contraction of the part touched, the diseased tissue will react with diminished vigor or not at all; it also shows diminution of the normal elasticity. After the acute stage is past, although the muscle resumes its function without pain, yet the diseased areas remain tender upon pressure. . . . When examining, it is necessary to compare the two sides of the body. Aside from other changes, the diseased side will always be found abnormally sensitive" (Adler, *loc. cit.*).

Course and Prognosis.—The course is uncertain. Some cases clear up rapidly, others are very obstinate. In a general way it may be said that muscular rheumatism runs a slower course than the articular variety, and also has a greater tendency to relapse, as slight lesions usually remain in the muscle substance after the subsidence of the attack. It also has a strong tendency to become chronic. Therefore the prognosis as to complete recovery should be guarded.

Treatment.—In all but very mild cases the patient should be put to bed whenever possible, in order that the affected muscles may be at rest. A brisk purge is essential, if it be our aim to promote elimination of the toxins. Further treatment depends upon the cause of the attack, in so far as the cause can be made out. If the affection be a true rheumatism, the salicylates must be given in full doses for two or three days; if it be an auto-intoxication, the salicylates are generally useless, and an eliminative treatment, as for gout and allied conditions, must be adopted. An exclusive milk diet, with the bowels freely opened every day, is useful, and this may be given to the walking cases, provided they will take enough—at least four quarts a day, and six if possible. Milk is diuretic, and comparatively free from toxalbumins. Local treatment, in the shape of counter-irritation in various forms, is usually necessary. It may take the form of a blister, or a few quick strokes with the actual cautery at white heat, or acupuncture, or painting the skin over the affected muscle, with guaiacol, or the oil of wintergreen, or a twenty-five-per-cent. alcoholic solution of menthol crystals. W. G. Thompson recommends injections of sterilized water into the deeper parts of the substance of the muscle. Adler commends massage very highly, but declares that the masseur must be specially trained to the work. Of course massage cannot be used until after the acute stage is passed.

The after-treatment of these cases is highly important. The patient must keep his skin in healthy activity by daily bathing. Overclothing must be avoided. The test of this is, that there shall be sufficient for comfort, but it must be so regulated that in any ordinary weather the skin shall not be moist except after brisk exercise. Moderate and regular daily exercise, in open air and daylight, promotes complete oxidation of the food, and thus protects the system against auto-intoxication. Regarding diet, it may be said that the albumins should be somewhat restricted. Alcoholic liquors should be taken only in small quantities. A good whiskey, well diluted, is probably the least harmful stimulant. Large quantities of water—four pints a day—should be taken to keep all the urinary salts in complete solution. Over-fatigue and sudden violent exertion are to be avoided.

Donald M. Barstow.

RHEUMATOID ARTHRITIS.—(Synonyms: Rheumatic gout; deforming arthritis; chronic rheumatic arthritis; rheumatic joint; osteo-arthritis.)

Definition.—A chronic and progressive disease of the joints characterized by deforming changes in the synovial membranes, cartilages, and bone, with peri-articular bony outgrowths which interfere to a greater or less extent with the mobility of the affected articulations.

Etiology.—As a rule the disease develops between thirty and fifty years of age, although it may occur in children under twelve. It exists with preponderating frequency in women, from one-half to four-fifths of the cases occurring in this sex, especially at the time of the menopause. Sterility and uterine or ovarian disease apparently predispose. There is in some cases a family history of a tendency to gouty or other disease of the joints, or to tuberculosis of the lungs; and two or more cases may occur in the same family. Worry, grief, mental shock or overwork, exposure to cold and dampness, insufficient diet, and local traumatisms appear at times to be exciting causes. There are two theories as to the essential cause of the disease; one, that it is of nervous origin; the other, that it is a chronic infection. According to the former theory the disease is akin to the arthropathies of nervous origin. Thus the joint changes in arthritis deformans are very similar to those which may occur as a result of locomotor ataxia, syringomyelia,

Digitized by Microsoft®

hemiplegia, and injuries of nerve trunks. The not infrequent presence of neurotrophic phenomena, such as marked muscular atrophy, glossy skin, and alterations in the nails and bones, is of some significance, so also is the occurrence of numbness, tingling, and severe pain, involving special nerve distributions. Moreover, the joint lesions are usually symmetrical.

www.libtool.com.cn

On the other hand, the idea that the disease will prove to be a chronic infection is gaining adherents, although a specific microbic agent has not as yet been identified. In favor of this view is the fact that, in a considerable proportion of cases, arthritis deformans follows an acute infection, especially gonorrhœa and epidemic influenza. In some instances the onset is acute and the joints are red, swollen, and painful; and in children there may be splenic enlargement and swelling of the lymphatic glands.

Pathology (or Morbid Anatomy).—The morbid changes begin in the cartilages of the affected joints, which after proliferating become softened and, especially in the centre and at the points of greatest pressure, are absorbed or worn away. The exposed articular bone surfaces become smooth and ivory-like (eburnated). The proliferating cartilages and synovial membranes at the border of the joint form an irregular fringe of nodules and polypoid bodies which ossify (osteophytes) and interfere more or less seriously with the mobility of the joint. The ends of the bones may become enlarged, and the ligaments are greatly thickened. Complete ankylosis is not infrequent, due principally to the locking of the joints by the osteophytic growths (Haygarth's nodosities) and the thickened ligaments. In elderly persons and in cases of long duration the articular ends of the bones may undergo wasting, so that the head of the humerus, or of the femur (morbus coxæ senilis), may practically disappear, causing partial dislocations and false joints. The affected articulations are more or less misshapen and the deformity may reach an extreme grade. When the hand is affected the fingers frequently bend laterally toward the ulnar side. The great toe is deflected toward the outer border of the foot. The vertebræ when diseased may be completely ankylosed by bony outgrowths, and the spinal column thus consolidated. Atrophy of the muscles about the joint, sometimes of extreme degree, is of common occurrence.

Symptoms.—Five varieties of the disease are recognized—the general progressive form, the monarticular form, the vertebral form, the form affecting children, and Heberden's nodes.

The *general progressive* form may be acute or chronic. The *acute* outbreak occurs especially in young women in connection with parturition and lactation, or in older women at the menopause; it is occasionally observed in children. The symptoms resemble those of rheumatic fever. A number of joints become swollen, seldom reddened, and there is a moderate rise of temperature. The subjects become anæmic, low-spirited, and lose flesh and strength. In some instances the disease may greatly improve, only to renew its onset under the influence of further child-bearing or nursing.

The *chronic* variety is that which is observed in the majority of the cases. As a rule one or two joints, usually of the hands, are first involved; then those of the knees and feet and other articulations; finally, in the severest cases, all the articulations may be implicated. The involvement is usually symmetrical. The earliest symptoms are slight swelling in or about the joints, and pain on movement with impaired mobility. There may or may not be effusion into the joint. The pain may be extremely severe and continuous, or slight and variable. It is usually worse at night and during the exacerbations. The disease progresses irregularly, days or weeks of improvement alternating with renewals of pain, swelling, and stiffness. Slowly the joints become deformed by ligamentous thickening and the formation of bony outgrowths. The mobility of the joint decreases and creaking or grating is felt or heard upon motion. In the end the joint may be completely immobile, owing to the checking action of the osteophytes and the fibrous thickening of the capsular ligaments. The disused muscles waste away, and when contractured may give rise to persistent flexion of the affected members. In the worst cases the patient is bedridden and almost if not quite helpless. In one case under observation practically every joint in the body was ankylosed; even the lower jaw was wellnigh immovable. Tingling, numbness, glossy or pigmented skin, onychia, rapid muscular atrophy, and increased reflexes have been observed. Anæmia and gastro-intestinal disturbances are not uncommon, especially during the exacerbations of the disease. The heart is not often involved, but in one personal case, that of a young woman, there were advanced arteriosclerosis and an aneurismal dilatation of the aorta.

The *monarticular* form affects especially the hip, knee, or shoulder, occurs mainly in old people, and not infrequently is an apparent sequel to an injury. The pathological changes are similar to those of the chronic general form, and the muscles early undergo atrophy. When affecting the hip the disease constitutes the morbus coxæ senilis, the anatomical alterations of which have been described.

The *vertebral* form, spondylitis deformans, is a progressive rigidity of the spine, due to ankylosis of the vertebræ. Two types are described. The first is the so-called spondylitis rhizomelia (Strümpell-Marie), which attacks men only at or beyond middle age. It begins usually in the hip-joints, which become ankylosed, the process subsequently extending to the spine and shoulder-joints, very rarely to the knee-joints. The spine becomes rigid, the ribs flexed, and there is some kyphosis. The dorsal and gluteal muscles are atrophied and exostoses are found upon the vertebræ and sacral bones. There is but little pain attending the process. In the second (Bechterew-Marie) type the disease begins in the spine, which becomes ankylosed and kyphotic, the shoulders stoop, the head is lowered and carried forward, and there is much intercostal pain, with anæsthesia, muscular atrophy, and other signs of involvement of the roots of the spinal nerves. The hip- and shoulder-joints are slightly if at all affected. The disease is often hereditary. There is little doubt that both types are forms of arthritis deformans, and are not, as formerly supposed, independent diseases.

Heberden's nodes, knobby enlargements of the proximal ends of the terminal phalanges of the fingers, are much more common in women than in men; they begin, as a rule, between thirty and forty years of age. They are regarded as indicative of a long life, but it has been stated that cancer occurs with undue frequency in women who have such nodosities. While the nodes are forming the affected joints may be tender and swollen, perhaps slightly reddened. Exacerbations may be excited by dietary errors, or slight accidental traumatisms; but in most instances the attacks alternate with periods of quiescence without apparent cause. Fortunately, those who develop Heberden's nodes seldom have the larger joints affected.

The *juvenile form* occurs more frequently in girls than in boys and, as a rule, before the second dentition. While the disease may be a replica of that affecting grown persons, the most important class of cases differ in many respects from the adult affection. The onset may be acute, with fever, possibly with chills, but generally the first symptom is a slight stiffness in one or two joints, others slowly becoming affected. There is no crepitus in the affected joints, and the main anatomical change is a general thickening of the periarticular tissues and enlargement of the joint with little or no alterations in the bones. The mobility of the joint is impaired, perhaps totally destroyed. There may be marked atrophy of the muscles. The most interesting feature of the malady is a general and marked swelling of the lymph glands, occurring especially in the cases attended by fever and increasing with the latter. The spleen also is enlarged and palpable. Profuse perspirations are rather common. The heart is rarely affected. The subjects are anæmic, weak, and ill-developed.

Digitized by Microsoft®

www.libtool.com.cn

DIAGNOSIS.—In the early stages it is always difficult and frequently impossible to distinguish arthritis deformans from chronic rheumatism. When the disease is well developed the diagnosis is seldom in doubt. The peculiar joint deformities in advanced cases are quite characteristic. The more acute cases may be mistaken for rheumatic fever, but the slighter fever, the lesser pain, redness, and swelling, and the usual absence of cardiac complications separate it from the latter. From gout arthritis deformans is distinguished by the absence of chalky deposits and, usually, of cardio-renal disease, as well as by the fact that gout usually attacks the metatarso-phalangeal joint of the great toe.

PROGNOSIS.—In a majority of cases the progress of the disease is arrested, leaving several joints more or less crippled. In other cases the disease advances irregularly, with periods of quiescence, and persists throughout the life of the patient. A few become helpless and bedridden. As a rule the milder forms of the disease are not incompatible with fair health and a long life, but the disability may be very great.

TREATMENT.—It is of prime importance to maintain the general health at its highest point. Plenty of fresh air, daily cool or cold sponging followed by vigorous toweling, well-ventilated sleeping-rooms, ample hours for sleep, daily exercise according to ability, laxatives and digestive tonics when needed, and a liberal dietary of meat, eggs, milk, butter, wine and malt liquors, should be considered essentials.

Local treatment embraces cold or hot compresses covered with oiled silk, and left on for two or three hours at a time, massage carefully given and long continued, persistent hot-air treatment (baking), small and repeated blisters, "striping" from time to time with the thermo-cautery, friction with ointments containing iodine and ichthyol, systematic passive movements, and even the forcible breaking of adhesions in selected cases.

Hydriatic treatment should be begun early and is of great value. At home a nightly plain hot bath, hot Nauheim bath, or hot-air bath may be employed. If the patient is able he should go to a hydriatic establishment in connection with a natural thermal or medicinal water, such as the Hot Springs of Virginia or Arkansas, Mt. Clemens in Michigan, Richfield Springs of New York, Green Sulphur of Florida, or Sharon Springs; Bath in England; Baden, Wiesbaden, Aix-les-bains, Carlsbad, Gastein, Homburg, or Wildbad on the continent of Europe, or the sand baths, mud baths, and peat baths of various localities.

Electricity may be employed, but its effects are uncertain.

Medicinal treatment is at times very helpful. Iron, arsenic, and cod-liver oil in full doses are the remedies that are especially indicated. Iodide of potassium (five to ten grains), or the syrup of the iodide of iron (ten to twenty minims) three times daily are especially useful if there is much periarticular thickening. In the acute polyarticular attacks the salicylates are unquestionably of great value. *Glentworth R. Butler.*

RHIGOLENE.—Of the products of the fractional distillation of petroleum the lightest is obtainable as a fluid by condensation, and consists mainly of the paraffin *butane*, a body gaseous under ordinary conditions. This condensed distillate is termed *cymogene*. The distillate of next higher boiling-point boils at about 18° C. (64.4° F.). Such distillate consists largely of the fluid paraffin *pentane* ("amylic hydride"), C_5H_{12}, and is the substance commonly known as *rhigolene*. Rhigolene is a colorless, mobile fluid of slight and not unpleasant odor and taste; very light, very inflammable, and, as its boiling point predicates, very volatile. It mixes in all proportions with common (ethylic) ether. Rhigolene was proposed by B. W. Richardson as a substitute for ether for the production of local anæsthesia by freezing, after his method. Because of the low boiling-point of rhigolene—lower than that of ether—the cold produced by the evaporation of a spray of rhigolene is very intense and very rapidly attained. Dr. Richardson observed an area of skin become hard, white, and insensible at the expiration of *two seconds* after beginning the driving upon it of a rhigolene spray. But such very rapid freezing Dr. Richardson found to be undesirable, because the intense cooling of the superficial frozen area prevents the abstraction of heat from below, and so limits unduly the depth to which the anæsthesia can be carried. Hence Dr. Richardson proposed a mixture of rhigolene and anhydrous ether in equal parts. Rhigolene dissolves camphor, spermaceti, and iodine, and has been used by Richardson, again, as a solvent of those bodies for use for local applications. A rhigolene solution of camphor and spermaceti together Richardson found to make an excellent conjoint cooling anodyne and healing application to burns. The vapor of rhigolene, inhaled after the manner of vapor of chloroform, is readily taken, and produces general anæsthesia with great rapidity. But in this application rhigolene has shown itself dangerous, and has never come into practical use.

Edward Curtis.

RHINOSCLEROMA.—A chronic infectious disease affecting chiefly the nose, the mucous membrane of the mouth, pharynx, and larynx. It is due to a bacillus resembling in some respects the bacillus of Friedländer, and is characterized by the formation of diffuse and nodular swellings of extreme hardness, often followed by dense cicatrices. It is a disease of extreme chronicity, and has not been found to be amenable to any form of treatment.

The disease was first described by Hebra in 1870 as a tumor formation situated in the nose or its vicinity. The growth is constant, but exceedingly slow; it is hard and indurated and sharply circumscribed, the surrounding tissue showing no inflammatory or other change. The growth appears in the form of smooth nodes of various size or as a diffuse induration. The surface is smooth and shiny, and either of a brownish-red or normal color. It is painless in itself, but painful on contact. It produces no danger to the organism save by mechanical interference with respiration.

Kaposi gave a more detailed description of the process in 1873. In this he calls attention to the frequent involvement of the soft palate, due to the extension of the process from the nose. It begins in the mucous membrane of the side of the nose or in the cartilaginous septum. It may produce narrowing and even complete closure of the nares, and from the nose it extends to the pharynx, to the upper lip, to the hard palate, and to the alveolar processes of the upper jaw.

We owe our chief knowledge of the disease to two monographs, one by Mikulicz (*Arch. f. Chirurgie*, 1876, vol. xxvii.), and the other by Wolkowitsch (*Arch. f. Chirurgie*, 1889, vol. xxxviii.). There have been in addition a series of publications of single cases often giving detailed histological reports, and the discovery of the bacillus by Fritsch in 1882 has been followed by a long series of articles on the presence of the bacillus, its relation to the lesions, its cultural characteristics, morphology, etc.

The investigations of Mikulicz were made on two cases. One of these had lasted for sixteen years, and the growth had so interfered with function that operative removal of a considerable part of it became necessary. The growth began on the inner surface of the left nostril as a small nodule, which gradually increased in size. Nodules accompanied by diffuse induration almost completely closed the nose and extended to the septum and the upper lip. The affected parts were dark red and extremely indurated. The nose, which was at first greatly enlarged, gradually sank and its form was lost. The infiltrated upper lip was drawn upward and backward, and the entire area affected became a flattened indurated mass. There was gradual narrowing of the mouth, which became so hard and stiff as to interfere with eating. The opening finally became so narrow that only the point of the small finger could be passed into it. An operation was performed consisting in enlargement of the

Digitized by Microsoft®

mouth by extensive removal of the indurated tissue about it. The entire upper lip and a part of the cheek were adherent to the alveolar processes. The middle of the hard palate was covered with irregular cicatrices, which extended to the soft palate and were joined with similar cicatrices in this. The diseased tissue, although so hard to the touch, gave little resistance to the knife and the hemorrhage was slight. In the second case the disease appeared as an enlargement and induration of the nose, which after five years became double in size. The tissue removed was similar in character to that removed in the first case, and was so hard that fair microscopic sections could be made of it in the fresh state.

www.libtool.com.cn

At the time of the publication of Wolkowitsch the disease had become much better known. Quite a number of cases had been published, and on account of the extent of the lesions in the pharynx, which had been largely neglected by the first authors, the name pharyngoscleroma had been proposed as a substitute for rhinoscleroma. It had been further found that the disease often extended into the lower part of the larynx, and especially on the lower surface of the vocal cords and sometimes into the trachea. The laryngeal and tracheal lesions have been specially studied by O. Chiari and Bendler. In 1873 Gerhardt described under the name of "chorditis vocalis inferior hypertrophica" a form of disease of the larynx which he characterized as a chronic inflammatory hypertrophy of the vocal cords leading to stenosis. From a review of the literature he concluded that the condition had been known before, but not recognized as an independent disease.

Langhofer in 1880 studied the condition histologically, and found the lesions characteristic of rhinoscleroma. He held the two conditions to be the same, and that scleroma could appear in the larynx and trachea independently of any affection of the nose. This was shortly confirmed by O. Chiari, and in 1885 Chiari and Rhiel collected thirty cases of rhinoscleroma, in nine of which the disease had extended into the larynx. In Bandler's case, which was studied from autopsy, the larynx was stenosed in high degree by a thick, hard mass of tissue extensively ulcerated. The trachea was stenosed; its wall was 0.75 cm. thick. This thickening came chiefly from the mucosa and submucosa, which was converted into a hard mass of tissue, partly covered with thickened epithelium and partly ulcerated. On the inner surface of the trachea there were radiate cicatrices. The infiltration extended down to the bifurcation, and for a distance of from 1 to 1.5 cm. into the primary bronchi. The lesion extended up to the pharynx and nares, but without altering the external appearance of the nose.

Wolkowitsch gave a complete clinical and anatomical description of eleven cases, together with short descriptions of all of the cases which he could collect from the literature. In his first case ulceration was prominent. The disease often begins with the appearance of a nodule or as an induration, either at the sides or in the median line of the nose. In certain cases the induration extends over the whole nose and down to the lip, or the chief extension may be backward, or it may extend in both directions. Ulceration is rarely a prominent feature, but in certain cases large crater-like ulcerations, with elevated indurated edges, are formed; they present some similarity to carcinoma.

In other cases the growth seems gradually to fill up the nose. It grows more rapidly from the interior than from the exterior. The nose becomes enormously enlarged and flattened laterally.

The disease is usually found in the lower classes, and it is difficult to get information as to the manner of onset. Sometimes catarrh was noticed as the first symptom. When ulceration is present, the ulcers discharge a thin fluid which is often offensive. There may be external nodules which represent an extension from the interior and give but little idea of the extent of the process. The upper part of the nose is not affected, so that the sense of smell is not lost as long as the external opening is left. In rare cases the disease begins in the pharynx and larynx, and the disease of the nose is secondary and may not appear. The lachrymal sac has been secondarily affected in a few cases, and the disease has also extended into the Eustachian tube. The deeper parts are rarely affected, but in some instances both thickening and ulceration of the cartilage and of the bones has been found. When the disease appears in the nostrils there is a great tendency for it to extend to the upper lip, especially upon the external surface. The nodules are often covered by a network of veins. The gums are thickened; irregular, hard, dark or bluish-red nodules, which sometimes extend to the mucous membrane of the palate, are formed on them. The teeth lose their direction, become pressed forward or backward, and often thrown out. The disease is almost invariably symmetrical, affecting chiefly the middle line and extending equal distances laterally. The growth extends very slowly but continuously. In one of Mikulicz's patients there was more rapid growth at each pregnancy. Like so many affections of the skin there is a continuous peripheral extension with central cicatrization and contraction. There seems to be but little tendency for the lesions to become the seat of pyogenic infections or other secondary processes.

In one case a carcinoma developed in the lesion after the disease had existed for twenty-five years.

The first histological examination was made by Kaposi, who regarded the process as a sarcoma. He found the papillary body and superficial corium thickly infiltrated by small cells, while the deeper layers showed a thick connective-tissue network with slight cellular infiltration. The next investigation was that of Geber, who disagreed with Kaposi, and considered the disease a chronic inflammatory process and not a tumor. Mikulicz also regarded it as a chronic inflammation. Microscopically, he found areas of round-cell infiltration, and, among these, cells which were much larger and paler, with a pale vesicular nucleus. The growth was sharply separated from the normal tissue. Proceeding from the normal tissue to the growth the first change seen was atrophy of the sebaceous glands and the hair follicles. The infiltration was chiefly in the deeper layers of the corium, the papillary body showing little change other than atrophy. Mikulicz considers that the lesions in the epithelium are due to the deep cellular infiltration; the vessels passing through this are in part compressed, and they serve rather the nutrition of the growth than that of the normal tissues. The sweat glands also become atrophied. The connective tissue at first is unaltered, its fibres being simply pressed apart. In places it loses its fibrillar character and the intercellular substance becomes homogeneous. Nerve bundles may be found running through the infiltration, but they seem to be especially resistant. The muscles are destroyed much earlier than the nerves. They are atrophied, often show the degenerative proliferation of nuclei, and in places where the infiltration is more rapid they become hyaline. Fat cells are often present to a considerable extent. Mikulicz thinks that the large cells arise from the connective tissue.

Cornil and Alvares in 1883 called attention to the appearance of hyaline masses in the large cells first described by Mikulicz. They found that the bacteria were in relation to the hyaline masses, which, as they supposed, in part represent the bacterial capsules, and in part are due to a hyaline degeneration of the cells brought about by the bacteria. Wolkowitsch believed that the large cells represented a special form of degeneration of the granulation cells. The hyalin has the general characteristics of hyalin as described by von Recklinghausen. The cells occasionally break down and leave the hyalin free. The peculiar refraction of the fresh tissue and its peculiar induration are due to the hyalin.

The rhinoscleroma bacillus was first described by Fritsch in 1882 in all of the twelve cases which he investigated. The bacilli have been found constantly by every investigator. They are present in large numbers, and are chiefly in the large cells, though they may be found between them; they vary somewhat in size; they are short,

Digitized by Microsoft®

often appearing in double form, and they present some resemblance to the pneumococci, but they are usually much larger. The capsule formation is a permanent characteristic and may be demonstrated even in the tissues. The best way of showing them is to harden the tissue in one-per-cent. osmic acid and then to stain it with some aniline color. The capsules by this means become very prominent, and have a grayish-brown color.

www.libtool.com.cn

From the appearance of the organism and from its cultural characteristics it was considered by many to be identical with the bacillus pneumoniæ of Friedländer, and a great deal of the bacteriological literature has been on this subject, but the general opinion now is that it is distinctly different. The organism in culture has the following characteristics: It forms a mucoid cap-like colony on gelatin plates; no gas in sugar-agar; no acid in milk-sugar bouillon. The best description of the differential diagnosis between the scleroma bacillus and Friedländer's bacillus is that of Paltauf, who investigated fifteen cases. The principal points of difference between the two are these: first, the superficial whitish extension of the scleroma bacillus on gelatin is drier and more consistent than the corresponding growth of Friedländer's bacillus; second, there is an entire absence of gas formation in sugar-agar; and, third, the organism develops very imperfectly on acid media.

The geographical distribution of the disease is narrow. The first cases were seen in Austria, and the disease has always been more frequent there than elsewhere. The disease is also not uncommon in Russia, where Wolkowitsch studied his cases, but Central America and chiefly the republic of San Salvador seem to be the principal seat of the disease after Austria. Cases have also been observed in France, Germany, Belgium, and Cairo. Only five cases have been reported in the United States, and only one of these was a native American.

The disease belongs to the general class of granulation tumors. The large cells are of the epithelioid character, and resemble the epithelioid cells formed in tuberculosis, and the masses of them may suggest some similarity to tuberculous granulation tissue. They do not undergo caseation, nor is there any necrosis in mass. They are particularly prone to hyaline degeneration, which appears to be due to the action of the bacilli, which they often contain in large numbers. With their complete hyaline degeneration they disappear, and their place is taken by dense masses of connective tissue, to the contraction of which the cicatrization is due. The formation of these masses of large cells appears to be the primary and essential process; the other lesions are those common to all similar processes. It is probable that we must regard the disease as due to the bacillus which is always associated with it. The disease is a peculiar one, and the bacillus is in relation with the cell formation, which constitutes its histological specificity. It is an organism which is easily cultivated, but no characteristic lesions can be produced by inoculation of animals. It is pathogenic only in large doses. In spite of its similarity to Friedländer's bacillus and to the group of the bacillus mucosus capsulatus, both in morphology and in some cultural characteristics, it should be considered to be an independent organism. None of these organisms lead to a proliferation of tissue, and their general action is to produce exudations. The narrow geographical distribution of the disease also points to a distinct etiology. In view of the wide distribution of the bacillus mucosus capsulatus, it is unlikely that a variety of this would have so restricted a field. *W. T. Councilman.*

RHODANIDES. See *Sulphocyanides.*

RHUBARB.—*Chinese Rhubarb; Rheum*, U. S. P.; *Rhei Radix*, B. P.; *Radix Rhei*, P. G.; *Rhubarbe de Chine, Rhubarbe de Muscovie, Rhubarbe de Perse*, Codex Med., etc.

The dried rhizome and larger roots of *Rheum officinale* Baill., *Rheum palmatum* L., and probably of other species of *Rheum* (fam. *Polygonaceæ*), deprived of the outer corky layers.

