LIST OF CONTRIBUTORS TO VOLUME VI.

www.libtool.com.cn

BENJAMIN VAUGHAN ABBOTT, M.A.*.....NEW YORK CITY, N. Y.
Counsellor and Attorney-at-Law; Author of "Abbott's Law Dictionary" and Various Digests.

SAMUEL W. ABBOTT, M.D..NEWTON CENTRE, MASS.
Secretary, State Board of Health of Massachusetts.

EDWARD WILLIAM ARCHIBALD, M.D......MONTREAL, CANADA.
Demonstrator in Pathology, McGill University; Clinical Assistant in Surgery, Royal Victoria Hospital.

GEORGE E. ARMSTRONG, M.D.........MONTREAL, CANADA.
Associate Professor of Clinical Surgery, McGill University; Attending Surgeon, Montreal General Hospital; Consulting Surgeon, Western Hospital and the Protestant Hospital for the Insane, Verdun.

JAMES RAE ARNEILL, M.D....ANN ARBOR, MICH.
Instructor in Clinical Medicine, Medical Department, University of Michigan.

ROBERT H. BABCOCK, M.D..........CHICAGO, ILL.
Professor of Clinical Medicine and Diseases of the Chest, College of Physicians and Surgeons, Chicago; Attending Physician, Cook County Hospital and Cook County Consumption Hospital; Consulting Physician, Mary Thompson, St. Anthony's, and Marion Sims Hospitals.

PEARCE BAILEY, M.D..........NEW YORK, N. Y.
Instructor in Neurology, Columbia University, New York; Consulting Neurologist to St. Luke's, Orthopædic, and Babies' Hospitals, New York.

FRANK BAKER, M.D...........WASHINGTON, D. C.
Professor of Anatomy, Georgetown University School of Medicine; Superintendent, National Zoological Park, Smithsonian Institution, Washington.

FREDERICK AMOS BALDWIN, M.D..ANN ARBOR, MICH.
Assistant in Pathology, Medical Department, University of Michigan.

LEWELLYS F. BARKER, M.D.......CHICAGO, ILL.
Professor and Head of the Department of Anatomy, University of Chicago and Rush Medical College.

DONALD McLEAN BARSTOW, M.D..NEW YORK, N. Y.

WATLER ARTHUR BASTEDO, PH.G., M.D NEW YORK, N. Y.
Instructor in Materia Medica at Cornell University Medical College in New York City; formerly Torrey Lecturer on Botany at the New York College of Pharmacy.

HENRY G. BEYER, PH.D., M.D.
Surgeon, United States Navy. Lecturer on Hygiene, Naval War College, Newport, R. I.

ROBERT PAYNE BIGELOW, PH.D .BOSTON, MASS
Instructor in Biology, Massachusetts Institute of Technology, Boston.

W. R. BIRDSALL, M.D.*.........NEW YORK, N. Y.
Formerly Physician to the Department for Nervous Diseases, Manhattan Eye and Ear Hospital, New York.

SETH SCOTT BISHOP, M.D., LL.D.. CHICAGO, ILL.
Professor of Diseases of the Nose, Throat, and Ear in the Illinois Medical College; Professor in the Chicago Post-Graduate Medical School and Hospital; Attending Surgeon, Post-Graduate Hospital, Chicago.

W. P. BOLLES, M.D...............ROXBURY, MASS.
Professor of Materia Medica and Botany, Emeritus, at the Massachusetts College of Pharmacy; Visiting Surgeon, Boston City Hospital.

B. MEADE BOLTON, M.D...........ST. LOUIS, MO.
Professor of Pathology, Marion Sims-Beaumont College of Medicine, St. Louis; formerly, Associate in Bacteriology, Johns Hopkins University, and Director of the Laboratory of Hygiene, Board of Health of Philadelphia.

MAJOR W. C. BORDEN........WASHINGTON, D. C.
Surgeon, United States Army.

RICHARD EWELL BROWN, M.D......NEW YORK, N. Y.
Assistant Attending Physician, Lying-In Hospital, New York.

GLENTWORTH REEVE BUTLER, M.D..BROOKLYN, N. Y.
Attending Physician to the Methodist Episcopal Hospital and to the Brooklyn Hospital; Consulting Physician to the Bushwick Central Hospital.

ARTHUR T. CABOT, M.D.... .....BOSTON, MASS.
Surgeon to Massachusetts General Hospital, Boston.

HUGH CABOT, M.D.................BOSTON, MASS
Assistant in Operative Surgery, Harvard University Medical School; Attending Surgeon, the Baptist Hospital, Boston.

WILLIAM HENRY CARMALT, M.D..NEW HAVEN, CONN.
Professor of Surgery, Yale University; Attending Surgeon, New Haven Hospital.

EMILE MONNIN CHAMOT, B.S., PH.D. ..ITHACA, N. Y.
Assistant Professor of Sanitary Chemistry and Toxicology, Cornell University; Lecturer on Toxicology, New York State Veterinary College, Ithaca, N. Y.

RUSSELL H. CHITTENDEN, PH.D...NEW HAVEN, CONN.
Professor of Physiological Chemistry, Yale University, and Director of the Sheffield Scientific School.

WILLIAM JUDKINS CONKLIN, M.D .....DAYTON, OHIO.
Consulting Surgeon, St. Elizabeth's Hospital and the Protestant Deaconess' Home and Hospital.

WILLIAM THOMAS CORLETT, M.D CLEVELAND, OHIO.
Professor of Dermatology and Syphilology, Western Reserve University; Physician for Skin Diseases, Lakeside Hospital; Consulting Dermatologist, Charity, St. Alexis, and the City Hospitals, Cleveland.

WILLIAM T. COUNCILMAN, M.D BOSTON, MASS.
Shattuck Professor of Pathological Anatomy, Harvard University Medical School.

Digitized by Microsoft®

MONTGOMERY ADAMS CROCKETT, M.D. . . . BUFFALO, N. Y.
Adjunct Professor of Obstetrics and Gynæcology, Medical Department, University of Buffalo; Gynæcologist to Buffalo General and Erie County Hospitals, Buffalo.

ALFRED C. CROFTAN, M.D. . . . CHICAGO, ILL.
Professor of Medicine, Post Graduate Medical College of Chicago.

www.libtool.com.cn

JAMES K. CROOK, A.M., M.D. . . . NEW YORK, N. Y.
Adjunct Professor of Clinical Medicine and Physical Diagnosis, New York Post Graduate Medical School; Attending Physician, Post-Graduate Hospital.

EDWARD CURTIS, A.M., M.D. . . . NEW YORK, N. Y.
Emeritus Professor of Materia Medica and Therapeutics, Medical Department, Columbia University.

CHARLES TOWNSHEND DADE, M.D. . . . NEW YORK, N. Y.
Assistant Dermatologist, Vanderbilt Clinic, Columbia University; Attending Dermatologist, Randall's Isl and Hospital, New York.

N. PENDLETON DANDRIDGE, M.D. . . . CINCINNATI, OHIO.
Lately Dean and Professor of the Practice of Surgery and of Clinical Surgery, Miami Medical College; Attending Surgeon, Cincinnati and Children's Hospitals.

NATHAN SMITH DAVIS, JR., M.D. . . . CHICAGO, ILL.
Professor of Principles and Practice of Medicine and Clinical Medicine, and Dean of the Faculty, Northwestern University Medical School; Attending Physician, Mercy Hospital and Wesley Hospital, Chicago.

ROBERT H. M. DAWBARN, M.D. . . . NEW YORK, N. Y.
Attending Surgeon, City and Polyclinic Hospitals.

D. BRYSON DELAVAN, M.D. . . . NEW YORK, N. Y.
Professor of Laryngology, New York Polyclinic; Consulting Laryngologist, General Memorial Hospital, and the Hospital for Ruptured and Crippled.

LYDIA M. DEWITT, M.D. . . . ANN ARBOR, MICH.
Assistant in Histology, Medical Department, University of Michigan.

FRANKLIN ABBOTT DORMAN, M.D. . . . NEW YORK, N. Y.
Instructor in Obstetrics, Columbia University; Assistant Attending Physician, Sloane Maternity Hospital, New York.

ISADORE DYER, PH.B., M.D. . . . NEW ORLEANS, LA.
Professor of Diseases of the Skin, New Orleans Polyclinic; Clinical Instructor in Dermatology, Medical Department of Tulane University, New Orleans; Consulting Dermatologist to the Eye, Ear, Nose, and Throat Hospital, New Orleans.

J. HAVEN EMERSON, M.D. . . . NEW YORK, N. Y.

BENJAMIN THOMAS FAIRCHILD, PH.D. . . . NEW YORK, N. Y.
Pharmaceutical Chemist.

EDWARD MILTON FOOTE, M.D. . . . NEW YORK, N. Y.
Instructor in Minor Surgery, Columbia University; Visiting Surgeon, City Hospital, New York.

ROBERT FORMAD, M.D. . . . PHILADELPHIA, PA.
Demonstrator of Normal Histology, Medical Department, University of Pennsylvania.

JOSEPH FRAENKEL, M.D. . . . NEW YORK, N. Y.
Instructor in Nervous Diseases, Cornell University Medical School in New York City; Physician to the Montefiore Home; Neurologist to the City Hospital.

ROWLAND GODFREY FREEMAN, M.D. . . . NEW YORK, N. Y.
Clinical Lecturer on Pediatrics and Chief of Pediatric Clinic, University and Bellevue Hospital Medical College; Attending Physician, Foundling Hospital and the Seaside Hospital of St. John's Guild, New York.

JAMES MAGOFFIN FRENCH, M.D. . . . CINCINNATI, OHIO.
Lecturer on the Theory and Practice of Medicine, Medical College of Ohio; Attending Physician, St. Mary's Hospital; Consulting Physician, St. Francis Hospital for Incurables.

SIMON HENRY GAGE, B.S. . . . . ITHACA, N. Y.
Professor of Microscopy, Histology, and Embryology, Cornell University.

JASPER JEWETT GARMANY, M.D., F.R.C.S. ENG. NEW YORK, N. Y.
Clinical Professor of Surgery, University and Bellevue Hospital Medical College, New York.

FREDERICK R. GREEN, M.D. . . . . . . CHICAGO, ILL.
Head Demonstrator of Anatomy and Instructor in Osteology, Northwestern University Medical School, Chicago.

JOHN GREEN, M.D. . . . . ST. LOUIS, MO.
Special Professor of Ophthalmology, Medical Department of Washington University, St. Louis.

JOHN GREEN, JR., M.D. . . . . ST. LOUIS, MO.

CHARLES RAVENSCROFT GREENLEAF . . . BERKELEY, CAL.
Colonel, United States Army, Retired.

HENRY EWING HALE, M.D. . . . NEW YORK, N. Y.
Assistant Demonstrator of Anatomy, Medical Department, Columbia University, New York.

MRS. JEANNETTE WINTER HALL, BERWYN, ILL.
Formerly, Student of the University of Leipsic, Germany, Department of Biology.

THOMAS HENRY HALSTED, M.D., SYRACUSE, N. Y.
Professor of Laryngology and Otology, Medical Department, Syracuse University; Laryngologist and Otologist to St. Joseph's Hospital, and the Women's and Children's Hospital, Syracuse.

ALICE HAMILTON, M.D. . . . . CHICAGO, ILL.
Professor of Pathology, Woman's Medical College of Northwestern University, Chicago.

GEORGE C. HARLAN, M.D. . . . PHILADELPHIA, PA.
Emeritus Professor of Diseases of the Eye, the Philadelphia Polyclinic Hospital and College for Graduates in Medicine; Attending Surgeon, Wills Eye Hospital.

CHARLES HARRINGTON, M.D. . . . BOSTON, MASS.
Assistant Professor of Hygiene, Harvard University Medical School.

HENRY FAUNTLEROY HARRIS, M.D. . . . ATLANTA, GA.
Professor of Pathology and Bacteriology, College of Physicians and Surgeons, Atlanta, Ga.

T. STUART HART, M.D. . . . NEW YORK, N. Y.
Clinical Assistant in the Departments of General Medicine and Diseases of the Nervous System, Medical Department of Columbia University, New York.

FRANK HARTLEY, M.D. . . . . NEW YORK, N. Y.
Clinical Professor of Surgery, College of Physicians and Surgeons, Columbia University, New York; Attending Surgeon, New York Hospital; Consulting Surgeon, General Memorial and French Hospitals.

GUSTAVUS P. HEAD, M.D. . . . . CHICAGO, ILL.
Professor of Laryngology and Rhinology, Post Graduate Medical School, Chicago.

Digitized by Microsoft®

C. JUDSON HERRICK, Ph.D. . . . Granville, Ohio.
Professor of Zoology, Denison University; Associate in Comparative Neurology, Pathological Institute of the New York State Hospitals.

GUY HINSDALE, M.D. . . . . Philadelphia, Pa.
Secretary, American Climatological Association.

www.libtool.com.cn

REID HUNT, Ph.D., M.D. . . . . Baltimore, Md.
Associate Professor of Pharmacology, Johns Hopkins University, Baltimore.

MILLER BANE HUTCHINS, M.D. . . . Atlanta, Ga.
Dermatologist to the Presbyterian Hospital, Atlanta.

E. FLETCHER INGALS, M.D. . . . . Chicago, Ill.
Professor of Diseases of the Chest, Nose, and Throat, Rush Medical College; Attending Physician, Cook County Hospital; Laryngologist, Presbyterian Hospital and St. Joseph's Hospital.

FRANK W. JACKSON, M.D. . . . . . New York, N. Y.
Instructor in Medical Diagnosis, Columbia University; Visiting Physician, Bellevue Hospital; Junior Physician, Roosevelt Hospital.

GEORGE THOMAS JACKSON, M.D. . New York, N. Y.
Instructor in Dermatology and Chief of Clinic, Medical Department of Columbia University; Consulting Dermatologist, Presbyterian Hospital and the New York Infirmary for Women and Children.

SMITH ELY JELLIFFE, M.D. . . . New York, N. Y.

CARL KOLLER, M.D . . . . New York, N. Y.

MAYNARD LADD, M.D. . . . . Boston, Mass.
Assistant in Diseases of Children, Harvard University Medical School; Assistant Physician to the Children's Hospital; Assistant Physician to the West End Nursery and Infants' Hospital, Boston.

FRANK WARREN LANGDON, M.D. . . . Cincinnati, Ohio.
Professor of Nervous and Mental Diseases, Miami Medical College and the Laura Memorial Woman's Medical College of Cincinnati; Lecturer on Clinical Neurology at the Clinical and Pathological School of the Cincinnati Hospital.

GUSTAV LANGMANN, M.D. . . . . . New York, N. Y.
Consulting Physician, German Hospital, New York; Fellow of the New York Academy of Sciences.

RALPH CLINTON LARRABEE, M.D . . . . . Boston, Mass.
Assistant in Histology, Harvard University Medical School; Physician to Out-Patients, Boston City Hospital.

EDWARD LEAMING, M.D. . . . . . New York, N. Y.
Instructor in Photography, College of Physicians and Surgeons, Medical Department of Columbia University.

HENRY LEFFMANN, M.D . . . . Philadelphia, Pa.
Professor of Chemistry and Toxicology, Woman's Medical College of Pennsylvania; Pathological Chemist to Jefferson Medical College Hospital; Honorary Professor of Chemistry, Wagner Free Institute of Science.

WILLIAM M. LESZYNSKY, M.D. . . . . . New York, N. Y.
Consulting Neurologist, Manhattan Eye and Ear Hospital; Neurologist to the Demilt Dispensary, the German Poliklinik, etc.

F. A. L. LOCKHART, M.D. . . . Montreal, Canada.
Lecturer in Gynæcology, McGill University; formerly Professor of Gynæcology, University of Bishops' College; Gynæcologist to Montreal General Hospital and Protestant Hospital for the Insane.

FRANK WORTHINGTON LYNCH, M.D. . Baltimore, Md.
Associate in Obstetrics, Johns Hopkins University, Resident Obstetrician, Johns Hopkins Hospital.

WILLIAM GEORGE MacCALLUM, M.D. . . . Baltimore, Md.
Associate Professor of Pathology, Johns Hopkins University; Resident Pathologist, Johns Hopkins Hospital.

CLARENCE ARTHUR McWILLIAMS, M.D. . New York, N. Y.
Attending Surgeon, Trinity Hospital; Assistant Surgeon, Presbyterian Hospital; Assistant Demonstrator of Anatomy, Cornell University Medical College in New York City.

HARRY T. MARSHALL, M.D. . . . Baltimore, Md.
Assistant in Pathology, Johns Hopkins University.

ALBERT P. MATHEWS, M.D . . . . . . Chicago, Ill.
Assistant Professor of Physiological Chemistry, University of Chicago.

LAFAYETTE BENEDICT MENDEL, Ph.D. . . . New Haven, Conn.
Assistant Professor of Physiological Chemistry, Yale University.

CHARLES SEDGWICK MINOT, M.D., LL.D. . . Boston, Mass.
Professor of Histology and Human Embryology, Harvard University Medical School, Boston.

LOUIS J. MITCHELL, M.D. . . . . Chicago, Ill.
Secretary of the International Association of Railway Surgeons.

DOUGLASS W. MONTGOMERY, M.D. . . San Francisco, Cal.
Professor of Diseases of the Skin, University of California.

BENJAMIN MOORE, M.A. . . . Liverpool, England.
Professor of Biochemistry, University College, Liverpool, England; Formerly Professor of Physiology, Yale University.

HOWARD MORROW, M.D . . . . San Francisco, Cal.
Clinician, Medical Department, University of California; Consulting Physician for Diseases of the Skin, Southern Pacific Railroad Hospital; Consulting Dermatologist, Children's Hospital, San Francisco.

WILLIAM S. MORROW, M.D. . . Montreal, Canada.
Lecturer in Physiology, McGill University; Clinical Assistant in Medicine, Royal Victoria Hospital.

ROBERT C. MYLES, M.D. . . . . . . New York, N. Y.
Attending Surgeon, Polyclinic Hospital, Department of Nose and Throat.

JAMES E. NEWCOMB, M.D. . . . . New York, N. Y.
Instructor in Laryngology, Cornell University Medical College in New York City; Laryngologist to Out-Patient Department, Roosevelt Hospital, New York.

ALBERT GEORGE NICHOLLS, M.D. . . . Montreal, Canada.
Lecturer in Pathology, Medical Department, McGill University; Assistant Pathologist, Royal Victoria Hospital, Montreal.

SAMUEL NICKLES, M.D . . . . Cincinnati, Ohio.
Emeritus Professor of Materia Medica and Therapeutics, Medical College of Ohio.

WILLIAM P. NORTHRUP, M.D. New York, N. Y.
Professor of Pediatrics, the University and Bellevue Hospital Medical College; Attending Physician, Presbyterian, Foundling, Willard Parker, and Riverside Hospitals.

Digitized by Microsoft®

WILLIAM OPHÜLS, M.D. . . . . SAN FRANCISCO, CAL.
Professor of Pathology and Bacteriology, Cooper Medical College; Pathologist to the Lane Hospital and the German Hospital, San Francisco.

EUGENE L. OPIE, M.D., ... BALTIMORE, MD.
Associate in Pathology, Johns Hopkins University.

EDWARD O. OTIS, M.D. . . . . BOSTON, MASS.
www.libtool.com.cn
Professor of Pulmonary Diseases and Climatology, Tufts College Medical School; Visiting Physician to the Free Home for Consumptives, Boston; Physician to the Department of Tuberculosis of the Lungs, Boston Dispensary.

RICHARD MILLS PEARCE, M.D. . . PHILADELPHIA, PA.
Demonstrator of Pathology, University of Pennsylvania.

W. F. R. PHILLIPS, M.D. . . . . . . WASHINGTON, D. C.
United States Weather Bureau, Washington.

N. J. PONCE DE LÉON, M.D. . . . . HAVANA, CUBA.
Deputy Health Officer of the Port of Havana, Cuba; Formerly Instructor in Medicine, Post-Graduate Medical School, New York; and Assistant Visiting Physician, Department of Diseases of Children, Dispensary of Cornell University Medical School.