The general features of the rhubarb plant are well illustrated by the common garden pie-plants, *R. rhaponticum*, etc. There are twenty or more species, all from Southern and Central Asia, the drug being collected in Northwestern China, Thibet, and the adjacent regions. Both of the above-named species have been introduced to cultivation in Europe, and have produced a drug identical in its essential features with Chinese rhubarb. The second named has not been cultivated upon a commercial scale, but *R. officinale* is quite extensively so cultivated in England. The product is smaller, retains more of its bark, is more spongy, and less esteemed than the Chinese product.

The underground portion consists of a short, thick, erect rhizome, which gives off several thick roots. These are dug in the autumn and the rhizomes and roots preserved separately, the former constituting the most and the more highly esteemed portions of the drug. They are two or three times as large as the roots. The outer corky bark layer is removed and the pieces are dried, mostly by being suspended upon strings passed through perforations made for the purpose.

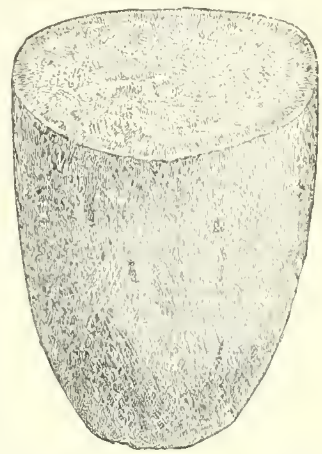

FIG. 4111.—Piece of Round Chinese Rhubarb, showing the white lozenge-shaped reticulation on its surface and the irregular medullary rays on the section. (Baillon.)

DESCRIPTION.—Rhubarb occurs mostly either in unevenly barrel-shaped pieces—from two to five inches in length and one-third to two-thirds as thick, the ends truncated, the surface showing the angular markings left by peeling, though these are more or less rounded off—or in longitudinal halves or slices of such barrel-shaped pieces. Usually the pieces are perforated by a rather large hole. The surface is of a bright light yellow and covered with a fine powder, which should consist of the rhubarb substance, but is sometimes powdered curcuma. That which has been kiln-dried or "high dried" possesses a surface roughened with broad ridges, separated by broad grooves, the latter frequently discolored to appear smudgy or blackish. The surface is less powdery. Underneath this superficial powder the surface of rhubarb is found reticulated, the oblong or lozenge-shaped ends of the reddish-brown or deep yellow-brown medullary rays being separated by intersecting bands of a grayish-white parenchymatic tissue. The fracture is irregular but not at all fibrous, and of a grayish-red color. Upon transverse section the larger (rhizome) pieces show, near the periphery, a nearly continuous circle of pretty stellate fibro-vascular bundles, these being wanting in the root pieces. Upon this transverse view the direction of the medullary rays is seen to be very irregular, less so toward the periphery. Rhubarb possesses a peculiar fine aroma, which, however, becomes coarse, heavy, and a little empyreumatic in the high-dried form. When chewed it produces a very gritty effect between the teeth, is mucilaginous, colors the saliva yellow, and imparts a bitter, astringent, and somewhat aromatic taste.

Powdered rhubarb is frequently adulterated, more especially with turmeric or curcuma. This may be recognized under the microscope by its large, solitary, oval

Digitized by Microsoft®

starch grains, and by the fact that the particles quickly impart a deep yellow color to a colorless volatile oil close to their margins, when placed in contact with it.

CONSTITUENTS.—From a therapeutic point of view most of the constituents which have been isolated from rhubarb are unimportant. An active substance which has been extracted (usually to the extent of from three to five per cent.) is "cathartic acid," common to a number of important purgative drugs. In doses of from three to five grains it produces the general purgative effects of rhubarb. It is, however, not a simple substance. The resinous constituents remaining after the extraction of the crystalline bodies named below appear also to be quite active. This resinous body has been separated into portions respectively called phæoretin, aporetin, and erythroretin. No one, however, has seriously proposed the substitution of the use of any one constituent of rhubarb for the entire substance or its preparations.

The three constituents which have attracted the most attention from a chemical standpoint, though the second only appears to have any activity, are chrysophanic acid (not an acid however), emodin, and rhein. They are successively, in the order named, oxidation products from some original body which has not been determined, thus: Chrysophanic acid, $C_{15}H_8O_2.(OH)_2$; emodin, $C_{15}H_7O_2.(OH)_3$; rhein, $C_{15}H_6O_2.(OH)_4$. Rheotannic acid is a glucoside yielding rheumic acid. There exist also an unstudied bitter principle, an odorous oil, also a derivative product, about two-thirds of one per cent. of fat, starch, and calcium oxalate, the last reaching to a fourth, or possibly more, of the weight of the drug.

HISTORY AND VARIETIES.—Rhubarb has been used in China from the remotest ages (2700 B.C., Flückiger), and possible references to it are found in the earliest European books on medicine. As early as the seventh century of our era, there can be no doubt of its occurrence in Europe, and by the tenth or eleventh it was well known and highly valued.

For about a hundred years previous to 1860 the Russian Government monopolized the rhubarb trade between Siberia and the Chinese provinces, and established an exceedingly strict inspection of all the roots exported that way, condemning and destroying all but those which were absolutely perfect. In this way an exceptionally fine quality was obtained, and exported, after its long hard journey, from Moscow. Curiously, in England and this country the old and entirely inappropriate name "Turkey rhubarb" was given to this variety. Since 1860 this inspection has been discontinued, and this grade of rhubarb has entirely disappeared from English and American commerce.

The great bulk of the present commercial product is known as Canton rhubarb, though this name also has ceased to be descriptive. Shensi rhubarb is preferred to Canton, and a specially fine variety is that known as Tze-chuen. The round pieces are in general preferred to the flat and the natural to the high-dried. For household use rhubarb is frequently cut into pretty little forms, fingers, crescents, stars, etc.

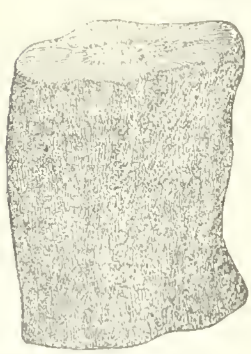

FIG. 4112.—European Rhubarb. (Flückiger.)

ACTION AND USE.—When chewed rhubarb stimulates the saliva. In small doses, in the stomach, it seems to act as a digestive stimulant; in larger ones it appears to be a simple purgative, hastening along the contents of the bowels by increased peristalsis carrying the liquid contents of the small intestine rapidly down, to soften and force along the more solid mass in the colon and rectum. Intestinal secretion is supposed to be less stimulated by it than by salines or the cathartic resins. Its coloring matters are absorbed, and may tinge the milk and urine.

Rhubarb is mild and fairly certain in its action; it produces comparatively little pain, no depression in moderate doses, and its action is not prolonged. The tannin in it is credited with producing some constipation after its use, but the simple emptying of the bowels without irritation of the mucous membrane would be enough to explain this result. Rhubarb is given in almost all conditions in which simply emptying the bowels is desired.

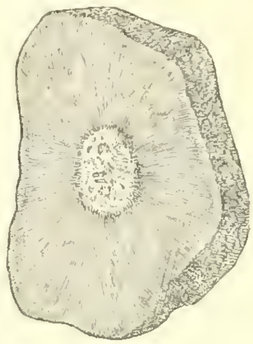

FIG. 4113.—European Rhubarb; surface of a transverse section. (Flückiger.)

ADMINISTRATION.—Rhubarb is offered by the Pharmacopœia in a great variety of forms; it is also found in a good many of the popular proprietary laxative mixtures. It makes a fine, deep yellow powder which is sometimes given, but not often, on account of its very nauseous taste. Two or three decigrams (gr. iij. to v.), once or twice a day, would be a very mild tonic-laxative dose; a single dose of 1 gm. (gr. xv.) is mildly, while one of 2 gm. (gr. xxx.) would be severely, cathartic. Rhubarb in substance is frequently taken by chewing and swallowing a piece of the root as large as a pea or a bean, once a day or so, preferably after eating; the taste, when the drug is used in this way, being less nauseous than that of the powder. The tonic, almost carminative, action of rhubarb upon digestion, has led to its being widely used in this way. The following are the preparations of the United States Pharmacopœia:

Extract, of about 300 per cent. strength; fluid extract; tincture, containing 10 per cent. each of rhubarb and glycerin and 2 per cent. of cardamom; aromatic tincture, twice as much rhubarb, 10 per cent. glycerin, 4 per cent. each of cassia-cinnamon and cloves, and 2 per cent. of nutmeg; sweet tincture, 10 per cent. each of rhubarb and glycerin, 4 per cent. each of liquorice and anise, and 1 per cent. of cardamom; compound powder, 25 per cent. of rhubarb, 65 per cent. of magnesia, and 10 per cent. of ginger; pills, each containing 0.2 gm. of powdered rhubarb and 0.06 gm. of soap; compound pills, each containing 0.13 gm. powdered rhubarb, 0.1 gm. purified aloes, 0.06 gm. powdered myrrh, and 0.005 c.c. oil of peppermint. From the fluid extract is prepared the syrup, of 10 per cent. strength, with 1 per cent. potassium carbonate, 5 per cent. each of glycerin and water, and a little spirit of cinnamon; also the mixture of rhubarb and soda, containing 3.5 per cent. each of sodium bicarbonate and spirit of peppermint, 1.5 per cent. fluid extract of rhubarb, 35 per cent. glycerin, and a little fluid extract of ipecac. The aromatic syrup is made of 15 per cent. of the aromatic tincture, with 85 per cent. of syrup.

ALLIED PLANTS.—The genus contains about twenty species, most of whose roots have qualities similar to the above. Several of these, *R. rhaponticum*, and others, are cultivated in Austria and elsewhere in Europe for this purpose, and the European product is trimmed and prepared so as closely to imitate the Chinese. It can generally be told by its duller color, more spongy texture, absence of gritty crystals when chewed, and the more regular arrangement of its medullary rays; the stellate spots are absent. It is very inferior to genuine rhubarb.

RICE. See *Starch*.

RICE BODIES.—(Synonyms: *Corpuscula Oryzoidea*; *melon-seed bodies*.) In chronic tuberculous affections of the tendon sheaths, bursæ, and synovial membranes,

Digitized by Microsoft®

there are frequently formed small hyaline bodies resembling grains of rice or boiled sago. On section they are either homogeneous or granular, or concentrically laminated. In the central portion there is usually a small cleft. Many of these bodies possess a definite capsule, which is narrow, and is made up of concentric layers containing a varying number of nuclei. In the main mass nuclei are either not present at all or are found in very small numbers. Others consist of a hyaline fibrous tissue which in certain parts may show few nuclei. Some are made up wholly of fibrin, while in others the fibrin consists of bands scattered throughout the connective tissue. Giant cells are often present. As shown by the staining reactions these bodies for the greater part represent organized masses of fibrin which have undergone a hyaline change. All stages of the process may be seen. Some of the bodies stain throughout as fibrin with the Weigert fibrin stain; in other cases the hyaline substance stains red with Van Gieson's method. Double staining shows in others the presence of fibrin threads in the midst of the hyaline fibrous tissue. Van Gieson's method causes some of the bodies to take a yellow or brownish stain, the material of which these are composed not giving a fibrin reaction. A deep diffuse blue staining with hæmatoxylin shows the presence of lime salts in others. There has been much dispute over the origin of the fibrin in these bodies, some writers holding that it is the result of a "fibrinoid degeneration" of granulation tissue. The actual facts, however, tend to support the view that the majority of these bodies are formed from masses of exudative fibrin, which becoming organized undergoes a hyaline change.

As shown by the staining the genesis and nature of these bodies must vary. They may consist of fibrinous masses loosened from a fibrinous exudate covering the inner surface of the tendon sheath or bursa; or of partly organized masses of fibrin which have become loosened. The most common mode of formation is from loosened masses of tuberculous or syphilitic granulation tissue. The inner surface of the tendon sheath or bursa in such cases presents a polypoid or villous appearance due to organizing masses of fibrin. The connective tissue grows into the fibrin, organizing it, and after organization becomes changed into a hyaline substance possessing no nuclei. At the end of the villi there are thus formed more or less firmly attached hyaline bodies, which when loosened from their attachments become rice bodies. Around the detached body fresh deposits of fibrin take place, through the organization of which the body acquires a concentric laminated appearance. The hyaline change may begin at the periphery or centre of the body, or in any portion of its substance. It is also probable that portions of necrotic tissue loosened from the inner surface of a tuberculous hygroma may give rise to rice bodies.

By the majority of writers the presence of rice bodies in the joints, in the sheaths of tendons, or in the bursæ, is regarded as positive evidence of the tuberculous nature of the affection. In the great majority of cases the process is undoubtedly tuberculous; tubercle bacilli may be found in numbers upon the surface of the rice bodies, and occasionally within their substance. The formation of these bodies is, however, characteristic of a fibrinous exudate within the structures named, whether due to tuberculosis, syphilis, or other infection. The number of the bodies bears a certain relation to the chronicity of the process.

In many cases great numbers of the bodies may be present within the distended sheath or hygroma. In some cases they may be distinctly felt, and give a marked crepitation when moved upon each other. On cutting into the sac the little hyaline bodies may roll out in great numbers. *Aldred Scott Warthin.*

RICHFIELD SPRINGS.—Otsego County, New York.

Post-Office.—Richfield Springs. Hotel and cottages.

Access.—From New York viâ New York Central and Hudson River Railroad; also viâ Delaware, Lackawanna, and Western Railroad. From Philadelphia viâ Delaware, Lackawanna, and Western Railroad. From Washington and Philadelphia viâ Pennsylvania Railroad.

This charming summer resort is picturesquely located on Lake Canandarago, at an altitude of 1,750 feet above the sea-level. Richfield may be classed among the most attractive of our summer resorts. In writing of his visit here Charles Dudley Warner well and truly said, "The charm of Richfield is in the character of its landscapes." It is scenery "that one grows to love, and that responds to one's every mood in variety and beauty. In a whole summer the pedestrian will not exhaust the inspiring views, and the drives over the hills, round the lakes, by woods and farms, increase in interest as one knows them better. The artist is here year after year, one season being too short to satisfy the demands which the charms of the region make upon his love of the beautiful." The art of man has added much to the natural attractiveness of the location. The greatest attraction of Richfield, however, is found in the fine White Sulphur Springs. There are sixteen springs at this resort, and some of them have become widely celebrated. The bathhouse in connection with the springs is one of the most complete in the world, and provides for the therapeutic use of water combined with massage and electricity in a thoroughly scientific manner. It contains sixty-seven rooms for sulphur baths, Turkish and Russian baths, a large swimming pool, a pulverization room, inhalation rooms for the treatment of bronchitis and catarrh, electrical rooms, douche rooms, and a sun bath. The bathhouse is situated on the grounds directly in front of the Hotel Earlington. The following analysis of the principal spring, known as the White Sulphur Spring, was made by Professor Chandler, of New York:

One United States gallon contains (solids): Sodium hydrosulphate, gr. 1.72; calcium hydrosulphate, gr. 0.09; potassium sulphate, gr. 1.67; calcium sulphate, gr. 112.34; strontium sulphate, gr. 0.01; magnesium sulphate, gr. 5.15; sodium hyposulphite, gr. 0.38; magnesium bicarbonate, gr. 31.74; sodium chloride, gr. 0.52; lithium chloride, gr. 0.02; silica, gr. 0.64; and traces of alumina, barium sulphate, iron bicarbonate, and calcium phosphate. Total, 154.28 grains.

Sulphureted hydrogen gas is present to the extent of 14.20 cubic inches in each gallon. This spring, it will be observed, is very heavily charged with sulphureted hydrogen gas. Other important springs at Richfield are the Iron and Magnesia Springs, besides additional sulphur springs. The drinking-waters are obtained from springs west of the village, and are pure and abundant. A course of baths at Richfield has been found of value in cases of insomnia from overwork, in nervousness, in stomach disorders resulting from abused digestion, in chronic malarial infections, in gout and rheumatism, and in some of the disorders of the liver and kidneys. The visitor will find in the Hotels Earlington, St. James, and smaller places accommodations to please any taste or exchequer. *James K. Crook.*

RICKETS.—(Synonyms: Rhachitis or Rachitis; Fr., *Nouure, Rachitisme;* Ger., *Rhachitis, Englische Krankheit.*)

Definition.—A general disease of infancy and early childhood, chiefly characterized by alterations in the bony skeleton and by impaired nutrition. In severe cases there may also be changes in the viscera.

History.—The disease was known to the writers of antiquity, but was often confused with other maladies causing deformities of the skeleton, especially with tuberculous spondylitis. We owe the first accurate description of the condition to the English physician Glisson, who published a work upon the subject in 1650. The disease seems to have been especially prevalent in England at that time and later, and has always been the subject of study by English physicians; hence its name of the Englische Krankheit.

During the eighteenth century the French physicians made many contributions to our knowledge of the rachi-

Digitized by Microsoft®

tic process, while more recently the Germans have been most active. Among the names which will always be connected with the history of the study of this important disease of infancy may be mentioned Trousseau, Guérin, Elsasser, Virchow, Kölliker, Rokitansky, and Kassowitz.

Etiology.—The nature of the agent which underlies the pathological changes www.libtool.com.cn rachitic children is still unknown. It has been assumed to be caused by an insufficient amount of calcium salts in the blood, and color has been given to this theory by the oft-quoted experiments of Sutton and others, in which rachitic changes were thought to be produced in animals by nourishing them on food practically free from lime salts. It has been recently shown, however, that the changes which were produced in animals by this means are rather those of osteomalacia than a true form of rickets. The similar belief that an imperfect absorption of the lime salts from the intestine was responsible for the rachitic condition has been shown to be untenable, for the urine of rachitic children contains an amount of calcium quite sufficient to supply the needs of the skeleton; and if larger amounts of calcium salts are administered to either rachitic or healthy children the excess is rapidly excreted in the urine.

The chemical theory that the lime salts either could not be deposited because of the diminished alkalinity of the blood or that they were dissolved out by the action of an acid circulating in the fluids of the body, has been shown to be without foundation. The blood of rachitic children contains neither an excess of acid nor an excess of alkali.

The view brought forward by Kassowitz that the bone changes are purely inflammatory in nature is not in entire accord with the anatomical findings. The most recent suggestions are that the disease is an infection or that it is an auto-intoxication. Neither view has been supported by sufficient experimental evidence to warrant its acceptance, however attractive the assumption may be. Although, therefore, we do not know the actual cause of the disease, there are many predisposing conditions which are known. Among these are chiefly imperfect food and unsuitable hygienic surroundings.

The disease is most frequently seen among the children of the poor, especially those who have been reared upon an artificial diet containing large quantities of carbohydrate and small amounts of fat. It is rare in children who have been breast-fed, the exceptions being principally the children of the laboring classes, where the mother begins to work soon after the delivery of the child, or in children who have been nursed for a long period until the milk becomes insufficient for the needs of the infant.

Children fed upon sweetened condensed milk are frequently rachitic, while those obtaining the unsweetened form are not likely to suffer. Boiling the milk is also thought to set up obscure changes in the composition of that fluid which affect the nutrition and may cause rickets and especially scurvy. The exact form in which the hygienic factors exert their influence is not so clear as it is with food. Some observers, notably Mey, are inclined to consider lack of light and fresh air as very potent forces in the production of the rachitic process; others, for example Lange, regard the hygienic factor as comparatively unimportant and, though acknowledging that the disease is more prevalent in cities where the hygienic surroundings are bad, they lay the most stress upon the food factor. It is certain, however, that rickets is very infrequent in the country, in high altitudes, and in the tropics. It is also true that the children born in these conditions are much more likely to be breast-fed than those in the tenement districts of large cities. The influence of race in the susceptibility to rickets is seen in the negro and in the Italians. The children of both of these races, when confined to the tenement districts in cities, offer our most marked examples of advanced and severe rickets. Congenital influences play some part in the causation of rachitis, though at present the trend of opinion is against a true congenital form of the disease. Cases so described are regarded as distinct from rickets, though showing bone lesions closely resembling those seen in rachitic children. Parental syphilis is a strong predisposing factor in the production of rickets, though it does not seem to be the cause of the disease, as Parrot attempted to show. Tuberculosis and alcoholism in the parents also predispose to rickets, chiefly by reducing the child's power of resistance. Both sexes are equally subject to the disease, though in hospital statistics a larger number of males will be noted. This apparent anomaly is due to the fact that a larger number of male children are received for hospital treatment than female, and large statistics, including private cases, will show about equal numbers affected. The clinical development of the disease is most noticeable in the second year of life, though a large proportion of children show signs of the disease during the first year. After the third year the disease is infrequent. Late cases have been described in children even up to the twelfth year, but such observations are extremely rare. The disease is one which concerns the period of the most active growth and formation of the bones, progressively diminishing as the skeleton assumes its definitive condition.

Pathology.—The constant and characteristic lesions of rickets are to be found in the bones; the visceral changes are comparatively slight and secondary. A rachitic bone, when examined in a fresh condition, is softer than normal, and the actively growing portions—that is, those parts near the epiphyseal junction in the long bones and the ossification centres of the cranial bones—are larger and much more vascular than in normal bones from a child of the same age. The periosteum is thickened and strips with some difficulty from the surface, leaving irregular areas of soft, newly formed bony tissue adherent to the inner layers of the periosteum. The bone from which the periosteum has been removed is soft and very vascular, and has a spongy appearance. The same changes may be noted if one of the long bones is split open and the internal layer of the periosteum is examined. The calcification zone at the epiphyseal junction, which in normal bone is well defined and narrow, is broad and not sharply defined in rachitic bone, and may be quite unrecognizable. In the later stages of the disease, when the acute process has ceased, the rachitic bone is usually harder than normal bone, especially where an active production of new bony tissue has taken place. This new-formed bone may resemble ivory in its density and texture. Frequently, however, when the restoration of the bone has been incomplete, it is soft and porous, and contains a considerable quantity of fat scattered through the substance. Such bones are very light and fragile, and green-stick fractures are frequent. The microscopical changes correspond to the gross lesions. The centres of the flat bones of the skull are vascular and the bony layers are replaced by osteoid tissue. This may be very abundant in amount, in which case the bone is so soft that it can be easily indented by the finger, and gives a soft crepitus when palpated, a condition known as craniotabes; or the osteoid tissue may be located in small areas, a few millimetres in diameter, and give the bone an appearance of a coarse sponge. The osteoid tissue may not ossify, and the aperture thus left in the bone may be closed simply by the pericranium. Such marked changes in the regular course of ossification of the cranial bones are as a rule rare, and confined chiefly to the posterior portion of the cranium.

The more frequent course is for the osteoid tissue to be gradually replaced by bone, either by direct ossification or by the replacement of the abnormal tissue by normal bone. When the osteoid tissue ossifies directly the structure produced is as a rule more dense than normal and resembles ivory. In the long bones the most marked lesions are at the epiphyseal junction. It should be remembered, in order to understand the pathology of the subject, that the bones grow in length at this point, while they increase in diameter by the production of new bone from the inner layers of the periosteum. At the same time the medullary cavity is enlarged by absorption of the inner layers of bone. In rickets the pathological

Digitized by Microsoft®

changes consist in the distortion of these normal conditions. The inner layers of the periosteum produce an excessive amount of very vascular osteoid tissue, which undergoes either ossification or absorption. The ossification which takes place is of a very imperfect sort, so that the new bone is soft, spongy, and very much more vascular than normal. In the medullary cavity the process of absorption is very irregular and often excessive in amount. The cavity may extend into the epiphysis, or it may be filled with osteoid tissue, which replaces the normal bone marrow and thus may contribute to the anæmia from which rachitic children suffer by directly diminishing the production of the blood cells. The course of the bone growth, which takes place at the epiphyseal junction, is also disturbed by a combination of the same processes which contribute to the irregular bone production by the periosteum. The cartilaginous area of the epiphyseal portion of the bone is broken up and penetrated by a vascular osteoid tissue, which may be prematurely ossified or may form marrow cavities. The cartilage cells also proliferate and become dislocated from their normal positions. Absorption of these masses may occur or they may become ossified. The normal calcification zone becomes irregular and is broken up by the advance of the osteoid tissue into the epiphysis. After a variable period of from three to eighteen months the active process ceases and the formation of bone begins in a normal manner. The swelling of the epiphyses diminishes, the extreme vascularity is reduced, and the areas of osteoid tissue become calcified. The structural reparation is never quite complete, though a large amount of the distortion of the bone may disappear.

The effect of these changes in the structure of the bones is first to delay their growth, and second to cause deformities. The results of the first condition may be seen in the small bodies and shortened limbs of children that have suffered from rachitis of a severe type. The softness of the bones permits their easy distortion under pressure, as is so well seen in the chest, while the deformity which results from growth alone is best noted in the square form of the cranium or in the curvatures of the upper extremities.

The lesions of the viscera are not an essential portion of the rachitic condition, but they are quite frequently met with in severe cases. The lungs frequently show acute or chronic bronchitis or a bronchopneumonia. When the deformity of the chest wall is considerable, the lungs may be the seat of a marked emphysema in the areas upon which there is no pressure, while those portions which are compressed by the incurving of the thorax may be in a condition of atelectasis. The spleen is frequently increased in size owing to an interstitial splenitis of a chronic form; the liver occasionally shows similar changes. The lymph nodes are often swollen and hyperplastic. Hydrocephalus is no more frequent in rachitic children than in others, the enlargement of the head being due to the increase in thickness of the cranial bones. The muscles of the body are flabby and atrophied.

Symptoms.—The symptoms of the disease vary with the stage of the malady. The earliest symptoms are restlessness during the night, sweating of the head, craniotabes, and the beading of the ribs. The beading of the ribs is an especially early and valuable symptom, and consists of a row of nodules formed at the costo-chondral junction. The beading is often more marked internally, especially in cases with extreme incurving of the chest wall. The craniotabes is often an early symptom, and may best be demonstrated by gently palpating the posterior surface of the head with the tips of the fingers. Small areas, softer than the remainder of the skull, will be felt, and the tissue may crackle under the pressure. In rachitic children the skull appears relatively large and the frontal prominences are well marked; alterations which, when associated with the prominent posterior part of the head, give to the latter the characteristic square appearance, the *tête carrée* of the French. The anterior fontanel is larger than normal, and its closure may be delayed even to the third or fourth year. The two lateral openings are often late in closing, as are also the sutures. The superior and inferior maxillæ are slightly distorted in severe cases, chiefly by muscular action. The teeth are delayed, not appearing until the end of the first year, or even later, and there are often irregularities in the time and order of appearance and arrangement of the different groups of teeth. Some observers consider the teeth of rachitic children to be especially prone to decay. The thorax, as has been mentioned above, is frequently deformed. In mild cases the only change noted is the swelling of the costo chondral junction, forming the so-called rachitic rosary. The flexibility of the bones of the chest permits the pressure of the atmosphere to exert a considerable influence in the production of deformities, so that a distinct depression frequently exists along the line of the ends of the ribs, or there may be a transverse groove parallel to the line of the insertion of the diaphragm. The deformities known as funnel breast and pigeon breast are largely dependent upon an antecedent rachitic process. Any obstruction to the free admission of air to the chest, such as is associated with chronic bronchitis, enlarged tonsils, or adenoid growths of the pharynx, is likely to exaggerate any chest deformity. The lessened capacity of the thorax causes the liver and spleen to be much more prominent than their increase in bulk from hyperplasia would warrant. The abdomen is usually distended, the enlargement being chiefly due to the distention of the intestines with gas, aided by the weak condition of the muscles of the gut wall and of the abdomen.

In rachitic children the spinal column is much more flexible than normal, owing to the imperfect ossification of the vertebræ and the relaxation of the spinal ligaments. When such children assume an erect position a marked kyphosis can usually be noted, which disappears when the child assumes a recumbent posture. The curve of the rachitic kyphosis is rounded in form, and involves the bodies of a number of vertebræ, in contrast with the sharp projection of the kyphotic curve in spinal tuberculosis. There is usually a compensatory lordosis in the lumbar region and rarely a left-sided scoliosis.

The clavicle and the scapula may be curved slightly. The pelvis is often the site of serious deformities. It is flattened laterally and the promontory approaches the arch of the pubis, which is also narrowed. The approximation of the promontory to the pubis is in part due to the rotation of the sacrum on a horizontal axis, in part to the inward displacement of the ischia. These pelvic deformities are often permanent, and render the bearing of children difficult or impossible. The extremities very early show the characteristic enlargement of the epiphyses, especially of the lower end of the radius, ulna, and tibia. Such epiphyseal swellings may also appear at the upper and lower ends of the humerus and femur, but are much less marked.

If the disease is of a severe type the diaphyses of the bones may become curved. The convexity of the femur is forward and outward; that of the tibia and fibula is often lateral, but may also be forward; that of the radius and ulna is toward the extensor surface, while the humerus is bent forward. The irregular growth of the epiphyseal ends of the bones, combined with the curvature, gives rise to deformities which are especially serious in the lower extremities. The axis of rotation of the knee-joint may remain horizontal, or, as is seen in advanced cases, the axis may be rotated either inward or outward, so that a simple osteotomy of one bone will not suffice to correct the deformity, but both the femur and the tibia will have to be severed and the axis of the joint restored to its normal rotation plane.

The cause of these deformities is not, as is usually assumed, the result of allowing the child to walk before the bones are sufficiently hard, but is due to the rachitic curvature of the shafts of the bones and to the uneven enlargement of the condyles of the femur. A moderate amount of deformity may be increased, however, by allowing the child to walk while the rachitic bone is still

Digitized by Microsoft®

soft. The other symptoms of the disease not connected with the skeleton are chiefly those relating to the digestive, respiratory, and nervous systems. The frequency of respiration of rachitic children is increased in those cases in which there exists a considerable diminution of the respiratory capacity, owing to the deformity of the chest wall and the pressure of the gas-distended intestines against the diaphragm. Bronchitis and atelectasis very frequently complicate the respiratory and circulatory changes produced by the narrowing of the thorax.

www.libtool.com.cn

Laryngismus stridulus is a not uncommon complication of rickets, and is responsible for a considerable proportion of the fatal terminations of the affection. General convulsions are a frequent complication of the disease, and tetany is also occasionally seen.

A chronic gastro-intestinal catarrh is usually present in rachitic children, and is easily increased in severity by slight indiscretions in diet. The stools are either constipated or thin and fluid. They are as a rule paler than normal and may be very foul-smelling. They contain an excess of calcium salts derived in part from the food and partly from the softening bone. The blood shows an anæmia of the chlorotic type with a moderate reduction of the red cells and a considerably lessened hæmoglobin content. A moderate leucocytosis may also exist, which is in all probability not characteristic of the disease, but is dependent upon the respiratory and intestinal complications. The urine shows no striking alterations. Occasionally there may be a trace of albumin present and a diminution in the excretion of the phosphates and the chlorides. There is no alteration in the amount of lime salts excreted in the urine.

Fever is not a regular accompaniment of the disease. When present it is due to one of the complications. The skin of the rachitic child is pale. Eczema is not infrequent, and occasionally multiple skin abscesses are seen. Severe sweating is the rule in all cases of rickets. The subcutaneous fat is well preserved, though the patients are soft and flabby.

Course and Prognosis.—Cases considered to be congenital rickets have been described by competent observers, but as a rule the symptoms of the disease begin in the latter half of the first year of life; and in a majority of the cases the disease runs its course inside of eighteen months or two years. Very chronic cases, lasting for years, are exceedingly infrequent. The condition which has been classed by some clinicians as acute rickets is probably a form of scurvy. The prognosis of an uncomplicated case of rickets is good so far as life is concerned. The disease is self-limited and often disappears without treatment when the child is old enough to begin a mixed diet. The prognosis of the bone deformities is not so good, and many of the severe cases are permanently deformed, though surgical interference will often allow the complete correction of the deformities of the lower limbs. Death results in all cases from some intercurrent disease and not from the bone lesions alone. Marasmus and laryngismus stridulus are responsible for a considerable proportion of the fatal cases, while the others are carried off either by bronchopneumonia, or by tuberculosis, or by some intestinal condition. Whooping-cough is an especially dangerous complication in rachitic children with marked deformity of the chest.

Diagnosis.—A well-developed case of rickets is easy of recognition, especially at a time when the bone lesions are most prominent; but in children in the early stages of the disease the diagnosis is more difficult, and must be made from the general symptoms. The most important of these are the restlessness at night, the sweating of the head, the general tenderness of the body, and the malnutrition. The craniotabes and the persistent and wide-open fontanel are valuable symptoms, as is also the late eruption of the teeth. The bone lesions of syphilis are in the nature of thickenings under the periosteum rather than of an increase in the size of the bone, and the necroses seen in syphilis are not present in rickets. The other evidences of congenital lues will aid in the differential diagnosis. Confusion between the kyphosis due to tuberculous spondylitis and that due to rachitic softening of the vertebræ and intervertebral cartilages will be avoided if it be remembered that the curve in tuberculous disease is sharp and affects the bodies of only one or two bones, while that due to rachitic disease is more gradual and less limited. The rachitic bones are not very tender to pressure, and the kyphosis can be overcome by placing the patient on a flat mattress. Pott's disease is rarely seen in children under two years of age, a time when rickets is most likely to be well developed.

Rickets is differentiated from scurvy by the absence of the ecchymoses and the changes in the gums.

Prophylaxis.—The prevention of the disease depends naturally upon the avoidance of the conditions determined as the immediate factors in the causation of the malady. This is perfectly possible among people of good circumstances, but becomes a matter of great difficulty when we must cope with the conditions of tenement life among the very poor.

Every care must be taken with the children of parents who have previously borne rachitic children, as the predisposition increases with each child. The mother should be allowed to nurse the child if it is possible for her to avoid hard, manual labor during the course of lactation. But if she is not able to do this, the better plan will be to feed the child on Pasteurized cow's milk. A convenient form of apparatus for this purpose, and one requiring a minimum of intelligence on the part of the user, is that devised by Dr. R. G. Freeman. During the hot season of the year the child should be sent to one of the seaside hospitals or to the country for a time; or if this is impossible, it should be given every opportunity to obtain fresh air that is possible.

Treatment.—The care of rachitic children should be begun as early as the diagnosis can be made, in order to prevent severe bone lesions and also to obtain the maximum result from the treatment, as the best results are secured in cases in which the disease has been recognized in the first stages. The diet should be altered from that under which the child has developed the disease to one which is more nearly normal. If the child is breast-fed the quality of the mother's milk should be determined, and if necessary it may be supplemented by cow's milk in the proper modification. If the mother cannot nurse the child, it must be fed upon properly prepared cow's milk. The diet should be rich in fats and proteids, and contain but a small amount of carbohydrates. This will eliminate all of the proprietary infant foods. Cod-liver oil should be administered in small doses as soon as the stomach will tolerate it. Arsenic and iron are useful to combat the anæmia. The excessive sweating may be relieved by cool sponging, and by atropine in doses of about gr. $\frac{1}{200}$ per day. Opinions vary as to the value of the phosphorus treatment of rickets. Originally recommended by Trousseau, it has been rendered popular through the efforts of Kassowitz, who regards it as a specific. It may be administered in the form of a solution in oil, made by diluting the official oil of phosphorus with olive oil, in doses of gr. $\frac{1}{200}$ three times a day after meals. The use of extracts of the thyroid, thymus, and adrenal glands has not given satisfactory results.

The hygienic treatment of the child is nearly as important as the correction of the food. The child should spend a large portion of the day in the open air and in the sun if possible. Such open-air treatment is best carried out in the country; but if this is impossible, the child should be taken on excursions on the water or to the country, and during the rest of the time be kept in the parks and open squares of the city. The roof of one of the tenement houses is better than the street for such a child, and if the weather is not too hot such a place is often the best possible. The child will be strengthened, and is much less likely to catch cold, if it is sponged off with cold water every day. The addition of some sea salt to the bath is of use if the child is strong enough to stand the stimulus, while massage or even gentle rubbing of the body and limbs before or after the bath is of the greatest value in keeping up the general nutrition.

Digitized by Microsoft®

The correction of the deformities of the extremities is a matter of surgical interference; but much can be done to prevent the curvature from becoming severe by not allowing the child to assume a posture which will increase the deformity, and also by keeping up the muscular tone. The kyphosis may be relieved by allowing the child to sleep on a flat, hard mattress without a pillow. If the deformity of the occiput is marked, the pressure may be prevented by the use of a firm horse-hair pillow with a concavity to receive the flattened portion. If the kyphosis is extreme in a child which is old enough to be about, and in which the bones of the legs are firm enough to permit walking, it may be advisable to fit the thorax with a jacket or a steel brace, which should be worn only when the child is in an erect posture. The use of braces in order to prevent or to cure deformities of the lower extremities is of but very slight benefit. It is better to wait in these cases until firm ossification of the bones has taken place and then to correct the deformity by a proper osteotomy. *Francis Carter Wood.*

RIGOR MORTIS. See *Cadaver, Legal Status of.*

RIO DE JANEIRO, BRAZIL.—Rio de Janeiro, the largest city in South America, with a population of about 779,000, is situated upon the western side of one of the most magnificent harbors in the world. It is in no sense a health resort,—indeed, quite the contrary,—but it is mentioned as an illustration of a tropical or equatorial climate, and also to convey some knowledge of its climate to those who for any reason, either temporarily or permanently, are obliged to reside there.

The city itself occupies flat land with hills in the outskirts, and beyond rise precipitously mountains of from fifteen hundred to three thousand feet high. Foreigners are advised to make some of the high-lying suburbs or towns in the vicinity their place of residence, at least during the warmer months, in order to escape the continuous heat and great atmospheric humidity which combine to make the climate of the city itself so debilitating.

The population of the city is a heterogeneous one, composed of Portuguese, Italians, Germans, French, English, and negroes. There are parks, a national library, museum, colleges, various schools, hospitals, and an observatory. An immense amount of coffee—said to be more than one-half of the world's product—is exported from here.

The water supply is good but somewhat inadequate, and the drainage is said to be satisfactory. Modern sanitary conditions exist. In the outskirts, among the hills and mountains, the scenery is most beautiful and the vegetation luxuriant.

The climate can be summarized as a moist, warm, tropical one; warmest in what is our winter and spring, and coldest in our summer and autumn, but at all times warm or hot. The rainfall is high, the largest amount occurring in our autumn and winter. The air is often sultry and very debilitating. There is generally a daily sea breeze from the south and southeast—part of the trade winds come from the southeast;—it begins about 1 P.M. and lasts until about four or five o'clock. The nights are usually calm. The climatic chart has been arranged from the very elaborate series of observations published by L. Cruls, director of the Observatory at Rio de Janeiro, and the reader who desires to make a more exhaustive study of this climate is referred to this work.

The temperature arrives at its maximum at the beginning of February, and at its minimum the beginning of July. The mean annual variation does not exceed 10.8° F., and the mean diurnal variation does not reach 5.4° F.

The humidity is really greater than would appear from the average relative humidity as shown in the table, on account of the high temperature, for a humidity of over seventy per cent. at a temperature of over 70° F. is very moist. The excessive moisture is one of the striking characteristics of this climate, and renders the heat so unbearable. The daily occurrence of the sea breeze, however, mitigates this condition. There is a large amount of cloudiness and there are but few clear days. The average yearly rainfall is 42.5 inches, and there are one hundred and twenty-seven days of rain. March and December are the rainiest months and July is the driest month. The most prevalent wind is from the south and southeast—the sea breeze,—and next in frequency is that from the northwest—the land breeze.

Yellow fever is generally prevalent during the warm months, and there are severe epidemics at intervals. In the lowlands intermittent fever prevails. The negro population suffers from smallpox. There is, at St. Sebastian, a large hospital which was founded in 1888, and which is devoted to the treatment of epidemic diseases. One would naturally infer that the mortality in such a climate and with so many epidemic diseases would be high, but from the official statistics the average mortality from 1897 to 1901 is found to be 19.4 per 1,000. Tuberculosis causes much the largest number of deaths of any one disease, and bronchitis and bronchopneumonia come next in frequency, while infantile diseases rank third. It would appear, then, that any one individual resident of Rio de Janeiro had many more chances of dying of tuberculosis than from yellow fever, and that this dread disease (tuberculosis) may be quite as prevalent in warm countries as in cold. *Edward O. Otis.*

made here to this region as a whole, and the reader is referred for more detail to the articles upon *Alassio, Bordighera, Cannes, Hyères, Nervi, Nice, Mentone, Monte Carlo*, and *San Remo*.

The Riviera is a strip of coast extending 323 miles along the shore of the Mediterranean, at the foot of the maritime Alps and their offshoots. The portion from Hyères to Genoa, 203 miles, is called the Western Riviera; and that extending from Genoa to Leghorn, 112 miles, the Eastern Riviera. It is the former portion that is the more frequented, and is what is generally meant when one speaks of the Riviera. The topography of this region is that of "a long shelf, or rather a series of shelves, on the south side of a very high mountain wall, which wall, up to the level of these shelves, is submerged in the waters of the sea" (Richards).

The general climatic features of all this region are the same, varying at one resort or another in certain minor aspects according to the local peculiarities of situation, principally with regard to shelter from the winds. These climatic features—and here the colder months of the year are only considered—are comparative warmth, moderate dryness, a large amount of sunshine, and great heat of the sun's rays; the small number of rainy days, and relative immunity from cold winds. No station is entirely exempt from these cold winds, but some are more exposed than others, as has been shown in treating of the various resorts. Moreover, the seasons differ from one year to another. The latitude of the Riviera has not so much to do in the production of its mild winter climate, but this is rather due to the protection afforded by the maritime Alps from the cold northerly winds, and also partly to the southern exposure and partly to the warm water of the Mediterranean Sea.

The mean temperature for the three cold months (December to February) according to Weber ("A System of Physiological Therapeutics," vol. iii., Book I., "Health Resorts," F. Parkes Weber, 1901), is from 47° F. to 49.8° F.; for the six cold months (November to April), about 51° F.

According to the same authority the mean relative humidity is from sixty-five to seventy per cent., and the annual rainfall from twenty-eight to thirty-one inches, the greater part falling during October and November.

The principal winds are the northwest—the "mistral," a cold dry wind prevailing in March; the northeast, or "bise," a cold wind; and the southeast, or "sirocco" a "warm, wet, enervating wind."

Quoting Weber again, "during the six winter months one hundred days or more may be expected to be fine enough for most invalids to be in the open air for several hours."

Besides the danger from the high winds, especially the dreaded "mistral," there is also to be mentioned the great difference between the sun and the shade temperatures, and the rapid fall of the temperature after sunset, with the increased humidity at that time. The dust is also an objectionable feature of this region. The Riviera season extends from about the end of October to the end of April. Abundant and good accommodations, all more or less expensive, are to be found in all the Riviera resorts.

As to the natural attractions of the Riviera, they are too well known to require any extended description. "Nothing," says Lindsay, "can exceed the loveliness of this strip of flowery coast land, with its jutting crags and circling bays, bounded on one side by spurs of the Alps, and on the other by the Mediterranean, now glittering in brilliant azure, again rippled into sapphire by the breeze." In comparing this region with the littoral of Southern California, the latter is undoubtedly superior in climate, but in beauty of scenery supplemented by art, the former is by far the more attractive.

The Riviera is visited in the winter by great numbers from Northern Europe, who desire to escape the cold and more or less cheerless winters of their own region. This climate affords a blessed relief for those who desire to spend the winter in a warm, sunny climate amidst most attractive surroundings. The aged, the feeble, the convalescents; those with diminished powers of resistance, and those suffering from various chronic affections with deficient powers of reaction, all find more or less comfort, relief, and healing here. The diseased conditions for which this climate is recommended are chronic bronchitis and emphysema, bronchial asthma, certain varieties of pulmonary tuberculosis, scrofula, chronic pneumonia, and anæmia.*

The Riviera is now easily and comfortably reached by steamers sailing from New York or Boston direct to Genoa, and from Genoa the railroad runs along the shore of the Mediterranean parallel with the celebrated Corniche road for a good part of the way. Express trains also run from Paris direct to the Riviera. *Edward O. Otis.*

ROANOKE RED SULPHUR SPRINGS.—Roanoke County, Virginia.

Post-Office.—Roanoke Red Sulphur Springs. Hotel and cottages.

Access.—Viâ Norfolk and Western Railroad to Salem, thence nine miles north to springs.

This resort is located under the shadow of the outlying ranges of the Alleghanies, twelve miles from Roanoke City. The manifold attractions of the Virginia mountain region find here a faithful exemplification. The high and dry location, the pure, fresh air, and the unsurpassable mountain scenery unite to form a most delightful summer health resort. In the hotel will be found all the comforts and attractions which go to render a stay at a watering place enjoyable. The Roanoke Red Sulphur waters have been examined by Prof. M. B. Hardin with results as follows: One United States gallon contains (solids): Calcium carbonate, gr. 6.54; magnesium carbonate, gr. 5.83; lithium carbonate, gr. 0.02; manganese carbonate, gr. 0.02; iron carbonate, gr. 0.06; sodium chloride, gr. 0.24; ammonium chloride, gr. 0.02; calcium chloride, gr. 0.03; strontium sulphate, gr. 1.71; calcium sulphate, gr. 2.19; sodium sulphate, gr. 3.04; potassium sulphate, gr. 0.33; sodium hyposulphite, gr. 0.03; ammonium nitrate, gr. 0.05; silica, gr. 0.83; organic matter, gr. 0.76; bicarbonates, gr. 5.96; and traces of copper carbonate, lead sulphite, barium sulphate, alumina, and arsenic. Total, 27.66 grains. The gases present in one gallon of the water are: Carbonic acid, 12.4 cubic inches; sulphuretted hydrogen, 2.44 cubic inches.

These waters are useful in those classes of cases which require a fairly concentrated sulphur water. They possess alterative, diuretic, and tonic properties. It will be observed that they contain an unusually large proportion of strontium, an element whose therapeutic properties are not as yet fully understood.

The following analysis of the chalybeate spring at this resort was made by Dr. H. Froehling: One United States gallon contains (solids): Calcium carbonate, gr. 0.45; magnesium carbonate, gr. 0.95; iron carbonate, gr. 2.09; manganese carbonate, gr. 0.09; sodium carbonate, gr. 0.44; bicarbonates, gr. 2; and very small quantities of sodium chloride, potassium sulphate, sodium sulphate, aluminum sulphate, aluminum phosphate, silica, ammonium carbonate, and organic matter. Total, 7.20 grains. Free carbonic-acid gas, 12.30 cubic inches. This water is very useful in anæmia and debilitated states of the system. The Roanoke Sulphur Springs are much resorted to in the treatment of chronic bronchial, pulmonary, and throat affections. The waters of the spring, combined with the wholesome atmospheric conditions of the neighborhood, are believed to be almost a specific for hay fever. *James K. Crook.*

ROCHESTER, NEW YORK.—Rochester, N. Y., a city of 162,608 inhabitants, is situated on both sides of the Genesee River, seven miles from Lake Ontario. It lies in the so-called "Lake Region" of the United States, which region has the climatic peculiarity of great winter cloudiness in comparison with that of the Oregon winter, and

* Vide: "A Joint Inquiry as to what kind of Patients should be Sent to the French Riviera," by Stanley M. Rendall, M.D., of Mentone, and Thomas Linn, M.D., of Nice.—The Climatologist, November 15th, 1891.

Digitized by Microsoft®

of the St. Lawrence Valley district. As will be seen by the climatic chart, the number of clear and fair days are least in winter, and the relative humidity is highest. The rainfall is least in autumn.

"During the six months, April to September inclusive, the relative humidity of the atmosphere is markedly lower at Rochester than at New York, and the cloudiness is nearly the same at the two places; during the midsummer months it is actually less at the former than at the latter. Thus, during the winter season, Rochester is decidedly damper and more cloudy than New York; during the summer season, and especially the midsummer season, New York is markedly damper and a trifle more cloudy than Rochester" (Richards, previous edition of the Handbook).

www.libtool.com.cn

Climate of Rochester, N. Y. Latitude, 43° 8′; Longitude, 77° 42′. Period of Observation, Thirteen Years.

	January.	February.	March.	May.	July.	August.	November.	Year.
Temperature (degrees Fahr.)—

Mean of coldest	16.9	18.5	24.9	46.9	62.1	60.6	31.5	
Highest or maximum	69.0	63.0	69.0	90.0	96.0	96.0	71.0	
Lowest or minimum	−12.0	−12.0	7.0	23.0	48.0	47.0	1.0	
Humidity—								
Average relative	80.1%	76.9%	75.7%	62.3%	66.7%	67.3%	75.5%	71.4%
Precipitation—								
Average in inches	3.31	2.68	3.41	3.31	3.52	3.05	2.91	36.78
Wind—								
Prevailing direction	W.	W.	W.	W.	W.	S. W.	W.	W.
Average velocity in miles	11.1	11.3	11.6	9.6	7.5	6.9	10.3	9 6
Weather—								
Average number of clear days	1.5	3.3	3.9	9.2	9.2	10.4	2.9	71.5
Average number of fair days	8.2	10.8	11.0	12.5	14.7	13.7	9.3	133.3
Average number of clear and fair days	9.7	14.1	14.0	21.7	23.9	24.1	12.2	204.8

It will further be noted from the chart that the temperature range is great, a characteristic of the climate in the temperate zone; and that the prevailing wind the year through is from the west or southwest. If this chart is compared with that of Portland, Me., given in the present volume, it will be seen that there is a close resemblance in many of the data. The temperatures are very nearly the same. At Rochester the average mean annual temperature is 46.8°, and at Portland, 46.5°; for the winter, in the former place, the average is 25.7°, and in the latter, 25.6° F.; and so of the other seasons. The rainfall for the year in Portland is 39.04 inches, and in Rochester, 36.78 inches. The average relative humidity is 71.4 per cent. at Rochester, and 69.7 per cent. at Portland. We notice, however, that there is more wind at Rochester, and the direction is more constant. When we come to the number of clear and fair days, there is a decided difference. While the number of clear days at Rochester is only 71.5 per annum, it is 107.7 at Portland; and the number of clear and fair days at the latter place exceeds by forty-seven the number at Rochester. More sun and less wind, then, are to the advantage of Portland.

Where an outdoor life under clear skies and in sunshine is desirable for a patient, it is evident that he must seek some other locality than that of this "Lake Region" as represented by Rochester.

Forty-four miles south of Rochester is situated the Jackson Sanatorium, for the treatment of certain chronic cases, such as neurasthenia, etc. It is said to be well equipped with apparatus for the various forms of treatment by hydrotherapy, electricity, etc.

Edward O. Otis.

ROCKBRIDGE ALUM SPRINGS.—Rockbridge County, Virginia.

Post-Office.—Rockbridge Alum Springs. Hotel and cottages.

Access.—Viâ Chesapeake and Ohio Railroad to Goshen, thence by stage to springs.

These springs are located in a glen-like nook formed by the spurs of the North and Mill Mountains, and they break forth from a mass of slate rock at the base of the ridge. This slate contains large quantities of alumina and the salts of iron, and the springs are formed by the percolation of water through this mass. Four different reservoirs, numbered respectively No. 1, No. 2, No. 3, and No. 4, have been formed. The immediate surroundings of this resort are very attractive. The hotel and cottages afford comfortable accommodations. The numerous springs here vary somewhat in their analyses, the proportion of alum ranging from 6.88 gm. per gallon in Spring No. 6, to 81.05 gm. in Spring No. 7. Different chemists have also arrived at different results in analyses of the same spring. The following analysis, by Prof. M. B. Hardin, of Spring No. 2, is fairly representative of the group:

One United States gallon contains: Sodium sulphate, gr. 0.03; calcium sulphate, gr. 3.23; lithium sulphate, gr. 0.02; magnesium sulphate, gr. 5.61; potassium sulphate, gr. 0.41; aluminum sulphate, gr. 42.61; manganesium sulphate, gr. 0.09; iron persulphate, gr. 1.95; nickel sulphate, gr. 0.14; calcium phosphate, gr. 0.17; sodium chloride, gr. 0.11; silica, gr. 3.70; sulphuric acid, gr. 3.83; and traces of cobalt sulphate, zinc sulphate, lead sulphate, ammonium nitrate, calcium fluoride, antimony, copper, arsenic, and organic matter. Total, 62.35 grains. The following gases were also found in one United States gallon: Oxygen, 1.49 cub. in.; nitrogen, 3.98 cub. in.; and carbonic acid, 10.89 cub. in. These have long been regarded as among the best alum waters known. They are clear and odorless, but possess a strongly astringent and styptic taste. Their temperature ranges from 50° to 56° F. They are of undoubted efficacy in cases requiring an astringent chalybeate. They have proved valuable in atonic and catarrhal states of the different mucous membranes—for example, in chronic diarrhœa, in leucorrhœa, in pharyngitis, in rhinitis, etc. They are very useful locally in scrofulous ulcers and in other slow-healing similar conditions. The waters sometimes prove purgative in large doses and are always diuretic in doses of one-quarter to one-half of a small tumblerful taken six, eight, ten, or twelve times a day. The effects of the water often last far beyond the period during which they are taken.

James K. Crook.

ROCK CASTLE SPRINGS.—Pulaski County, Kentucky.

Post-Office.—Rock Castle. Springs Hotel.

These springs are located in the Rock Castle River, and are accessible by the Louisville and Nashville and Queen and Crescent Railroad lines. There is daily connection by stage with morning and afternoon trains at London. The situation is one of great natural charm

Digitized by Microsoft®

and beauty, being in the heart of the Cumberland Mountains, at an elevation of over two thousand feet above the sea-level, and surrounded by a vast natural park of pine trees. The pure air and equable temperature, as well as the isolation from the thoroughfares of travel, combine to render the location one of exceptional freedom from the ills of hot weather. A comfortable hotel, with ample arrangements for the comfort of guests, is at hand. The surrounding forests, hills, and fields offer many attractions for the botanist, the naturalist, and the sportsman. The following analysis was made by Dr. Robert Peter: One United States gallon contains: Iron carbonate, gr. 0.84; calcium carbonate, gr. 2.58; magnesium carbonate, gr. 0.86; calcium sulphate, gr. 0.17; magnesium sulphate, gr. 0.12; sodium sulphate, gr. 3.09; sodium chloride, gr. 0.15; silica, gr. 0.74. Total, 8.55 grains. A considerable quantity of free carbonic acid gas is also present.

The waters of the springs have been in use since 1843. They are said to possess excellent tonic and diuretic properties. It is also maintained that the location is very beneficial for cases of hay asthma, nasal catarrh, laryngitis, etc.

James K. Crook.

ROCK ENON SPRINGS.—Frederick County, Virginia.

POST-OFFICE.—Rock Enon Springs. Hotel.