GEORGE M. PRICE, M.D. . . . . . NEW YORK, N. Y.
Medical Sanitary Inspector, Health Department of the City of New York.

JAMES J. PUTNAM, M.D. . . . . BOSTON, MASS.
Professor of Diseases of the Nervous System, Harvard University Medical School.

LEOPOLD PUTZEL, M.D. . . . . . . NEW YORK, N. Y.

CHARLES E. QUIMBY, M.D. . . . NEW YORK, N. Y.
Formerly Professor of Medicine, the University and Bellevue Hospital Medical College; Visiting Physician, City Hospital.

OTTO GUSTAF RAMSAY, M.D. NEW HAVEN, CONN.
Professor of Obstetrics and Gynæcology, Yale University; Obstetrician to the New Haven Hospital.

JOSEPH RANSOHOFF, M.D. . . . CINCINNATI, OHIO.
Professor of Anatomy and Clinical Surgery, Medical College of Ohio; Surgeon to the Cincinnati, Good Samaritan, and Jewish Hospitals, Cincinnati.

CHARLES RICE, PH.D.*. . . . . . NEW YORK, N. Y.
Formerly Chemist of Department of Public Charities and Correction, New York City; and Chairman of Committee of Revision and Publication of the Pharmacopœia of the United States of America.

GEORGE L. RICHARDS, M.D. . . FALL RIVER, MASS.
Otologist and Laryngologist, Fall River Union Hospital.

HUNTINGTON RICHARDS, M.D. . . CONCORD, N. H.

CHARLES W. RICHARDSON, M.D. . . WASHINGTON, D. C.
Professor of Laryngology and Otology, Columbian University, Washington, D. C.

C. EUGENE RIGGS, M.D. . . . . . . ST. PAUL, MINN.
Professor of Nervous and Mental Diseases, Medical Department, University of Minnesota; Neurologist to St. Luke's, St. Joseph's, City and County Hospitals, St. Paul.

LOUIS WARNER RIGGS, PH.D. NEW YORK, N. Y.
Instructor in Chemistry and Physics, Cornell University Medical College in New York City.

WILLIAM CABELL RIVES, M.D. . . WASHINGTON, D. C.
Formerly Visiting Physician to the Newport Hospital, Newport, R. I.

HUNTER ROBB, M.D. . . . . CLEVELAND, OHIO.
Professor of Gynæcology, Western Reserve University; Gynæcologist-in-Chief to the Lakeside Hospital, Cleveland.

ISABEL HAMPTON ROBB. . . . NOTTINGHAM, OHIO.
Late Superintendent of Nurses and Principal of Training School of Johns Hopkins Hospital, Baltimore, Md.

J. WEST ROOSEVELT, M.D.*. . NEW YORK, N. Y.
Formerly Visiting Physician, Bellevue and Roosevelt Hospitals.

THOMAS MORGAN ROTCH, M.D. . . BOSTON, MASS.
Professor of the Diseases of Children, Harvard University Medical School; Physician to the Infants' Hospital, Boston; Physician to the Children's Hospital, Boston.

HENRY H. RUSBY, M.D. . . . . NEWARK, N. J.
Professor of Botany, Physiology, and Materia Medica, New York College of Pharmacy; Professor of Materia Medica, University and Bellevue Hospital Medical College.

WILLIAM EDWARD SCHROEDER, M.D. . CHICAGO, ILL.
Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Cook County, Wesley, and Provident Hospitals, Chicago.

R. J. E. SCOTT, M.D. . . . . NEW YORK, N. Y.
Attending Physician, Bellevue Hospital, Out Patient Department; Gynæcologist, Demilt Dispensary, New York.

FRANCIS J. SHEPHERD, M.D. . . . . MONTREAL, CANADA.
Professor of Anatomy and Lecturer on Operative Surgery, Medical Department, McGill University; Senior Surgeon, the Montreal General Hospital.

BEAUMONT SMALL, M.D. . . . . . . OTTAWA, CANADA.
Attending Physician, St. Luke's General Hospital, Ottawa; Consulting Physician, the Children's Hospital; Late Examiner in Materia Medica, College of Physicians and Surgeons, Ontario.

ANDREW HEERMANCE SMITH, M.D. . NEW YORK, N. Y.
Emeritus Professor of the Practice of Medicine, New York Post Graduate Medical School; Attending Physician, Presbyterian Hospital; Consulting Physician, St. Luke's Hospital, New York.

S. EDWIN SOLLY, M.D., M.R.C.S. ENG. . . COLORADO SPRINGS, COL.
Ex-President of the American Climatological Association.

BRIG.-GEN. GEORGE M. STERNBERG. . WASHINGTON, D. C.
Surgeon General, United States Army, Retired.

THOMAS D. SWIFT, M.D.*. . . . . NEW YORK, N. Y.
Formerly Visiting Physician, Demilt Dispensary, New York.

HENRY LING TAYLOR, M.D. . . NEW YORK, N. Y.
Professor of Orthopedic Surgery, New York Post Graduate Medical School and Hospital; Assistant Orthopedic Surgeon, Hospital for Ruptured and Crippled; Consulting Orthopedic Surgeon, New York State Epileptic Colony, Sonyea, N. Y.

HENRY SWIFT UPSON, M.D. . . CLEVELAND, OHIO.
Professor of Diseases of the Nervous System, Western Reserve University; Attending Physician, the Lakeside Hospital, Cleveland.

Digitized by Microsoft®

ALBERT VANDER VEER, PH.D., M.D.... ALBANY, N. Y.
Professor of Didactic, Abdominal, and Clinical Surgery, Albany Medical College; Attending Surgeon, Albany Hospital; Consulting Surgeon, St. Peter's Hospital, Albany.

FREDERICK HERMAN VERHOEFF, M.D.... BOSTON, MASS.
www.libtool.com.cn
Pathologist, Massachusetts Charitable Eye and Ear Infirmary; Assistant in Pathology, Harvard University Medical School; Assistant Ophthalmic Surgeon, Carney Hospital, Boston.

JAMES DITMARS VOORHEES, M.D ..NEW YORK, N. Y.
Instructor of Obstetrics, College of Physicians and Surgeons, Columbia University; Assistant Attending Physician, Sloane Maternity Hospital, New York.

HENRY BALDWIN WARD, PH.D. . LINCOLN, NEB.
Dean of the College of Medicine and Professor of Zoology, the University of Nebraska.

ALDRED S. WARTHIN, M.D... ANN ARBOR, MICH.
Junior Professor of Pathology, Medical Department, University of Michigan.

GEORGE A. WATERMAN, M.D...... BOSTON, MASS.
Assistant in Neurology, Harvard University Medical School; Assistant Physician, Neurological Department of the Massachusetts General Hospital; Assistant Visiting Neurologist to Long Island Hospital, Boston Harbor.

GROVER W. WENDE, M.D....... BUFFALO, N. Y.
Clinical Professor of Dermatology, University of Buffalo; Physician for Diseases of the Skin at the Erie County Hospital, the Hospital of the Buffalo Sisters of Charity, and the German Hospital.

FRANK FAIRCHILD WESBROOK, M.D.... MINNEAPOLIS, MINN.
Professor of Pathology and Bacteriology, University of Minnesota; Director of the Minnesota State Board of Health Bacteriological Laboratory.

CHARLES JAMES WHITE, M.D. . BOSTON, MASS.
Instructor in Dermatology, Harvard University Medical School; Assistant Physician to the Skin Department, Massachusetts General Hospital.

JOSEPH H. WHITE, M.D...... WASHINGTON, D. C.
Assistant Surgeon General, Public Health and Marine Hospital Service of the United States.

HAROLD WILLIAMS, M.D.......... BOSTON, MASS.
Professor of Theory and Practice of Medicine, Tufts College Medical School; Physician to Boston Dispensary.

HERBERT U. WILLIAMS, M.D.... BUFFALO, N. Y.
Professor of Pathology and Bacteriology, Medical Department, University of Buffalo, N. Y.

JOHN C. WISE, M.D. .... WASHINGTON, D. C.
Medical Director, United States Navy.

RUDOLPH A. WITTHAUS, M.D..NEW YORK, N. Y.
Professor of Chemistry, Physics, and Toxicology, Cornell University Medical College in New York City.

ALFRED C. WOOD, M.D...... . PHILADELPHIA, PA.
Demonstrator of Surgery and Instructor in Clinical Surgery, University of Pennsylvania; Assistant Surgeon, Hospital of the University of Pennsylvania; Attending Surgeon, the Philadelphia, St. Timothy's, and St. Agnes's Hospitals, Philadelphia.

FRANCIS CARTER WOOD, M.D . NEW YORK, N. Y.
Instructor in Clinical Pathology, Columbia University; Pathologist to St. Luke's Hospital, New York.

PHILIP ZENNER, M.D.......... CINCINNATI, OHIO.
Clinical Lecturer on Diseases of the Nervous System, Medical College of Ohio.

A REFERENCE HANDBOOK

OF

THE MEDICAL SCIENCES.

MOSS, CORSICAN.—*Mousse de Corse*, Codex Med.; *Helminthocorton*, Worm Moss, etc. The alga properly known by this name is *Alsidium Helminthocorton* Ag. (order *Florideæ*), a small, brown, marine plant, with a tufted thallus of simple or sparsely forked, pointed, thread-like branches, from 3 to 4 cm. long. It is a native of the Mediterranean Sea, and was formerly collected on the shores of the island of Corsica, from which it receives its name. The anthelmintic mixture, however, still to be found in European pharmacies under this name, includes, besides this, several other related algæ, among which species of *Ceramium*, *Polysiphonia*, *Gigartina*, etc., are commonly met with. There is nothing unusual in the composition of any of the above to explain their former reputation as vermicides; they contain iodine, bromine, soda, etc., in composition, and an abundance of vegetable jelly.

As a medicine Corsican moss is of the past. A decoction is occasionally given to children as a domestic remedy for lumbrici, etc. *W. P. Bolles.*

MOSS, ICELAND.—Cetraria. "Cetraria Islandica (L.) Ach. (Class *Lichenes*)" (U. S. P.). This is a good-sized terrestrial lichen, with an upright or ascending, long and narrow, leathery, wavy-margined, olive-green thallus, several times dichotomously branched or irregularly fan-shaped, with linear or cuneiform lobes. *Apothecia* shield-shaped on the upper surface of the thallus. This lichen grows in great abundance on the surface of the ground in open woods and heaths, and on mountain sides, in the arctic and the colder temperate regions of both hemispheres.

It is a valuable pasture plant in the extreme North, and is also employed as an article of human food in parts of northern Europe. Its medical employment is one or two centuries old.

Dried Cetraria is thus described:

From 5 to 10 cm. long, foliaceous, irregularly branched into fringed and channelled lobes, brownish above, whitish beneath, and marked with small, depressed spots; brittle and inodorous; when softened in water, cartilaginous, and having a slight odor; its taste is mucilaginous and bitter.

It should be freed from pine leaves, mosses, and other lichens, which are frequently found mixed with it.

Composition.—About two-thirds of it is *Lichenin* or *moss starch* $(C_6H_{10}O_5)_n$, a starch-like substance, structureless, soluble in boiling water, the solution gelatinizing upon cooling. It is an article of commerce as a gelatinous mass or a white powder. The properties of this substance are purely demulcent. *Cetrarin* or *cetraric acid* $(C_{18}H_{16}O_8)$ is the bitter principle, and gives to the drug its slight medicinal properties. It occurs in commerce in white masses of fine needle-shaped crystals, soluble in boiling alcohol, in alkalies, and very slightly in water. It is distinctly stomachic, like other bitters, and antiemetic. It also has the distinct property of increasing the red corpuscles of the blood. It is therefore in an exceptional manner tonic. Isolichenin is very similar to lichenin, but gives the starch reaction with iodine. It is apparently not active.

Iceland moss is a very useful demulcent, and has gentle tonic qualities, for which it is indebted to the two active principles above mentioned. It has no specific action upon the bronchi or lungs, and its value in bronchitis, etc., for which it is mostly prescribed, must be due to its combined demulcent and tonic actions. Dose, indefinite; a decoction is official.

Cetrarin is given alone for all except the demulcent properties, in doses of 0.01 to 0.02 gm. (gr.ij.–v.).

Henry H. Rusby.

MOSS, IRISH.—Chondrus. *Carrageen*. "*Chondrus crispus* Stackhouss, and *Gigartina mamillosa* J. Agarch (class *Algæ*)" (U. S. P.). A reddish-brown or purplish alga, with a flat, many-times forked or lobed thallus, of very variable appearance, sometimes with broad, flat, wedge-shaped, wavy, and incised, margined lobes, at other times with linear, roundish, blunt, or emarginate ones. It is from 5 to 20 cm. high, of a translucent, gelatinous consistence. The fructifications (cystocarps) are embedded in the substance of the thallus, along the smaller branches, where they can be felt as little, wart-like indurations beneath the surface. This alga grows abundantly along the rocky shores of Western Europe

Fig. 3575.—Irish Moss. (Luerssen.)

Digitized by Microsoft®

and Eastern America, that is, on each side of the North Atlantic. It has for a long time served as an innutritious food, and as the basis of vegetable jellies for the table; it is also, in some localities, fed to cattle, and used as a stuffing for cheap mattresses. Its employment in medicine is of recent date, and entirely unimportant. It is collected on the c[illegible]where in Europe, also upon that of New England and elsewhere in America. For medical or table use it is bleached in the sun, washed, and dried.

www.libtool.com.cn

Description.—Irish moss shrinks considerably in drying, and if exposed to the sun, or repeatedly wet and dried, bleaches to a yellow color. It is, when dry, hard, horny, and brittle, but resumes its original size and consistence after long soaking in water. In boiling water it almost completely dissolves. Taste mawkish, mucilaginous, and more or less saline, according to the thoroughness with which it has been cleansed. It will make a stiff jelly with twenty or thirty times its weight of water.

Composition.—Chondrus consists chiefly of a mucilage, common also to many other algæ, swelling and nearly dissolving in water, and drying to a hard, transparent substance. It is precipitated by alcohol, and holds tenaciously about one-seventh its weight of mineral matter. It contains, in common with other marine algæ, minute quantities of iodine and bromine compounds.

Medical Employment.—For colds, coughs, and especially acute pharyngitis, a thin mucilage (decoction) made of Irish moss is a popular household remedy, and corresponds exactly with the mucilage of elm and flaxseed, made in the same way. It may be sweetened and flavored with lemon. Boiled with milk it makes an agreeable jelly ("blanc-mange"), often used as a sick diet, whose value depends on the milk.

W. P. Bolles.

MOSSES.—(Class *Musci.*) The true mosses, while very ornamental, and of great biological and botanical interest, are insignificant from an economic standpoint, while to the Materia Medica they yield not one important substance. Some of them, like Sphagnum and Polytrichum, have, upon totally unscientific grounds, been used domestically in menstrual disorders. Others, like *Funaria hygrometrica* Hedw., have some reputation as expectorants, the effect probably depending chiefly upon the syrup used as a vehicle. Many have been very useful, in the absence of more refined agents, as substitutes for tow, oakum, and lint. The preceding, much used under the title of Mosses, are not of this class at all.

Henry H. Rusby.

MOUNTAIN SICKNESS. See *Altitudes, High.*

MOUNTAIN SPRINGS.—Lancaster County, Pennsylvania.

Post-Office.—Ephrata. Hotel.

Access.—Viâ Reading Railroad. Trains leave Reading Terminal, at Twelfth and Market Streets, Philadelphia, daily, except Sundays, at 10 A.M. and 4 P.M., arriving at the springs at 12 41 and 6:45 P.M.

This pleasant resort is located on the western slope of the Ephrata Mountain, one of the highest points of land in Lancaster County. Many charming features of climate and scenery are united here. The visitor will find pure air, a comfortable and well-kept hotel, excellent fishing, and delightful surroundings at this summer resting-place. The water of the Mountain Springs is celebrated for its purity and sparkle. It has not been analyzed, but we are credibly informed that it contains iron and carbonic acid gas. The springs discharge about three thousand gallons per hour. *James K. Crook.*

MOUNT CLEMENS MINERAL SPRINGS.—Macomb County, Michigan.

Post-Office.—Mount Clemens. Hotels.

Access.—From Detroit viâ Chicago and Grand Trunk Railroad, twenty miles northeast. These waters are very strong brines, as shown by the following analyses made by Prof. S. P. Duffield:

One United States Gallon Contains:

Solids	Mount Clemens Mineral Well. Grains.	Media Spring. Grains.	Soolbad Spring. Grains.
Calcium carbonate	0.98	91.0	Trace.
Magnesium carbonate	.7	.7	Trace.

Carbonic acid	5.85		
Nitrogen	Present.		

These waters resemble those of Achsel-Mannstein, in Bavaria. It is necessary to dilute them both for internal use and for bathing. They have acquired considerable reputation in the treatment of scrofulous disorders of the skin, bones, and joints, and for the improvement and even cure of paralysis when the disease depends chiefly upon innervation without decided lesion of the brain or spinal cord. Cases of chronic rheumatism with stiffened joints and obstinate cases of neuralgia may also find relief. The waters are used commercially.

James K. Crook.

MOUNT DESERT, MAINE.—The island of Mount Desert, the largest one on the New England coast, lies off the coast of Maine, nearly midway between Portland and Eastport, about one hundred and ten miles east of Portland and forty miles southeast of Bangor. It is a very popular summer resort and has wide notoriety.

The island has an area of about one hundred square miles, and is fourteen miles long and eight miles wide at the widest part. A chain of mountain peaks extends across it from southeast to northwest, these peaks being separated from one another by deep gorges and ravines, which at several points descend below the level of the sea.

The average elevation above the sea-level is almost 500 feet, and Green Mountain, the highest point, is 1,527 feet in height. The coast line is bold and rocky and much indented. "Somes Sound," a fiord of the sea seven miles long, runs up to nearly the centre of the island, cutting through the centre of the mountain range. The various indentations, or bays, furnish many good harbors, such as Bass Harbor, Southwest Harbor, Northeast Harbor, Seal Harbor, and Bar Harbor—the finest of all, lying upon the broad Frenchman's Bay.

The island is well wooded with pine, balsam, and spruce, although numerous fires have made sad havoc with the forests. Inland, in the valleys and high up among the mountains, are many beautiful lakes and ponds, the most extensive being Eagle Lake at the foot of Green Mountain, Echo Lake, Jordan's Pond, and Long Pond.

Lying about Mount Desert are numerous smaller islands which are attractive and picturesque, the principal of

Digitized by Microsoft®

which are the Porcupines at Bar Harbor, the Cranberry Islands, near Southwest Harbor, and Bear, Baker's, Duck, Greening's, and Sutton Islands. "The western sides of the mountain range slope gradually upward to the summits, but on the east they confront the ocean with a series of stupendous cliffs" ("Appleton's General Guide to the United States and Canada").

www.ltbtool.com.cn

The island is of granite formation, exhibiting evidences of the great glacial movement; and the soil is dry and porous. On the northern side the mainland is separated from the island only by a narrow stream, and a bridge affords communication between the two. The scenery of the island is most attractive, varied, and grand, affording innumerable delightful excursions by land and by sea. Good roads and footpaths extend in every direction, and in the town of Eden alone there are one hundred and twenty miles of excellent road. The reader is referred to the various guide books for an enumeration and description of the many excursions and various points of interest. Mount Desert has become such a popular resort that every facility is afforded the visitor for enjoying and exploring its beauties. Local steamers run from one point to another of the island; hotels and boarding-houses of various prices abound; and the island can be easily and comfortably reached either by rail or by boat from Boston and Portland.

Bar Harbor is the most frequented and fashionable resort, and the cottage life has quite supplanted that of hotels and boarding-houses. Here beautiful and luxurious cottages abound, and in the season the social life resembles that of New York or Philadelphia in winter.

Every kind of outdoor and indoor diversion is afforded. There are many clubs and churches of various denominations. The Kebo Valley Club offers opportunities for golf on its attractive grounds, and sometimes during the summer the North Atlantic Squadron pays a visit to Bar Harbor, and during "Squadron Week" social gayety is at its height.

The water supply of Bar Harbor is taken from Eagle Lake, two hundred and forty feet above the village, and is abundant and pure. There is also an extensive and thorough system of sewerage. There are adequate protection against fire; many shops and good markets; excellent postal, telegraph, and telephone accommodations; two banks; a good police force; an intelligent and efficient board of health, and good medical service. The streets are lighted by electricity, which is also furnished to private residences.

Northeast Harbor and Seal Harbor are much frequented by "cottagers," and at the former is the attractive Episcopal Church founded by Bishop Doane of Albany. Southwest Harbor is beautifully situated at the entrance to Somes Sound, and is a favorite resort for those desiring a more quiet and simpler life. Indeed, almost any portion of the island has its especial attractions for the summer resident, and one can visit the island year after year and always find some new portion to explore. "On the coast of America it (Mount Desert) has no rival, except, perhaps, at the bay of Rio Janeiro" (Appleton, *loc. cit.*).

Through the kindness of William Miller, Esq., of Bar Harbor, who made the observations, and the chief weather forecaster at Boston who placed them at my disposal, the following compilation has been made of the climate of Mount Desert. In general it may be said that the summer climate is a cool, invigorating one, with a fair number of clear days and the average amount of rain for this latitude. Fogs are not infrequent and they sometimes last for several days or even a week.

There are no recorded observations of the humidity, but it cannot be very different from that of Eastport on the same coast, about eighty miles to the northeast. There the average relative humidity for July is 78.7 per cent.; August, 78.9 per cent., and for the year 76.3 per cent. The variations in temperature are considerable, and the air is apt to be chilly and damp. Such a climate would hardly be suitable for the delicate, for those who had a tendency to or were suffering from pulmonary or bronchial troubles, or from neuralgia. For any one who needs the influences of a bracing, cool, summer climate, or for a convalescent from any acute disease, who is well on the road to recovery, it can be recommended. It is also useful in some cases of neurasthenia and insomnia.

Some patients who are subject to hay fever find immunity on the island at one or the other harbors, especially at Northeast Harbor. *Edward O. Otis.*

MOUTH, DISEASES OF. See THE APPENDIX.

MUCOID DEGENERATION. See *Degenerations, etc.*

MUCOUS MEMBRANES: INFLAMMATIONS OF.—The subject of inflammations of the mucous membranes is treated in this article in only a very general way. The specific inflammations (diphtheria, tuberculosis, syphilis, rhinoscleroma, gonorrhœa, erysipelas, influenza) will be discussed under their respective heads; the object of this article being to include only the simple nonspecific forms of inflammation of these structures according to the definition of inflammation as given by Ziegler—namely, a tissue lesion accompanied by circulatory disturbances, an exudate, and tendency toward repair.

ETIOLOGY.—Although inflammations of different mucous membranes have somewhat different etiological factors, all have to a varying degree a common etiology.

The causes of inflammations of the mucous membranes are direct or indirect. Among the indirect causes are changes in temperature, gout, rheumatism, bad hygiene, decayed teeth, diseases of the circulatory, digestive, or respiratory systems, reflex influences, and idiosyncrasy.

The direct causes of inflammations are thermal, electrical, chemical, mechanical, neoplastic, and bacterial.

The application of hot or cold liquids and instruments to the mouth, pharynx, vagina, or urethra may cause a stomatitis, pharyngitis, colpitis, or urethritis. Breathing of hot air may cause a tracheitis or a bronchitis.

Electricity, applied by means of an electrical sound to the œsophagus or urethra, may cause an inflammation of the mucosa.

Certain chemicals, both organic and inorganic, produce inflammation when they come in contact with mucous membranes. The irritating substance may be mineral acids, alkalies or salts, gases, organic compounds, and

bacterial toxins. Nitric, sulphuric, or hydrochloric acid, sodium or potassium hydroxide, and nitrate of silver will cause a stomatitis, rhinitis, or pharyngitis, and, if the irritants are swallowed, an œsophagitis and gastritis may follow. Gases (hydrogen sulphide, ammonium sulphide, chlorine) cause an inflammation of the respiratory tract or the pharynx. The organic compounds and the toxins produce marked effects on the digestive tract. These poisons are taken into the body as such or they result from decomposition of food or are germ excretions. If the irritation produced by these substances is marked, a gastritis or an enteritis will follow.

www.libtool.com.cn

The mechanical agents which cause inflammation are foreign bodies. Poorly fitting pessaries may cause colpitis, an improper plate in the mouth a stomatitis, or masturbation may cause a urethritis. Trauma of any sort is a direct etiological cause of many non-purulent inflammations of mucous membranes, and is the avenue of entrance of germs, so that it is a predisposing factor of many purulent inflammatory conditions. Of the foreign bodies, dusts of certain trades (mining, marble cutting, painting, milling) cause a chronic inflammation of the respiratory tract. The introduction of foreign bodies into the vagina, uterus, bladder, or nose will produce similar conditions unless they are removed.

Bacteria are the most important etiological agents of inflammation. The germs may be saprophytic or pathogenic, causing inflammation by decomposition, or becoming virulent and pathogenic. The pathogenic bacteria produce inflammation by means of their toxins which act as irritants.

CLASSIFICATIONS OF INFLAMMATIONS OF MUCOUS MEMBRANES.—The factors which enter into inflammatory phenomena are the tissue lesion, circulatory disturbance, the exudate, and the tendency toward repair. Based upon this the following classification of inflammations of mucous membranes is offered.

Inflammations of Mucous Membranes.
- Acute.
  - Catarrhal.
  - Muco-purulent.
  - Purulent.
  - Fibrino-purulent.
  - Fibrinous.
  - Hemorrhagic.
  - Gangrenous.
- Chronic.
  - Hypertrophic.
  - Atrophic.

According to the amount of the reaction on the part of the connective-tissue elements, the general division of inflammations into acute and chronic is made. The term acute is applied to those inflammations in which the fixed connective-tissue cells have not begun to show a reactive change other than the sudden defence needed to protect themselves from the injurious agents. No fibroblasts or angioblasts are seen in sections of such inflammatory processes.

According to the lesion and exudate which they show the acute inflammations of mucous membranes may be divided into catarrhal, muco-purulent, purulent, fibrino-purulent, fibrinous, hemorrhagic, and gangrenous.

Sooner or later, if the irritation causing the inflammation continues, the fixed connective-tissue cells, especially the endothelium, show a reactive change, and form a fibroblastic connective tissue, which later becomes firm scar tissue.

Chronic inflammations of mucous membranes are divided into *hypertrophic* and *atrophic*, depending upon the changes in the mucosæ themselves. Chronic hypertrophic inflammations are characterized by hypertrophy of the epithelial elements of the mucosæ such as occurs in chronic hypertrophic rhinitis or in chronic endometritis. In chronic atrophic inflammations, on the other hand, the glands and epithelial lining cells undergo atrophy such as occurs in chronic atrophic gastritis.

Acute Catarrhal Inflammation.—Any mucous membrane (mouth, nose, pharynx, larynx, etc.) may be the seat of a catarrhal inflammation. On macroscopical examination, the surface of the mucous membrane presents a shiny, glistening coating due to a thick, stringy, more or less homogeneous exudate. Sections of these mucous membranes show that their epithelial cells are swollen and the cell protoplasm is replaced by a finely granular or slightly stringy homogeneous substance (mucin), which stains deeply with Delafield's hæmatoxylin. The nuclei of these cells are pushed to one side or toward the base of the cell and stain faintly with nuclear stains. The epithelial cells lining the glands show a similar change. The submucosa is œdematous and may show an infiltration of leucocytes and few red blood cells. The œdema and the leucocyte exudate may extend into the muscular layers.

FIG. 3376.—Acute Catarrhal Bronchitis. *a*, Ciliated cells; a_1, deep cell layers; *b*, goblet cells; *c*, markedly mucoid cells; c_1, mucoid cells with mucoid nucleus; *d*, desquamated mucoid cells; *e*, desquamated ciliated cells; *f*, layers of drops of mucus; f_1, layer of stringy mucus and pus corpuscles; *g*, excretory duct of a mucous gland filled with mucus and cells; *h*, desquamated epithelium of the excretory duct; *i*, intact epithelium of the excretory duct; *k*, swollen hyaline basement membrane; *l*, connective tissue of the mucosa, partly infiltrated with cells; *m*, dilated blood-vessel; *n*, mucous gland filled with mucus; n_1, lobule of mucous gland without mucus; *o*, migrating cells in the epithelium; *p*, cellular infiltration of the connective tissue of the mucous glands. (Ziegler.)

Acute Muco-Purulent Inflammation.—Change of temperature, some irritating dusts or gases will produce in mucous membranes, especially of the respiratory tract, an inflammation characterized by a light yellow, semitranslucent, slightly stringy fluid exudate which is tenacious and adheres to the mucous membrane. The mucosa is swollen and the vessels are injected. Microscopically the picture presented is the same as that in a catarrhal inflammation, with the exception that a more marked leucocyte infiltration exists in all the layers and the exudate contains more leucocytes than does that of the catarrhal form.

Acute Purulent Inflammation.—Bacteria are the most frequent causes of this form of inflammation of a mucous membrane, but certain foreign bodies and drugs will produce identical phenomena. Foreign bodies in the nose, œsophagus, or bladder will cause a purulent rhinitis, œsophagitis, or cystitis. Turpentine or phenol in the mouth will produce a similar condition, and bacteria will cause a purulent inflammation of any mucous membrane. Macroscopically, the mucous membranes affected with acute purulent inflammation are reddened and swollen

Digitized by Microsoft®

and their surfaces are covered with a thick yellowish or greenish-yellow, semifluid, opaque exudate. Microscopically, the epithelial cells lining the mucosa show a simple coagulation or liquefaction necrosis. The exudate is composed of cell débris, desquamated epithelial cells, and necrosing leucocytes. The connective tissue of the mucosa and submucosa, and often of the muscular layer, shows a marked leucocyte infiltration which may contain a varying number of red blood cells, and the vessels are congested and the connective-tissue fibres are swollen, due to œdema.

www.libtool.com.cn

Acute Fibrino-Purulent Inflammation.—The same agents which cause a purulent inflammation may cause a fibrino-purulent condition, depending upon the lesion produced. Cystitis which follows sounding of the bladder or results from an enlarged prostate or from calculi is very frequently a fibrino-purulent inflammation; and a foreign body in the vagina or rectum may cause a similar condition. The mucous membrane is covered by a yellowish-gray or greenish, tenacious exudate which adheres to the surface and when it is pulled off leaves a reddened surface. The mucosa is thickened and reddened, and the submucosa and muscular coats are œdematous and congested. Sections of the organ affected with fibrino-purulent inflammation show an exudate made up of a varying amount of stringy, granular, or hyaline fibrin, which forms a network enclosing desquamated epithelial cells and collections of necrosed or necrosing leucocytes. The epithelial cells of the mucosa are desquamated and show fatty degeneration, cloudy swelling, or necrosis. In the subepithelial connective tissue of the mucosa and in the submucosa are masses of leucocytes which may be degenerating and which are surrounded by œdematous connective-tissue fibres.

Acute Fibrinous Inflammation.—The ordinary pus germs in the rectum, vagina, mouth, pharynx, or nose may produce an acute fibrinous inflammation. Fraenkel's pneumococcus and Friedländer's pneumobacillus will produce on the tonsils and in the pharynx, larynx, and nose a similar condition; furthermore, this form of inflammation is the cause of death in cystitis due to enlargement of the prostate or to calculi, and fibrinous proctitis or enteritis may follow prolonged rectal feeding in cachectic individuals. The difference between this form of inflammation and fibrino-purulent inflammation is shown in the character of the membranous exudate. In the

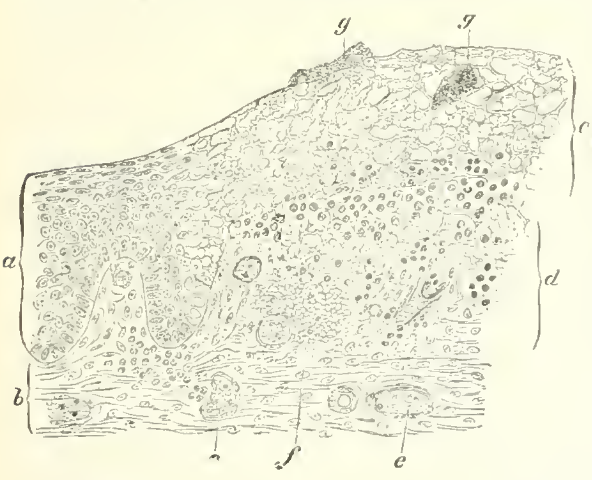

FIG. 3377.—Acute Fibrinous Inflammation of the Uvula. *a*, Normal epithelium; *b*, connective tissue of the mucous membrane; *c*, reticulated fibrin; *d*, connective tissue of the mucosa infiltrated with fibrin and round cells, and partly necrotic; *e*, blood-vessels; *f*, hemorrhage; *g*, masses of micrococci. (Ziegler.)

former the color of the membrane is pearly white or light yellow streaked with red, and the membrane itself is spongy and adherent to the surface, and when it is forcibly removed it leaves a reddened surface, usually differing from the diphtheritic membrane due to the Klebs-Loeffler bacillus in the fact that the latter can be withdrawn only with great difficulty and leaves a depressed surface which looks like an ulcer. Microscopically, the mucous membrane which is the seat of an acute fibrinous inflammation is covered with an exudate composed of granular, stringy, or hyaline fibrin, which forms a firm network enclosing few leucocytes, red blood cells, and desquamated epithelium. The epithelial cells lining the mucosa show a simple or coagulation necrosis, and

FIG. 3378.—Chronic Atrophic Enteritis. *a*, Glandular layer reduced to one-half its height; *b*, muscularis mucosæ; *c*, submucosa; *d*, muscularis; *e*, mucous membrane entirely atrophied. (Ziegler.)

the nuclei do not stain; fine threads of fibrin separate the epithelial cells and extend deep into the submucosa; leucocytes and red blood cells are scattered throughout the mucosa and submucosa and to a slight extent in the muscular layers, and the connective tissue of all the layers is markedly œdematous.

Acute Hæmorrhagic Inflammation.—The poisons produced by putrefaction outside of, and taken into, the body, cause a hemorrhagic gastritis and enteritis. Turpentine and croton oil in large doses produce a similar condition. The mucosæ vary in color from dark red to brown and are greatly swollen, and the contents of the stomach and intestine are streaked with fresh and decomposed blood. Microscopically, the epithelial cells lining the lumina show cloudy swelling, fatty degeneration, simple necrosis or coagulation necrosis; the spaces between the epithelial cells are occupied by œdema and red blood cells, the connective tissue of the mucosa and submucosa shows a varying number of red blood cells scattered or collected in small masses, and all the blood-vessels are greatly congested.

Acute Gangrenous Inflammation.—The bronchi frequently become the seat of this form of inflammation; in some of the cases the disease having originated by the penetration of an ulcer from an œsophageal diverticulum into the bronchi, while in others it represents a simple extension of a gangrenous process in the lung. The presence of foreign bodies in the nose, œsophagus, or vagina, or the occlusion of the nutritive vessel of any mucous membrane, or a simple trauma may eventuate in an acute gangrenous inflammation. The condition is accompanied by foul odors, caused by hydrogen sulphide, ammonium sulphide, etc. The mucosa in the early stages resembles that of acute purulent inflammation, with the exception that the pathological changes are more marked. In the later stages the mucosa may slough away and the necrosis may be so extensive that the deeper layers are involved.

Chronic Hypertrophic Inflammation.—This form of inflammation is most often found in the uterus, but hypertrophic rhinitis is common. The mucous membrane is thickened and varies in color from gray to gray-pink; the glands of the affected mucous membrane become hypertrophic and some become cystic; and, finally, the connective tissue of the mucosa becomes increased in bulk.

Chronic Atrophic Inflammation.—The prolonged use of alcohol will cause this condition in the stomach, and caries of some part of the bony framework of the nose or the mere presence of a foreign body somewhere in the nasal cavities is competent to produce chronic atrophic rhinitis. The mucosæ are thin and in the stomach the outer layers become atrophic; the glands of all surfaces

Digitized by Microsoft®

affected show marked atrophy and their epithelial cells show mucous degeneration; and the connective tissue of the mucosa and submucosa is greatly increased and may cause constriction of the lumina of some glands. In the latter event these glands become cystic, and the muscular coats undergo marked atrophy.

Frederick H. Baldwin.

MULLEIN. See *Scrophulariaceæ.*

MULTIPLE PROGRESSIVE HYALOSEROSITIS.—DEFINITION.—An inflammatory affection of the serous membranes, of chronic and progressive development, characterized by a peculiar overgrowth of fibrous tissue with hyaline metamorphosis.

This disease is a very remarkable one, and, judging from published cases, somewhat rare. Examples have been recorded in Germany and Austria chiefly by Hamboursin,[1] Weiss,[2] Curschmann,[3] Vierordt,[4] Riedel,[6] Rumpf,[7] Pick,[8] Schupfer,[9] Siegert,[10] Schmaltz and Weber,[11] Rose,[12] Strajesko;[14] in England by Hale White[5]; in America by Nicholls[15] and Herrick.[16] It is only lately that a complete study of this disease has been attempted (Nicholls), and now that special attention has been called to it we may expect in the near future to have many more cases recorded, for the disease is probably not so rare as has been thought.

The affection may begin in various ways, so that differing clinical types are produced. Sometimes the capsule of the liver is chiefly affected, and it is to this class of cases that the terms "diffuse chronic hyperplastic perihepatitis," "chronic deforming perihepatitis," "Zuckergussleber," have been applied. In other cases it is the pericardium or the pleura that is first involved. Nevertheless, in whatsoever way the disease may begin, or in whatever part it may attain its greatest intensity, it is to be noted that the process is everywhere essentially the same, since it becomes diffuse and involves one serous membrane after another in a steady progression. Consequently the term *multiple progressive hyaloserositis*, denoting as it does an inflammatory process at once chronic and continuous, and emphasizing the peculiar hyaline change which is so striking an element in the anatomical picture, is perhaps the most suitable term to employ.

DISTRIBUTION.—The disease appears to be widely disseminated, being found in all countries and all climes; sex appears to have but little importance; the cases hitherto recorded have been chiefly in males. With regard to age, the youngest patient affected was aged four, the oldest eighty years; those below middle age are probably the most likely to be affected.

FIG. 3379.—Section of Liver, Showing well the Glisson's Capsule Thrown into Folds, with the Deposit of Hyaline Fibrous Tissue upon the Surface. (Nicholls.) (Winckel objective No. 5, without eyepiece.)

MORBID ANATOMY.—Two types of the affection have been described, the sporadic and the diffuse. Except for peculiarities in localization and extent, these forms are, anatomically speaking, essentially the same. The characteristic lesion is the formation of isolated nodules or continuous sheets upon the serosæ of a pearly white material having a dense, cartilaginous consistency. This substance has been compared to the sugar upon a cake (*Zuckerguss*) and to porcelain. When forming a definite membrane it varies in thickness from a few millimetres to from 1 to 5 cm., and can be readily stripped off the subjacent organs without injury to their substance. On section the membrane has a semitranslucent, almost gristly appearance.

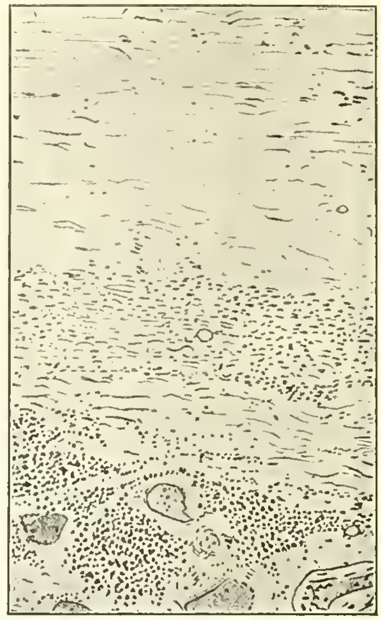

FIG. 3380.—Section of Peritoneal Membrane in the "Zuckerguss" condition, Showing Perivascular Leucocytosis and Hyaline Degeneration of the Superficial Fibrous Tissue. (Nicholls.) (Camera lucida drawing; Reichert objective No. 3.)