ACCESS.—Viâ Valley Branch of the Baltimore and Ohio Railroad to Winchester, thence by coach over picturesque mountain road sixteen and one-half miles to springs. Time from Washington, six and one-half hours.

This resort is located in the great North Mountains. It is surrounded by the primeval forest, and nestles under the shadow of a majestic peak in a romantic gorge, through which flows Laurel Brook, a beautiful stream which is supplied by the mountain springs, and which winds about the hotel and its attractive lawn. The locality is free from swamp lands and malaria. The hotel has a location of twelve hundred feet above tide water. This is a model caravansary, and the visitor may feel assured that every device for his comfort, health, and amusement has been arranged for by the thoughtful proprietor. The scenery in the neighborhood is exceptionally fine. Close to the hotel are three mineral springs, which have been found to possess well-marked medicinal properties.

The *Chalybeate Spring* was analyzed by Professors Gale and New, of the Smithsonian Institute, Washington, who found it to contain, in one United States gallon, the following solid constituents: Sodium carbonate, gr. 1.21; calcium carbonate, gr. 5.13; calcium sulphate, gr. 3.56; magnesium sulphate, gr. 12.89; magnesium chloride, gr. 1.12; iron oxide, gr. 14.25; manganesium oxide, gr. 1.05; alumina, gr. 0.80; silica, gr. 0.42. Total, 40.43 grains.

The water resembles that of the Pyrmont Spring in Waldeck, Germany. It is a strong chalybeate, and possesses aperient and diuretic properties.

A qualitative analysis of the *Alkaline Spring* by Professor Lupton, late of the University of Virginia, showed the presence of potassium and magnesium carbonate, sodium chloride, calcium sulphate and carbonate, silica, and carbonic, sulphuric, and hydrochloric acids. The water is antacid, diuretic, and aperient, and is used in affections of the kidneys and urinary passages, in dyspepsia, in gout, and in catarrhal affections.

The *Old Capper Spring* once gave its name to the resort, and it is styled Capper's Springs in the older books. It has been in use for more than a century. The water is described as being efficacious in rheumatism and in diseases of the skin, and as a cure for certain of the intestinal worms.

White and blue sulphur springs of excellent quality are also found in the neighborhood. The following data show the mean temperature at Rock Enon for July and August during the past ten years: July, 7 A.M., 66° F.; 12 M., 77°; 3 P.M., 78°; 6 P.M., 75°; and 10 P.M., 66.25°. For August, at the same hours, the record was 64.5°, 74.5°, 76°, 73°, and 66° F.

James K. Crook.

RODENT ULCER. See *Carcinoma of the Skin.*

ROENTGEN RAYS, USE OF, IN MEDICINE AND SURGERY.—The discovery by Wilhelm Conrad Roentgen, in 1895, of the kind of radiant energy now known as the Roentgen or *x*-rays, was at once recognized as giving a most important addition to the armamentarium of the diagnostician in surgery. With improved apparatus and technique, and with more extended experience, the application of the Roentgen rays has gradually extended until their use is now universally regarded not only as indispensable in surgery, but as most valuable for diagnosis and therapy in many diseases not classed as surgical.

Nature and Action of the Roentgen Rays.—The Roentgen rays are produced by the passage of an electrical current of *small volume* and *high tension* through a specially constructed vacuum tube of high exhaustion. If an electrical current is passed through a glass tube from which the air has been but partly exhausted, an arc of light will be projected from the cathode (negative pole) to the anode (positive pole). If a similar tube of high exhaustion is used, no arc of light will form, but a peculiar fluorescence will appear at the anode. This fluorescence appears to emanate from any body exposed to the cathode of a vacuum tube. In the ordinary Roentgen-ray tube, the anode is a platinum plate placed in a line with the cathode, and the electrical energy passing from the cathode falls upon the anode, and from thence both fluorescent and Roentgen rays are projected. If the cathode is concave and directed toward the side of the tube, fluorescence will appear to emanate from the side of the tube at the point toward which the cathode is directed. Not only does the body fluoresce upon which the cathode rays are directed, but it will glow with heat if the electrical current is strong. In consequence, if the cathode rays are directed toward the side of the vacuum tube, the tube will become heated at the point of impingement, will soon soften and be destroyed by the giving way of the melted glass. For this reason the cathode rays are in practice directed toward a platinum plate which forms the anode, and which is set at an angle of about 45°, so that the Roentgen rays are directed from it outward at about a right angle to the long axis of the tube (Fig. 4114).

The visible fluorescence which appears in the tube must not be mistaken for the Roentgen rays.

The Roentgen rays are themselves *invisible*, and are appreciable to the senses only by their effect upon cer-

FIG. 4114.—Diagram of Roentgen-Ray Tube with Lines of Roentgen Radiation. The lines diverging from the anode show by their relative proximity to each other those parts of the hemisphere in front of the anode which are more or less acted on by the Roentgen rays.

tain substances. This effect is manifested in three ways: (*a*) by the fluorescence of certain chemical substances when the rays fall on them; (*b*) by the reduction, when exposed to the rays, of certain silver salts ordinarily used for photography; and (*c*) by changes produced in living tissues when the rays act upon them for a sufficient length of time.

The first of these effects, *i.e.*, the fluorescence of cer-

www.libtool.com.cn
Digitized by Microsoft®

tain chemical substances, is the means used for producing visual effects directly from the vacuum tube. When the Roentgen rays fall upon certain substances, notably calcium tungstate, the double cyanide of platinum and ba-

FIG. 4115.—Diagram showing the Fluoroscopic Method of Obtaining Visual Images by Roentgen Radiation. *a*, Anode; *b*, Roentgen rays passing to light-excluding chamber with fluorescent screen *d*, on which appears the fluorescing image formed by rays passing by or through the object *c*.

rium, platinum and magnesium, platinum and potassium, zinc oxide, etc., these substances glow with visible fluorescent light, the fluorescence in a degree depending upon the number and strength of the impinging rays.

This property of producing visible fluorescence is utilized to give visual effects from the rays. A chemical substance which will fluoresce, usually the double cyanide of potassium and barium, is spread and fixed on some plane surface which is opaque to light. Upon excluding light and allowing the Roentgen rays to pass through the support and fall upon the coated surface, this is seen to glow to a degree depending upon the amount of radiant energy which falls upon it. The amount of energy affecting the fluorescent surface depends upon the energy given out by the tube, the distance of the tube from the plate (the effect varying inversely as the square of the distance), and the extent to which the passage of the Roentgen rays to the fluorescent surface is obstructed by objects placed between the sensitive surface and the tube (Fig. 4115).

The visible images produced by the Roentgen rays are in every sense shadow pictures. The objects outlined by the rays are not themselves seen, but only their shadows cast upon a fluorescent screen or impressed on a photographic plate. It is of the greatest importance in interpreting these shadow images to recognize the fact that they are shadows and not real images of the objects observed.

Roentgen rays are always projected in straight lines from the fluorescing anode, and unlike light rays they are incapable of refraction, dispersion, or regular reflection. Consequently the shadow images formed are similar to shadow images made by ordinary light when projected from a point, and therefore depend for shape and size not only upon the shape and size of the object projecting the shadow, but upon the position in which the object is placed, its relative distance from the source of the rays, and the plane upon which the shadow is cast. These facts are of the utmost importance in judging the radiographic image, and a competent observer in reaching a conclusion always considers all these factors and their relation to each other. Correct estimation of the relative value of these factors is of especial importance in ascertaining the size and position of foreign bodies lodged in the tissues, and is to be particularly considered in medico-legal cases where deformity may be inferred from malposition of tube or plate, or from erroneous reading of the shadow picture.

In addition to their non-deviation from the direct lines in which they are projected, Roentgen rays differ from light in that they are capable of passing through or penetrating all substances. This transparency (to use the term) to Roentgen radiation is not, however, the same with all substances, but appears to be in large measure in inverse ratio to the density of the substances. The property of obstructing the passage of the rays differs markedly with different tissues, both normal and abnormal, of the human body; and as the rays which pass through the least resistant tissues are thus able to exert their greatest effect upon the fluorescent screen or photographic plate, the shadow image gives the outlines of certain tissues, and by difference in density it may furnish evidence of normal and abnormal conditions. Thus, for instance, not only are the outlines of a long bone clearly marked out by the rays, but the medullary cavity is shown as well; and, while in radiographs of the normal lung the denser bronchi only are shown, in pulmonary tuberculosis the tuberculous thickenings from their greater resistance to the rays appear as clearly defined shadows.

As to the real nature of the Roentgen rays many hypotheses have been advanced, some physicists holding that they are longitudinal vibrations of the luminiferous ether, others that they are minute particles of matter driven out from the cathode, and others that they differ from ordinary light rays only in the number of vibrations. While consideration of these hypotheses is of interest to the physicist, to the physician and surgeon the practical facts are: (*a*) that *Roentgen radiation is a form of energy projected in straight lines from its source*; (*b*) *that the ease of its passage through the human body depends upon the structure and density of the tissues*; (*c*) *that it is capable of producing molecular and chemical changes in certain substances used for making its action visible, such as the fluorescent screen and photographic plate*; *and* (*d*) *that it can produce tissue changes by affecting the metabolic action of living cells.*

Practically, the selection of apparatus which will best produce these visual, chemical, and physiological effects is a matter of much importance, and as there are many variations in type of apparatus for producing Roentgen radiation, a careful study of the apparatus and the principles upon which they are constructed is necessary before they can be properly understood and judicious selection made.

ROENTGEN-RAY APPARATUS.—There are two types of apparatus commonly employed for producing the electrical current of small volume and high tension necessary to excite the vacuum tube to Roentgen radiation—the static machine and the induction coil.

The Static Machine.—The static machine is the only apparatus in which an electrical current of required strength and tension is directly produced. In this apparatus the electrical current is produced by the machine and carried direct to the tube, the electrical energy given out being derived from the mechanical energy used in driving the machine. Two forms of static machine are most used—the Wimshurst and the Holtz. Of these the Holtz form is most used in America, while the Wimshurst is almost exclusively used in England. The use of static machines for Roentgen-ray work is much more common in the United States than in any other country. In this country much attention has been paid to this form of apparatus, and a type of apparatus considerably modified from the original Holtz has been developed, which is, with certain limitations, quite satisfactory. The machines now most used (Fig. 4116) have from eight to sixteen circular glass plates mounted on an axle. These plates rotate in one direction, and between them are fixed inductor plates of glass.

The special *advantages* of the static machine are that it is easy to operate, that with ordinary care it is not liable to get out of order, and that it is capable of producing a steady and fairly powerful output, which is not injurious to vacuum tubes. For good work it is necessary to have a static machine of large size, twelve to sixteen plates, thirty-two inches in diameter, or even larger, and it should be driven not by hand but by power, a one-half horse-power motor with speed regulation being required to give good results. The *disadvantages* of the machine

Digitized by Microsoft®

are that it occupies much space, that it is liable (unless carefully managed) to fail in damp weather, and that as powerful effects cannot be obtained with it as with the larger coil apparatus. Under proper management a

www.libtool.com.cn

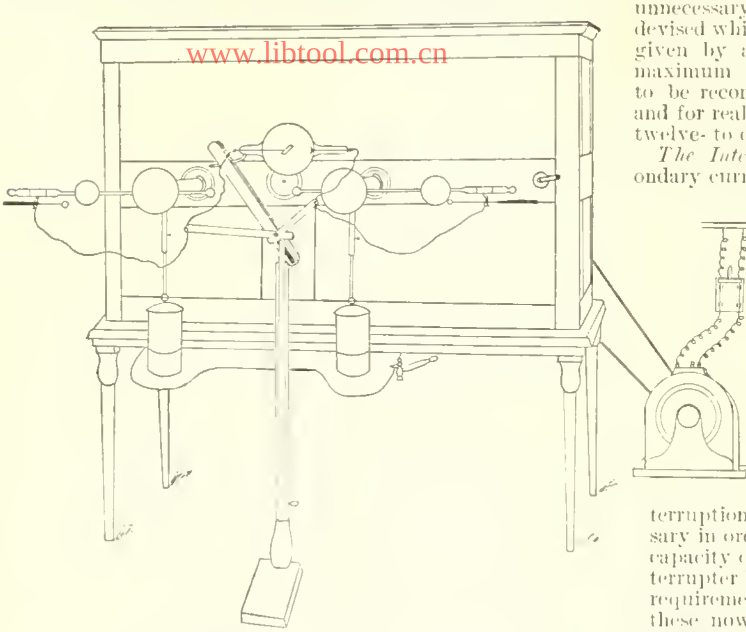

FIG. 4116.—Static Machine Arranged for *x*-Ray Work.

large static machine will do satisfactory fluoroscopic and photographic work, but where therapeutic work has to be done the majority of operators consider a coil apparatus indispensable. With a static machine great care must be taken to keep its interior free from moisture; a tight case and the occasional use of calcium chloride for drying being necessary. In operating it, steady and sufficiently rapid revolution of the plates and careful attention to the use of the "spark gaps" and Leyden jars is indispensable to success. The static machine is to be particularly recommended where commercial electrical currents for running a coil cannot be had, as under these conditions a large static machine run by a water, steam, or gasoline engine will give much better satisfaction than a coil apparatus energized by a primary battery.

Coil Apparatus.—The principal parts of a coil apparatus are the induction (Ruhmkorff) coil, the interrupter, the vacuum tube, and a suitable electrical source. In the coil apparatus, the secondary current of small volume and high tension necessary to excite the vacuum tube is obtained by induction from a primary current of large volume and relatively low tension. The primary current is obtained from primary batteries, storage batteries, or dynamos—when from the latter, the dynamo current for electric lighting is usually employed—and is carried to the coil by insulated wires. In the coil (Fig. 4117) the primary current traverses that part of the coil which is called the primary and, being interrupted with high frequency by the interruptor, by induction produces a current of high potential in the secondary part of the coil, from which it is carried by insulated wires to the vacuum tube.

The Induction Coil.—Induction coils are made of various sizes and are wound to correspond to the primary current by which they are supplied, whether from battery or from dynamo. They should be used only with the current for which they are designed. Their size is given in inches, this indicating the length of spark they give when supplied with a proper current. The longer the spark length, the greater the care which must be employed in manufacturing the coil (to prevent its being destroyed by the powerful currents which are necessary to energize it) and the more the resulting work which the coil is capable of doing. For practical Roentgen-ray work, coils exceeding eighteen inches in spark length are unnecessary, as the vacuum tube has not yet been devised which can dispose of all the electrical energy given by an eighteen-inch coil when giving its maximum output. Coils below six inches are not to be recommended except for very light work, and for really satisfactory work coils giving a large twelve- to eighteen-inch spark are to be preferred.

The Interrupter.—To produce the required secondary current it is necessary more or less rapidly to interrupt or break the primary current. The interrupter is a most important part of the coil apparatus. The essentials of a good interrupter are suddenness of break, good contact at the make, and adjustment for regulating the frequency of the interruptions. The greater the abruptness with which the current is cut and the more instantaneous and perfect the contact when the current is made, the greater will be the effect on the secondary coil; also adjustment for regulating the frequency of the interruptions and the length of the make is necessary in order to adjust the induced current to the capacity of the tube in use. Many forms of interrupter have been devised in order to meet these requirements. There are three main types of these now used—the vibrating spring type, the mercury type, and the electrolytic type. Of these different types the vibrating spring interrupter (Neff's hammer) is the original and simplest form (Fig. 4117).

An upright spring, carrying a heavy piece of iron at its upper end, is fixed on the baseboard so that the iron head is opposite one end of the core of the coil. On the face of the hammer furthest from the core is fixed a piece of platinum, and opposite this is another piece of platinum fixed in the end of a screw held in a brass pillar. The electrical current is carried from one pole of the battery through the coils of the primary to the vibrating hammer, thence, when the platinum points are in contact, to the screw and from it to other pole of the battery. The current magnetizes the soft-iron core, which attracts and pulls the hammer toward it and away from the

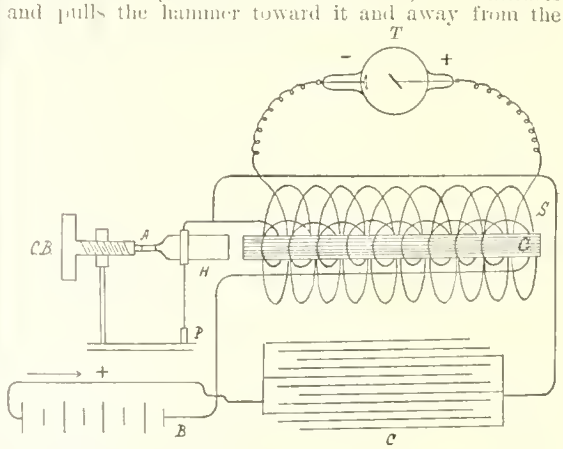

FIG. 4117. Diagram of Induction-Coil Apparatus with Vibrating Hammer Interrupter. *A*, Contact; *B*, battery; *S*, secondary; *C*, soft-iron core; *H*, hammer; *c*, condenser; *T*, tube.

screw. This breaks the current, the core is demagnetized, and the spring carries the hammer back against the screw, which again completes the circuit, and the process is repeated. By adjusting the screw and the

Digitized by Microsoft®

tension of the spring, the rate of the vibrations and the relative length of break and contact can be regulated to a certain degree to correspond with the tube used.

The advantage of this interrupter is its simplicity, but it is not adapted to coils giving a spark over six inches

www.libtool.com.cn

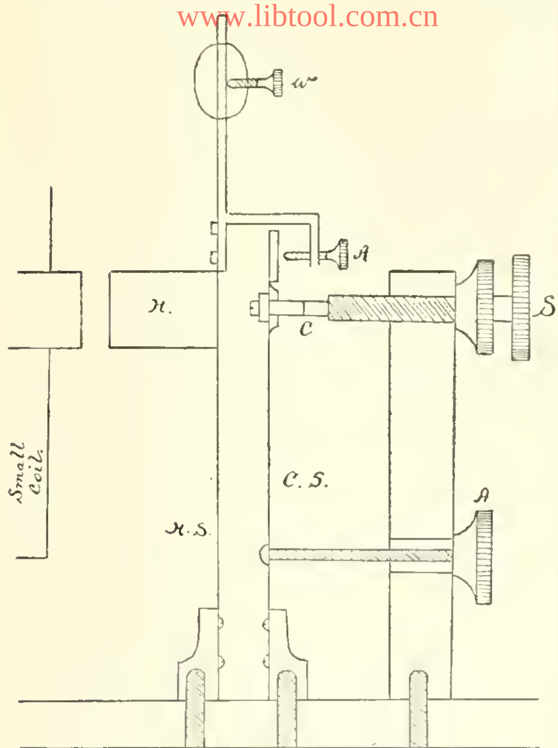

FIG. 4118. Diagram of Independent Vibrator. h, Hammer; w, movable weight; h. s., hammer spring; c, contact points; c. s., contact spring; A, S, A, adjusting screws.

in length. The break made by it from its occurring when the hammer starts to move, is not abrupt, and the contact from the wearing of the platinum is apt to be imperfect. Also the intense heat developed at the point of contact sometimes welds the platinum points together and stops the working of the apparatus. Large coils, requiring heavy currents, cannot be used with the interrupter, both from the liability of welding the platinum and from the jumping of the current across the gap at the break.

The *independent vibrating interrupter* (Fig. 4118) is a modification of, and a great improvement on, the Neff hammer. With it coils up to fifteen inches, energized by commercial currents up to one hundred and ten volts, can be quite satisfactorily worked. In this form the interrupter is operated by a secondary battery connected by a shunt from the main circuit, and is entirely independent of the main coil.

In this interrupter the current passes from the battery to the coil and returns (Fig. 4118) through *c.s.*, *c.* and *S*, unless broken at *c*. The current is broken at *c*, by the screw *a* striking the contact spring, when the hammer is attracted by the core of the small coil. This interrupter gives a relatively long contact, and the break is very sudden as the contact spring is struck when the hammer is moving at high speed. The rapidity of the interruptions can be varied in wide range by raising or lowering the movable weight (*w*) on the hammer spring. The advantages of this form of interrupter are that it is easy to manipulate, that it does not readily get out of order, and that it gives good results on all but the largest coils.

Mercury Interrupters.—The mercury interrupters are of two types—the dip interrupters and the turbine. The dip interrupter (Fig. 4119) consists of a small electric motor which, when in motion, rapidly dips one or two silver needles, hung on an eccentric of the shaft, into mercury, overlaid with petroleum, contained in glass receptacles.

The needles being connected with one pole of the battery and the mercury with the other, the current is made and broken by the entrance and exit of the needles from the mercury, while the number of interruptions is regulated by the speed of the motor, and the relation of make to break is determined by the time the needles remain in or out of the mercury.

The *turbine interrupters* (Fig. 4120) consist essentially of a hollow metal cylinder in which openings are cut, and within which a rapidly revolving turbine wheel, by centrifugal force, throws outward a stream of mercury. The cylinder being connected with one pole of the current and the wheel and mercury with the other, the current is made when the stream of mercury impinges against the wall of the cylinder and is broken when it passes through the openings. The rapidity of the interruptions can be regulated by the speed of the motor which runs the turbine wheel, and the length of the make and break, by the size of the openings in the cylinder and the distance between them. In practice, the openings are triangular sectors, and the relation of make to break can be varied by raising or lowering the cylinder. The break, from the force with which the mercury is thrown, is extremely sudden. The mercury is used dry, and requires only occasional cleaning.

The dip and turbine interrupters give the highest attainable results. They can be used on the largest coils and with direct currents up to two hundred and fifty volts. The turbine are in many respects better than the dip interrupters, as they are easier to manage and, in the best forms, are capable of more varied adjustment. They are expensive, compared with other interrupters, but for critical and professional Roentgen-ray work are unexcelled.

Electrolytic Interrupters.—These interrupters are entirely different in principle from those above described. Their action

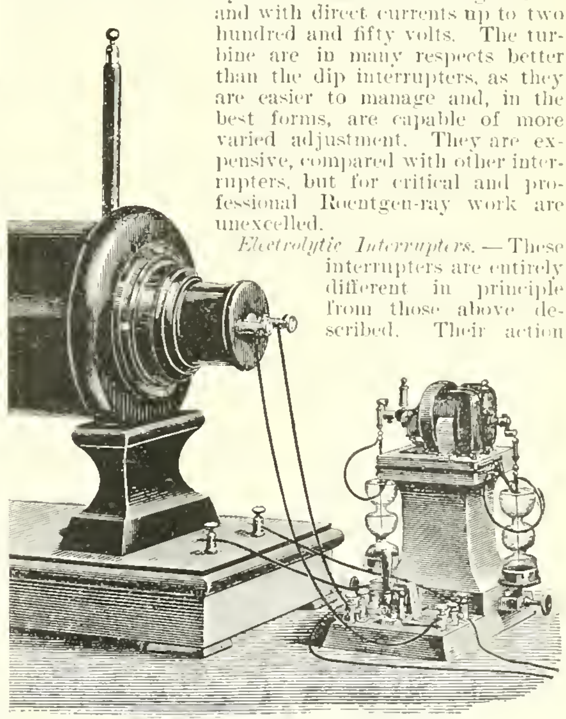

FIG. 4119. Coil with Mercury Dip Interrupter.

depends upon the electrolytic action of an electrical current. These interrupters consist essentially of a large sheet of lead connected with the negative pole of an electrical current and a small surface of platinum connected to the positive pole, both being immersed in dilute sulphuric acid (Fig. 4121). When a current is passed, electrolytic action occurs in the fluid and the sudden formation and disappearance of a non-conducting

Digitized by Microsoft®

Roentgen Rays.

envelope of gas about the exposed platinum alternately breaks and makes the currents. In practice, at least forty volts at the terminals of the interrupter must be used to give good results.

These interrupters, from the rapidity of the interruptions, give a steady and intense light for fluoroscopic purposes, but for photographic work the radiation is not so energetic as that given by the mercury interrupters. The advantages of this interrupter are its cheapness and simplicity. Its disadvantages are that it is not fully controllable, that it is liable to explode, and that it is not possible to work it long at a time, as the fluid soon becomes overheated.

www.libtool.com.cn

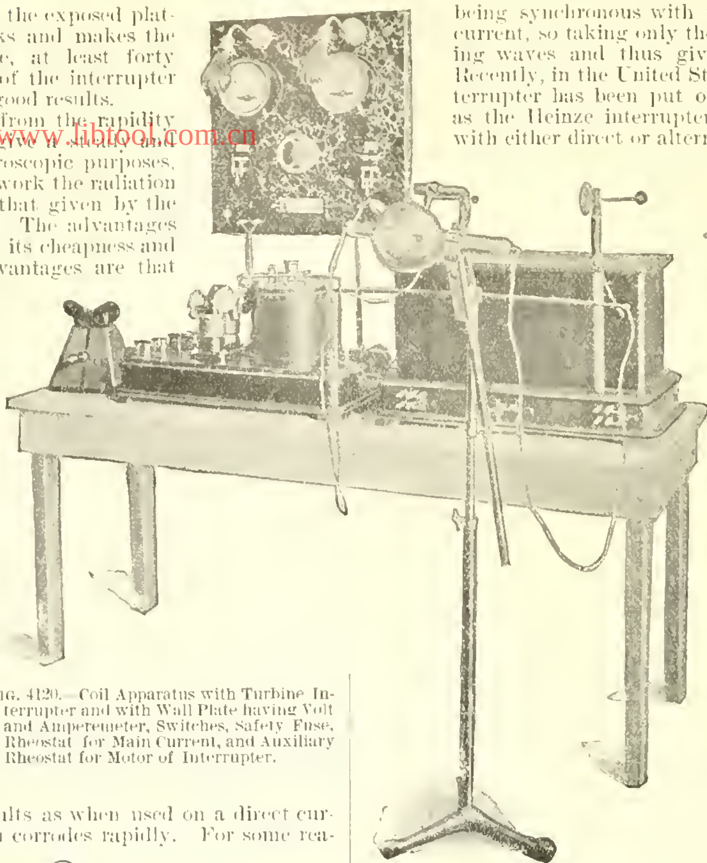

FIG. 4120.—Coil Apparatus with Turbine Interrupter and with Wall Plate having Volt and Amperemeter, Switches, Safety Fuse, Rheostat for Main Current, and Auxiliary Rheostat for Motor of Interrupter.

Interrupters for Use with Alternating Currents.—All the interrupters so far discussed, with the exception of the electrolytic type, can be used only on *direct* currents. The electrolytic interrupter can be used on an alternating current, and is the cheapest method of using such a current; but it does not give as good results as when used on a direct current and the platinum corrodes rapidly. For some rea-

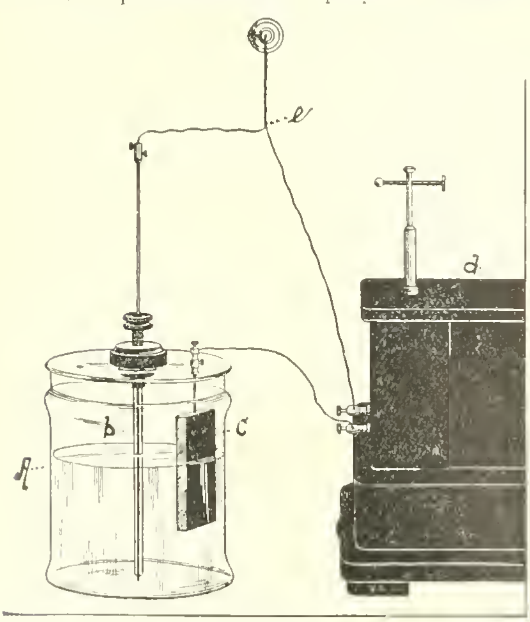

FIG. 4121.—Electrolytic (Wehnelt) Interrupter. *A*, Interrupter; *b*, platinum wire in porcelain cylinder; *c*, lead plate; *d*, coil; *e*, wires connecting interrupter and coil with an electrical source.

son the electrolytic interrupter does not explode or "choke" (cease working) on alternating currents.

Synchronous interrupters of the turbine mercury type are considerably used abroad for utilizing alternating currents. They depend in principle upon the make being synchronous with the alternation of the current, so taking only the crest of the alternating waves and thus giving a direct current. Recently, in the United States, a form of dip interrupter has been put on the market, known as the Heinze interrupter, which can be used with either direct or alternating currents.

This interrupter consists essentially of a small motor whose crank eccentric rapidly carries a platinum needle into and out of dilute sulphuric acid. The principle is a combination of the mercury dip and the electrolytic. The interrupter is completely under control when working with a continuous current, and by means of the control lever the make and break of the interrupter can be made synchronous with the alternations of an alternating current, and so send a unidirectional current through the coil.

The Condenser.—This part of a coil apparatus (Fig. 4117, *e*) consists of a number of sheets of tinfoil, insulated from each other, and connected with the wires by which the coil is connected with the electrical source. The function of the condenser is to act as a sponge and, when the interrupter breaks the current, instantly to absorb the electricity in the primary and so completely and immediately to demagnetize the core, thus greatly increasing the energy in the secondary. So energetic is this action that a twelve-inch coil without a condenser will barely give a two-inch spark. The condenser is usually placed in the base of the coil, but may be mounted separately. With the electrolytic interrupter no condenser is used.

Vacuum Tubes.—Tubes are graded from low (soft) to high (hard). A high or hard tube is one of high vacuum. These tubes require powerful currents to excite them, and they produce rays of great intensity. With such tubes the shadows of the bones viewed with a fluoroscope appear gray, and metallic objects are readily seen through them. Tubes of this character are very energetic in action on the photographic plate, and are useful for work through thick parts, as the hip, pelvis, or head.

A low or soft tube is one of low vacuum. Low tubes are readily illuminated by currents of low power, and therefore give rays of low intensity and penetration. Between the low and high tubes there are all gradations. Low tubes have too little penetration for work with any but extremely thin parts of the body, while very high tubes give such powerful rays that sufficient contrast between the bones and surrounding tissues is lost and critical differentiation of structure is impossible. Moderately high tubes are best for general work both in radiography and in therapy.

In using a vacuum tube it is necessary to adapt the current to the tube or the tube to the current, or both to each other. The current is regulated in the static machine by the rapidity of revolution of the plates and by adjustment of the spark gaps. In the coil apparatus the

Digitized by Microsoft®

Roentgen Rays.

strength of the primary current is regulated by a rheostat, and the quality of the secondary current is conformed to the tube by adjustment of the interrupter. With respect to conforming the tube to the current, tubes are divided into non-regulating and regulating tubes.

Regulating tubes consist of the usual vacuum tube with a small attachment containing a chemical which when heated gives off vapor and reabsorbs it when cooled. When the vacuum of the tube becomes too high it can be lowered by heating the bulb by the passage of an electrical current, so forcing vapor into the tube. A very ingenious and useful self-regulating tube has been devised by Queen (Fig. 4122). In this the chemical is heated by the current passing to an adjustable spark point, and by adjusting the distance of this point from the cathode connection any desired degree of vacuum may be maintained.

In tubes to be used with the powerful currents given by the larger coils and rapid interrupters, special provision has to be made to prevent rapid destruction of the anode by the powerful cathode stream which impinges upon it.

Where the current is moderately powerful, tubes with extra thick anti-cathodes will resist the cathode stream. With powerful apparatus the water-cooled tube (Fig. 4123) must be used. In this tube the anti-cathode is placed at the base of an inwardly projecting cylinder, so that it can be kept cool by running water and thus withstand the great energy developed.

Success in the use of the Roentgen ray-apparatus depends largely upon proper manipulation of the tube and the current supplied to it. When a tube is used, care should be taken not to allow the platinum anode to become overheated. As a rule, radiation is at its best when the anode is just short of white heat at its centre, where the greatest energy of the cathode stream is exerted. For this radiation, tubes with thick or water-cooled anodes are required, as thin anodes are soon perforated and destroyed. When in operation the tube should be constantly watched, for on account of the heat developed the vacuum in the tube becomes gradually lower, and as the current passes more readily the anode may become overheated unless the operator reduces the current. Tubes become higher with use. When a tube refuses to illuminate, careful application of heat will overcome its resistance for a time; but, with use, it will finally become so hard that no current can pass through it. When this occurs, re-exhaustion is the only remedy.

Electrical Sources.—Three sources of electrical current are used for Roentgen-ray purposes—dynamos, storage batteries, and primary batteries.

The *dynamo currents* generally used are from commercial electric-light circuits, and this kind of current is best

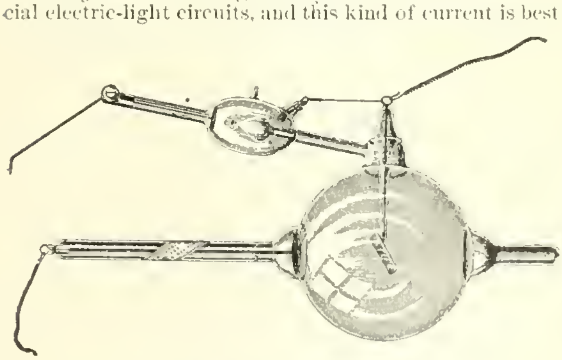

Fig 4122.—Queen Self-Regulating *x*-Ray Tube.

for Roentgen-ray work, where it can be had, as it affords sufficient energy to operate the coil and the discharge may be made as heavy as desired. Commercial currents are either continuous or alternating. The *continuous current*, unless of very high voltage, can be carried direct to the coil, requiring only a rheostat for regulating it and a safety fuse to prevent accidents. These currents are usually one hundred and ten volts, and all forms of interrupter can be used with them. Currents of higher voltage may be used, but with two hundred and twenty volts, or higher, the "reactive kick" of the primary becomes so great as to be a source of danger to the oper-

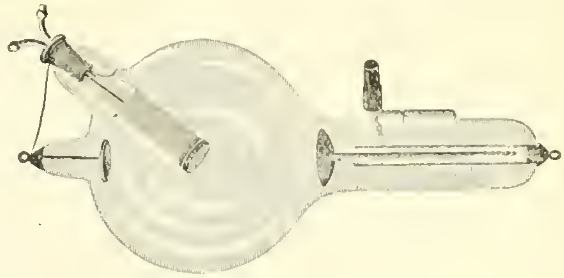

Fig. 4123. Water-Cooled Tube.

ator in case of accidental contact with certain parts of the apparatus. With these high-volt currents it is best to use a current transformer which reduces the current to a point of safety.

The *alternating current* can be used only with an electrolytic interrupter, a Heinze interrupter, or a synchronous mercury interrupter.

Storage Batteries.—Next to a dynamo current that from a storage battery gives best satisfaction. Storage batteries, like batteries generally, have the disadvantage of being more or less difficult to keep in order. The "chloride accumulator" is probably the best type and, in its more compact form, is useful for making part of portable apparatus. These batteries can be charged from dynamo currents or from primary batteries. To charge from an alternating current, a current rectifier which takes only the crests of the alternating waves, must be used. To give a good output, a little more than one cell of a battery is required for each two inches of spark length given by the coil.

Primary Batteries.—This form of electrical source is the least desirable of any used for energizing coils for Roentgen-ray work. Primary batteries are bulky, require a great deal of attention to keep them in order, and are expensive to maintain. They can be recommended for use only where commercial circuits or storage batteries cannot be employed. Any of the more energetic forms of battery will run a coil, but, from the trouble incident to working them, only one form—the Edison-LeLande battery—can be satisfactorily used for this purpose. This battery requires comparatively little attention, and gives a very constant electromotive force. About four battery cells are required for every two inches of spark length given by the coil.

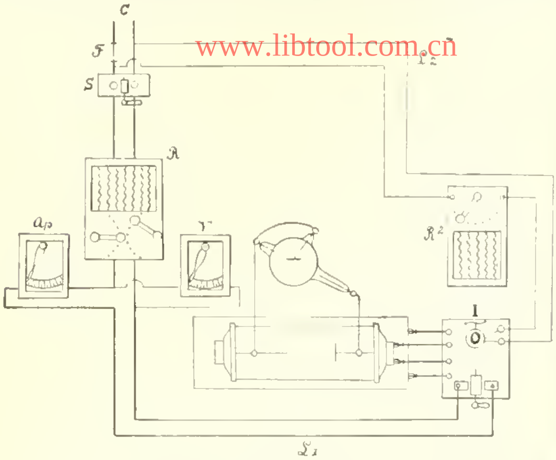
Installation of Apparatus.—The method of assembling a coil apparatus depends upon the current supplied, the form of interrupter used, and the size of the coil. With a small apparatus having a hammer interrupter and energized by a primary or storage battery, it is only necessary to connect the coil direct to the battery. When a continuous commercial current is used a safety fuse and rheostat should be placed in the main circuit to protect the coil from injury and to regulate the current. When a mechanical interrupter is used it is run by a shunt from the main circuit, and should have a separate rheostat and safety fuse (Fig. 4124).

In installation of the larger coils the addition of a volt and ampere meter is useful to show the quantity and quality of the current, and wall plates are made having safety fuse, rheostats, and volt and amperemeters conveniently assembled on them (Fig. 4120). With an electrolytic interrupter the installation is somewhat simplified, as the interrupter is placed directly in the circuit which supplies the coil (rheostat and safety fuse being used) and a condenser is not required (Fig. 4125).

Surgical Uses of the Roentgen Rays.—The principal surgical uses to which Roentgen radiation is put

Digitized by Microsoft®

are: (*a*) to diagnose fractures and determine the form and extent of the bone lesions; (*b*) to diagnose dislocations; (*c*) to determine the existence and extent of acute, chronic, and neoplastic pathologic changes in the bones;



www.libtool.com.cn

FIG. 4124.—Diagram of Installation of an Apparatus with Mechanical Interrupter. *C*, Wires to maintain circuit; *F*, safety fuse; *S*, switch for connecting current; *R*, rheostat for current to coil; *Ap*, *V*, ampere and volt meters; *Li*, wires to coil; L_2, wires to interrupter; R^2, rheostat for interrupter; *I*, interrupter.

(*d*) to determine bone malformations and deformities; (*e*) to determine the presence and location of foreign bodies.

The peculiar resistance of osseous tissues to the Roentgen rays makes traumatisms of these particularly easy to determine. By the proper use of the rays the presence or absence of fracture, and, if present, the form and extent of the bone trauma can be accurately determined. Cases of difficult diagnosis are made plain, and since the rays have come into use it has been demonstrated that fracture is present in many obscure cases thought to be severe strain or sprain. The attention of the writer has been particularly called to this fact in connection with injuries of the knee-joint. Recently two cases of persistent lameness were referred to him, which were supposedly due to severe strain. In one of these cases the external condyle of the femur was split off to the intercondyloid notch (Fig. 4126) with no displacement, and in the other the internal tuberosity of the tibia was similarly fractured. In both these cases no crepitus could be elicited; the only prominent symptoms were persistent swelling and pain at the joint and the patients walked about with the aid of a cane.

Not only has the use of the rays given the surgeon a sure method of determining the presence of fracture, but it has greatly increased his knowledge of fractures resulting from indirect and direct violence, particularly those forms which are due to gunshot injury. The facts disclosed have been extremely valuable from the standpoint of treatment, for it has been conclusively proven that conservatism is indicated even in cases of most extensive bone lesion, provided the wound is not infected. In fact, as a result of Roentgen-ray observations combined with clinical experience, the rule may now be formulated that whatever the extent or form of a fracture, if no infection is present, operation is contraindicated, unless the bone fragments are so displaced that they produce deformity, may interfere with the function of the part, or are pressing upon vital or important structures.

When the diagnosis lies between a suspected fracture and a dislocation, as in obscure injuries of the elbow-joint, the rays at once determine the matter accurately. They are equally effective in showing the result of treatment, and at once enable the surgeon to determine whether or not a dislocation or fracture has been properly reduced (Figs. 4127 and 4128).

In determining the presence and extent of bone lesions it is most important that the rays be properly used. As before stated, visual effects from the rays are from observed shadows, and these shadows depend for shape and size not only upon the shape and size of the objects casting the shadows, but upon the relative position of the light and object and their distance from each other. For these reasons, to reduce distortion to the minimum, radiographs should always be made with the tube so placed that the anode will be as nearly as possible on a line perpendicular to the long axis of the bone above the place of fracture, and at least eighteen inches distant from it. Also, when the part injured admits, radiographs should always be taken from two directions, preferably at right angles to each other. Unless this precaution is taken, a fracture may be overlooked from the fragments overlying each other in a direct line and so throwing a straight continuous shadow, when a radiograph taken at another angle will at once show a displacement.

In this connection the *medico-legal* aspects of radiography may be considered, and here again the fact must be emphasized that radiographs are shadow pictures, not actual pictures of the objects themselves, that consequently the images are *never* accurate representations of the objects, that distortion is always present to greater or less extent, and that proper reading of radiographs can, in difficult cases, be arrived at only after much experience on the part of the expert; and then information must be at his disposal, giving the relative position and distance from each other of the tube, the plate, and the object radiographed. It is also primarily essential to expert opinion that this opinion be based upon full knowledge of radiographic pictures of normal structures, particularly of the shadow images given by the bones at the articulations.

For medico-legal as well as for diagnostic purposes, it is to be noted that *bone callus* is at first quite transparent to Roentgen rays, so much so that a fracture which is quite firmly united may show on the photographic plate as though no callus existed, and so give the appearance of an ununited fracture. For this reason the Roentgen rays cannot in all cases be relied on to give the actual condition of union or non-union of fracture.

The Localization of Foreign Bodies in the Tissues and in the Body Cavities.—The advantages of the Roentgen rays over all other means of locating foreign bodies are now so well understood that their use has practically entirely superseded all other methods.

The difficulties of using the probe for locating lodged missiles is well known. The contractility of tissues

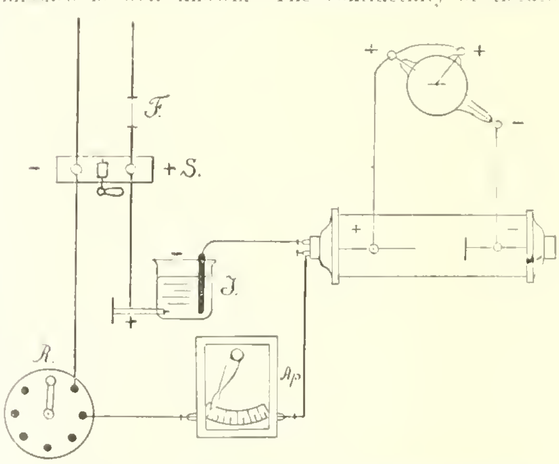


FIG. 4125.—Diagram of Installation of Apparatus with Electrolytic Interrupter. *S*, Switch; *F*, safety fuse; *R*, rheostat; *Ap*, amperemeter; *I*, electrolytic interrupter.

and the shifting of muscular and fascial structures by change of position may completely obstruct the wound track; and after the wound is healed, unless the foreign

Digitized by Microsoft®

Roentgen Rays.

body can be felt beneath the skin, its localization by other than the Roentgen rays is usually impossible. With these all parts of the body may be painlessly and safely explored, and the presence or absence of foreign bodies determined, and if found, they may be accurately located. In a great majority of cases the localization of a foreign body in the tissues is a comparatively simple process.

www.libtool.com.cn

Direct observation with a fluoroscope or a radiographic picture will give all necessary information. In such cases the position of the foreign body relative to surface markings and points on the bones will materially aid in determining its position.

The depth at which a foreign body lies and its position may be determined with absolute accuracy by views taken at different angles. The principle involved is that as the anode, the object, and the shadow of the object are always in line, when two observations are made with the position of the anode changed, it must follow that the object must lie at a point where the lines drawn from the shadow to the anode at each observation cross each other. In other words, if two observations are made with the anode in different positions for each, and these positions and the places where the shadows of the object fall at the surface of the body are marked, the object can be located at the point where lines cross each other, which are drawn from the positions occupied by the anode to the places on the surface of the body where the shadows of the object were cast. Various means have been devised for determining the positions of the anode and the shadows of foreign bodies relatively to the surface of the body. Of these the MacKenzie-Davidson apparatus, or one of its modifications, is most convenient and accurate, and with such apparatus foreign bodies can be located with mathematical exactness.

FIG. 4126.—Radiograph showing Fracture of the External Condyle of the Femur.

For locating foreign bodies in the eyeball, Dr. Sweet has invented a very ingenious and satisfactory apparatus.

Calculi.—Recently great advances have been made in determining the presence of pathologic foreign bodies in the urinary and gall bladders and in the kidney.

The pathologic concretions formed in these organs, from their difference in composition and consequent resistance to the Roentgen rays, differ materially in the case with which they may be detected. Those calculi which contain inorganic material, such as the mineral salts, may be most easily made out. For this reason gall stones are difficult to radiograph, as they are generally composed of organic matter. Uric-acid calculi are quite transparent to the rays and consequently difficult to determine. For these reasons while a radiograph showing a shadow cast by a calculus is proof positive of the presence of a calculus, the absence of a shadow is no indication that a calculus may not be present, as the calculus may be so transparent as to cast no shadow. However, with proper technique, the presence of calculi may be demonstrated, when present, in a large percentage of cases.

FIG. 4127.

FIG. 4128.

FIGS. 4127 AND 4128.—Radiographs of a Fracture of the Radius and Ulna before Reduction (Fig. 4127), and after Reduction and Wiring (Fig. 4128).

Digitized by Microsoft®

FIG. 4129.—Calculi in the Pelvis of the Kidney. Radiograph made with intensifying screens—exposed one second. (Ziemssen-Rieder.)

For the detection of calculi the character of the tube is of the greatest importance, a "critical tube," giving the maximum of differentiation, being necessary. The difficulties incident to this work are well known to all practical workers, but advances are constantly being made, and here it is well to mention the work recently done with the aid of *intensifying screens*. In this method a photographic film is placed in a light-tight envelope, between two screens coated with fluorescent salts. When exposed to the Roentgen rays the intensifying screens fluoresce and so greatly shorten the time of exposure. In this way almost instantaneous exposures may be made through the thickest part of the body (Fig. 4129).

With improved technique much has been done in determining the pathological conditions of the organs within the thorax. The value of the rays in determining *tuberculous* changes in the lungs is now fully recognized, and must rank with, if not higher than, auscultation and percussion. In fact, by the rays tuberculous changes may be determined fully as early in most cases as by physical signs, while the location and extent of the pathological changes can be definitely shown (Fig. 4130).

Similarly, empyema and pleurisy with effusion can be shown by the shadows given by the fluids in the pleural cavity.

In diseases of the *heart* and *aorta* the alterations in form of these organs are plainly and accurately shown, thereby enabling the observer to determine definitely the condition present. In valvular disease the shape and size of the heart are more accurately determined than is possible by most careful percussion. Likewise in aneurism of the arch of the aorta, the abnormality in form of the aorta is shown, so giving invaluable aid to the diagnostician (Figs. 4131 and 4132).

RADIOTHERAPY.—The therapeutic uses of the Roentgen rays depend upon their ability to affect the metabolic action of the body cells. When living tissue is exposed for a sufficient length of time to rays having considerable power, peculiar changes are effected in the cells, these changes being expressed first by increased cellular activity, and afterward by cell death. These cell changes are not produced at once, as when ordinary heat is applied to a part, but appear only after a considerable time has elapsed. Thus in the *x-ray burn*, due to exposure of the skin to too powerful or too prolonged exposure to the Roentgen rays, the first signs appear usually about the third day after the exposure. The first evidence of the effect of the rays is a slight redness of the skin. This deepens and extends, and in a day or two small blebs appear, which break, and from these tissue destruction extends by cell necrosis until finally large denuded areas may form, which are very painful and slow to heal. The action of the rays upon the body cells has been ascribed to the true light rays given off from the vacuum tube, but it is really due to the Roentgen rays, as the skin is affected when covered by a sheet of hard rubber, which shuts off all light rays, but allows the Roentgen rays to pass readily.

So far, the therapeutic use of the rays has been mainly confined to diseased conditions of the skin, the mucous membrane, and the tissues lying directly beneath them.

The effect of the rays upon the deeper tissues, both

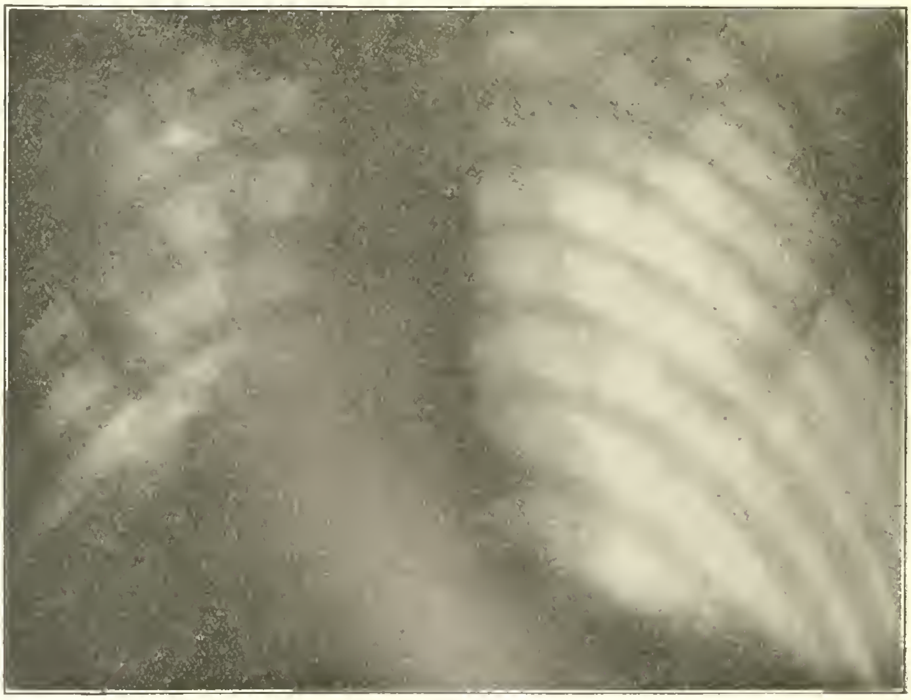

FIG. 4130.—A Radiograph of the Chest showing Tuberculosis of the Left Lung; the Right Lung Normal. (Ziemssen-Rieder.)

www.libtool.com.cn
Digitized by Microsoft®

normal and abnormal, is a field having many possibilities, but one in which no definite results have yet been recorded.

In certain pathological conditions of the skin and subcutaneous tissues many brilliant cures have been made, and radiotherapy is now acknowledged to be a most valuable aid to the practitioner. Thus, cases of lupus,

www.libtool.com.cn

3. The "normal exposure" in a single sitting, and await reaction.

Treatment by any of these methods is appropriate under proper conditions. The second is the method to be preferred, inasmuch as the first is tedious for both patient and physician, and the third demands a certain experience on the part of the operator. After the first

FIG. 4131.

FIG. 4132.

FIGS. 4131 AND 4132.—Radiographs showing Normal Heart and Aorta (Fig. 4131), and an Aneurism of the Arch of the Aorta (Fig. 4132).

eczema, sycosis, favus, epithelioma, rodent ulcer, and carcinoma have been relieved or cured without producing any inflammatory reaction or inconvenience to the patient.

Practical Application of Radiotherapy.—Radiotherapy requires a complete armamentarium consisting of an induction coil of at least twelve-inch spark length, an interrupter capable of adjustment, and a suitable vacuum tube, preferably of the regulating kind. In treatment much depends upon the tube used. With a low tube the radiant energy is not powerful, penetrates but little, and in consequence its action is largely confined to the superficial tissues. With an extremely high tube the radiation is very penetrating, and appears to pass too deeply, or through the part exposed. A *medium* tube is, therefore, best in that its radiation penetrates sufficiently and yet is largely absorbed by the tissues.

The tube used should be capable of producing a good picture of the thorax of a medium-sized man, when viewed through the fluoroscope at a distance of 60 cm. from the focus. With a tube of this kind the time required for each sitting will be between five and twenty minutes. Although a five-minute exposure will produce a slight effect, a radiance lasting twenty minutes may be regarded as the "normal exposure." Such an exposure will have the following results: On normal skin, after a period of latency of fourteen days, the hair will fall out, accompanied by an erythema lasting a few days; on skin affected with sycosis the loss of hair will occur as early as the eighth day, accompanied by the formation of numerous pustules; lupus tissue will become exfoliated after a lapse of a week. On the other hand, the effect of a normal exposure of twenty minutes can be produced by dividing the action of the radiance over several sittings of shorter duration.

Taking into consideration the intensity of the radiance, the number of séances, and the length of intermissions, we may formulate the following three methods of radiotherapy:

1. Daily sittings, with a radiance of slight intensity, lasting five minutes, continued until the first symptoms of reaction appear.

2. (*a*) Sittings, with a radiance of medium intensity, twice a week until reaction begins to be manifest (about two weeks); or (*b*) three or four sittings, with a radiance of medium intensity, given on alternate days.

sign of reaction appears it is advisable to await the termination of the characteristic inflammatory process, and then, if necessary, repeat the exposure. If, in using the second and third methods, absolutely no reaction occurs at the end of three weeks, we may feel justified in repeating the "normal exposure"; if, however, a mild reaction, non-progressive in character, has taken place, an additional exposure, less than normal, can be applied. As stated above, the second "normal exposure" is made after the subsidence of the inflammatory reaction excited by the first; thus this treatment may involve, in accordance with the nature of the case, repetition of *x*-ray applications extending over months or even years. Often in cases of hypertrichosis, in some cases of sycosis, and in nearly all cases of herpes tonsurans and favus, a single "normal exposure" usually suffices, *i.e.*, by using method No. 3, a perfect cure results after a single sitting.

Finally, it may be stated that radiotherapy is as beneficial in the hands of an expert as it may be harmful if improperly used. Over-exposure or too frequent exposure to powerful radiation may induce a severe ulcerative process, which is very painful, slow to heal, which may even endanger life, and require surgical intervention before a cure can be effected.

The physician can no longer shield himself behind a supposed idiosyncrasy of his patient. It appears that patients in poor health, whose vital resistance is lowered, are more easily affected by the rays than are persons in full health, and this should be taken into account; but, in general, the tissue changes induced are directly in proportion to the amount of radiant energy which falls upon the part.

THE THERAPEUTIC ACTION OF LIGHT.—Actinotherapy, like radiotherapy, is based upon the effect which light produces upon living cells. This effect is mainly manifested in two ways: (*a*) the effect of light upon the organism generally; and (*b*) the local effect of light.