In the sporadic form the material usually forms flattened plaques, but may occur in elevated or even polypoid nodules. The favorite sites of localization are the capsules of the spleen and liver, the diaphragm, and the pleuræ. When affecting, as the process usually does, more than one serous sac, no order of involvement is absolute, but combinations are numerous.

With regard to the diffuse form, in the majority of cases the capsules of the liver and spleen, the pericardium and the lower portions of the pleuræ are involved. It is the rule also for more or less implication of the general peritoneum to occur. This results in induration and contraction of the great omentum and the mesentery; the omentum is frequently converted into an irregular tumor-like mass or a thick fibrous cord crossing the abdomen transversely. The contraction of the mesentery leads to dislocation of the intestines so that they lie bunched up along the spinal column. Bands of adhesions, fibroid and velamentous in character, are found connecting adjacent structures and are likely to be met with between the liver and spleen and the diaphragm and between the coils of intestines. While all or most of the serous membranes are involved in the process, they do not all present the same grade of affection. Thus, while one membrane presents the typical "icing" appearance, the other serous sacs may be obliterated by simple fibroid adhesions or traversed by bands, or in other cases may contain a fibrinous or fibrino-purulent exudation.

In the perihepatic form, where the brunt of the disease falls upon the liver and diaphragm, the liver is usually diminished in size and much altered in shape, becoming somewhat globular; the edges are rounded and the anterior border is often rolled back upon the upper surface. The gall-bladder is usually contracted and enclosed in a dense mass of hyperplastic tissue. The surface of the liver, after the investing crust is removed, which may readily be done, is smooth or at most slightly uneven. On section the organ usually shows brown atrophy, fatty degeneration, with some passive congestion. Cirrhosis of the organ does not occur as a rule; at most there is a slight thickening of the septa passing in from the capsule. The spleen is often enlarged, generally covered with the "icing" membrane, and deformed. With regard to the pleuræ, the right is as a rule more seriously involved than the left; the bases of the sacs are the sites of election

Digitized by Microsoft®

for the process. The lungs are usually atrophied and partially collapsed. Chronic adhesive pericarditis, or, more correctly, mediastino-pericarditis, is frequently found. More rarely an acute exudative pericarditis is present, and more rarely still the pericardium may be normal. Occasionally the pericardial sac is only partially obliterated, and when the adhesions are denser on the right side toward the diaphragmatic surface. Calcareous deposits are sometimes met with in the adhesions. The heart is often small and may show the results of pericardial adhesion, namely, dilatation and insufficiency of the valves.

www.libtool.com.cn

The kidneys in most instances show no special abnormality except possibly congestion. In a few cases interstitial fibrosis has been found. The digestive tract shows but little disturbance; the stomach and colon may be found adherent to adjacent parts. A duodenal ulcer was found in one case. Icterus is never present, unless the case is complicated by cirrhosis of the liver or by obstruction to the common bile duct. As complicating conditions which hasten the fatal termination, acute pneumonia, pericarditis, pleurisy, peritonitis, and osteomalacia may be mentioned. A striking feature of the diffuse form is ascites, which is usually extreme. The ascitic fluid is of pale straw color, high specific gravity, containing flakes of fibrin, and has all the appearances of an inflammatory exudate. Anasarca is usually not marked until toward the end.

In addition to the form just described it should be stated that an increasing number of cases of serositis of this hyperplastic type are being reported as due to tuberculosis. It is beginning to be recognized that tuberculosis is not necessarily destructive, but, on the contrary, may be constructive;—instead of extensive caseation and softening we may have the formation of a hyperplastic hyaline membrane with little or no caseation. In many cases it is only the discovery of the specific bacillus which will reveal the true nature of the process. It used to be thought that cases of the perihepatic or "Zuckergussleber" type, to which Curschmann first drew attention in his classical paper, were never due to tuberculosis; but this is certainly incorrect. Recently Strajesko (*loc. cit.*) and James B. Herrick (*loc. cit.*) have recorded typical cases undoubtedly of tuberculous origin.

Hyperplastic tuberculosis of the serous membranes is in my experience not very uncommon, but it is certainly rare for it to attack the capsule of the liver, the pericardium, and the right pleura in such a way as to simulate Curschmann's "icing" liver and atrophic cirrhosis. The lesions produced are not unlike those of the simple or non-tuberculous form, the main difference being that the process is not so liable to be concentrated on any special organ, but is more generalized over the serosæ. Again, ascites is usually less marked and fibroid adhesions are more numerous. The membrane produced is rarely smooth and glistening, but is covered with fibrin and shaggy adhesions. A hypertrophic fibro-hyaline membrane may be produced also in this form, but in it caseous masses can generally be made out, disclosing the etiology of the case; the caseation may, however, be very trifling.

FIG. 3381.—Tuberculous Perihepatitis. The illustration shows the thick hyaline and caseous membrane produced in the chronic hyperplastic type. (Nicholls.)

Microscopically the membrane in the simple form is composed of parallel laminæ of connective tissue showing marked hyaline thickening of the fibrillæ. In the deeper portions newly formed capillaries can be made out with some perivascular leucocytosis, and "Mastzellen" are numerous. *Macroscopically* the membrane has all the appearance of an organizing deposit upon the serosæ,—a deposit in which hyaline degeneration constitutes the most striking feature. In the tuberculous form the connective-tissue fibrillæ interlace freely, and there are usually multiple areas of caseation with numerous giant cells. Hyaline degeneration is also present, but is rarely so marked as in the simple form. Tubercle bacilli can usually be demonstrated readily on making smears from the deposit.

In the tuberculous form, unlike the first variety, the liver is usually enlarged and often shows signs of miliary tuberculosis with slight interstitial fibrosis. Old tuberculous foci are usually found in the lungs, pleuræ, and peribronchial glands. The case often terminates with a generalized miliary infection.

Etiology and Pathogenesis.—Two views have been advanced as to the causation of the disease. The first is that of Pick, who regards the primary condition as an adhesive pericarditis which leads to portal obstruction and the so-called "cardiac" cirrhosis of the liver, eventually resulting in ascites and thickening of the liver capsule. The objections to Pick's view briefly are, that cases occur in which pericardial adhesion is absent, and in most of the recorded cases it has been shown that portal stasis was not present; nor, again, does the development of the physical signs accord with what should occur were Pick's view correct. It must be said that all those who have carefully studied the question are agreed that the overgrowth of fibrous tissue and the ascites are due to an inflammatory process involving the various serosæ. Most cases give a history of some previous acute inflammatory disease, and the development of the lesions can usually be traced from one serous membrane to another. Cases have been known to follow acute rheumatism, typhoid fever, whooping-cough, measles, malaria, and perityphlitis. The transmission of the infective agents from one serous sac to another takes place by means of the lymphatics. In the tuberculous form, which is anatomically strictly comparable to the simple type, the true nature of the disease is of course obvious. With regard to the ultimate nature of the process in the simple form, some little doubt must still exist; but it is probable that micro-organisms of low virulence are at work.

The inflammatory process usually begins in the peritoneal cavity in the form of a hepatitis or perihepatitis, or, more rarely, about the stomach and duodenum; it extends to the right pleura and eventually to the pericardium. Next in frequency, the primary lesion is a chronic pericarditis with adhesion extending to the right pleura and thence to the peritoneum; more rarely still, chronic pleurisy may extend to the liver capsule. The process is accompanied by an exudation of sero-fibrinous fluid into the abdominal cavity, which fluid tends to be abundant owing to the involvement of the absorptive surface of the peritoneum by the dense fibrous deposit, and also from the fact that the contracting fibrous masses sometimes lead to pressure upon the inferior vena cava and portal vein, thus promoting ascites. The liver gradually diminishes in size, and the spleen becomes enlarged in the later stages when passive congestion be-

Digitized by Microsoft®

comes marked. Gout and alcoholism appear to have little to do with the process. Syphilis has been known to produce chronic adhesive and membranous peritonitis (Lancereaux), but as yet no case of multiple hyaloserositis has been recorded as due to this cause.

Clinical Course.—The sporadic form being entirely of pathological interest and giving rise to no characteristic symptoms may be dismissed from consideration. In the diffuse variety, the most striking clinical symptoms are those to which Curschmann first drew attention, namely, shortness of breath, slight general weakness, and a gradually increasing and refractory ascites. The resemblance to atrophic cirrhosis of the liver is striking. Most cases begin insidiously and give a history of indefinite disturbance from the first, such as anorexia, dyspnœa, and epigastric pain. In other cases the disease begins acutely with fever, rigors, and epigastric pain, during which time the liver region becomes tender and swollen. The affection ultimately becomes chronic and periods of latency alternating with exacerbations are the rule. According to the manner of onset we can recognize two main types: first, the *perihepatic*, and second, the *mediastino-pericardial*.

In the first, after more or less evidence of involvement of the liver capsule, such as pain and tenderness in the right hypochondrium, with or without fever, ascites develops and the liver is found to be enlarged. It is frequently observed later that one or both of the pleural cavities contain fluid, or the mobility of the lungs is impaired by adhesions. Finally, in most cases, although exceptions occur, there develop evidences of adhesion of the pericardium, and dilatation of the veins of the neck, chest, and arms may be noted. As the disease becomes well established the liver becomes smooth, hard, and gradually contracts, while the spleen steadily enlarges and may become palpable. Anasarca appears only in the later stages.

In the second type, the earliest signs are referable to an indurative mediastino-pericarditis, namely, pain in the chest, cough, palpitation of the heart, dyspnœa, cardiac dilatation, and possibly the pulsus paradoxus and systolic retraction of the chest wall. Signs of pleural effusion or adhesion appear and the process eventually spreads to the liver capsule. As before, the liver is large and smooth, but contrary to what occurs in the perihepatic form, anasarca is an early, though it may be a transient sign. As time goes on the liver decreases in size and ascites makes its appearance.

In all forms, eventually, paracentesis becomes necessary and must be repeated at gradually diminishing intervals. The condition of the liver and spleen can be made out only after free tapping. Digestive disturbances when present are trifling, such as anorexia, constipation, or diarrhœa; jaundice does not occur in uncomplicated cases. Albuminuria is found occasionally and is attributable to passive congestion of the kidneys. Fever is usually absent except during an exacerbation or complication. The disease is essentially chronic, lasting for from two to sixteen years. The sufferers may not be seriously incapacitated for work for long periods, but the condition proves singularly refractory to treatment and relapses are frequent. Death occurs usually from some acute complication, lobar pneumonia, or peritonitis.

The tuberculous form of the disease, as the cases of Strajesko and Herrick have shown, may occasionally present almost exactly the clinical picture of the "icing" liver of Curschmann's description. Little is known of this form as yet, but, so far as my experience goes, the only differences between the simple or non-tuberculous and the tuberculous forms are, that in the latter the liver remains enlarged to the end, fever is more constant, and the disease tends to run a more rapid course. In fact, most cases of tuberculous origin run a course very similar to that of chronic tuberculous peritonitis, with the addition of evidence of the involvement of the other serous membranes. There is little in the physical signs to suggest a chronic hyperplastic lesion rather than an exudative one in these cases, unless the liver capsule is chiefly involved. Unlike what takes place in the non tuberculous form, ascites is rarely extreme and sacculation of the abdominal fluid is more likely to occur. Usually, too, the disease begins with signs of tuberculous involvement of the lungs, pleuræ, peribronchial glands, or, in the female, the tubes and ovaries.

Diagnosis and Prognosis.—The diagnosis lies between chronic hyperplastic perihepatitis, atrophic cirrhosis of the liver, and carcinoma of the peritoneum, for in all there may be ascites, more or less abdominal pain, and, in most, induration of the great omentum. The combination of extreme ascites with relatively little anasarca, an adhesive pericarditis, pleural exudation, or adhesion, particularly if on the right side, should always arouse a suspicion of multiple progressive hyaloserositis, and especially perihepatitis.

Perihepatitis is differentiated from atrophic cirrhosis by the fact that portal congestion does not occur except

Table of Differential Diagnosis.

Special features.	"Zuckergussleber."	Atrophic cirrhosis of liver.	Chronic tuberculous peritonitis.	Carcinoma of peritoneum.
Age	Occurs about middle life or later.	Oftenest about middle age	Commonest between ages of twenty and forty.	Occurs late in life.
Sex	Slight predominance in favor of males.	More frequent in males	Predominates in females	More frequent in females.
Previous history	Often a history of acute pericarditis or perihepatitis.	History of alcoholism, syphilis, or digestive disturbances.	Often a chronic cough; diarrhœa, or general tuberculosis.	In some cases a history of cancer of stomach or ovaries.
Alcoholism	No influence	Frequently present	Unimportant	Unimportant.
Syphilis	No influence	Occasionally present	Unimportant	Unimportant.
Heredity	No influence	Unimportant	May be family taint	Unimportant.
Incidence	Acute becoming chronic or insidious from the first.	Insidious	Onset may be acute or insidious.	Insidious.
Chronicity	Cases last for years	May last for years	Prolonged	Fairly rapid course, with cachexia.
Fever	Generally absent except during exacerbation or some complication.	May be afebrile; when present is slight.	Usually slight, often absent	Rarely absent; due to complications.
Pain	Indefinite and trifling	Trifling	Apt to be troublesome	Variable.
Digestive disturbance	Trifling or none	Constant; dyspepsia, nausea, vomiting, gastric hemorrhage, melæna.	Fairly common	Often marked.
Ascites	Constant and extreme	Constant	Never extreme; may be absent; may be hemorrhagic.	Moderate grade; may be hemorrhagic or pseudochylous.
Anasarca	Constant but slight	Relatively slight	Trifling	Slight.
Jaundice	Absent in pure cases	Occurs in twenty-seven per cent. of cases.	May occur exceptionally	Common, when liver is involved.
Liver	Not cirrhotic; at first enlarged then small, smooth	Cirrhotic; at first enlarged, then small and warty.	Often enlarged	May be enlarged, with nodules.
Spleen	Gradual enlargement	Gradual enlargement	Nothing special	Nothing special.
Omentum	Thickened and contracted.	Normal	Often matted up	Often matted up.

much later on and is never marked; secondly, severe digestive disturbances, such as dyspepsia, vomiting, hæmatemesis, and melæna, are not present. Jaundice does not occur except in the rare event of a mixed cirrhosis accompanying perihepatitis, a case of which has been recorded by Rose.[12] The liver is never warty; signs due to cholæmia do not occur. Further, the great omentum is nodular and contracted, while in cirrhosis it never is.

www.libtool.com.cn

In carcinoma of the peritoneum, when the liver is enlarged, jaundice is often present, the course is fairly rapid, cachexia and digestive disturbances are marked. There is usually some evidence of cancer of the stomach or ovaries.

Having diagnosed the presence of chronic perihepatitis, it is next necessary to determine if it be tuberculous or not. In the tuberculous form ascites is rarely so extreme; abdominal pain and tenderness are apt to be more marked and the liver is enlarged throughout. Careful examination of the lungs, lymphatic glands, testes, ovaries, and Fallopian tubes, as well as of the urine, fæces, and sputum, should be made. In suitable cases tuberculin injections should be tried. The preceding table presents in a convenient form the main points characterizing the various infections likely to be confused. Diagnosis may, however, be very difficult and often impossible.

The prognosis should be guarded; the disease is essentially chronic and may last for years without seriously incommoding the patient. The simple form is steadily progressive and invariably fatal. The tuberculous form is also practically always fatal, but may possibly heal after suitable interference. Tuberculous cases and those complicated with adherent pericardium run a more rapid course than the others. The special risk to life arises from some intercurrent complication.

Treatment.—No specific medication has been devised. The chief point is to meet the symptoms as they arise. Pain may be relieved by hot fomentations and opium. To relieve the ascites, diuretics have been recommended, notably caffeine in doses of 0.1 to 0.15 gm. six to ten times daily; digitalis and diuretin may be tried. When ascites is extreme, tapping must be resorted to. Some cases, especially the tuberculous forms, may be benefited by laparotomy. Needless to say, the patients must be kept under the best hygienic surroundings.

MUMMIFICATION. See *Necrosis*.

MUMPS.—(Synonyms: Cynanche parotidæa; parotitis; parotiditis; Fr., *Oreillon*; Ger., *Ziegenpeter*.)

Mumps is an acute, infectious disease, self-limited, and characterized by inflammation of the parotid, and sometimes of the submaxillary and sublingual glands, with a tendency to involve the mammæ, testes, and ovaries.

Nature and Etiology.—Mumps prevails widely as an epidemic, and also occurs in the sporadic form.

It is propagated by a specific virus the nature of which has thus far eluded the search of bacteriologists. Numerous organisms have been found in the blood, saliva, and other secretions by Bordas, Capitan, Charrin, Boinet, and others, but the cultures obtained have failed to stand the crucial test of reproduction by inoculation. The disease is communicated by contact with the infected, and by the intermediation of various substances to which the virus adheres. The contagious principle is supposed to be chiefly transmitted by the breath, and is capable of reproducing the disease from the beginning of the parotid swelling up to ten days or two weeks after the fever has subsided. It is highly contagious. When the disease breaks out in schools, children's hospitals, or other institutions where large numbers of young people are congregated, few escape, unless protected by a previous attack. However, the susceptibility is not the same in all individuals.

It is quite rare in infancy and after the middle period of life, occurring chiefly in youth and early manhood. Males are more prone to attack than females. Like the diseases of the class to which it belongs, it rarely occurs more than once in the same individual.

It is more apt to prevail during the winter and spring, but epidemics have been observed at all seasons. Bad hygienic surroundings certainly favor its diffusion.

Morbid Anatomy.—The opportunity for post-mortem examination in cases of mumps, for obvious reasons, is very limited. On this account pathologists differ as to the seat of the morbid process; some locating it in the gland proper, and others in the periglandular connective tissue. Among those who maintain the glandular origin, some hold that it is rather the fibrous stroma which supports the acini than the acini themselves, which are primarily involved.

The weight of authority is in favor of the initial lesion being a catarrhal inflammation of the gland ducts, but the local swelling which gives character to the disease is unquestionably largely due to an infiltration of the surrounding cellular tissue. The swelling disappears by the absorption of the exudation, and only in very exceptional instances does suppuration take place.

Occasionally the glands remain enlarged for a considerable time, and, in very rare instances, the enlargement and hardening are permanent. Atrophy of the parotid and other affected glands has been observed as a result of an attack of mumps.

Symptoms.—The period of incubation varies greatly and is estimated by different authors at from seven to twenty days. Premonitory symptoms are, in most instances, either absent, or so mild as to attract little attention. When present they are those commonly met with in mild febrile attacks: chilliness, hot flushes, languor, anorexia, and sometimes vomiting and diarrhœa.

Very exceptionally the initial symptoms assume a grave character, and the disease is ushered in with high fever, profound depression, persistent vomiting, and, in children so predisposed, with convulsions.

Pain and tenderness in the region of one or both parotid glands, if not present from the beginning of the illness, speedily make their appearance, and are never delayed longer than twenty-four or thirty-six hours. Swelling appears simultaneously with the pain and tenderness. It is at first noticed in the depression between the mastoid process and the ramus of the jaw, and is confined to the gland. The adjacent cellular tissue is soon invaded and the tumefaction extends forward on the face and downward and backward on the neck.

The degree of enlargement varies greatly, being at times moderate and confined to the parotid region, and in other cases involving a large portion of the face and neck. When both parotids are involved and the swelling is fully developed the configuration of the face is peculiarly altered, the lower half of the face being enormously widened and the outline of the chin lost in the œdema of the neck. The swelling is firm, slightly elas-

Digitized by Microsoft®

tic, and moderately sensitive to pressure. The head is fixed with the face directed straight forward, or, if but one parotid is affected, the head will be inclined to the diseased side. The skin usually preserves its natural color, but may be red and glossy. Slight desquamation may take place after the inflammation has subsided.

More or less fever is always present, lasting, in cases of moderate severity, not more than four or five days, but occasionally it is intense, protracted, and attended with delirium and prostration.

The œdema generally extends internally, affecting to a greater or less degree the mucous membrane of the tonsils and pharynx. The secretion of saliva may not be materially altered in quantity, but dribbles continuously from the half-open mouth.