The Effect of Light upon the Organism as a Whole.—The effect of light upon living organisms is shown in nature in a multitude of ways, and is illustrated by the difference in appearance presented by plants grown in the shade and the same species grown in sunlight; also, it is well known that persons who live in dark or ill-lighted habitations lack the ruddy, healthful appearance of those who habitually live out of doors. It is true that while this difference in vitality is due not alone to the dimin-

Digitized by Microsoft®

ished amount of light, but is largely owing to other unfavorable conditions, such as lack of fresh air, exercise, etc.; still, light is a decided factor in favoring health, and is one of the agents which, combined with fresh air, exercise, sanitary habitation, and suitable climatic conditions, is of the greatest benefit in the treatment of debilitating diseases.

www.libtool.com.cn

The efficacy of a combination of the above-named factors in the treatment of *tuberculosis* is too well known to require discussion, and the accentuation of the light factor by the use of "light baths" is an important addition to the therapy of this disease. It is true that the use of sun baths dates back to remote antiquity, but the fact that the skin and soft parts are more or less permeable to rays of ordinary light has not until recently been conclusively demonstrated. The bactericidal effect of the actinic rays has now been conclusively shown, and the beneficial effect of sun baths in pulmonary tuberculosis has been ascribed by some to the bactericidal action of light; but it is more probable that the good effect of sunlight is due to a general favorable stimulation of the body cells, whereby their metabolic activity is increased and the tissue resistance to bacterial action is raised.

The Local Applications of Actinotherapy.—The local use of light for the cure of disease is in many ways analogous to the use of Roentgen radiation.

Both light rays and Roentgen rays appear to act by altering the metabolic action of the cells upon which their energy is exerted, but the resulting cell changes caused by these agents appear to be materially different. The effect of Roentgen radiation upon living tissue has been discussed under radiotherapy, to which the reader is referred for an account of the tissue changes produced by that agent. The effect of light in the treatment of pathologic conditions appears to be largely, if not entirely, due to the chemical or actinic effect of certain of the light rays. Relative to the biologic and therapeutic effects of light, it is important to note that light is not a simple entity, but that every ray consists of a series of distinct parts, each of which has its particular properties. The effects of solar radiation may be arranged in three different groups—heat, light, and chemical action. The heat rays are mainly found in the infra red, red, and orange of the spectrum; the yellow and green rays make the strongest impression upon the human retina, while chemical action is chiefly found in the blue, violet, and ultra-violet rays. While all solar wave lengths, even the infra red rays, induce chemical change under favorable conditions, the ultra-violet, violet, and blue are the most powerful in the order mentioned. This chemical action of certain light rays is particularly shown in the action of light in reducing silver salts in photographic processes. The same rays of solar light which produce chemical changes in inorganic compounds produce vital chemical or metabolic action in living cells. The action of light upon the skin has been noted by mountain climbers, who suffer from "sunburn," due to the intense action of sunlight in high altitudes, where the cold is so great as to negative the supposition that the sun's heat could produce the condition. This inflammation of the skin, *erythema solare*, was formerly called erythema caloricum, as it was thought to be due to overheating of the integument. This heat theory of erythema was first combated by Charcot in 1859, and has since been entirely refuted by the fact that severe erythema occurred in persons travelling among ice fields and in the polar regions with the temperature much below zero, and in persons exposed to an electric arc light, where the light is intense and the heat faint.

Widmark, of Stockholm, by the use of glass and rock-crystal plates, demonstrated experimentally that the power of light to affect living tissue rested mainly in the violet end of the spectrum. Glass absorbs most of the ultra violet rays from an electric light, but rock crystal allows them to pass through. With a rock-crystal lens Widmark caused the rays from a twelve hundred candle power arc light to become parallel. When the rays were directed upon the skin and a glass plate interposed, so obstructing the ultra-violet rays, no inflammation was produced, but when a rock crystal plate was used which allowed the ultra-violet rays to pass, a severe inflammation was set up.

The experiments of Widmark were corroborated by those of Finsen; and the latter's application of the principles adduced to the treatment of certain pathological conditions of the skin, notably lupus vulgaris, gave rise to the so-called Finsen treatment of skin diseases and the red-light treatment of smallpox.

The treatment of *smallpox* by red light has given remarkable results. By the exclusion of all except the red rays of light the course of the eruption and of the disease itself in many cases is markedly changed. The unfavorable action of light upon the course of smallpox was noted by Picton in 1832, by Black in 1867, and by Barlow and Waters in 1871, but it was reserved for Finsen (1893) to define a treatment based upon the deleterious effect of the actinic rays. Arguing from the fact that the actinic rays are able to produce inflammation in the healthy tissues, he arrived at the conclusion that their exclusion in inflammation of the skin might be beneficial. This view is supported by the fact that in smallpox the deepest eruptions are found on the hands and face, which are the parts of the body most exposed to light. Total exclusion of light or the exposure of the skin to those rays only which are not harmful (non-actinic rays) is therefore indicated. As total darkness is not conducive to the patients' well-being, it is preferable to let them lie in a room lighted by red light only, the red rays being non-actinic and therefore harmless. The arrangement of the red room is very simple, being similar to that of the dark room used in photography. The window panes should be of red glass, or, where a room has to be extemporized, the room may be darkened by thick curtains at the windows and illuminated only by the light from red lanterns, such as are used for photographic purposes. Upward of two hundred cases of smallpox treated by this method have been reported, and all physicians who have given their experience with the method state that the results are remarkably good. If the patients were brought into the red light before the beginning of the suppurative stage, as a rule no suppuration occurred. The vesicles continued clear and after a few days dried to crusts, which fell off without leaving a scar. By the non-appearance of suppuration all the symptoms dependent upon that condition were absent. When the primary fever disappeared, the temperature remained about normal and the secondary fever of suppuration did not occur. In consequence the duration of the disease was shortened and the mortality lessened.

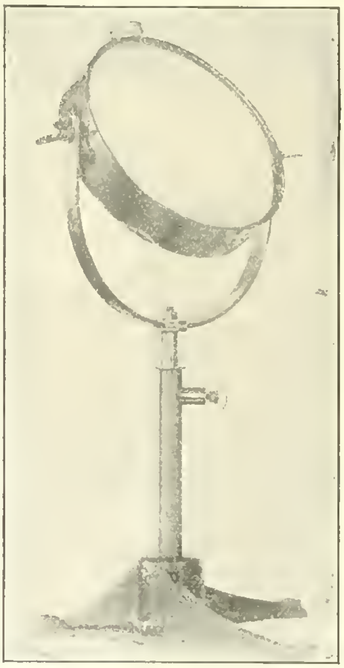

FIG. 4133.—Finsen Apparatus for Use with Sunlight.

Recently Finsen's red-light treatment has been tried in other infectious exanthemata, and Backmann and Chati-

Digitized by Microsoft®

nière have obtained especially satisfactory results with it in the treatment of measles.

Actinotherapy after Finsen's Method.—The Finsen method of the local treatment of skin diseases has for its practical basis the experiments made by himself and Widmark in producing local inflammation of the skin by the ultra-violet rays. In theory this treatment rests upon the many experiments showing that the chemical rays affect the metabolic action of living cells and cause the death or inhibit the growth of bacteria. The investigations of Bie and others have shown that the bactericidal power of light resides almost exclusively in the blue, violet and ultra-violet rays, and that only a small percentage of such potency exists in the red, yellow, and green. The rays of light which have strong bactericidal action are, therefore, the same as those which will produce inflammatory action in the skin. That light can pass through the skin was demonstrated by Godneff. He placed small glass tubes containing silver chloride under the skin of dogs and cats and then kept some of the animals in the dark and others in direct sunlight. After an hour he removed the tubes and found the silver chloride blackened in those animals kept in the light, but not in those kept in the dark.

Finsen then demonstrated that actinic light better penetrated those tissues which are deprived of blood. His treatment, therefore, consists of concentrating actinic light through rock crystal lenses upon living tissue made ischaemic by pressure. Sunlight or artificial light may be used, but the latter is most generally useful, as it is always available and controllable. When sunlight is used it is concentrated on the part by a large hollow lens composed of a flat and a convex glass enclosed in a brass ring (Fig. 4133). The lens is filled with a watery ammoniacal solution of copper sulphate. The water absorbs the infra-red (dark heat) rays and the blue solution absorbs a part of the red, yellow, and green rays.

www.libtool.com.cn

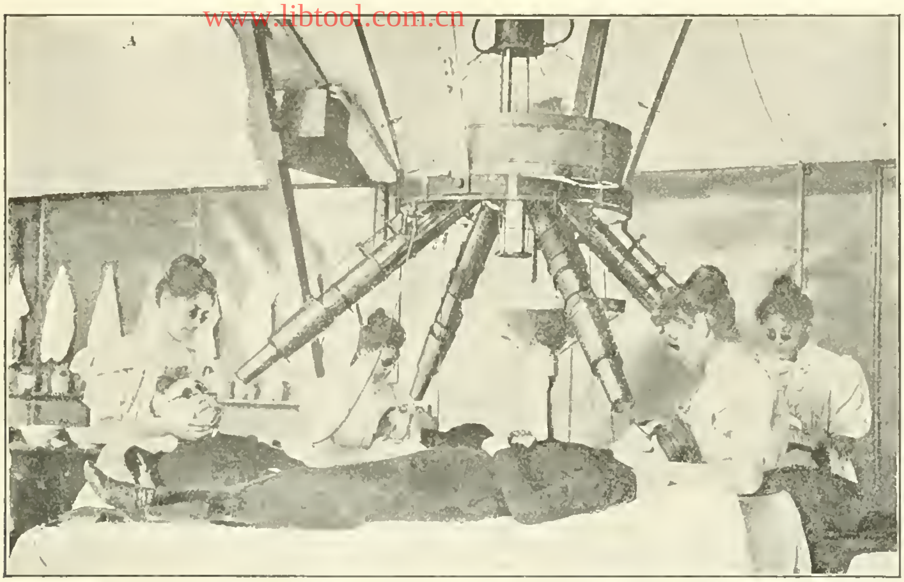

Fig. 4134.—Finsen Apparatus for Treatment with Electric Light. (Bie.)

In treatment by electric light an arc lamp, taking sixty to eighty ampères of current, is used. Current from an electric-light circuit is used, the amperage being raised and the voltage reduced by a converter constructed for the purpose. The apparatus consists of three parts: (1) the light; (2) the cooling apparatus; (3) the light-concentrating apparatus (Fig. 4134). The arc light is surrounded by a shade to prevent the eyes of those present from being dazzled. From this light there radiate four or more telescopes, each telescope conveying the light to a patient. The telescope lenses are of rock crystal, as this obstructs the active rays less than any other material. The space between two of the lenses is filled with water

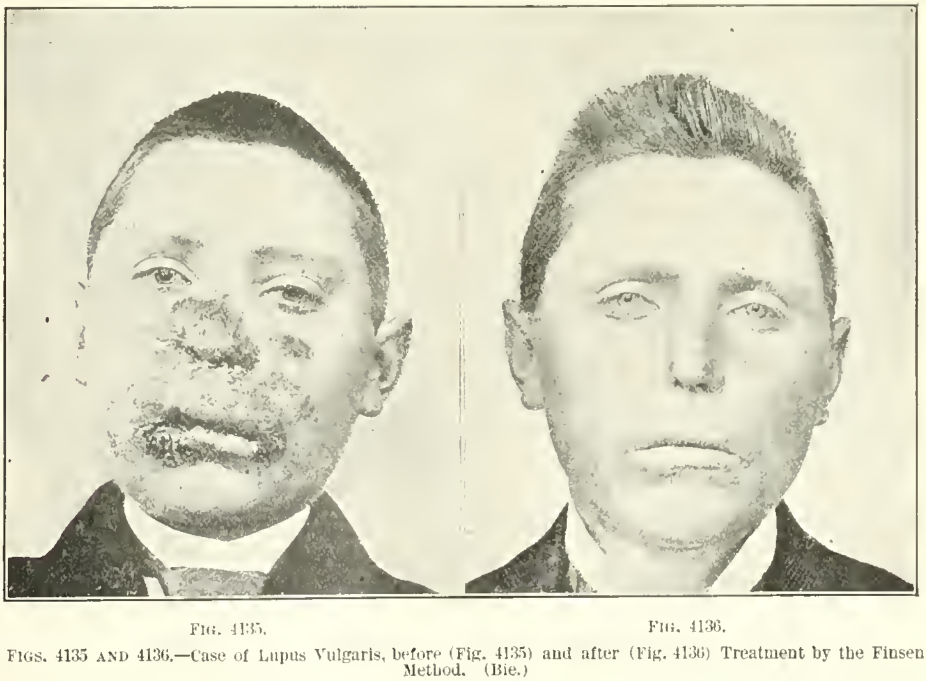

Fig. 4135. Fig. 4136.

Figs. 4135 and 4136.—Case of Lupus Vulgaris, before (Fig. 4135) and after (Fig. 4136) Treatment by the Finsen Method. (Bie.)

Digitized by Microsoft ®

to moderate the temperature, and an enclosing water-jacket still further reduces the heat. The lenses are so arranged as to render convergent the divergent rays from the arc light; these rays then being brought to a focus by a lens cooled by water and held by a nurse and pressed by her firmly on the part treated. The patient lies on a table or is seated in an adjustable chair, the position of which can be varied so that the light will fall perpendicularly on the surface to be treated. Each application lasts about an hour and is repeated daily. Although the light is cooled in its passage through the concentrating apparatus, it is yet too hot to be directed on the skin without detriment; hence the water-cooled lens, applied to the skin, is used in all cases whether sunlight or electric light is used. The effect of the treatment on the patient is in no way painful. A few hours after the first application there is a certain amount of "reaction"; the part swells, becomes reddened and tender, but there is little pain. The reaction varies in degree in different cases, being always seen in lupus vulgaris, but does not occur in lupus erythematosus. The beneficial effects of the treatment are often manifested in a few days, and recovery sometimes follows a very few applications. Generally fifteen to twenty-five applications must be made before a cure is effected. The results are very satisfactory; the skin becomes soft, smooth, and pliable, and scarring is hardly noticeable, other than to the extent dependent upon the tissue destruction caused by the disease (Figs. 4135 and 4136).

The Finsen method has been most successfully used in the treatment of lupus vulgaris, but recently encouraging reports have been made of the treatment of alopecia areata, epithelioma of the skin, and nævus vasculosus.

William Cline Borden.

ROETHELN.—Definition and History.—Roetheln is an exanthematous disease of mild character, attended with a slight elevation of temperature, propagated by contagion, and bearing a close resemblance to measles and scarlatina. It is widely known in this country under the above appellation, and also, in common parlance, by the term "German measles." The latter name, being English, is generally used. Thus in its nomenclature Roetheln resembles the other exanthemata, which have each a technical and a common name. The Germans, however, use the names Roetheln and rubeola as synonyms; and this tends to confusion, since we signify by rubeola the different disease, true measles or morbilli. Various other names have been given to the disease by different writers, prominent among them being epidemic roseola, rubeola scarlatinosa, rubeola morbillosa, rubeola notha, and rubella. The last-mentioned name has been suggested as most appropriate, since it is a diminutive of rubeola, and thus the two words express the analogy existing between the two diseases, just as do the terms variola and varicella. For the reason, however, that Roetheln is more widely recognized, the writer retains it in this article.

Roetheln is, so far as definite knowledge is concerned, a new disease. As late as 1886 the "Index Medicus" gives it no separate place, and the articles on the subject are grouped under the heading of measles; yet the number of communications, treating of this affection, which have been written during the past ten years or so (1877–1887), will aggregate more than one hundred. Before that time, however, the disease had been from time to time spoken of, as far back as a century and over; though until the time of the present generation the greater number of observers did not consider it a distinct disease, but believed it to be a modification of measles, generally, and, in some instances, of scarlatina. Mention was made of epidemics in 1845 and 1853, and in 1873–74 the disease was carefully described, though under the name of epidemic roseola. In Germany attention was given to the subject many years before any English or American writings appeared. Now almost all physicians grant its individuality, and the arguments supporting this view will be presented hereafter.

Age of Patients.—Roetheln is generally classed as one of the diseases of childhood; and, since there are no clearly proved instances of its second appearance in the same individual, it follows that those affected are usually young in years; the general rule being that any one of the contagious exanthemata is experienced but once in the lifetime of an individual. Still, it is much less prominently an affection of infants and children under five years of age than are the other eruptive fevers. Adults are frequently attacked, but the majority of those who suffer from this disease contract it some time before the age of puberty. In other words, the time of life when susceptibility is greatest is between the ages of two and fifteen years. Young infants do not seem to contract it, and it is believed that sucklings are not susceptible. As, however, it is a disease of less frequent occurrence than measles or scarlatina, and as it seems to be less actively contagious than those diseases, many growing children escape it; and these facts constitute a possible explanation of the circumstance that adults are not infrequently attacked during the prevalence of an epidemic.

The season of the year does not seem to exert any influence on its prevalence. Epidemics occur indifferently in hot and in cold weather.

Etiology.—Roetheln is propagated by contagion, and by this means alone. The materies morbi is believed to be portable, but the cases in which the source can be traced point toward the necessity of close contact for the transmission of the disease from the sick to the well. In a single epidemic the total number of cases among those unprotected by having previously experienced the disease is found to be small in comparison with the other contagious exanthemata. Especially is this noticeable with reference to measles, which will attack, simultaneously or successively, all the susceptible children in a household almost with certainty; while we generally meet with a single, or perhaps two, cases of Roetheln, and the greater number of those exposed, in greater or less degree, escape. J. Lewis Smith, in one epidemic, saw forty-eight cases in twenty-one families—an average of a little more than two to each family. In an institution, such as an orphan asylum, the number of cases would be comparatively larger, since the exposure would be of necessity greater at first. Isolation, therefore, can be expected to accomplish more in the direction of prevention than it does with measles or scarlatina.

Roetheln is encountered almost exclusively in epidemics, and sporadic cases are very rare. This is probably more decidedly the case with this disease than it is with scarlatina, and possibly also with measles.

Considerable difficulty is experienced in tracing cases of Roetheln to their sources—largely, no doubt, because affected persons are frequently unconfined, owing to the general mildness of the disease, and the absence of alarm concerning it. Undoubtedly, however, if its origin could always be traced, an exposure to contagion would be discovered. In other words, it is practically certain that the disease does not originate *de novo*; nor is it produced by general causes, such as improper hygienic surroundings in the matter of poor ventilation, overcrowding, or insufficient or improper dietary conditions. On the contrary, it is not found to be a disease of greater proportionate prevalence in tenement-house districts, where the conditions referred to are in prominent existence. A large proportion of the cases are encountered in the families of the better classes, and, most of all, in institutions, such as orphan asylums.

We may reasonably conclude that Roetheln is less actively contagious than measles or scarlatina, since so many of those exposed escape. Under the same conditions of exposure the number of cases arising of either of those two diseases would probably considerably exceed those of Roetheln.

The age at which susceptibility is greatest has been mentioned, being considerably more advanced than that which obtains with the other exanthemata; but as yet there is little definite knowledge as to the stage of the

www.dbtoof.com.cn
Digitized by Microsoft®

disease itself in which propagation by contagion is most likely to occur. We can only say that the probability is in favor of contagiousness during the whole course of the disease—from the time when prodromal symptoms, if present, appear, until the eruption has entirely disappeared.

www.libtool.com.cn

Clinical History.—*Stage of Incubation.*—Much attention has been given to the duration of the stage of incubation—the time elapsing between a traceable exposure and the onset of the disease. This is frequently made difficult of accurate investigation for the reason before mentioned, that isolation is not observed because of the mild character of the affection, and sometimes even confinement within doors is not enforced. The general experience is that this stage occupies from fourteen to twenty-one days; though in some epidemics the duration has been considerably less. Shuttleworth had the opportunity of ascertaining, in an asylum, that twenty-one days lapsed after the first case appeared before the second occurred, isolation being enforced, and two days later two fresh cases developed. Goodhart says that the incubation, in twenty-three out of twenty-five cases, was from fourteen to twenty-two days. Edwards gives six days as the shortest and twenty-one days as the longest. Cheadle ascertained it to be eight days in one instance, nine in another, and (approximately) twelve days in five more. Griffith's experience was that in twenty-six cases the eruption appeared between the fifth and twelfth days after the first case was discovered. Therefore it must be granted that considerable variation exists in the length of this stage, although we may consider that a period of fourteen days represents the average. The incubative stage of measles is much more constant—standing, as it does, at thirteen and fourteen days.

Stage of Invasion.—In very many instances the eruption is the first thing which calls attention to the existence of sickness. Since many of the patients are old enough to describe any subjective symptoms which may be present, it follows that the stage of invasion is frequently attended with little or no disturbance of general health. With children too young to describe their own sensations, the attention of parents is often attracted by no manifestation whatever—such as restlessness, or crying, or digestive disturbance—until the eruption becomes visible. It is, however, probable that there is always present a slight rise of temperature, not sufficient to cause discomfort; and close questioning might elicit an admission of a feeling of malaise. But, as stated, the breaking out of the rash is what causes uneasiness, and leads patients or parents to consult a physician for the purpose of ascertaining the nature of the sickness.

There are, on the other hand, cases in which there is more or less decided disturbance of health prior to the appearance of the eruption. Epidemics undoubtedly vary greatly in severity, as do individual cases in a single epidemic; and from the average of descriptions it would appear that the disease is more severe, as well as of more frequent occurrence, in Europe than in the United States. These more severe cases present certain indications of sickness, before the rash appears, which, taken in connection with known exposure, point toward Roetheln as the oncoming disease; but in themselves they have little value as regards the differential diagnosis, especially, from scarlatina and measles. The symptoms, when present, have special reference to the mucous membranes of the air passages, and to the digestive system. They are: mild inflammation of the throat and tonsils, shown by swelling and redness on examination, and by pain and slight cough; a slight degree of coryza; conjunctival irritation, lachrymation, and a little tendency to œdematous swelling of the eyelids. Nausea and anorexia have been frequently observed, and in rare instances vomiting. Frontal headache in a few instances is the source of much discomfort. The digestive disturbances appear to have been prominent in some and absent in other epidemics. With these symptoms—and, it is not improbable, in their absence—there is a rise of temperature to 99° or 100° F. in mild, and as high as 103° F. in severe, cases. In addition to these indications there is one symptom highly characteristic of the fully developed disease, as will hereafter be seen,—a symptom which has been observed in the prodromal stage. This is enlargement of the post-cervical lymphatic glands—not those at the angle of the jaw, as obtains in scarlatina and diphtheria, but those in the back of the neck. This enlargement should always be looked for, since it is the only feature of diagnostic value in the stage of invasion. Jaccoud found it, in five out of thirty-two cases, four or five days before the efflorescence. Associated with this, stiffness of the neck with pain on movement of the head, in slight degree, should be sought for.

Any throat inflammation present might easily be accounted for in expecting scarlatina to develop; and coryza, cough, and conjunctival irritation belong to the clinical history of measles. Rise of temperature also, of course, accompanies the onset of both these diseases; and consequently, excepting only the glandular enlargement, so far as these general symptoms are concerned, it is only in their lesser degree of severity that they are characteristic of Roetheln rather than of the other two affections.

These indications, when present, precede the eruption by a period, in the great majority of cases, of less than twenty-four hours; although in some instances malaise is present for three or four days before this stage is ended. Cheadle, in describing a severe epidemic, observed that the prodromal symptoms persisted longer in severe than in mild cases. Edwards gives the average duration as three days.

It is therefore observable that the stage of invasion, when present, is subject to considerable variation—both as to length and severity—and is, in fine, a much more uncertain quantity than is that of scarlatina or measles.

Stage of Eruption.—The prominent feature of the disease is the eruption, often, as before stated, being the only phenomenon perceptible, and generally being by far the most prominent manifestation of a condition of sickness. Very great differences, in different epidemics and in individual cases, are to be found; and, considering the eruption alone, a diagnosis might well be difficult, if not impossible. As the symptoms other than the eruption, such as those found in the prodromal stage, present considerable variation, and as this fact holds with the eruption itself, we may conclude that the disease, as a whole, is far less *stable* than scarlatina and measles. These are more than variations of degree—they affect the essential characters of the symptoms and of the eruption.

Scarlatina, for instance, may be very mild or very severe as regards the throat inflammation and fever; and its eruption may be difficult of detection, or as marked as a pronounced rash of erysipelas; but these are differences of degree, and the sore throat and eruption are uniformly present, and are *sui generis*. The same rule holds with measles. The essentials of the disease—the catarrh of the respiratory tract, and the characteristic eruption—may, one or both, be very mild or very severe; but they must both be present in any case in which the diagnosis is undoubted. Roetheln, on the other hand, may consist, from beginning to end, of the eruption only, or may present some of quite a variety of symptoms affecting the mucous membranes of the air passages or of the digestive apparatus.

Regarding the eruption itself, its characteristic points are as follows: Its color is generally a pale rose, less distinctly rose-hued than that of measles. It is very frequently brownish, brownish-red, and sometimes quite distinctly brown, with no tinge of rose or pink to be detected, and giving the general effect of duskiness.

As to location, no part of the surface is entirely exempt. The palms of the hands, the soles of the feet, and the scalp have been observed to present it; although usually it is not to be found in those regions. As a general rule, the face, trunk, arms, and legs break out successively before the final disappearance of the rash; although cases are often described in which the affected area is much less extensive.

Either the face or the upper part of the body may be

Digitized by Microsoft®

www.libtool.com.cn

first affected, and the spread of the eruption is rapid—one day or less sufficing for its appearance on the remoter parts after its initial appearance. The maximum of intensity is very quickly attained. Beginning on the face, for example, in very faintly marked spots, after a period of a few hours, and certainly within one day, it will be at its height, and the spots will be plainly visible. Then a fading process sets in, gradually progressing, accompanied with, or followed by, some desquamation, and continuing for about two days; so that, in any selected locality, from the first appearance to the final disappearance, an average period of three days is occupied. This, however, is not a definitely fixed time; sometimes it embraces but two days, and at other times it is protracted to six or seven.

The duration of the eruption as a whole, without reference to any special part of the surface, is consequently a little longer than that of its presence in a given locality—by the time occupied in the spreading from the region first to that last attacked. As this generally requires one day, or somewhat less, the eruptive stage of the disease can be expected to continue about three days on the average, though subject to the variation spoken of, having as extremes two and seven days. It will be observed, from the rapidity of development in a selected locality as compared with the rapidity of the spreading to other regions, that different parts will present the eruption in greatly varying conditions; and that at no given time will it be at its maximum uniformly over the entire surface of the body. In other words, it may even reach its height in one part before appearing in another. This is a point of value in diagnosis, and of contrast to scarlatina and measles, in both of which there is generally a stationary period as regards the spread and intensity of the eruption after the maximum has been attained.

The eruption is papular. If the hand is passed gently over it, a sense of roughness, at least, is perceptible, showing a certain degree of elevation above the surrounding skin. From this very slight condition of elevation differences are to be found up to a state in which the elevation is distinctly and at once visible—as much so as in a fully developed rash of measles. But, in some degree, elevation of the spots is always present, and therefore it is a mistake to describe the eruption as macular.

The size of the papules is one of the points in which there is considerable variation. In general they are smaller than the papules of measles, varying from the diameter of a pin's head to that of a pea. In a certain proportion of cases the spots are so small as to constitute mere punctation, and the skin presents the appearance of being covered with innumerable fine dots. They are of irregular shape, but with a more decided tendency to assume the circular form than is observed in the spots of measles. In a given case there is generally some uniformity in the matter of size—either the papules are for the most part of the larger size, or they are nearly all small. Still greater differences of size have been described, however, papules of one-third of an inch in diameter having not infrequently been encountered.