Tinnitus aurium and earache are often experienced, and there may be a temporary or permanent impairment of hearing. The movements of the jaw are, of necessity, greatly impeded and very painful. Speech is difficult, and the voice is husky or muffled.

Mastication and deglutition are almost entirely suspended, the patient enduring the pangs of hunger rather than undergo the suffering required to satisfy his wants.

Mumps usually affects both parotids, but not simultaneously; the left is most frequently the first to become involved, and in from two to four days afterward, or even when the swelling has disappeared, the opposite gland becomes the seat of disease. Not infrequently the affection is limited to one side.

Very often the submaxillary and sublingual glands are affected conjointly with the parotids. Dr. Penzoldt, of Erlangen, records an epidemic of mumps which fell under his observation, in which there were many cases in which the disease process was almost wholly confined to the submaxillary glands.

The swelling reaches its height in from two to five days, remains stationary about forty-eight hours, and then rapidly subsides, making the duration of the attack from ten to fourteen days.

Complications and Sequelæ.—These relate especially to affections of the nervous and glandular systems. The tendency for the inflammation to invade by so-called metastases other and remote glands is a singular and interesting feature of the disease. As was originally pointed out by Niemeyer, it is probably not a true metastasis. The testes in males and the mamma and ovaries in females are the organs of special election. This complication is much commoner in males than in females, and less common in childhood than in adult life. When the testicle is invaded, it becomes swollen and painful, and there is often effusion into the tunica vaginalis, with œdema of the scrotum. Bruising of the testes is said to invite the disease.

The migration may take place at any period of the parotid swelling, which then usually subsides, but occasionally the two inflammations run their course together. Sometimes the inflammation of the parotid disappears suddenly before the advent of the metastatic affection; in this event, alarming constitutional symptoms are liable to supervene. There may be high fever, headache, delirium, or profound collapse, which promptly disappear on the appearance of the local lesion. The new affection runs a course very similar to that of the original disease, and lasts about the same length of time.

Atrophy of the testicles sometimes results, or their function may become impaired from occlusion of the spermatic duct.

Meningitis is in evidence in a very large percentage of the fatal cases of mumps. Various diseases of the nervous system have been recorded as complications (insanity, neuritis, hemiplegia, facial paralysis), but certainly in many, if not most, instances, they were mere coincidences.

Otitis media is not uncommon and occasionally terminates in permanent deafness. In a few cases a complete loss of hearing in one ear takes place without the slightest evidence of the presence of the inflammation in the corresponding middle ear; thus warranting the belief that the lesion—whatever may be its nature—must in these cases be located in the cochlea or in the auditory nerve at some point in its extra-labyrinthine course.

Albuminuria with convulsions has been noted.

Prognosis.—Mumps is a mild though painful disease, and almost invariably runs a favorable course. The inflammation of the parotid rarely leads to the formation of an abscess, contrasting, in this respect, strongly with the non-specific form of parotiditis which occurs in the course of typhoid fever and other maladies.

Occasionally a hard, painless enlargement of the gland is left, which persists for a variable time and disappears, but which in very exceptional instances may be permanent.

The Diagnosis is rarely attended with difficulty. The disease can scarcely be mistaken for any affection other than the non-specific inflammations of the parotid glands, which occur as complications of various constitutional diseases.

The comparative mildness of the general symptoms, the speedy resolution of the swelling, and the epidemic character of mumps, contrast strongly with the preceding severe illness and the inherent tendency to suppuration which constitute the clinical features of the non-specific or symptomatic parotiditis.

Treatment.—The treatment is purely symptomatic. The disease is self-limited and runs a definite course, uninfluenced by the administration of drugs.

The patient must remain indoors, preferably in bed, even in mild cases, until convalescence is assured.

On account of the difficulty in swallowing, the diet should be exclusively fluid. If there should be high fever, a bath or surface sponging with tepid water will be of service. Should there be much pain or restlessness, an anodyne, preferably Dover's powder or chloral, may be prescribed; otherwise refrigerant diaphoretics, such as a solution of bitartrate or citrate of potash, or the neutral mixture of the Pharmacopœia (see under *Potassium*), will meet all of the indications. External fomentations to the neck are both useful and grateful to the patient. Soap liniment, to which a little deodorized tincture of opium may be added, warm olive oil, or the tincture of belladonna and glycerin (ʒ i.–℥ i.), are eligible preparations for external use.

When metastasis to the testes or other glands takes place, the new affection should be treated in the same manner as if it had occurred independently of the parotid inflammation. The writer has obtained excellent results in orchitis from the inunction of guaiacol (ʒ i.) and lanolin (ʒ iij.–iv.). When it is applied from two to four times daily the pain and swelling usually promptly subside. If the onset of the metastasis is heralded by great prostration, or by alarming symptoms of any kind, stimulants must be freely given and warmth applied to the body.

A course of tonics is advisable should convalescence be tardy. *W. J. Conklin.*

MUSCARINE. See *Poisonous Plants.*

MUSCLE.—Histology of Muscular Tissue.—Muscular tissue (Lat., *Tela muscularis;* Ital., *Tessuto muscolare;* Fr., *Tissu musculaire;* Ger., *Muskelgewebe*) is the tissue in the animal body the physiological characteristic of which is its power of contracting in one direction, thus giving rise to definite movements. It is composed of structural elements, the length of which is usually much greater than the breadth. Muscular tissue in some form is present in all the groups of animals, except the *Protozoa.**

Anatomically or morphologically, muscular tissue is of two kinds: (A) *Striated or striped muscular tissue*, that in which the structural elements or fibres are marked by distinct transverse, and usually much less distinct, longitudinal striations. The structural elements are uni- or

* Among the *Protozoa*, the striated ectoplasm of some infusoria and the contractile stalk of *Vorticella* are perhaps physiologically muscular tissue, but they can hardly be so considered anatomically, since these organisms are supposed to be unicellular.

FIG. 3382.—Transection of the Occipitoscapularis Muscle of the Cat, to show the Components of an Ordinary Striated Muscle. The whole muscle and the fascicles were outlined with the camera lucida at a magnification of about twenty diameters. The muscular fibres, the artery, vein, and nerve were not drawn to scale. (Drawn by Mrs. Gage.) *a*, Artery; *em*, endomysium, the connective tissue between the individual fibres; *epm*, epimysium, the connective tissue surrounding the entire muscle and giving off (*pm*) the perimysium, which combines the fibres into bundles of fascicles of various sizes; *ms*, muscle spindle; *n*, nerve; *v*, vein (*cf.* Figs. 3395, 3400).

ments are apparently homogeneous, or marked by fine longitudinal striations only. The elements are mostly uninucleated (Figs. 3406 to 3409).

STRIATED MUSCULAR TISSUE.—This, in man and many of the lower animals, is the so-called flesh or lean meat. It is usually collected into more or less distinct masses, termed *muscles;* and in every case, whether the muscle is in distinct masses or not, it is composed of structural or histological elements, which, when viewed lengthwise under a microscope, are characterized by an appearance of being composed of alternating dark and light segments (Figs. 3383 to 3404); this gives the elements their transversely striated appearance. Physiologically, striated muscle is characterized by the rapidity and energy of its contraction.

Distribution.—Striated muscular tissue is present in all vertebrates and in some members, at least, of all the great groups of invertebrates except the *Protozoa*. Structurally and physiologically, striated muscular tissue in vertebrates is of two kinds: (A) The skeletal, or the so-called muscle of animal life, which is mostly voluntary; (B) the cardiac, or the muscular tissue of the heart, and the other pulsating organs of the blood-vascular system. This is wholly involuntary, and belongs to the tissues of organic life.

Skeletal or Voluntary Muscular Tissue (muscles of animal life).—In man and the mammals, this tissue forms from forty to forty-five per cent. of the entire body weight. Its specific gravity is about 1.058. It is usually collected into distinct muscles, the ends of which are in most cases attached to some firm part (bone or cartilage) by means of fibrous connective tissue.

Distribution: In man and the mammals generally, this tissue forms the muscles of the trunk and extremities, those moving the globe of the eye and all those of the ear, those moving the lips, and those moving the skin (*platysma myoides* in man, the cutaneous muscles over nearly the entire body in many mammals). It is also present in the tongue, pharynx, larynx, the true sphincter of the urethra, and the ectal sphincter of the anus; in mammals possessing them, it is found in connection with Cowper's and the anal glands. In the œsophagus of man, the horse, and some other animals, striated muscle is usually present only in the pharyngeal half; in ruminants, the dog, cat, rabbit, house mouse, rat, and many other animals, it extends to, or nearly to, the stomach; and in the rat it is even continued upon the stomach from the cardiac end of the œsophagus. In many of the lower vertebrates, besides the muscles of the trunk and limbs, striated muscular tissue is found in situations where it is not present in man. *In birds*, in the iris and choroid; *in snakes*, around the poison glands; *in fishes*, in the wall of the stomach of *Cobitis fossilis* and *Syngnathus acus*, and in the intestine of *Tinca chrysitis;* in *amia* it forms a double layer over the surface of the lung-like air bladder, and is present in the trabecula-like cords within it; in *lepidosteus*, it is very abundant in the trabeculæ within the air bladder; in *polypterus* there is present an enclosing sheet of muscle for the air bladder as in *amia*.

Constituents of Striated Muscular Tissue.—These are: (A) the essential and characteristic, elongated and transversely striated muscular fibres (Figs. 3383 to 3396); (B) blood- and lymph vessels (Figs. 3382 and 3396); (C) nerves (Fig. 3382); (D) muscle spindles (Fig. 3400) (E) a considerable quantity of adipose and connective tissue (Figs. 3382 to 3385.) The connective tissue of a muscle has received special names according to its position in the muscle: (*a*) *epimysium* or *perimysium externum* (Fig. 3382, *ep*). This is the connective tissue which forms a kind of envelope or sheath for the entire muscle, (*b*) *perimysium* (Fig. 3382, *p*). This is the connective tissue which extends into the muscle from the epimysium. It combines the fibres into bundles (*fasciculi, fascicles*, or *lacerti*) of various sizes, and separates the fascicles from one another; (*c*) *endomysium*. This is the minute network of connective tissue extending from the perimysium into the fascicles, and separating the individual fibres from one another. Finally, connective tissue, commonly in dense masses or tendons, serves to connect the muscles to other parts, usually bones or cartilages, which are moved when the muscle contracts.

Fascicles (fasciculi or lacerti) and their Relations in a Muscle.—In some muscles, as the sartorius, the muscular fascicles extend from end to end of the muscle. In such a case, if the muscle has a broad tendon of origin and insertion, the fascicles are usually nearly parallel and of nearly the same length. Where, however, one or both ends are fusiform, as in the biceps brachii and the gracilis of man, the central fascicles are considerably the longer. In penniform and bipenni-

(Drawn by Mrs. Gage.) *m-c*, Muscle corpuscles; *t-i*, tendon of insertion; *t-o*, tendon of origin; *t'*, tendinous expansion over the surface of the muscle (it is thickest near the tendon of origin); *t''*, extension of tendon through the middle of the muscle. It thickens toward the tendon of insertion.

Digitized by Microsoft®

form muscles the fascicles are placed obliquely to the long axis of the muscle, and extend for a comparatively small part of its entire length. In case of the bipenniform muscles—biceps brachii of the cat (Fig. 3383), rectus femoris of man—the tendon of origin and the tendon of insertion extend along the entire length of the muscle, on the surface, and also in the central part. This arrangement of the tendon in the penniform and bipenniform muscles renders it obviously impossible to expose the muscular substance in dissection so that it shall show to the best advantage. In most muscles the component fascicles are approximately parallel with one another, although not necessarily with the long axis of the muscle. In bipenniform muscles the fascicles are parallel with one another on the same side, but at an angle with those of the opposite side (Fig. 3383); they are likewise oblique to one another in the fan-shaped muscles like the pectorals and the latissimus.

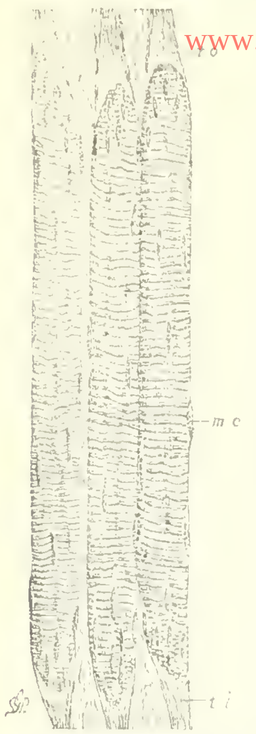

Fig. 3384. Diagram of a striated Muscle in which the Fascicles are composed of but One Length of Fibres, which are of nearly Equal Length. It also represents a muscle in which the fibres are parallel and extend from end to end of the muscle. (Drawn by Mrs. Gage.) *m-c*, Muscle corpuscle; *t-i*, tendon of insertion; *t-o*, tendon of origin.

Fibres and their Arrangement in a Fascicle.—It was long supposed that the individual fibres forming a fascicle were coextensive with it, and therefore, except with the penniform and bipenniform muscles, with the muscle itself. It was shown, however, by Rollett,[1] Herzig, and Biesiadecki,[2] that the fibres may end within a fascicle, being attached to a tendon at but one extremity, or at neither. It is now believed that a fibre rarely exceeds from 40 to 100 mm. in length, while a muscular fascicle may be, in some cases, ten or twenty times that length, or even longer. In man and some of the larger animals Felix[6] has isolated fibres from 120 to 130 mm. in length, although he found the majority of the fibres much shorter. If the fascicle is not over 40 mm. long, the fibres usually extend parallel with one another from end to end of the fascicle; and where the fascicle is parallel with the long axis of the muscle, and the muscle itself does not exceed 40 mm., the individual fibres likewise extend its entire length (Fig. 3384), as in the occipitofrontalis and many other muscles of the cat, the stapedius, intercostals, and some other muscles in man. Where, however, the fascicles considerably exceed 40 mm. in length, the fibres which originate in the tendon of origin or insertion by blunt ends, terminate by fusiform ends at different levels within the fascicle (Fig. 3388, *A*). Where the fascicles greatly exceed 40 mm. in length, part of the fibres originate and terminate as just described, while those which fill the intervening space are tapering and slender at both ends (Fig. 3388, *B*). In most cases in which the fibres become tapering and end within a fascicle, each tapering end is applied closely to a fibre of full size (see Fig. 3388 and below, under Termination of the Fibres).

In small animals, like the common mouse and bat, in which none of the muscles attains a length of 40 mm., one would naturally expect all the fibres to extend the entire length of the muscle; but from an extended investigation of the house and field mouse, of the mole and bat and English sparrow, it was found by Susanna P. Gage[3] that while many of the fibres did extend the entire length of the muscle, many others ended within it either with simple tapering points or with several branches, and even by anastomoses with other fibres (Fig. 3389). Herzig and Biesiadecki found in the muscles of the frog some of the fibres extending the entire length of the fascicle, while others terminated within it. As stated above, the fibres in a fascicle are approximately parallel, and the fascicles, composed of but one length of fibres (Fig. 3384), show the same number of fibres in transection at any level, and each fibre is of nearly the same diameter throughout its entire length, except at the extreme ends (Fig. 3384). In a fascicle composed of two or more lengths of fibres, the number of fibres varies in transections made at different levels, and the same fibre is not of uniform diameter throughout its entire length (Fig. 3388). Independently, however, of the tapering ends of the fibres in fascicles composed of two or more lengths of fibres, the several fibres of a fascicle in all forms of muscles vary greatly in diameter, and there is also a great difference in the number of fibres in the different fascicles (Figs. 3382, 3411). The coarseness or fineness in texture of a muscle to the naked eye, depends mostly on the relative abundance of the perimysium and the *number and the size* of the fibres in the component fascicles (Figs. 3382, 3416).

Termination of Striated Muscular Fibres.—(A) *Termination in Tendon.*—The most common mode is in a dense, usually rounded or flattened mass of connective tissue called a tendon. This is always less bulky than the muscle, and consists of a continuation of the connective tissue of the muscle, and of the special minute tendinous prolongations of the individual fibres which reach the tendon (Figs. 3383 to 3385). All muscular fibres ending in tendon, or apparently directly upon some hard part—bone or cartilage—terminate as just described, without

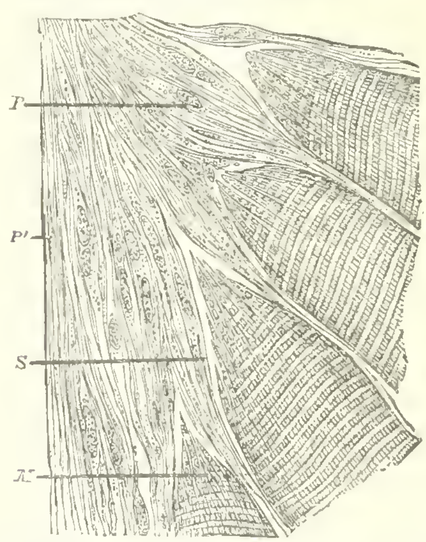

Fig. 3385. To show the Attachment of Muscle to Periosteum (apparent direct attachment to bone), also an Oblique Muscular Attachment. From the scapula of a cat. Magnified 500 diameters. (Heitzmann.) *M*, Tendinous ends of a striated muscular fibre (four are shown); *P*, perimysium; this intermingles with the periosteum, and with the short tendinous prolongations of the individual fibres, serves as a tendon; *P'*, periosteum; the perimysium and tendinous prolongations of the muscular fibres intermingle with the fibres of the periosteum and become lost in it; *S*, sarcolemma; apparently continued as part of the tendinous prolongation of the fibre.

regard to the angle of attachment; there is simply a difference in the length of the tendinous prolongations of the fibres (Fig. 3385).

When a muscular fibre reaches a tendon, the sarcous substance (see below) ends bluntly (Figs. 3383 to 3388). In some cases the end is divided into several short finger-

Digitized by Microsoft®

like processes, and in most cases the supply of nuclei in the muscular and tendinous substance is abundant. Whatever the form of the terminal part of the sarcous substance, the fibre appears to be directly continued by a bundle of tendinous tissue, which soon loses itself in the general mass of the tendon (Figs. 3383 to 3388). This appearance is clearly seen in the dead muscular fibres of all the animals examined, both in sections and in isolated fibres. When the muscle is stained with acid fuchsin and picric acid, the muscular substance is yellow and the tendinous substance pink. The appearance is then that the tendon fits into all the crevices at the end of the terminating fibre as if the muscle end with its terminal processes had been inserted into a plastic tendinous substance. The tendinous substance is also extended along the sides of the fibre and merges into the endomysium (Fig. 3387). It was long held by most histologists that this appearance indicated that at its termination in a tendon the sarcous substance merges directly into tendinous substance, and with the sarcolemma (see below), forms the tendinous insertion of the fibre. At the present day, however, many histologists believe that the sarcolemma of a muscular tibre is continued around the end of the fibre, and that the tendon is simply cemented to it (Fig. 3386). The sarcolemma has never been separated from the tendon, so that, if this view is correct, the connection between the sarcolemma and tendon is more intimate than that between the sarcolemma and sarcous substance. This interpretation is a natural, and almost necessary, outgrowth of the cell doctrine of Schwann[18] and his followers, which teaches, above all things, the independence of the individual structural elements. And these writers consider the sarcolemma a kind of cell wall; it must, therefore, necessarily entirely enclose the fibre, and the tendon be cemented to it at the end of the fibre. To the constantly increasing number of biologists who believe, not in the independence, but in the interconnection of the structural elements of the body, there seems no inherent improbability in the view that muscle may merge into tendon, and the sarcolemma become continuous with, and form part of, the tendon. The appearances obtainable by treating dead muscular fibres with various reagents, and by the study of living fibres, give, in the present state of knowledge, justification to either interpretation.