Generally the skin between the papules presents a perfectly healthy appearance, although careful investigation will occasionally reveal the existence of minute fine lines or processes connecting adjoining papules. A general erythematous redness of the skin has also been noticed. Confluence of the papules is very rare, though not uniformly absent.

Vesicles have been observed, but this has clearly been a coincidence, and not at all a part of the ordinary course of the eruption. They are probably found quite as often with measles, and in either case must be regarded as anomalous. The eruption has been observed to disappear suddenly, and after a short time to reappear; and unusual warmth, as from heavy clothing, renders it more distinctly visible. A certain amount of itching is often present, though not severe, and the heat and burning, which are a source of discomfort in scarlatina and measles, are not at all pronounced in Roetheln.

To sum up the characteristics of the eruption, we may make a division of the cases into two classes, which correspond with the descriptions formerly given of rubeoloid Roetheln on the one hand, and scarlatinoid on the other. In each variety the resemblance to the other disease, as far as the eruption is concerned, may be very close—often sufficiently so to render the diagnosis extremely uncertain, if the other points of history and symptomatology be not carefully considered.

In the first class of cases, comprising the greater number, the papules are of larger size, perhaps abundant enough to be considered confluent, of somewhat irregular shape, pale rose color, and raised considerably above the skin. It will be seen that this state of affairs can obtain with measles quite as well as with Roetheln.

In the second class the papules are smaller, more circular in shape, less elevated above the skin, of darker hue, much more numerous, and sometimes very closely aggregated, so as to give the punctated appearance alluded to. If this be the appearance, there may easily be nothing in the eruption by which to discriminate it from a scarlatinal rash at the onset or during the first day of the disease. A fully developed rash of scarlatina is continuous, leaving no skin normal in appearance between the eruptive spots; and in Roetheln the papules are distinctly separated from each other.

If, therefore, an extreme case of either variety be taken, it will be found that other points in symptomatology and history are requisite, and possibly a delay for one or two days may be necessary, in order definitely to eliminate doubt in the diagnosis.

Desquamation.—Desquamation is the mode, or perhaps a better term would be the accompaniment, of the termination of the eruption, beginning on the second or third day. It is furfuraceous in character, never occurring in large scales or pieces of skin as in scarlatina. It is fine, and in this resembles more the desquamation of measles. It is much less decided than in scarlatina, and is often so slight in amount as to be perceived only on very careful inspection, and frequently passes unnoticed by either the patient or the physician. Many writers on the subject do not make mention of the process, and frequently the statement is made that it is not a part of the clinical history of the disease. The writer cannot contradict this, though holding the view that it is present in some degree in all cases. As fading of the color of the eruption very quickly sets in, and is progressive until its final disappearance, the desquamation is the accompaniment of this.

The desquamation is not to be found affecting at one time the entire surface which has presented the eruption. It follows the appearance of the rash, and, consequently, is visible on one part of the surface before it is on another. Furthermore, it does not take place over the entire affected surface—much of the eruption fades away without desquamation, and the latter is to be searched for about the trunk, legs, and arms especially. The face and extremities usually escape. In this there is another point of resemblance to measles.

Following the customary division of the eruptive fevers into stages, we may consider the stage of desquamation, fading, or decline, to occupy the time from the second day of the eruption to the end of the disease. But it must be borne in mind that the line of division between these two stages, *i.e.*, of eruption and of desquamation, is much less distinctly marked than in scarlatina or measles.

Occasionally a faint staining or pigmentation has remained for several days after the disappearance of the rash proper.

Symptoms Other than the Eruption.—These have been in part considered under the head of premonitory symptoms, or those presenting themselves in the stage of invasion, and are, in great part, simple continuations of them. They are found, like those of scarlatina and measles, to have special reference to the mucous membranes of the nose, throat, and conjunctiva, together with more or less disturbance of the digestive functions. The inflammatory condition of the throat and tonsils, which is

Digitized by Microsoft®

the most frequent of these symptoms, varies greatly in degree, and, beginning in the stage of invasion, persists up to the time when the rash has reached its height, and then subsides with the disappearance of the rash. Slight cough sometimes persists for a few days longer. The conjunctival irritation and the œdematous swelling of the eyelids are not often wanting, and follow much the same course as the throat symptoms.

www.libtool.com.cn

The nausea, which presents itself often enough to call for special mention, is generally noticeable only until the rash has developed.

The tongue is commonly coated, but does not at all present the appearance of the strawberry tongue of scarlatina. All these symptoms, when present at all, are of decidedly milder character than they are in scarlatina and measles.

The temperature range has been referred to as being liable to differences in epidemics and in individual cases. As a general rule, the rise is much less than that of the two other diseases. An elevation of from one to two degrees—to 99.5° or 100.5° F.—is what we may look for; it persists for about three days, and in the given case does not present the fluctuations characteristic of measles, but remains at the same level until its final subsidence.

The pulse and respirations are accelerated in proportion to the rise of temperature.

In general a severe case presents a greater variety of these symptoms, as well as a greater severity, and a mild case, absence, or nearly such, of them.

The single phenomenon, over and above the eruption, which is characteristic, and one might almost say pathognomonic, of Roetheln, is the enlargement of the post-cervical and suboccipital lymphatic glands. Probably in no case is it found wanting. This occurs at the onset of the disease, and therefore, as stated, may not infrequently be discovered before the appearance of the eruption. The number of glands affected varies from one or two up to seven or eight. Search should be made for them from the occiput down to the level of the shoulders, and toward the middle of the neck rather than at the sides or near the angle of the jaw. In scarlatina, diphtheria, and other throat affections, the glands which present enlargement are those at the angle of, as well as beneath, the lower jaw. In such instances the swelling seems to be proportionate to the severity of the throat inflammation, and to be associated with it, as in adenitis in the neighborhood of inflammation elsewhere in the body. But the adenitis of Roetheln cannot be so explained, as it is found equally in the cases with considerable sore throat, and in those with none. Therefore it should be regarded as a distinct phenomenon of the disease, and not as an accessory.

Associated with the enlargement is stiffness of the neck, and pain on moving the head, in some degree, though never very severe. The enlargement itself varies, the glands being of about the size of a split pea or bean; suppuration does not occur, and the swelling and pain subside with the disappearance of the eruption. Occasionally a single gland will remain perceptibly enlarged, though painless, for an indefinite length of time.

Valuable as this point is, there are yet sources of error, and glandular enlargement from other causes must be excluded.

The condition which we recognize as struma, indicating the general condition of ill health due to bad hygienic surroundings and malnutrition, has, as a prominent feature, general glandular enlargement, perceptible in the groins, axillæ, etc., as well as in the neck; and syphilis may present the same condition. Accordingly, search should be made in those other localities before assigning a cervical adenitis to an oncoming, or present, attack of Roetheln. Enlargement of the glands at the angle of the jaw is to be attributed to other causes. Children with eczema capitis have, almost always, large lymphatic glands in the neck.

During an epidemic of measles in 1886, the writer made investigation with special reference to this point, and found that in twenty-four out of twenty-nine cases an enlargement of glands exactly similar to that of Roetheln was present, and constituted a prominent feature of the cases. This was evidently a peculiarity of that epidemic, as the writer has neither before nor since found it to be the case, except in isolated instances. Griffith states that he has not infrequently found it. Care was taken to render the diagnosis of measles certain, and mention is made of this point here to show that the adenitis characteristic of Roetheln is not absolutely pathognomonic, and will not in itself suffice for differential diagnosis from measles.

Non-identity with Measles and Scarlatina.—The writer has, of necessity, made frequent mention of Roetheln as contrasted with scarlatina and measles, and the reasons for considering it to be an independent disease must now be considered. There are still some who consider it a hybrid, consisting of elements drawn from both those diseases, and being intermediate in character between them. This position is scarcely tenable, and is not supported by clinical facts; since the greater number of cases, though having points in common with both, present, each one, strong points of resemblance to one or the other of the two affections, and not to both at the same time. That is, any single case is either decidedly scarlatinoid or decidedly rubeoloid; and the differential diagnosis lies between two and not three diseases. Furthermore, hybrids are not at all common, and analogy is opposed to this view. Generally, what is called a hybrid can be resolved into its elements, and may be pronounced a conjunction of two or more diseased conditions. Undoubtedly scarlatina and measles may be found coexisting in the same individual, or following each other so closely as to overlap, the inmates of a household being exposed to and contracting both diseases at the same time, or in rapid succession. These cases, however, present the phenomena of both diseases in such a manner and degree as to exclude uncertainty in the diagnosis, and they bear no closer resemblance to Roetheln than does any single well-pronounced case of either disease.

The question of its identity with one or the other of these diseases calls for more careful consideration.

There are but few who believe Roetheln to be identical with scarlatina, but many consider it of the same nature as measles. In a scarlatinoid case the principal points in common are: the short period of invasion, the existence of some sore throat, and the fine punctate appearance of the rash at first. Roetheln is liable to be confounded only with a very mild case of scarlatina; for the vomiting, high fever, pronounced sore throat, and characteristic tongue of average scarlatina are not encountered in the former disease. The points of difference are most prominent in the longer duration of the eruption in scarlatina, its greater uniformity, its macular character, the nature of the desquamation, and the presence of sequelæ which do not occur in Roetheln. In addition to which the adenitis of Roetheln is not to be found in the other disease.

As to measles, the similarity also exists in a certain proportion of cases of mild character. The symptoms which may be common to both are the rose color and papular character of the rash, the shorter duration of the period of eruption, the fine desquamation, and possibly the adenitis. The main point of difference is the presence, in measles, of two or three days of fever, with catarrhal inflammation of the respiratory mucous membranes, uniformly preceding the eruption. The sequelæ of measles, also, are not to be expected in Roetheln.

As stated, these resemblances are encountered only in extreme cases. Average cases of each disease have special characteristics sufficient to clear away doubt; and the differences just enumerated go far toward proving non-identity in either direction. But the strongest reason for believing in the individual nature of Roetheln—constituting, indeed, a conclusive proof—is that no mutual protection is afforded. That both scarlatina and measles are, if the expression be allowed, autoprophylactic has been proven by thousands of observations. Second attacks of scarlatina are so rare as to be curiosities in the history of medicine; and with measles, although the

Digitized by Microsoft®

rule is not so free from exception, yet a second attack is a very infrequent occurrence. This rule applies to Roetheln. As yet there are few, if any, authentic records of second attacks. But when the question of mutual protection, which would be a *sine qua non* to the supposition of identity, is considered, the most conclusive evidence of its absence is www.libtool.com.cn

Of J. Lewis Smith's 48 cases, 19 had had measles, and 1 contracted the disease subsequently. Of Shuttleworth's 30 cases, more than half had had measles, and 4 scarlatina. In one case the patient had measles five months, and scarlatina one month, before. In 13 of the cases, in which subsequent observation was possible, 7 contracted measles and 6 scarlatina after the lapse of a few years. Goodhart observed that 39 out of 63 cases had had measles.

Instances might be multiplied to a very large number, but it is unnecessary; for the non-existence of mutual protection is too well established to admit of doubt. There is, however, another aspect of this question, or, rather, another explanation of the facts, which has been presented with considerable appearance of probability. It is that Roetheln is simply the modification of measles presented in second attacks, bearing the same relative position that varioloid does to smallpox. There are two reasons for regarding this position as untenable. The first is, that pronounced attacks of true measles have, in a large number of instances, followed, and not preceded, Roetheln, and these cases have presented no modification in kind or severity of the symptoms which go to make up the clinical history of measles. This applies with equal force to scarlatina. The second reason is, that in the individuals who have been the subjects of second attacks of measles, the symptoms have been as uniform and pronounced as in the first.

On the contrary, a much closer analogy can be traced between smallpox and varicella on the one hand, and measles and Roetheln on the other. The ratio is much the same in regard to corresponding severity, and in similarity of appearance of the eruption.

The final separation, in the minds of medical men, of the former pair from each other was beset by the same uncertainties as that of the latter.

Another fact of significance is that Roetheln occurs in epidemics, when neither scarlatina nor measles is prevailing; and, in the same epidemic, most of the cases will be rubeoloid, and a smaller number scarlatinoid.

Text book descriptions of measles commonly refer to a variety of the disease under the designation of "rubeola sine catarrho," this name indicating a condition in which there is fever, with an eruption similar to that of ordinary measles, and at the same time absence of the inflammation of the respiratory apparatus. Perhaps it is fair to regard these as cases of Roetheln; and a significant observation made by Watson, in his "Practice of Medicine," gives support to this view. He says: "It is observed that rubeola sine catarrho confers no protection against recurrence—is commonly succeeded by an attack of measles in its true form." Meigs and Pepper make the same observation as to their experience.

To summarize, the points demonstrating the non-identity of Roetheln with measles or scarlatina are:

1. The difference in clinical history.
2. Absence of mutual protection.
3. Absence of modification in second attacks of those two diseases.
4. Occurrence of epidemics while the other two are not prevailing.
5. In any epidemic, resemblance of some of the cases to one, and of some to the other, of the two diseases.

A further differentiation of the two varieties into two distinct diseases is possible; but it would be a refinement almost beyond our present powers of observation.

DIAGNOSIS.—The diagnosis is principally made by process of exclusion, because, at the outset, the presence of scarlatina or measles is generally suspected. From scarlatina at the outset, or in the first day or two of sickness, in certain mild cases, the points of difference are: In Roetheln, the absence of, or presence in a milder degree, of sore throat; the absence of the strawberry tongue, and the existence of a whitish coating if any change be present; the absence of continuity of the eruption; and the presence of post-cervical adenitis, the glands at the angle of the jaw being unaffected. After the lapse of two or three days the course of the eruption in Roetheln is to reach its maximum and begin to disappear quickly, and the desquamation, when perceptible, is fine, and not in flakes or patches of some size.

Pronounced cases of scarlatina do not resemble Roetheln sufficiently to render the diagnosis uncertain.

From measles the discrimination is to be based mainly on the absence of the stage of fever with catarrh preceding the eruption, or its very mild character and shorter duration. The cervical adenitis has much weight, though it is not absolutely conclusive. Though the rash may very closely resemble that of measles, yet the papules are less elevated, smaller, less aggregated, less decidedly rose-colored, and run their course more quickly—desquamation setting in two or three days before it would be likely to occur in measles.

Subjoined is a comparative table of these three diseases in their different stages, giving also the average duration of each stage:

ROETHELN.	SCARLATINA.	MEASLES.
	Stage I.—Incubation.	
Duration, six to twenty-one days.	Two to fourteen days.	Twelve to fifteen days.
Inconstant.	....	Constant.
	Stage II.—Invasion.	
One day or less.	Less than one day.	Two to four days.
Often absent.	Never absent.	Never absent.
Malaise, slight.	Vomiting.	
Sore throat and lachrymation.	Decided sore throat.	Drowsiness, cough, coryza, conjunctivitis, photophobia.
Cervical adenitis.		
Temperature, 99°-100°	Temperature, 103° +.	Temperature, 102° +.
	Stage III.—Eruption.	
Three days.	Six to eight days.	Four to five days.
Begins on face or chest.	Begins on chest.	Begins on face.
Papular, slightly.	Macular.	Papular, decidedly.
Pale rose, or darker and brownish.	Deep-red scarlet.	Rose.
Not continuous.	Continuous.	Not continuous.
Ceases spreading in one or two days.	Ceases spreading in three or four days.	Ceases spreading in two or three days.
No stationary period.	Stationary period of two to three days.	Stationary period of two to three days.
Burning or itching, slight.	Burning, often great.	Burning and itching, decided.
	Stage IV. Desquamation.	
Very slight and fine.	In scales of quite large size.	Furfuraceous, and often not pronounced.
Overlaps stage of eruption.	Preceded by stationary period.	Preceded by stationary period.
Last two or three days.	Lasts ten days, and sometimes longer.	Lasts about four days.
		Leaves dull-colored stains.
	Complications.	
	Acute form of Bright's disease.	Bronchitis.
None characteristic.	Rheumatism.	Pneumonia.
	Otorrhœa, and necrosis of temporal bone.	Tuberculosis.
		Inflammation of the intestines.

In addition to these other exanthemata, certain simple skin diseases must be considered in the diagnosis. Sometimes the eruption of miliaria papulosa (prickly heat) resembles that of Roetheln; but it occurs in well-defined patches of several inches in diameter, is associated with unusual sweating, and lasts many days longer. Also, there are no febrile and constitutional symptoms accompanying miliaria, and the itching is usually great.

The most careful investigation possible into the origin or sources of contagion should be made; and in cases of

Digitized by Microsoft®

doubt a positive diagnosis should be withheld for one or two days. It may be advisable to explain the uncertainties, and to adopt the precautions as to isolation, etc., necessary in scarlatina.

Complications.—Complications or sequelæ characteristic of the disease do not exist. A condition of transient albuminuria is spoken of, but it is not indicative of renal disease. After the rash disappears we may expect to find the usual condition of health present. The prognosis is therefore good.

Treatment.—Because of the mildness of the disease there is generally nothing called for in the matter of medication—simple restriction of diet and avoidance of exposure during the continuance of the elevated temperature being all that is necessary. Practically the interest and importance attaching to Roetheln lie in recognizing it as a separate disease, and in the exclusion of the more serious affections, scarlatina and measles.

Bibliography.—Besides the treatises of Meigs and Pepper, J. Lewis Smith, Vogel, Day, Goodhart, Eustace Smith, and Ellis, on "Diseases of Children"; those of Bristowe, Bartholow, Loomis, Aitkin, and Flint, on the "Practice of Medicine"; and DaCosta's work on "Medical Diagnosis," the following articles may be mentioned: Hardaway, in "Pepper's System of Medicine"; Hartshorne, in "Reynolds' System of Medicine"; Thomas, in "Ziemssen's Cyclopædia"; Cheadle, Shuttleworth, and Squire, in the Trans. Internat. Med. Cong., 1881; Griffith, in the New York *Medical Record*, July 2d and 9th, 1887; Edwards, in the *Am. Jour. Med. Sci.*, 1884; Jones, *Boston Med. Journ.*, 1881; Sholl, *Med. and Surg. Reporter*, 1882; T. D. Swift, *N. Y. Medical Journal*, November 27th, 1886; Harrison, *Am. Journ. Obstet.*, 1885; Duckworth, Erskine, and Gowers, in London *Lancet*, 1880; Dukes, *ibid.*, 1881; Yonge-Smith, *ibid.*, 1883 and 1886; Strover and Jaccond, *ibid.*, 1886; Shuttleworth, Brown, Burnie, Davis, Rooke, and Wilson, in *Brit. Med. Journal*, 1880; Byers and Sadell, *ibid.*, 1881; Lawrence, *ibid.*, 1882; Shackelton and Cullingworth, *ibid.*, 1883; McLeod, *ibid.*, 1885; and Ryle, *ibid.*, 1886.

Thomas D. Swift.

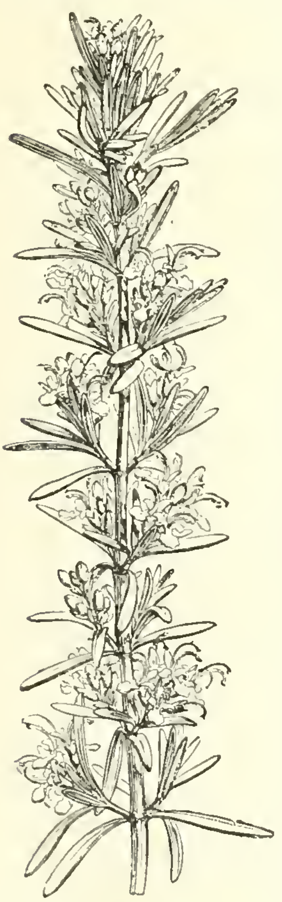

Fig. 4137.—Rosmarinus Officinalis: flowering branch. (Baillon.)

ROSEMARY.—*Roris marini.* (*Rosmarinus*, U. S. P. 1880.) The dried leaves of *Rosmarinus officinalis* L. Fam. *Labiatæ.*

These leaves are obtained from a small, slender, evergreen, blue-flowered shrub, native of the Mediterranean region, and somewhat cultivated for medicinal purposes and as a decorative shrub. The flowering twigs are also sometimes employed. The leaves are about 2.5 cm. (1 in.) long, oblong, but so strongly recurved at the edges as to appear linear in the dried condition, obtuse at both ends, destitute of a petiole, entire, coriaceous, dark-green with a slight bluish cast above, and grayish-green and densely woolly and glandular underneath. The odor is characteristic and somewhat camphoraceous, the taste aromatic, pungent, and somewhat terebinthinate. Although the use of the drug has now largely been superseded by that of its one or two per cent. of volatile oil, the action is not quite the same in both of them, since the drug itself also contains considerable tannin and resin and a little bitter substance. The latter, therefore, is a useful aromatic bitter and tonic. The fresh decoction, or the fluid extract, applied to unhealthy wounds, is a good vulnerary, though somewhat irritating unless carefully employed. The dose of rosemary is 0.5–1 gm. (gr. vij.–xv.)

Oil of Rosemary (*Oleum Rosmarini*, U. S. P.) presents the appearance of a colorless or at most a pale yellow fluid, has a specific gravity of from 0.895 to 0.915, is freely soluble in alcohol, and possesses the characteristic odor of the drug and a similar and somewhat camphoraceous taste. It contains cineol, borneol, and camphor, with other less important substances. It possesses all the activity of the drug, but in an intensified degree. It is often given internally as a carminative and general intestinal stimulant, though its use has greatly declined. The dose is from one to five minims. It enters into the compound tincture of lavender. Owing to its actively local stimulant or irritant properties, it is considerably used as a local application for promoting the nutrition of the skin and also as a vulnerary. *Henry H. Rusby.*

ROSEOLA.—Roseola is often incorrectly used as synonymous with rubella or Roetheln. Unquestionably many efflorescences which have been called roseola are in fact the efflorescences of rubella, and the reverse is quite true, that many of the reported cases of rubella are nothing more nor less than roseola. When properly used, the word roseola should simply indicate a rose-colored rash, a form of erythema, and should not be spoken of as a specific disease.

A roseolous efflorescence may often precede the appearance of the exanthemata of rubella, scarlet fever, measles, variola, and vaccinia, but should not be confounded with the specific efflorescences which are characteristic of these affections, and which usually occur later in the course of the disease. A roseolous rash may also occur in other conditions such as cholera, typhoid, diphtheria, and malaria—in fact, in almost any condition which gives rise to fever. If the word is to be used at all, one should designate the disease accompanying it, as, for instance, "roseola syphilitica," "roseola vaccinia," "roseola febrilis," "roseola typhosa," etc., but the tendency is to drop the term entirely from medical nomenclature.

Whereas the roseolous erythema may closely resemble the efflorescence of rubella, measles, or scarlet fever, it has the following points of distinction: It is neither contagious nor epidemic; there are no characteristic prodromal symptoms; it is not confined to any special portion of the body; there is either no fever at all, or, if the fever be present, it does not run a characteristic course; it may last a few hours, or it may disappear after a few days without desquamation; the erythematous areas are not so crescentic as in measles nor so punctiform as in scarlet fever.

A roseolous rash is very common in infants and in children as a result of dentition, gastric or intestinal disturbances, or in connection with the many febriculæ seen in early life, for which no sufficient cause can be found. Again, it may occur in infants who are in perfect health, and in whom nothing else abnormal may be detected. It is in these special cases that the term "roseola infantilis" has been used. *Maynard Ladd.*

ROSES.—The genus *Rosa* L. (fam. *Rosaceæ*) comprises upward of a hundred species of prickly shrubs. Although of little medicinal value, strictly speaking, these species contribute several articles possessing important uses in flavoring, perfuming, and coloring and exerting a mild stimulant, antispasmodic or tonic action. Three of these articles are official, as follows:

Rosa Gallica or *Red Rose*, "the petals of *Rosa Gallica* L., collected before expanding."

Digitized by Microsoft®

Rosa Centifolia, White Rose, Pale Rose, or *Hundred-leaved Rose*, "the petals of *Rosa centifolia* L."

Oleum Rosæ, Oil of Rose, Otto or *Attar of Rose*, "a volatile oil distilled from the fresh flowers of *Rosa Damascena* Miller."

Although the red rose plant is native in Europe and adjacent Asia, the official product is obtained wholly from cultivated plants, chiefly in Southern and Central Europe, especially in France. The peculiar structure of the flower renders it quite an easy matter to collect the cones of unexpanded petals. The calyx lobes, having spread backward before the opening of this cone, a sharp knife is drawn about the base of the latter, which is then lifted off, leaving the stamens still attached to the rim of the calyx tube. The cones are then very carefully dried in the shade, or they may be packed in salt. In the finest grades they mostly cohere in the cone, though loose petals may also be of fine quality. They should preserve a deep purple-red color and a fine velvety surface, as well as a strong and fine rose odor. The taste is bitterish, astringent, and very slightly acrid. The individual petals have a roundish outline, a notched summit, and a very short, broad, yellowish-white basal claw. Fragrant as they are, the amount of volatile oil in them is minute. The important constituent is a beautiful bright red, readily soluble coloring matter. Mildly astringent properties are imparted by a small amount of gallic acid. Small amounts of fat and quercitrin also exist. Red rose is practically inactive, though a sentimental effect is often gained by administering it in mild cases of hysteria. The Pharmacopœia provides a fluid extract, made with diluted alcohol and 10 per cent. of glycerin, and a confection consisting of 8 per cent. of the No. 60 powder, 64 per cent. of sugar, 12 per cent. of clarified honey, and 16 per cent. of stronger rose water. There is an official 12.5 per cent. syrup of the fluid extract. Red rose also enters into the pills of aloes and mastiche. There is, of course, no particular dose.

White rose is native of Western Asia, and is believed by some to be a mere variety of the red. Its constituents are identical with those of red rose except that the amount of coloring matter is extremely small. The use of this drug is therefore restricted almost wholly to flavoring. It is likely to be dropped from the next edition of the Pharmacopœia.

Rosa Damascena, the Damascus rose, is cultivated for the production of rose oil, chiefly in Bulgaria. This oil, being then exported and repacked in other countries, becomes the chief source of the various commercial brands bearing other geographical names, although a moderate amount of this product is actually distilled from roses grown in other countries. The oil is simply distilled with water. The following is the official description:

"A pale yellowish, transparent liquid, having the strong, fragrant odor of rose, and a mild, slightly sweetish taste.

"Specific gravity: 0.865 to 0.880 at 20° C. (68° F.).

"It is but slightly soluble in alcohol, and neutral to litmus paper moistened with alcohol.

"The congealing and melting points of the oil are subject to some variation, depending upon the amount of stearopten, but, when slowly cooled to a temperature usually between 16° and 21° C. (60.8° and 69.8° F.), it becomes a transparent solid, interspersed with numerous slender, shining, iridescent, scale-like crystals. Upon the application of the heat of the hand, the crystals should float in the upper portion of the liquefied oil.

"If to five drops of the oil, contained in a test tube, five drops of concentrated sulphuric acid be added, a reddish-brown, thick mixture will be produced, but no white fumes or tarry odor should be developed, and the fragrant odor of the oil should not be destroyed. If this mixture be then shaken with 2 c.c. of alcohol, the resulting liquid may be turbid, but should be nearly colorless, and should not at once assume a red or reddish-brown color (absence of *oil of ginger-grass* or *Turkish oil of geranium*, from *Andropogon Schœnanthus* L. [Fam. *Gramineæ*], and of oil of *rose geranium*, from *Pelargonium Radula* [Cavanilles] Aiton, *Pelargonium capitatum* Aiton, and *Pelargonium odoratissimum* [L.] Aiton; Fam. *Geraniaceæ*)."

The important odorous constituent of rose oil is geraniol, long regarded as a distinct substance under the name "rhodinol." There is also a small quantity of citronellol. Various derivatives of these also occur.

Although rose oil undoubtedly has antispasmodic and stimulant properties, practically its entire use is for perfuming and flavoring.

Official *rose water* may be regarded as indirectly a preparation of rose oil, although not prepared from that substance. It is recognized under two titles, namely, *Aqua Rosæ*, or *Rose Water*, and *Aqua Rosæ Fortior*, or *Stronger Rose Water*. The latter is the water, saturated with the oil, obtained as a by-product in the distillation of rose oil. The former is made by mixing, immediately when required for use, equal volumes of the stronger rose water and distilled water. From stronger rose water is prepared the *Ointment of Rose Water* or *Cold Cream* (*Unguentum Aquæ Rosæ*, U. S. P.), made with 12.5 per cent. of spermaceti, 12 per cent. of white wax, 60 per cent. of expressed oil of almond, 19 per cent. of stronger rose water, and 0.5 of 1 per cent. of sodium borate, these figures being approximate, since part of them respond to weights, part to measures.

In addition to the above official products, there is used in Europe, and there to only a very slight extent, a confection made from the fruits of *Rosa canina* L., the *dog rose*. This fruit contains only sugar, malic and tannic acids, and their compounds, and is a very inferior preparation.

Rosaceæ.—This great family includes several subfamilies regarded by many botanists as themselves entitled to family rank (*Pomaceæ*, the apple family; *Drupaceæ*, the prune family, etc.). Thus considered, it is doubtless the most important fruit-producing family, yielding raspberries, blackberries, strawberries, plums, peaches, cherries, and similar stone fruits, the apple, pear, quince, medlar, etc. From a medicinal point of view, the family is of considerable importance, yielding the almonds, wild cherry, North American ipecac, koosso, prune, quillaja, blackberry bark and the roses, all elsewhere considered, besides a number of minor drugs, several of which are considered below.

Raspberry, or *Rubus Idæus*, U. S. P., is the fruit of *Rubus Idæus* L., the cultivated red raspberry of European nativity. The Pharmacopœia provides that the American wild red raspberry (*R. strigosus* Mx.) or the black cap (*R. occidentalis* L.) may be employed in the absence of *R. Idæus*. This fruit contains only sugar, fruit acids, and their salts, like others of its class, and its medicinal properties are merely those of a mild laxative, refrigerant, and antiscorbutic. Its fine flavor and beautiful red color make it a very useful adjuvant or vehicle, and an official syrup of the fresh fruit is provided for this purpose. Although not official, a similar syrup made of strawberries is in common use.

Astringent Drugs.—Probably the most common and important property of the drugs of the rose family is their astringency, due to the presence in them of considerable quantities of tannin. In such products as the leaves of the blackberry, raspberry, and strawberry, this tannin is accompanied by appreciable quantities of gum, thus favorably modifying the action, and these are very largely employed as domestic astringents. *Tormentilla*, the rhizome of *Potentilla Tormentilla* L., as well as the rhizomes of other species of *Potentilla*, contains about the same amount of tannin as geranium, and is similarly employed. The same is true of *Sanguisorba* and of various species of *Acæna*, and of the root and bark of several species of *Spiræa*, *Hardhack*, or *Steeple Bush*, the leaves being also employed like those of the strawberry and raspberry. Under the names *Meadow Sweet*, *Queen of the Meadow*, and *Ulmaria*, the leaves of *Spiræa Ulmaria* L. are also employed in the same way.

ROSSCOMMON SPRING.—Monroe County, Pennsylvania.

Post-Office.—Wind Gap. Hotel.

Access.—From Philadelphia viâ Reading Railroad; from New York viâ Central Railroad of New Jersey. The Rosscommon depot is only a few hundred feet from the hotel.

www.libtool.com.cn

The summer resort known as Rosscommon is situated in the Wind Gap of the Blue Ridge Mountains, on the north incline of the range, one thousand feet above tide water. The location is fifteen miles west of the Delaware Water Gap, twelve miles from Stroudsburg, and fifteen miles from Easton. The hotel, known as the Rosscommon Inn, is situated on a handsome plateau, half a mile square, and surrounded by forests. The neighborhood is entirely free from malaria and mosquitoes, and a fine breeze prevails almost constantly; hence the name Wind Gap. The accommodations at the inn are plain and unpretentious, but very comfortable and home-like. The spring, discovered a few years ago, adds considerably to the attractions of the place. The water flows from a fissure in the rock at the bottom of the spring, and constantly discharges a large volume of carbonic acid gas. It was analyzed in 1887 by Prof. William H. Chandler, of the Lehigh University, with the following result:

Neutral (lightly carbonated). One United States gallon contains: Sodium chloride, gr. 0.08; sodium sulphate, gr. 0.09; potassium sulphate, gr. 0.05; magnesium sulphate, gr. 0.02; calcium carbonate, gr. 0.39; magnesium carbonate, gr. 0.10; silica, gr. 0.47; iron carbonate, a trace. Total solids, gr. 1.20. Carbonic-acid gas (free and partially free), 1.42 cubic inches.

This analysis does not present a mineral water in the strict acceptation of the term. It is probable that very few common potable waters would show so light a mineralization: yet it is entirely free from organic matter, and has sufficient gas to give it a bright sparkle and to render it very palatable. The water is bottled and sold.

James K. Crook.

ROYAL GORGE HOT SPRINGS.—Fremont County, Colorado.

Post-Office.—Canyon City. Hotel.

Access.—From Denver viâ Denver and Rio Grande Railroad. Canyon City is also the western terminus of the Arkansas Valley branch of the Atchison, Topeka, and Santa Fé Railroad.

The town of Canyon City, with a population of thirty-five hundred inhabitants, is rapidly becoming a charming city of healthful and comfortable homes. It is the county seat of Fremont County, and is situated on the north and south banks of the Arkansas River, one hundred and sixty miles south by west of Denver, and one hundred miles below Leadville. The scenery about the place is grand and romantic to a high degree. A walk of a few minutes takes the tourist to the famous Royal Gorge, where the granite cliffs tower 2,000 feet above the head. The altitude of the springs is 5,200 feet above the sea-level. The location is protected by the mountains on three sides, and the report of the United State Meteorological Bureau shows that for any given month in winter the temperature on an average is six degrees warmer than at any other point in the State. The rainfall is only fourteen inches per annum, and it is said that there are over three hundred sunny days in every year. The capacity of the hot springs is difficult to estimate, as they break out into the Arkansas River in several places. One of them, which issues from the earth a little above low water, yields fifteen gallons per minute, but the combined flow of the springs would be many times greater. Within half a mile of the hot springs are cold soda and iron springs. Excellent bathing facilities have recently been provided at the hot springs. The following analyses are by Prof. Oscar Loew, of the United States Geological Survey. That of the Royal Gorge Hot Springs shows that one United States gallon contains: Sodium carbonate, gr. 73.20; magnesium carbonate, gr. 12.80; calcium carbonate, gr. 33.50; sodium sulphate, gr. 79.30; sodium chloride, gr. 18.20; lithium chloride, a trace. Total, 217 grains. Temperature of water, 102° F.

The analyses of the Royal Gorge Cold Soda and Iron Springs show that one United States gallon contains:

Solids.	Iron Duke. Grains.	Little Ute. Grains.
Sodium chloride	83.00	118.00
Sodium sulphate	12.20	12.10
Sodium carbonate	76.80	76.40
Calcium carbonate	33.00	22.50
Magnesium carbonate	14.60	14.00
Iron	Traces.	Traces.
Lithia	Traces.	Traces.
Total	219.60	243.00

The waters of both cold and hot springs are highly charged with carbonic acid gas. The hot baths here are strongly recommended for rheumatism and skin diseases. Dr. Prentiss, of Canyon City, informs us that persons suffering from pulmonary trouble are usually much improved by a sojourn in the sunny, even climate of this region.

James K. Crook.

ROYAT-LES-BAINS, FRANCE.—This well-known French spa is situated in the centre of France, being one of a group of mineral-spring resorts in this region of the Auvergne Mountains. Not far distant are Mont Dore, La Bourboule, Chatel Guyon, Vichy, and others.

Royat, a small town of 1,528 inhabitants, is beautifully situated in a narrow valley watered by the Tiretaine, and surrounded by the lower Auvergne Mountains. All the surrounding country is charming, and there are many most attractive excursions, particularly to the Puy de Dôme, where an extensive and grand view is obtained. This resort has been called the "Ems" of France, but in climate, picturesqueness, and charm of situation it is far superior to the German spa.

The climate exhibits the characteristics of a mountain climate of moderate elevation, the altitude being 1,475 feet. There are sudden transitions of temperature; sudden storms of wind and rain with thunder; a dry atmosphere; and brilliant sunshine. The soil is volcanic, and the dust from such a soil is abundant and blown about in clouds by the wind. The peculiar situation of Royat itself, as Yeo says ("Health Resorts," J. Burney Yeo), also modifies the climate. "Lying as it does in the floor of a somewhat narrow valley, surrounded on all sides by mountains, and open only to the east, running, moreover, in a direction east and west, and facing the east, it is particularly exposed to the direct heat of the sun." "It is therefore," continues Yeo, exceedingly difficult to find any kind of shady walks in the immediate vicinity of Royat when the sun is up and the sky is cloudless." Therapeutically the climate is invigorating and refreshing.

The waters are what are known as "warm muriated alkaline," containing bicarbonates of soda, potash, lime, and magnesia, together with chloride of sodium and a small amount of lithia. Arsenic in very minute quantity is also found in these waters, as are also the salts of iron and manganese. All the springs are rich in free carbonic acid gas. The natural temperature of the water is from 68° to 95° F. In this country the Healing Springs of Virginia and the Hot Springs of North Carolina are somewhat similar in their composition and uses. There are four principal sources: the Eugénie, St. Mart, Cæsar, and St. Victor. The Eugénie is the warmest (95.9° F.), and is the most highly mineralized. The St. Victor contains the most iron and arsenic. These springs together furnish 1,522,000 litres of water a day. The water is clear and transparent, and has no odor.

The waters of Royat are employed for drinking, bathing, gargling, and inhalation. The bathing establishment is complete, and said to be one of the finest in France. A specialty of this spa is the running water bath, where the water is led directly from its source and at its natural temperature into the bathtub, and con-

Digitized by Microsoft®

stantly flows in and out. There are arrangements for douches with massage attached to each bath, and also independent apparatus for douches of various forms. There are inhalation rooms; facilities for gargling, irrigation, and pulverization; baths and douches of water charged with carbonic acid gas; hydro-electric baths; a large public swimming bath; and a gymnasium.

www.libtool.com.cn

The chief drinking fountain is from the Eugénie Spring, and is situated in a pleasant park. The water is very agreeable to drink. There are two casinos with music, concerts, balls, and theatrical performances. "The excursions," says Yeo (*loc. cit.*), "are numerous, varied, and interesting; for no more remarkable country to the geologist, the naturalist, and the archæologist can be found than this great mountainous district of extinct volcanoes, old mediæval towns, historic churches, and Roman and even earlier remains."

The accommodations are abundant, good, and of reasonable price. Although open throughout the year, the season is from the 15th of May to the 15th of October.

Royat is about nine hours distant from Paris viâ Clermont-Ferrand, which is fifteen minutes distant from Royat.

The disorders for which these waters are of value are chiefly arthritic and anæmic affections. Rheumatism; gout associated with anæmia; skin diseases, such as eczema, acne, and pityriasis; chronic laryngitis and bronchitis; bronchial asthma; neuralgia; sciatica; atonic dyspepsia; various uterine affections; gouty glycosuria; biliary and renal lithiasis; neurasthenia; and various forms of anæmia are all treated here. The contraindications are organic cardiac affections, a tendency to hemorrhage, organic affections of the central nervous system, scrofula, and other tuberculous affections.

For the after-treatment the seaside for a short time is recommended, except in joint and bronchial affections, for which a winter in the south of France is preferred.

Not far from Royat is Durtol, 1,705 feet high, where is a sanatorium, opened in 1898.

For a further consideration of this resort, as well as others in France, the reader is referred to "Stations Hydro-Minérales, Climatériques, et Maritimes de la France," Paris, 1900. *Edward O. Otis.*

RUBBER.—*Elastica*, U. S. P. *Caoutchouc*, Fr. Cod.; *India rubber*, *Gum elastic*, etc. The concrete milk juice of several species of *Hevea*, Aubl. (fam. *Euphorbiaceæ*), known in commerce as *Para rubber*.

From a commercial standpoint, the substance bearing the above names is derived from a large number of milky-juiced plants, growing in the tropics of both the Old and the New World, these plants belonging to many and distantly related families, but more especially, in the order named, to the *Euphorbiaceæ*, *Urticaceæ*, *Apocynaceæ*, and *Asclepiadaceæ*. Besides these, which yield rubber on a commercial scale, the substance caoutchouc occurs in small amounts in a very large number of milk juices.

The rubbers from these different botanical sources naturally differ widely in appearance and quality. Some of them—perhaps more because of the manner in which the milk juices are treated than because of natural differences in the latter, they being often mixed with ashes, soap, and other substances, and allowed to ferment in holes in the ground—are quite unfit for official use. Others, though clean, and not, strictly speaking, objectionable, are inferior from the standpoint of deficiency in their useful properties. Para rubber has been selected for official purposes because of its cleanliness, purity as caoutchouc, high elasticity, durability, and ready solubility in appropriate liquids.

Origin.—The plants yielding Para rubber are large trees, frequently exceeding a hundred feet in height and five or six feet in diameter, growing in the valleys of the Amazon and its tributaries. The basin of the Madeira and its tributaries produces the largest amount. Though mostly exported viâ Para, whence the name, much of the same grade comes out through the west coast of South America. The milk juice is obtained by gently tapping the outer and middle bark layers with a sharp pick and catching the exudation in small cups attached to the trees. The milk is then gathered and carried to the smoking stations, where it is coagulated in successive layers upon a flat wooden paddle, by being held in the smoke of smothered fires, special articles being preferred for this fuel. When a suitable quantity has been gathered upon the paddle, an incision is made at the upper end of the mass, called a *bolacho* or "bottle," to permit of its being slipped off from the end of the paddle. It then possesses a flat form, a whitish color, and smooth surface, and may weigh from a few up to seventy-five pounds, or even more. The product of the upper tributaries is usually in bolachos of about twenty-five pounds, the larger bolachos coming mostly from the lower Madeira. The rubber soon begins to turn yellow, then brown, and ultimately black, first upon the surface and then gradually toward the interior, the complete process of darkening requiring several years. At the same time it loses water, and of course weight. It may be exported in the original bolachos, but owing to the danger of adulterants in the form of sand, stones, etc., it is now mostly cut into small pieces in Para.

Description.—The following is the official description of elastica:

In cakes, balls, or hollow, bottle-shaped pieces, externally brown to brownish-black, internally brownish or of lighter tint; very elastic; insoluble in water, diluted acids, or diluted solutions of alkalies; soluble in chloroform, carbon disulphide, oil of turpentine, benzin, and benzol. When heated to about 125° C. (257° F.) it melts, remaining soft and adhesive after cooling. Odor faint, peculiar; nearly tasteless.

Composition.—The percentage of caoutchouc in india rubber varies with the amount of water which the substance has lost. In its original liquid condition there is said to be about thirty-two per cent. of this hydrocarbon ($C_{20}H_{32}$). With caoutchouc exist a little wax, a free acid, and some proteid matter. There is a little free carbon, which results from the smoking process.

Properties and Uses.—On continued exposure to the atmosphere, rubber undergoes changes which render it brittle and weak, and this may be prevented by keeping it under water, which preserves it by inducing superficial fatty changes. *Vulcanized rubber* is produced by combining the original rubber with sulphur, under the influence of heat, by various processes. It still retains its elasticity, but becomes harder and is no longer soluble in the same liquids as before. *Hard rubber* or *ebonite* may be obtained by combining rubber with various other substances than sulphur.

Strictly speaking, rubber has no medicinal properties, since it is insoluble in all the fluids of the body. The original milk, being drunk by mistake, has invariably coagulated into an insoluble mass in the stomach, the result being fatal in the absence of surgical treatment. Its uses are wholly mechanical. The most important is as a mass for plasters. Such a mass possesses very good qualities, although experiments seem to indicate that the effect of the incorporated medicinal substance is somewhat less than when combined with the official plaster mass. Rubber mass adhesive plasters for surgical dressings, Esmarch's and other elastic bandages and wrappings, orthopedic appliances, nipples, syringes (hard and soft), pessaries, artificial teeth, specula, catheters, etc., represent important uses of rubber, which require only enumeration. Articles of rubber, either hard or soft, should be kept in a closed box or drawer, and occasionally used or washed to prevent their becoming too dry and brittle. Silver instruments should never be kept in the same enclosure with them. Soft rubber is spoiled after a short time by oils and fats, and eventually hardens in spite of precautions.

By dissolving rubber in appropriate liquids, with or without the addition of other adhesives, various forms of cement or glue can be obtained, and impervious coverings can be produced by applying such substances and permitting evaporation. *Henry H. Rusby.*

RUBELLA. See *Roetheln.*

RUBIDIUM AND AMMONIUM BROMIDE.—A double salt having the chemical formula $RbBr.3NH_4Br$. It is a white or yellowish-white crystalline powder, soluble in water, and possessed of a cooling and saline taste.

This salt has been proposed as a more suitable means of administering bromine than the ordinary ammonium, potassium, or sodium salts. Laufenauer (*Therap. Monatsch.*, August, 1889), reasoning from the fact that lithium bromide is more powerful than ammonium bromide, the sodium salt more so than the lithium, and the potassium salt still more powerful, was led to believe that the more strongly electro-positive the salt, and the higher its atomic weight, the greater its power in disease. As rubidium is powerfully electro-positive and has a high atomic weight, the bromide of rubidium and ammonium was prepared, and in a series of experiments was found to prove more satisfactory than the other bromides in epilepsy and other conditions in which bromides are indicated.

Further use of the drug has proved its efficacy, but has not shown any decided advantage over other bromides. It, however, has not the depressing effects of the potassium salts, and may be given where the more common compound has to be discontinued. As an anti-epileptic remedy, it is given in doses of sixty to ninety grains in divided portions. As a hypnotic and sedative, sixty grains may be given in a single dose.

Rubidium bromide and *rubidium iodide* have also been prepared, but their therapeutic value has not been established. *Beaumont Small.*

RUBINAT MINERAL SPRINGS.—Province of Lerida, Spain. These springs, which supply the well-known waters of the Rubinat group, are located at a high elevation in the Pyrenees, near the village of Rubinat. We are informed that some of the springs have been known from time immemorial, and were resorted to in the Middle Ages by pilgrims from all over the kingdom. In recent years the waters have come into commercial use, and those of some of the springs are exported in large quantities to the American markets. Among the better known waters of the group are the Rubinat-Condal, Rubinat-Serre, and Rubinat-Llorach, all of which are extensively sold in the United States. Following are analyses of the first two:

Rubinat Condal.—One United States gallon contains:* Sodium sulphate, gr. 5,407.34; potassium sulphate, gr. 13.22; magnesium sulphate, gr. 183.97; calcium sulphate, gr. 109.44; sodium chloride, gr. 115.94; silica, alumina, ferric oxide, gr. 2.08; loss, gr. 0.98. Total, 5,832.97 grains.

Rubinat Serre.—One United States gallon contains:* Sodium sulphate, gr. 4,695.97; magnesium sulphate, gr. 135.54; calcium sulphate, gr. 79.57; calcium bicarbonate, gr. 29.40; sodium chloride, gr. 262.23; potassium silicate, gr. 36.83. Total, 5,239.54 grains.

These analyses show very potent waters of the sulphated saline group. They owe their purgative properties chiefly to the presence of the sulphate of sodium in large quantities, although both contain considerable sulphate of magnesia. They act as very efficient saline cathartics and are indicated in conditions where such remedies are useful. The dose varies from one to eight or nine ounces, according to the indications, and the water is best taken in the morning, on rising. According to the author's observation these waters are not so likely to cause griping as are some of the stronger bitter waters. *James K. Crook.*

RUE.—*Ruta.*—The leaves of *Ruta graveolens* L. (fam. *Rutaceæ*).

This is a perennial herbaceous or partly woody plant, two or three feet in height. It has pale green, cylindrical, branching stems, alternate, smooth, light green, glandular dotted leaves, which usually dry yellowish; the lower twice or three times pinnate and long petioled, the intermediate once or twice pinnate, the uppermost simple and sessile; divisions wedge-shaped, rounded, or blunt at the extremity. Flowers yellowish, in a terminal corymb, with the parts in fours or fives; stamens twice as many; sepals small, pointed; petals large (one-half inch long), rounded and hooded at the ends, narrow below. Fruit a dry, dehiscent capsule, containing numerous angular, blackish seeds. Rue is a native of Southern Europe, the Levant, etc., and is also cultivated. It has a strong disagreeable odor, and a bitter, sharp taste.

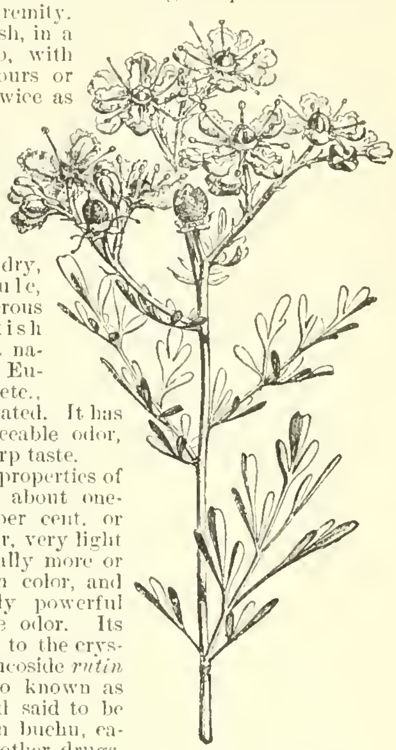

FIG. 4138.—Flowering Branch of Rue. (Baillon.)

The aromatic properties of rue are due to about one-fourth of one per cent. or less of a peculiar, very light volatile oil, usually more or less yellowish in color, and of an extremely powerful and disagreeable odor. Its bitterness is due to the crystalline yellow glucoside *rutin* ($C_{42}H_{50}O_{25}$), also known as *rutinic acid*, and said to be contained also in buchu, capers, and some other drugs. Considerable quercitin and sugar also occur.

ACTION AND USES.—Rue is one of the most ancient of drugs. Its action appears to be that of the volatile oil, differing chiefly in its lesser intensity. Taken internally, in small doses, it is stomachic, laxative, and stimulant to the secretions, especially to those of the intestine and kidneys. In somewhat larger doses it is a powerful anti-spasmodic. It also acts as an emmenagogue, and is in overdoses an irritant intestinal and renal poison and an abortifacient. Among the ancients it was used for its aphrodisiac properties. The dose of the drug ranges from ten to twenty grains, and it is best given in the form of a twenty-per-cent. tincture, made with diluted alcohol, dose fifteen to sixty minims.

Oil of rue was official in the United States Pharmacopœia of 1870 and 1880. It possesses all the above-named properties of rue in a greatly intensified degree. It is a powerful counter-irritant, capable of producing vesication similar to that from croton oil. It is a well-known and dangerous abortifacient, and is capable of acting as a fatal irritant-narcotic intestinal poison. It is not often given internally at the present time. The dose is from two to five minims. *Henry H. Rusby.*

RUTLAND, MASSACHUSETTS. — Rutland, Mass., situated in almost the geographical centre of Massachusetts, fifty-four miles from Boston, is the seat of the "Massachusetts State Sanatorium" for pulmonary tuberculosis, the first institution of the kind established in the United States, having been opened for patients October 1st, 1898.

* Converted from grams per litre.

Digitized by Microsoft®

The site occupied by the sanatorium and its grounds consists of about two hundred and fifty acres of land, at an elevation of 1,160 feet, protected on the northwest by a wooded hill rising 100 feet higher. The climate is that of inland New England modified by the elevation. The winters are cold and long, with much snow, and the temperature is very variable. The average annual rainfall is high, and although, taking the year through, there is a good deal of sunshine, there are usually not many successive sunny days. The atmosphere, however, is pure and free from dust, and there is a clear sweep of country round about.

www.libtool.com.cn

The sanatorium buildings consist of a series of one-story wards radiating toward the south, connected by a long convex corridor. In the rear toward the north are the kitchen, dining-room, assembly hall, heating, electric and laundry departments. At the centre of the curved corridor and connected with it by an open passageway is the administration building, looking toward the south. The patients sleep, for the most part, in open wards, there being only a few isolated rooms. At the southern termini of the wards are sun rooms and piazzas. In the neighboring woods are various picturesque camps made of boughs and other material where much of the daytime is spent both in summer and winter. There are accommodations for two hundred and fifty patients and still further additions are contemplated. (Plate LI.)

The whole establishment is under the charge of a resident physician and superintendent, with two visiting and several house physicians. Only the incipient cases are received, or those whose condition offers a reasonable hope of radical improvement. Both male and female patients are received.

The treatment is the hygienic-dietetic, essentially the same as that which is pursued in all modern sanatoria for pulmonary tuberculosis: "Constant life in the open air: judicious exercise, varying with individual cases, in conjunction with the 'rest cure'; and a properly regulated diet of nutritious food" (Bowditch, Sixth Annual Report, 1902). It is a part of the regulations that patients must spend at least *eight hours* out of doors daily, unless excused by the physician; and that all windows are to be opened and closed by the nurse or attendant only. When there is a driving storm, and in winter when the patients are getting up or going to bed, the windows of the wards are closed, but at other times they are constantly kept open. "Medicines are used as little as possible."

Male patients, whose condition will permit it without injury, are utilized in light work upon the farm connected with the institution. Most patients are obliged to furnish $4 a week toward their board, which is somewhat less than half of the actual expense.

As to the results obtained, the last report, up to September 30th, 1902, shows 72 per cent. of the incipient cases for the previous year apparently cured or arrested, and 19 per cent. of the moderately advanced cases. Taking all stages of the disease, there were 48.33 per cent. apparently cured or arrested, and 43.49 per cent. improved. This for the previous year.

For a more extended consideration of the yearly results and of the subsequent histories of former patients, the reader is referred to the yearly reports of the trustees published by the State. For a more detailed description of the sanatorium and the treatment, one is referred to the article of Dr. V. Y. Bowditch, one of the visiting physicians, in the *Boston Medical and Surgical Journal* for February 8th, 1900; also to the yearly reports of the sanatorium.

Numerous boarding-houses and small sanatoria have sprung up in the vicinity, most of them conducted by former patients; they receive consumptives at a moderate rate, and carry out the "treatment" as learned in the sanatorium. *Edward O. Otis.*