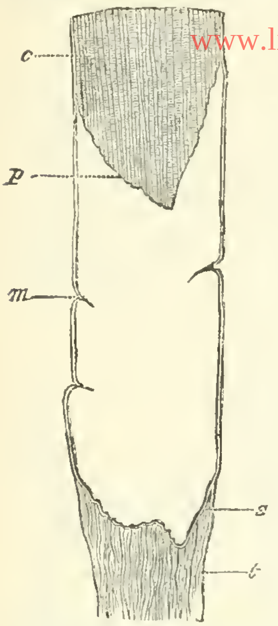

FIG. 3386.—Muscular Fibre from the Gastrocnemius of the Frog, to show the Termination of a Muscular Fibre in Tendon. Magnified 140 diameters. (Ranvier.) *c*, Muscle columns; *m*, a fold in the empty sarcolemma; *p*, retracted conical termination of the sarcous substance; *s*, sarcolemma reflected over the end of the fibre and adhering to the tendon; *t*, tendon.

(B) *Termination of Fibres within a Muscle.*—The statements of histologists concerning the termination of fibres within a muscle and the relations of the terminal ends are so various, or directly conflicting, that some of the more positive statements will be given before stating what seems, according to the writer's observations, to be the condition. Frey, 1880: "While it was formerly supposed that every transversely striated fibre continued throughout the entire length of its muscle, more recently numerous exceptions to this have been observed; that is, muscular fibres which terminate in a point, or some other form, at a greater or less distance from the tendinous extremity. Such primitive fasciculi have their connection with the tendon, to a certain extent, in the interstitial connective tissue." Klein, 1883: "The individual fibres have only . . . a relatively limited length, so that, following an anatomical fascicle from one point of its insertion to the other, we find some muscle fibres terminating, others originating. This takes place in the following way: The contents of a fibre suddenly terminate, while the sarcolemma, as a fine thread, becomes interwoven with the fine connective tissue between the muscular fibres." Landois, 1885: "Within a short muscle, *e.g.*, stapedius, tensor tympani (of man), or the short muscles of a frog, the fibres are as long as the muscle itself. Within longer muscles, however, the individual fibres are pointed, and are united obliquely by cement substance with a similar bevelled or pointed end of another fibre lying in the same direction." Schaefer, 1882: "In a long fasciculus a fibre does not reach from one tendinous attachment to the other, but ends with a rounded extremity, invested with its sarcolemma, and cohering with neighboring fibres."

According to the writer's observations on many different muscles of cats at all ages, and less extended observations upon human muscles and on those of the house mouse, the fibres which terminate within a muscle always do so with a very tapering end, the extremity becoming thread-like, and losing its striation. The muscle corpuscles (see below) are also numerous near the end, and in some cases the fibre seems to terminate as a branched corpuscle (Fig. 3388, *C*). Small lateral branches, some of them striated, were also present in many cases (Fig. 3388, *C*). Where the fibres were apparently undisturbed in their relations, the terminal part, for a considerable distance, was parallel and closely connected with a fibre of full size, the tapering end following accurately the outline of the fibre to which it was applied, curving outward over a muscle corpuscle (Fig. 3388, *m-c*), or when the large fibre was corrugated, following the curves accurately. Herzig and Biesiadecki[9] describe long lateral branches, some of which even anastomose in the intramuscular endings of fibres in the horse.

As shown in Fig. 3389, branched and even anastomosing terminations are not uncommon in the smaller animals, as the house mouse.

The fibres arising from the same tendon and terminating within a muscle may be of various lengths; in such a case the longer ones may apply their tapering ends to fibres of full size coming from the opposite tendon (Fig. 3388, *A*, 3389), while the shorter ones may either apply themselves to fibres from the opposite tendon, or to the longer fibres from the same tendon. In the latter case the shorter fibre has always been observed to terminate before the longer one commenced to taper. When a fascicle is three or more fibres in length, the fibres may be of various lengths, as stated above, but the fibres not joined to the tendon of origin or insertion are tapering at both ends. All the fibres lap sufficiently to apply their tapering end to fibres having their full diameter (Fig. 3388, *B*). In

FIG. 3387.—Two Adjoining Striated Muscular Fibres from the Proximal or Upper End of a Human Sartorius to show their Tendinous Connections. (Drawn by Mrs. Gage.) Magnified about 350 diameters. The tendon in each case seems to be a direct continuation of the muscular fibre, and to extend up on the side of the fibre for a short distance (*cf.* Fig. 3386).

all the numerous preparations observed by the writer, the muscular fibres terminating within a muscle were always very slender and tapering at their termination

www.libtool.com.cn

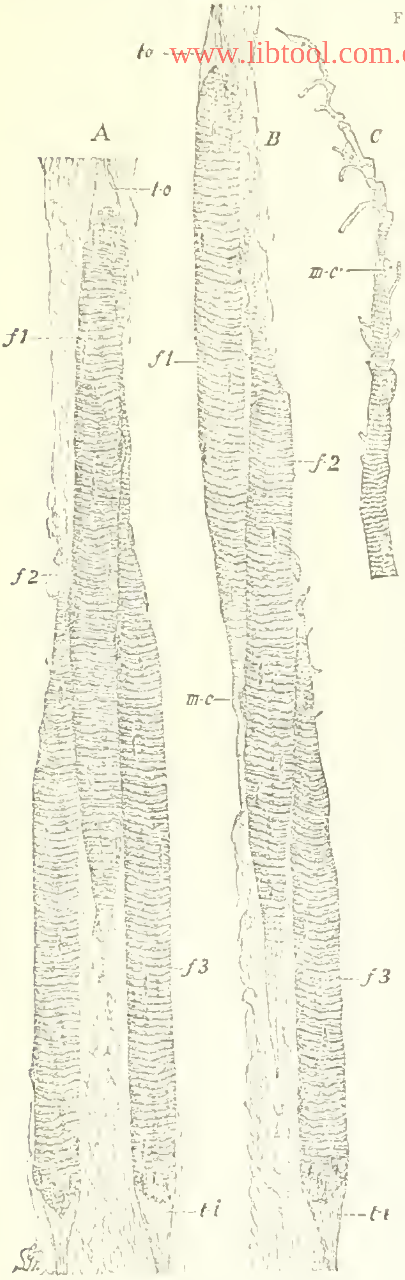

FIG. 3388.—Diagrams to show the Relation and Termination of Fibres in Fascicles composed of Two or more Lengths of Fibres. (Drawn by Mrs. Gage.) *A*, Fascicle composed of two lengths of fibres. The fibres terminate by rounded ends at the tendon of origin and insertion, and in the midst of the muscle by tapering ends which are applied to the other fibres, where they are of full size. *f* 1, Fibre arising at the tendon of origin and terminating in the midst of the muscle; *f* 2 and *f* 3, fibres of different lengths arising at the tendon of insertion and terminating in the midst of the muscle; *t-i*, tendon of insertion; *t-o*, tendon of origin. *B*, A fascicle composed of three lengths of fibres; only the ends reaching the tendons are rounded, the others are tapering and are applied to neighboring fibres, as in *A*. *f* 1, Fibre arising at the tendon of origin and terminating in the midst of the muscle; *f* 2, fibre with two tapering ends, both of which terminate in the midst of the muscle; *f* 3, fibre terminating by a rounded end in the tendon of insertion, and by a tapering end in the midst of the muscle; *m-c*, muscle corpuscle. This one projects beyond the surface of *f* 2, and the tapering end of *f* 1 curves over this corpuscle. A similar condition is shown in *f* 1, *A*; *t-i*, tendon of insertion; *t-o*, tendon of origin. *C*, The terminal part of a fibre ending within a muscle. Drawn with a camera lucida at a magnification of 425 diameters. The details of structure were determined with a $\frac{1}{18}$ homogeneous immersion objective, and added free-hand. *m-c*, Muscle corpuscle. The one to which the line extends projects markedly, and is in the angle formed by a lateral branch. The lateral branches are numerous, and some of them show distinct transverse striations. Just beyond the corpuscle to which the line extends the transverse striation ceases on the fibre. At the end is an enlargement or corpuscle, with a thread-like continuation.

(Fig. 3389) and two tapering ends were never seen to lap and be cemented together; but the slender termination of one fibre was almost invariably applied to a fibre of full size, and terminated before the supporting fibre commenced to taper. The apparent termination of a fibre by a rounded end within a muscle is due, in many cases at least, to the tearing and retraction of the sarcous substance, and sometimes also of the sarcolemma. In the great majority of cases observed, in which a fibre was in its natural relations to the other fibres, and seemed to end by a blunt or rounded extremity within the fascicle, the empty sarcolemma was traced to the other broken end. When the hollow sarcolemma appears of about the size of a muscular fibre (Figs. 3386, 3391), the true relations of the broken ends of the fibre are readily determined; but in many cases the stretched sarcolemma collapses and tapers to a point about midway between the severed ends of the sarcous substance, and often both the broken ends cannot be seen in the same field of the microscope.

(*C*) *Termination of Muscular Fibres in the Skin.*—The attachments of the cutaneous muscles to hard parts, and the terminations of the fibres within a muscle, are as described above for the ordinary muscles. At their cutaneous termination the fibres (in the cat at least) taper somewhat gradually, lose their transverse striation, and, finally, become indistin-

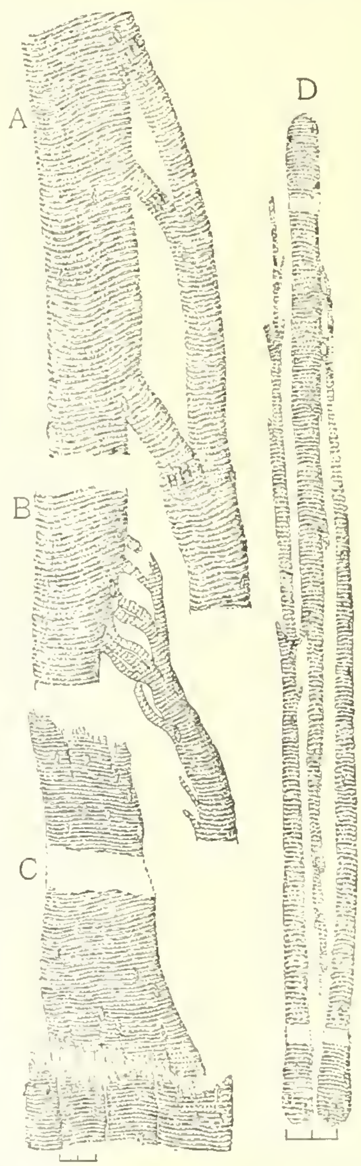

FIG. 3389.—Figures showing the Relations of Muscular Fibres in Small Animals. (From Susanna P. Gage.) *A*, An anastomosis of two fibres in the connecting branches of which are seen a number of longitudinal clefts. The smaller fibre ends with the upper branch. The larger fibre has its maximum size at the upper end, and from the lower part was traced 4 mm. to its tapering, branched intramuscular end, one of the branches forming an anastomosis with another fibre. (From the biceps femoris of a house mouse.) *B*, Termination of an intramuscular end by anastomosis. Anastomosing branches were given off for a whole millimetre, that is for the whole length of the tapering part. (From the biceps femoris of a house mouse.) *C*, Tendinous ends of the rectus abdominis of a house mouse. The two tendinous ends are shown in the upper fibre, which was 5 mm. long. Opposite the lower tendinous end of the large upper fibre are four smaller fibres from the next segment. *D*, Anastomosis of one tapering fibre with two others from the opposite tendon, showing in a typical way the relations of anastomosing, intramuscular ends to one another. The part between the breaks was 3 mm. long, while the whole muscle was 17 mm. long. The intramuscular ends are branched and two of them, after anastomosing, seemed to end freely. (From the biceps femoris of the house mouse.)

guishable from the white fibres of the corium. In some animals, as the rat, the fibres at their cutaneous termination, in the lips at least, divide into several branches, which taper gradually or somewhat suddenly, lose their striation, and in some cases appear to terminate in connective-tissue corpuscles; in others they become indistinguishable from the white fibres of the corium (Fig. 3390).

www.libtool.com.cn

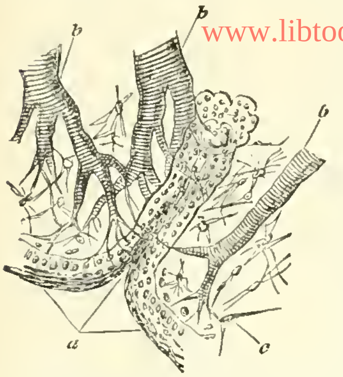

Fig. 3390.—Section of the Lip of the Rat through the *Musculus Levator Labii Superioris*, to show the Branching of the Fibres and their Termination in the Corium. (Busk and Huxley.[5]) *a*, Epidermis and aperture of a sebaceous gland; *b*, muscular fibres branching and terminating in the corium after tapering and losing their transverse striations; *c*, connective-tissue corpuscle.

(D) *Termination of Muscular Fibres in Mucosa.*—If one end of the muscle is attached to some hard part, or if the fibres terminate within the muscle, the attachment of the fibres to the tendon, and the termination within the muscle are as described above for the ordinary skeletal muscles. The ends of the fibres terminating in the mucosal corium, taper, sometimes branch, always lose their striation, and are lost in the fibrous tissue of the mucosa.

(E) *Termination of Striated Muscular Fibres in Hollow Viscera, and in Connection with Unstriated Muscular Fibres.*—In the œsophagus, urethra, etc., where the fibres for the most part have no connection with a definite tendon of origin or insertion, they end by tapering extremities, the tapering part being joined to fibres of full size, as the ordinary skeletal muscles (Fig. 3388). Where the striated fibres mingle with, and are gradually replaced by, unstriated fibres, as at the gastric or lower end of the œsophagus, the long tapering ends of the striated fibres are surrounded on all sides by the unstriated fibres, to which they seem to be cemented as the unstriated fibres are cemented to one another (Fig. 3406).

In all cases (skin, mucosa, hollow viscera, and in the interior of muscles where the fibres gradually taper to thread-like terminations), the sarcolemma, if present on the tapering ends, is so closely connected with the fibre that it is exceedingly difficult or impossible to demonstrate it; and near the end of the fibre the striation is so gradually lost that it is difficult or impossible to locate the exact termination of the sarcous substance and the beginning of the tendinous substance—if it may be so called. No one has ever been able to show a relation of the non-striated termination of the tapering fibres to the sarcolemma, anything like that shown in Fig. 3386; and according to Busk and Huxley,[5] such tapering fibres with non-striated endings furnish conclusive proof that the sarcous substance merges directly into tendinous substance. According to Beale, fibrous degeneration of the sarcous substance points in the same direction.

Branching of Striated, Skeletal, Muscular Fibres.—In the invertebrates striated muscular fibres frequently branch and anastomose, especially in the walls of the alimentary canal. In vertebrates these fibres rarely divide, except when terminating in mucosa or skin. Kölliker described tree-like branchings in the mucosal ends of the muscular fibres of the frog's tongue; and Herzig and Biesiadecki have described and figured muscular fibres from the frog's tongue which possess tree-like branches at both ends. According to Klein, branching fibres have also been found in the tongue of the newt, bat, sheep, goat, cat, and man. Salter[17] could not demonstrate them in man. Branched terminations in the tongue of mammals are certainly greatly in the minority, and are much more difficult of demonstration, than in the tongue of the frog. In the skin of the rat's lip branching fibres have been described by Busk and Huxley (Fig. 3390). Finally, the ordinary skeletal muscular fibres are sometimes dichotomously divided. This is especially evident in the tapering ends of fibres terminating within a muscle (Fig. 3388, *C*). Short finger-like divisions at the tendinous ends of fibres are common (Fig. 3387).

Structure of a Striated Muscular Fibre (*Primitive Fasciculus or Fascicle*).—The striated muscular fibres are the structural or anatomical elements of the skeletal or voluntary muscular tissue. They are cylindrical or prismatic in form, and rarely extend the entire length of a muscle, most of them being considerably shorter. In diameter, the general average in man is from 30 μ to 65 μ, being somewhat larger in the male than in the female; in the cat 25 μ to 90 μ; in mammals below man 45 μ; in birds 31 μ; in reptiles and amphibia, 56 μ; in fishes 100 μ; in insects 63 μ. The variations in size in the same animal are very great, *e.g.*, in man some of the fibres are 125 μ, while others are only 10 μ in diameter.*

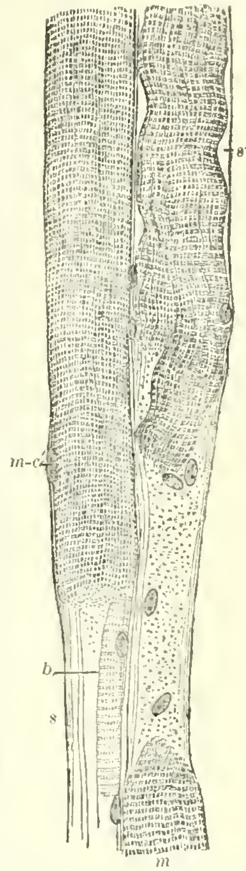

Fig. 3391.—Parts of Two Muscular Fibres from the Adductor Magnus of a Dog, to show the Sarcolemma between the Broken and Retracted Ends of the Sarcous Substance. Magnified 270 diameters. (Ranvier.) *b*, A thin layer of sarcous substance adhering to the sarcolemma. This sometimes adheres all the way around and gives a striated appearance to the sarcolemma; *m*, sarcous or muscular substance; *m-c*, muscle corpuscle. In the fibre at the right some muscle corpuscles have been separated from the fibre and remain in the empty sarcolemma; *s*, sarcolemma; *s'*, opposite a space between the sarcous substance and the sarcolemma.

Structurally, most of the fibres are composed of two very different parts—an enclosing membrane, sarcolemma, and the contractile or sarcous substance, which includes the muscle corpuscles.

Sarcolemma (*Myolemma, Primitive Sheath*).—It was shown by Bowman[4] and Schwann,[18] independently, that most striated muscular fibres are covered by a thin, elastic, and transparent membrane, comparable if not identical with, a cell membrane. It has not been demonstrated in the striated muscular fibres of amphioxus and petromyzon (Balfour), nor in many of the fibres of the tongue of man and other animals (Busk and Huxley[5]), nor in fibres of the eyelid and eyeball, nor in most of those of the myelo-hyoid of the green tree frog (Beale[3]). According to some writers it is not present in developing fibres, except near the end of development. In its chemical and physical nature the sarcolemma is quite similar to elastic tissue, so that when the dead fibres are dissected with needles, either before or after special chemical treatment, the sarcous substance (see below)

* It is not stated by the authors from whom the above figures were taken (Kölliker and Bowman) whether, in obtaining the diameter of the fibres, the cut ends, as seen in transections, were measured, or whether isolated fibres were measured, nor whether care was taken to avoid tapering ends of fibres terminating within a muscle. In the measurements given for the fibres of the cat by the writer, only isolated fibres were measured, and care was taken to measure them only where they were of full size.

Digitized by Microsoft®

is more often torn than the sarcolemma, which remains intact and connects the severed ends of the sarcous substance (Fig. 3391). The sarcolemma, under favorable circumstances of light and preparation, does not appear homogeneous, but fibrillated and punctated, and in some cases there seems to be a connection between the sarcolemma and the endomysium. Occasionally, when the sarcous substance is torn and retracted, a thin layer remains adherent to the sarcolemma around part or the whole of the circumference. In such a case the sarcolemma appears striated, but much less opaque than the whole fibre (Fig. 3391). When the entire sarcous substance retracts, the sarcolemma appears like a hollow transparent sac, and is often folded (Figs. 3386, 3391). If the fibres are considerably stretched in preparation, the sarcolemma joining the broken ends of the sarcous substance may become very slender and appear like a tendinous termination. In most cases, however, the sarcolemma may be traced between the retracted ends of the sarcous substance, although both ends may not be visible in the same field of the microscope. Whether the sarcolemma simply encloses the sarcous substance as the finger of a glove covers the finger, or whether it has a structural connection with the sarcous substance, is not yet determined. According to the views of Krause, delicate partitions arise from the sarcolemma and pass entirely through the muscular fibre, dividing it into compartments. When the sarcolemma of insects is slightly raised from the surface of the fibre, it is wavy, and at the part of the wave nearest the sarcous substance a delicate process is seen to extend to the muscular substance. This appearance was pointed out and figured by Bowman, and may be seen with the greatest clearness in the muscular fibres of the larva of *corydalis*. The common appearance in vertebrate muscle is that shown in Figs. 3386, 3391, where the sarcolemma seems to be simply an enclosing sac.

www.libtool.com.cn

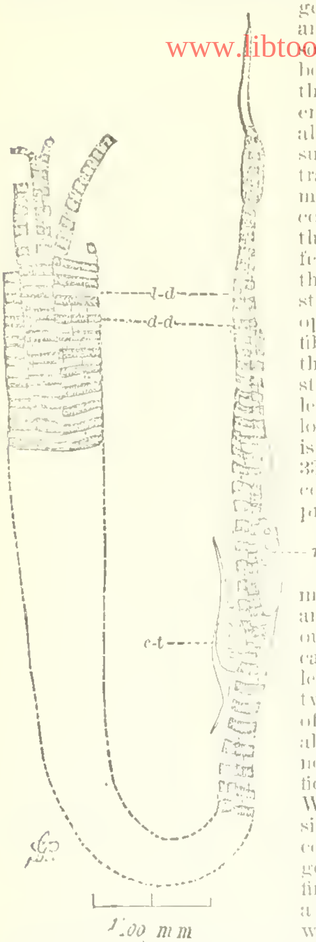

FIG. 3392.—The Terminal Part of a Muscular Fibre ending within a Muscle, to show the End of the Fibre, Isolated Fibrils, and the Various Discs which are sometimes seen in Mammalian Muscle. From the latissimus of a kitten five weeks old. The fibre is not striated beyond the swelling near the terminal end, and a striated branch is present on the right side just beyond the large muscle corpuscle. At the larger end the discs are displaced so that part of a dark disc is opposite a light disc. The entire length of fibre here shown is 0.95 mm. The intermediate part, indicated by dotted lines, is greatly abbreviated. Drawn with a camera lucida at a magnification of 800 diameters. All the details of structure were determined with a $\frac{1}{18}$ homogeneous immersion objective. (Drawn by Mrs. Gage.) *c-t*, Connective-tissue corpuscle partly covering the fibre; *d-d*, dark disc. This is very distinctly divided into two equal parts by a narrow light band (middle or Hensen's disc, compare Fig. 3393); *l-d*, light disc. This is divided into two equal parts by a narrow dark band (membrane of Krause, intermediate disc, compare Fig. 3393); *m-c*, muscle corpuscle. The cell body, nucleus, and nucleoli are all very distinct.

Sarcous Substance (*Muscular or Contractile Substance*).—The substance proper of the striated muscular fibres is divided into two constituents: (1) the more or less homogeneous, semiliquid intermediate substance or *sarcoplasm*, corresponding to the hyaloplasm of undifferentiated cells; and (2) the *fibrils* or sarcostyles, corresponding to the spongioplasm or network of many cells. The fibrils are arranged longitudinally, and are believed to be composed of thicker and thinner segments. The space unoccupied by the fibrils is filled by the sarcoplasm. As the thicker segments of the fibrils are opposite one another throughout the entire fibre, there is given the appearance of a dark segment or disc followed by a light segment when the muscle is studied under the microscope with transmitted light. The dark disc corresponds to the thicker part of the fibrils, and the light disc to the thinner part where the sarcoplasm is in greatest abundance. The longitudinal arrangement of the fibrils gives also the appearance of longitudinal striation; but this is usually less marked than the transverse striation. While the appearance of a striated muscular fibre is so evident and characteristic, the finer structure has proved one of the most difficult problems in histology.*

The difficulty of the investigation is greatly increased because it is so hard to distinguish between appearances which may be purely optical and those which are due to structural differentiation. The case is well stated by Bowman (1840): "The improvements which have taken place in the construction of microscopes appear, indeed, to have only afforded grounds for new differences of opinion"; and by Leydig (1885): "The complexity of structure of muscular tissue, and the fineness of its component parts give rise to so many doubts that one is often led to wish that it were possible to go beyond the present attainable enlargement and perfection of the microscopic image." The most varied animals are selected from which to obtain muscular tissue for this most difficult investigation; insects and crustacea are favorite objects, from the distinctness of the structural details in their muscular fibres. No matter what animal is chosen, it is too often assumed that the structure of all striated muscle is identical with that under consideration—an as-

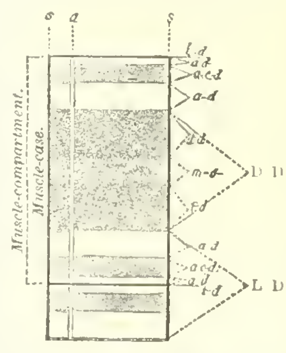

FIG. 3393.—Diagram to Show a Muscle Compartment, a Muscle Case, and the Discs into which a Muscle Compartment is divided, according to some Histologists. Modified from Engelmann. (Drawn by Mrs. Gage.) *Muscle compartment:* This one of the series of segments of which a striated muscular fibre is supposed to be composed. It includes one entire dark disc (*D-D*) and half a light disc at each end of the dark disc. It therefore corresponds in extent to a Bowman's disc. For those who accept the existence of Krause's membrane, it is the part of a muscular fibre between two such successive membranes. *Muscle case:* This, according to Krause, comprehends a sarcous element (muscle prism), with a limited amount of intermediate substance at the sides and ends. The whole case is enclosed by Krause's membrane at the ends, and a special membrane at the sides. In the figure, the muscle case is the part of the muscle compartment between s and *a*; *D-D*, *dark-disc*, composed of two dark bands (*d-d*) separated by a lighter disc (*m-d*), *middle disc of Engelmann*, or Hensen's disc. *L-D*, *light disc*. This is composed of two symmetrical halves, each half forming the end of a muscle compartment. Each half is composed of two light discs (*a-d*), and a granular disc (*ac-d*), the so-called *granular* or *accessory disc*, and the disc *i-d* (*intermediate disc*), the latter forming the boundary between two successive muscle compartments. Krause's membrane is usually said to consist of the intermediate disc and the two adjacent accessory discs, with the light discs between them.

* In the epidermis of *lampreys*, and perhaps also in some other fishes, there are large clavate cells which resemble very strikingly short pieces of striated muscular fibres. Not only is the agreement very marked, both in ordinary and polarized light, but the resistance of these cells to the action of caustic potash is like that of muscular tissue (Max Schultze, Arch. f. Anat. u. Phys., 1861, p. 281).

sumption which often requires the imagination to fill out details not visible when muscle, other than that taken as the standard, is examined. From his own study, the writer believes that all the appearances described by original observers may be demonstrated, if muscles from a sufficiently great number of animals are studied both before and after the application of a sufficiently large variety of chemical agents, and if a microscope having sufficient range of magnification and excellence of image is employed.

www.tbtool.com.cn

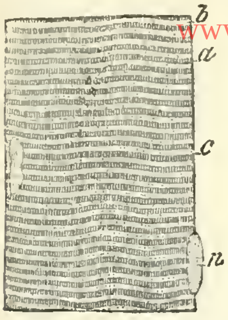

FIG. 3394.—Part of a Muscular Fibre from the Adductor Magnus of a Rabbit, to show the Appearance to an Extended Mammalian Muscular Fibre. Magnified 700 diameters. (Ranvier.) *a*, Dark disc; *b*, Krause's membrane or intermediate disc; *c*, light disc; *n*, muscle corpuscle seen in profile.

It was shown by Bowman,[4] whose paper in the "Philosophical Transactions," 1840, is the most prominent landmark for the histology of striated muscular tissue, that the fibres have a tendency to break up into fine fibrils (*primitive fibrillæ*), which extend parallel with the long axis of the muscle, and appear in structural details like the entire fibre, and that they may also break up into discs which are at right angles to the long axis of the fibre. In breaking into discs (*Bowman's discs*), the plane of cleavage is through the middle of the light disc (Figs. 3392, 3393;) each disc of Bowman is therefore composed of an entire dark disc, with half a light disc at each end. These appearances were considered by Bowman to indicate, not the existence of fibrils and discs in the living muscle, but of minute rounded or angular particles (*Bowman's sarcous elements*), which form the true contractile part of the fibre; and that these are connected together on all sides by a more fluid and non-contractile substance, sarcoplasm—that connecting the sarcous element end to end into fibrils—differing somewhat from that connecting them side by side into discs, as is shown from the fact that the reagents causing the muscle to divide into fibrils do not cause it to break readily into discs, and those causing the fibre to divide into discs do not cause it to break readily into fibrils. When, however, the cementing materials at both the sides and ends give way, the sarcous or ultimate elements of the fibre are, according to Bowman, isolated. Bowman's views were so simple, and so in accordance with observed facts, that they were almost universally accepted. There is, however, great difficulty in deciding what should be considered a primitive fibril composed of a single row of sarcous elements placed end to end, as it is possible to separate a fibre into fibrils so small that the structural characters are difficult of determination. The term *sarcous element*, to indicate the ultimate structural and contractile part of a muscular fibre, has been retained by most histologists, although the interpretation of what constitutes a sarcous element varies with almost every original investigator.

The following are a few of the more important modifications or enlargements of the views of Bowman upon the intimate structure of striated muscular tissue:

(A) *Action of Polarized Light.*—It was shown by Bruecke (1857) that the sarcous elements of striated muscular tissue are *anisotropic* (doubly refractive), and act like positive uniaxial crystals, while the intermediate substance is *isotropic* (singly refractive). As the sarcous elements retain their anisotropic character apparently unchanged during the shortening and broadening of contraction, Bruecke supposed that they were not simple but compound bodies, and he applied the term *disdiaclasts* to what he considered the elementary particles composing the sarcous elements, thus borrowing the terminology of Bertholin, who used this term to designate the hypothetical crystals of calc spar. On the whole, it cannot be said, however, that polarized light has been of material aid in comprehending the structure and action of muscular tissue.

(B) *Muscle Compartments, Additional Discs.*—It was shown by Bowman that, in addition to the broad light and broad dark discs, there sometimes appeared a narrow, dark line in the light disc and a narrow light band in the dark disc (Fig. 3392). The dark line in the light disc was also figured and described by Busk and Huxley, who considered it a disc composed of a row of minute sarcous elements. It has also been insisted on by Sharpey and Martyn, and later by Krause. Krause interpreted it as a continuous membrane (*Krause's membrane*, intermediate disc), extending from the sarcolemma and dividing the muscular substance into compartments (*muscle compartments*) which apparently correspond exactly in extent to the discs of Bowman (Fig. 3392). The view that Krause's membrane is a real structure, which extends from the sarcolemma through the fibre, thus making a complete partition, is supported by the fact that when the sarcolemma of insect muscle is partly torn from the fibre, delicate processes are often seen to extend to or toward the sarcous substance from the sarcolemma opposite the middle of the light disc. This appearance has not been observed and figured for mammalian muscle. The view of a continuous membrane making a partition in the fibre at regular intervals is opposed by the fact that a worm has been seen to move along within the sarcous substance from end to end of the fibre. Furthermore, the sarcous substance of the fibre closed up behind the worm, and the fibre appeared as before and still showed unmistakable contractions. Also, that in living and contractile muscular fibres of insects, which are apparently uninjured, the discs sometimes become displaced for a short distance along a sharp line, so that a dark disc is opposite a light disc. The displacement of the discs is shown in Fig. 3392, but here it might have been due to the traction exerted in preparation, and hence does not bear upon this question as does the displacement of the discs in the living and uninjured fibre.

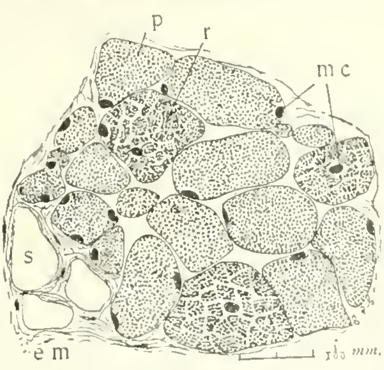

FIG. 3395.—Fascicle of Human Striated Muscle to show the Diversity in Size of Fibres, the Muscle Columns, and the Position of the Nuclei. (Drawn by Mrs. Gage.) Magnified about 350 diameters. *em*, Endomysium or connective tissue between the individual muscular fibres. In the lower left-hand corner some of the fibres are absent, the endomysium alone showing. *mc*, Muscle corpuscles. In muscular fibres with much sarcoplasm and evident muscle columns, some of the nuclei are in the middle of the fibre instead of at the surface; *p*, pale fibre with evenly distributed fibrils, and little sarcoplasm, and the nuclei all at the surface; *r*, red fibres showing abundant sarcoplasm and evident muscle columns. Some of the nuclei are in the middle of the red fibres; *s*, spaces from which the muscle fibres have been removed to show clearly the surrounding endomysium.

Besides the discs just considered, German investigators have described others which are shown in the diagram (Fig. 3393).

(C) *Muscle Cases.*—Besides the muscle compartments Krause considers that each sarcous element (muscle prism) is entirely enclosed by a membrane (Krause's membrane) forming the end, and a special membrane forming the sides (Fig. 3393).

Digitized by Microsoft®

(D) *Cohnheim's Areas, Muscle Columns.*—Cohnheim, in 1863, showed that in transections of frozen muscular fibres, there appeared dark polygonal areas (Cohnheim's areas), surrounded by narrow light lines. He supposed that the dark areas were the cut ends of sarcous elements, and the light intermediate substance was the lateral cementing material. It was found, however, that a Cohnheim's area might be far too large to represent a section of a single sarcous element, and the area often showed a punctated appearance, hence arose the conception that in a striated muscular fibre the fibrils are arranged in bundles (*muscle columns*, Kölliker; *primitive muscular cylinders*, Leydig, Fig. 3386), something as an entire muscle is made up of fascicles (Fig. 3382), and that Cohnheim's areas represent sections of the bundles of fibrils (muscle columns), so that a transection of an entire muscular fibre has the same general appearance as the transection of an entire muscle. This is most striking in fibres with a large amount of sarcoplasm (Fig. 3395).

www.libtool.com.cn

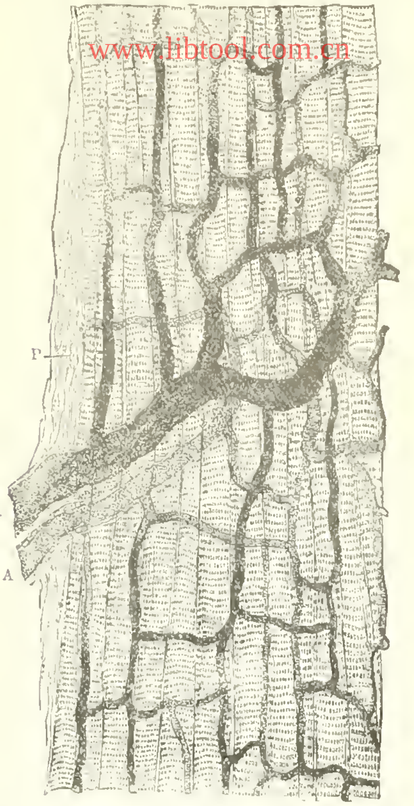

Fig. 3396. Blood-Vessels of Striated Muscular Tissue. From a cat. Magnified 300 diameters. (Heitzmann.) *A*, Artery; *P*, perimysium; *V*, vein.

(E) *The Reticulated Arrangement of Contractile Substance.*—Heitzmann[9] (1873) introduced a new idea as to the structure of striated muscular tissue—viz., that, like simple protoplasm, the sarcous substance is made up of a reticulum of the true contractile matter, the meshes of this reticulum being filled by a more fluid intermediate substance. According to this view, the reticulum is so arranged that the nodal or crossing points (sarcous elements) are at regular intervals both transversely and longitudinally, the transverse row giving the appearance of a continuous dark disc, and the longitudinal row of a fibril. The light disc is traversed by the filaments of the reticulum, which pass between the nodal points. This hypothesis, with unimportant modifications, is now adopted by many histologists, and appears to be most in harmony with the latest views concerning histological structure.

(F) *Red and Pale Muscle.*—It has been known for a long time that some muscles, independent of their contained blood, are red and others pale. Ranvier[14] drew especial attention to this fact and pointed out an easy object for study in the semitendinosus of the rabbit for red muscle and the semimembranosus for pale muscle. Structurally the red muscle is characterized by abundant sarcoplasm, so that the fibrils are not very compact; the nuclei are not all at the surface, but some of them are between the well-marked muscle columns. The longitudinal striation is evident. With pale muscle the sarcoplasm is relatively small in amount, the nuclei are at the surface and the longitudinal striation is not well marked. In man the red and pale fibres are frequently intermixed in the same muscle (Fig. 3395). Muscle tissue called upon for almost constant contraction, like the diaphragm, has also much sarcoplasm.

Vascular Supply of Striated Muscle.—As in other tissues, the blood- and lymph vessels of muscular tissue do not enter the structural elements or fibres, but are in the connective tissue surrounding them.

(A) *Blood-vessels.*—The blood-vessels of this tissue are very numerous, and are estimated to contain one-fourth of the blood in the entire body. As a rule, each muscle receives two or more arteries, and gives off a corresponding number of veins. The larger vessels run in the perimysium, and send small branches into the fascicles, where they break up into a characteristic, parallelogrammic network of fine capillaries, the longer part of the mesh extending parallel with the fibres. The capillaries are the smallest in the body, many of them being smaller than the blood corpuscles of the animal to which they belong. In man the size varies from 3.5 μ to 6.5 μ (Kölliker, 1867) (Figs. 3382, 3396). It was shown by Ranvier that in red muscle the transverse branches of the capillary network and the smallest veins often possess saccular dilatations which are supposed to serve as reservoirs of oxygenated blood to supply the muscles during a long-continued contraction, or to act as receptacles during a maximal contraction.

(B) *Lymphatic Vessels.*—The lymphatic vessels of striated muscular tissue are supposed to be numerous. They lie between the fibres in the perimysium and endomysium, and are said by Klein "to have the shape of continuous long clefts or channels."

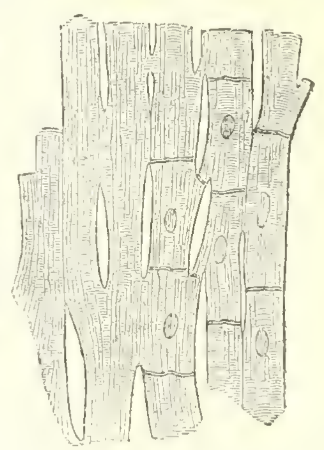

Fig. 3397.—Cardiac Muscular Tissue from a Warm-blooded Animal, to show the Form, Branches, and Relations of the Cardiac Muscle Cells. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically. Magnified. (Schweiger-Seidel.)

Nerves of Striated Muscle.—The nervous supply of striated muscle is exceedingly abundant, and consists of both motor and sensory fibres. The special terminations of the nerves in the tissue will be considered under Nerves (*q.v.*).

Muscle Spindles.—Bodies of fusiform shape discovered by Kölliker[11] (1862) in the breast muscle of frogs. About the same time Kühne found similar bodies in mammalian muscles. It was discovered also that these spindle-shaped bodies contained one or more striated muscle fibres. The muscle fibres within the spindle were named by Kölliker, Weismann's fibres, in honor of their discoverer. The more common designation, however, is *intrafusal fibres*.

Digitized by Microsoft®

A muscle spindle consists of a thick, fusiform envelope of laminated fibrous tissue, somewhat comparable with the capsule of the Pacinian bodies. In the long axis of this fusiform envelope, and frequently passing through its entire extent, is a bundle of small muscle fibres. Entering at one of the poles and near the middle two or more nerve fibres join the spindle. The sheath of Henle of the nerve fuses with the wall of the spindle. Blood-vessels and lymphatics are also present (Fig. 3400).

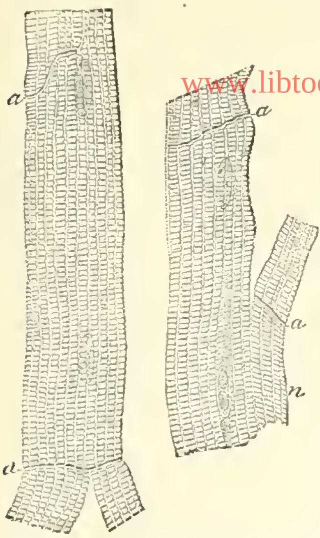

FIG. 3398.—Cardiac Muscle Cells of the Left Ventricle of a Dog, showing the Form, Branches, Nuclei, and striæ of the Cells. The longitudinal, transversely striated bands in each cell represent muscle columns. Magnified 600 diameters. (Ranvier.) *a*, Intercellular cement at the junction of the cells; *n*, nucleus. The one opposite the *n* shows a conical mass of unstriated protoplasm at each end.

These muscle spindles are most frequently found near a nerve and a blood-vessel (Fig. 3411, *D*). In mammals they vary from 1.5 to 10 mm. in length, and from 0.15 to 0.4 mm. in diameter. Sometimes the spindles are compound, two or three being placed side by side, or end to end.

The muscular fibres (intrafusal fibres) in a spindle vary in number from one to twenty; but a number varying from three to ten is most common in mammalian muscle. In size they are usually much smaller than the ordinary fibres of the muscle in which they are situated. This is more marked in adult than in new-born animals. The size of the intrafusal fibres varies from about 5 μ to 20 μ in diameter. They are characterized by coarser striation and the nuclei are in many cases in the middle of the fibre instead of at the circumference. Frequently also in the middle of the spindle the nuclei are so numerous that the striation is lost or obscured (Fig. 3400, *A*).

FIG. 3399.—Cardiac Muscle Cells, showing their Form, Branches, Nuclei, and Striæ. From the heart of a young rabbit.* Magnified 425 diameters. (Schaefer.) *a*, Line of junction between the cells (intercellular cement); *b*, *c*, branches of the cells.

The significance of these bodies has been much discussed, and various conclusions have been reached. Experiments by Sherrington and others make it almost certain that the bodies are innervated by both motor and sensory nerves, and the belief is becoming general that they are in some way connected with the muscular sense (Batten[2]) (Huber and DeWitt[20]).

CARDIAC MUSCULAR TISSUE.—*Distribution.*—Cardiac muscular tissue is present in the heart of all vertebrates, and, so far as has been investigated, in all those parts of the blood-vascular system exhibiting rhythmical pulsations, as the *conus arteriosus* of amphibia and many fishes, and the great veins next the heart in mammals.*

In the cold-blooded animals, fishes, amphibia, and reptiles, cardiac muscular tissue is composed of striated cells which are much longer than broad, and which as a rule are considerably branched and contain a single nucleus (Figs. 3401–3404).

In warm-blooded animals—birds and mammals—cardiac muscular tissue is in the form of anastomosing segments or fibres with nuclei at more or less regular intervals along the fibres.

By caustic potash and other dissociating agents it is easy, in the new-born and young, to separate the cardiac meshwork into segments which are usually branched and with a single or double nucleus in each segment (Figs. 3399, 3413–3415). These segments with their branches have the appearance of cells, and are so considered by

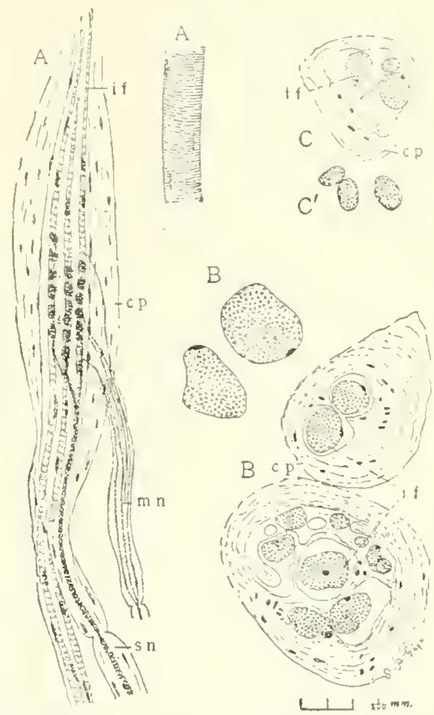

FIG. 3400.—Muscle Spindles. (Drawn by Mrs. Gage.) *A*, Longitudinal view of a muscle spindle from the striated muscle of the rabbit (modified from Kölliker); *cp*, connective-tissue capsule with nuclei; *if*, intrafusal striated muscular fibres in the long axis of the spindle—near the middle they are thickly nucleated; *mn*, motor nerve distributed to the spindle; *sn*, sensory nerve entering near the pole of the spindle. The sensory nerve is usually very large. *A′*, An ordinary muscular fibre of the rabbit drawn at the same scale as the spindle to show the comparative size and fineness of striation. *B*, Transection of a compound muscle spindle from the human sartorius magnified 350 diameters (*cf.* Fig. 3410, *D*); *if*, intrafusal muscular fibres. Two were present in the upper and nine in the lower spindle; the diversity in size is well shown in the lower spindle; *cp*, connective-tissue capsule of the spindle, this appears to be composed of nucleated laminæ something as in the Pacinian bodies. *B′*, Two ordinary striated fibres near the spindle and drawn at the same scale for comparison. *C*, Transection of a muscle spindle from the sartorius of a child at birth. Magnified 350 diameters (*cf.* Fig. 3410, *C*); *if*, intrafusal fibres; *cp*, connective-tissue envelope or capsule. *C′*, Three ordinary muscular fibres near the spindle and drawn at the same scale for comparison. They are no larger than the intrafusal fibres.

most anatomists. In the adult it is much less easy to separate the heart muscle into these cell-like masses. In sections parallel with the so-called fibres, appearances

* This figure appeared in Quain's "Anatomy," eighth edition, p. 119, but the source was not given. On inquiry, Dr. Schaefer informed the writer that the cells are from the heart of a young rabbit.

* According to the investigations of Ranvier, the muscular tissue of the rhythmically pulsating *lymph hearts of amphibia* is in structure like the ordinary skeletal muscles, except for a greater tendency to branch; also, like the skeletal muscles, its motor nerves are paralyzed by curare.

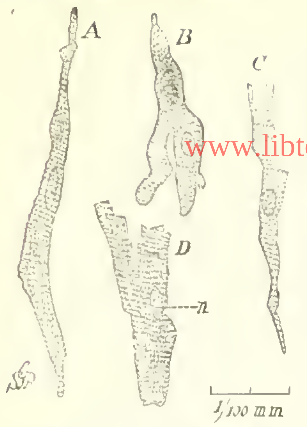

FIG. 3401.—Cardiac Muscle Cells from the Ventricle of a Minnow, to show the Forms of the Cells with their Branches, Nuclei, and Striæ in the *Teleostean Fishes*. *A*, Cell approximately fusiform in outline; *B*, branched cell, which appears granular rather than regularly striated; *C*, cell with depression, in which a rounded end like the branch of *B* fits when the cells are in their normal relations (compare the middle cell and its relations in Fig. 3415); *D*, cell approximating in shape the cardiac muscle-cells of warm-blooded animals; *n*, nucleus. In cells *A*, *C*, the transverse striæ distinctly cross the nucleus.

like those in Fig. 3397 are readily obtained if one omits the apparent division into cells. In the adult, the heart seems to be made up of a sponge-work of muscle substance. It is believed by some of the later investigators (v. Ebner and Heidenhain) that in the course of development the muscle cells form a kind of syncytium, and that in the adult at least no true cell boundaries are present.

Intimate Structure.—Whatever may be the true interpretation of the cellular nature of adult heart muscle, the intimate structure is comparable with red rather than with pale skeletal muscle, that is, the sarcoplasm is relatively abundant, and the longitudinal striation usually quite evident. The nuclei are always in the muscle substance and not at the surface (Fig. 3405).

A *sarcolemma* like that of skeletal muscle is not present, but the large amount of sarcoplasm forms not only a mass within the fibre but a kind of mantle over the surface, and this gives the appearance of a sarcolemma. As the so-called Krause's membrane seems to pass from the surface of this sarcoplasmic mantle across the muscle substance, the likeness is quite striking to insect muscle. The sarcoplasmic mantle is often

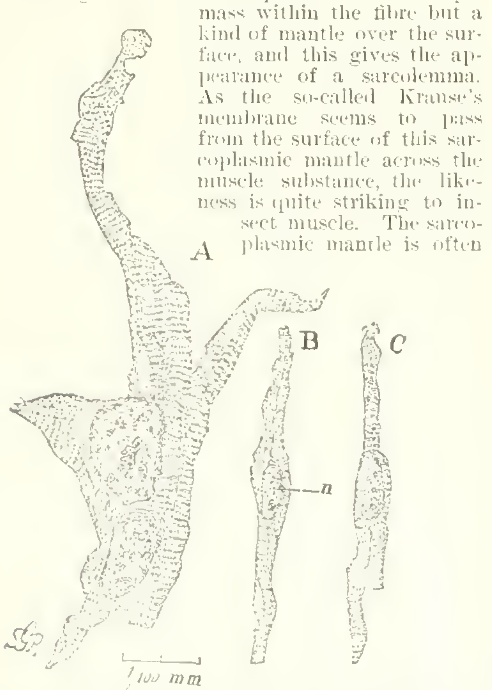

FIG. 3402.—Cardiac Muscle Cells from the Ventricle of *Necturus lateralis*, to show the Various Forms of Cells and their Structural Details in a *Perennibranchiate Amphibian*. *A*, Large branched cell with two nuclei which contain numerous nucleoli. Near the end of the longest branch the regular transverse striation is replaced by irregularly arranged granules. Large cells like this are common in the heart of *Necturus*; they are plate-like, as was determined by a profile view; *B*, *C*, cells of approximately the same thickness as breadth; they form the great bulk of the heart, and usually are branched; *n*, nucleus with nucleoli.

wavy also, and the Krause's or intermediate membrane seems to be attached to the hollow of the wave.

Blood- and Lymph Vessels of Cardiac Muscular Tissue.—The vascular supply of this tissue is very copious. The cardiac muscle cells are enclosed in a parallelogrammic network of capillaries, and the rootlets of its veins are formed by the union of several capillaries at the same point. The larger veins possess valves in man and the higher mammals at least. The lymphatics are numerous and consist of passages and spaces in the intermuscular connective tissue (perimysium) which communicate with the subpericardial lymph vessels.

Nerves of Cardiac Muscular Tissue.—Myelinic and amyelinic nerve fibres and small ganglia are very numerous

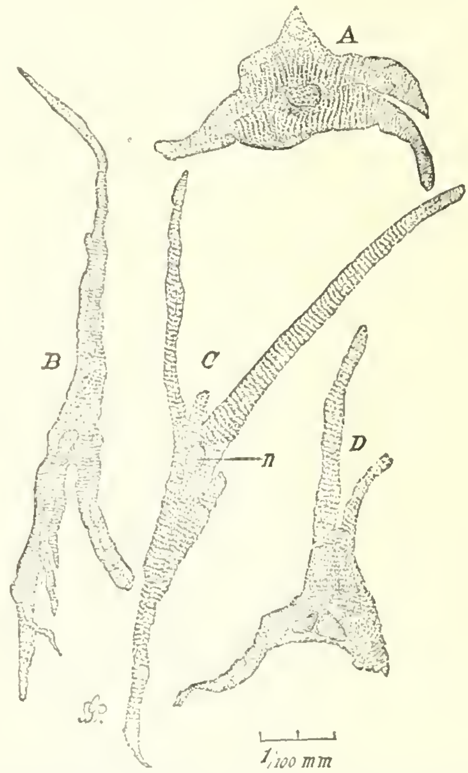

FIG. 3403.—Cardiac Muscle Cells from the Ventricle of a Toad (*Bufo lentiginosus*), to show the Various Forms of Cells and their Structural Details in an *Anourous Amphibian*. The striation is rather fine throughout, and toward the ends is, in many cases, replaced by irregularly arranged granules. *A*, *D*, Broad-branched cells. Cells of this kind are plate-like, as was determined by causing them to roll over so that a profile view could be obtained; *B*, *C*, branched cells of approximately the same thickness as width. Both these cells would be nearly fusiform if the lateral branches were removed; *n*, nucleus. In *D*, two nuclei are present.

in the heart. The fibres extend in every direction between the muscle fibres. The special mode of their termination will be discussed under *Nerves* (*q.v.*).

SMOOTH OR UNSTRIATED MUSCULAR TISSUE.—This is the contractile tissue in the animal body, composed of elongated, mostly uninucleated, fusiform cells or fibres, which are arranged in membranes, sheets, plexuses, or scattered bundles, in the various organs.

Distribution.—This tissue is present in many invertebrates and in all the classes of vertebrates. In man and most mammals it is found in the following situations: (A) *Throughout the alimentary canal*: (1) muscularis mucosæ; (2) muscular coats of the stomach and intestines, part of the œsophagus, and in the œsophageal accessory muscles; (3) as membranes or scattered bundles in the ducts of the salivary glands, in those of the pancreas and of the liver, in the intestinal villi, and in the gall-bladder.

Digitized by Microsoft®

(B) *Respiratory organs:* in the trachea, bronchi, infundibula, and, according to some authors, in the alveoli of the lungs. (C) *Urinary organs:* in the medullary portion of the kidney (Jardet[10]), in the calyces and pelvis of the kidney, in the ureter, urinary bladder, and urethra. (D) *The generative apparatus:* (1) *male*, in the dartos of the scrotum, epididymis, vas deferens, vesiculæ seminales and musculi ejaculatorii, prostate, Cowper's glands, and the corpora cavernosa; (2) *female*, in the ovary, Fallopian tubes (oviducts), in the uterus and all its ligaments, in the vagina, corpora cavernosa; in the nipples, and the surrounding areolæ. (E) *Vascular system:* in the endocardium, semilunar valves, middle coat of almost all the blood-vessels and larger lymphatics, in the adventitia of some arteries and veins, and in some of the lymphatic glands. (F) In the capsule, and in many mammals also in the trabeculæ of the spleen. (G) *In the skin* in connection with the sweat and ceruminous glands, and forming the arrector pili. (H) *In the eye and its vicinity*, the *musculus orbitalis et palpebralis* of H. Mueller, in the orbital fissure and forming the ciliary muscle (tensor choroideæ or muscle of accommodation), the sphincter and dilator of the pupil.

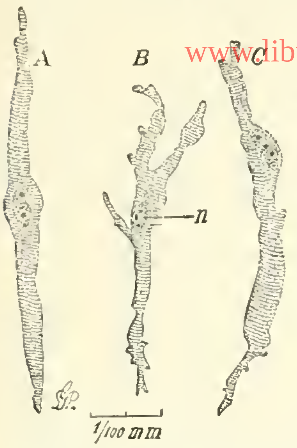

FIG. 3404.—Cardiac Muscle Cells from the Ventricle of a Young Alligator, to show the Various Forms of Cardiac Muscle cells and their Structural Details in the Heart of a Reptile. *A*, Fusiform cell; *B*, *C*, branched cells. These make up nearly the entire mass of the heart, very few being simple spindles like *A*; *n*, nucleus in which the nucleoli are very distinct.

Figs. 3401 to 3404 are at a uniform magnification of 500 diameters. The drawings were made with a camera lucida, and the finer details of structure were determined with a $\frac{1}{18}$ homogeneous immersion objective, and added free-hand. (Drawn by Mrs. Gage.)

Constituents of Unstriated Muscular Tissue.—These are: (A) The contractile or muscular fibre cells or fibres forming the essential elements. (B) Connective tissue forming a kind of perimysium which surrounds the muscular tissue and, penetrating between the fibres, combines them into bundles. (C) Blood- and lymph vessels and nerves.

Relations of the Fibres.—The fibres forming a bundle or fascicle are cemented to one another throughout their entire extent, lapping and interlacing so that apparently solid bundles or membranes without fissures are formed (Fig. 3406). As a rule, there are no distinct tendons for unstriated muscular tissue, since in muscular membranes which entirely surround an organ, tendons would be unnecessary; and in other cases the close relations of the fibres to the surrounding fibrous tissue, and the commingling of its perimysium with the surrounding fibrous tissue, serves to connect the muscles to the part to be acted upon. In special and rare cases, tendons appear to be formed by the insertion of single unstriated fibres into the fork of an elastic tissue fibre.

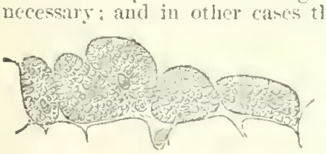

FIG. 3405.—Transection of Five Cardiac Muscle Cells, to show the Form and Relations of the Cells in Section, and the Central Position of the Nucleus in Three of Them. In the other two the section was not at the level of the nucleus. The minute dark areas in the cells represent sections of muscle columns (Cohnheim's areas). Magnified 550 diameters. (Ranvier.)

Intimate Structure of Smooth or Unstriated Muscular Fibres (muscular or contractile fibre cells, smooth or plain muscular fibres or muscle cells, non-striped or non striated muscular fibres, unstriped or unstriated muscular fibres or muscle cells, involuntary muscular fibres, fibre cells, or muscle cells). As stated above, smooth or unstriated muscular tissue is composed of special fibres or cells which form the essential and contractile part of the tissue. They are also its anatomical or structural elements, and are in general fusiform, sometimes branched, and usually contain but a single nucleus (Figs. 3406, 3409). The fibres vary greatly in size, ranging from 30 μ long and 4 μ wide to 230 μ long and 15 μ wide. In the gravid uterus they may attain a length of 500 μ. Those of the vascular system are usually smaller than those in other situations, and they are almost invariably of very irregular outline (Fig. 3408).

Nucleus.—The nucleus is usually oval in outline (rod-shaped in those of the vascular system), and averages about 15 μ to 20 μ long and 4 μ to 10 μ wide. It extends lengthwise of the cell, and often contains one or more nucleoli (Figs. 3406, 3408, and 3409). A complex intranuclear network has been described by recent authors. At each end of the nucleus there is in many cases a conical mass of granular matter; this is supposed to be protoplasm not yet differentiated into contractile substance.

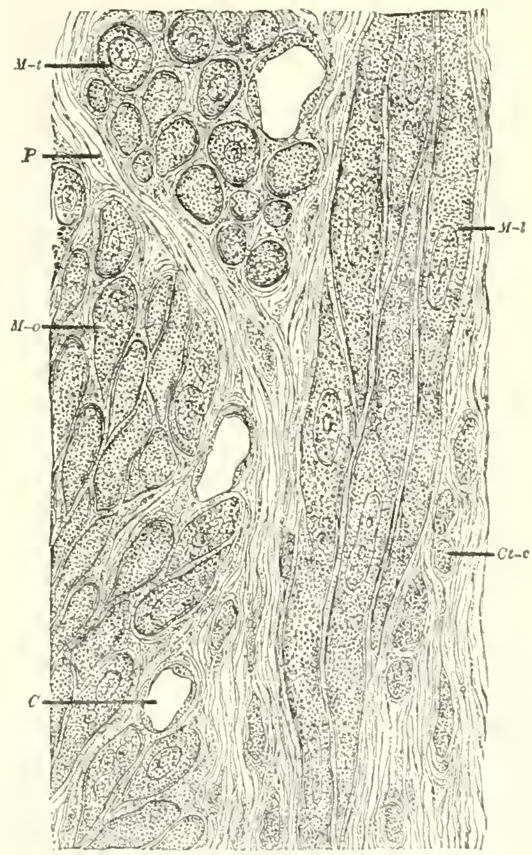

FIG. 3406.—To show the Form and Relations of Smooth Muscular Fibres in their Length and in Direct and Oblique Sections. From the human uterus shortly after delivery. Magnified 500 diameters. (Heitzmann.) *C*, Capillary (the cut ends of two other vessels are shown in the figure; *Ct-c*, connective-tissue corpuscle, or plastid in the perimysium; *M-l*, smooth or unstriated muscular fibres shown lengthwise and in their normal relations to one another; *M-o*, ends of smooth muscular fibres cut obliquely; *M-t*, ends of smooth muscular fibres cut transversely; *P*, perimysium, or interstitial connective tissue.

Contractile Substance of the Smooth or Unstriated Muscular Fibres.—In the fresh condition, and after many methods of preparation, the smooth muscular fibres appear homogeneous, except for a few scattered granules, the nucleus, and the slight amount of granular matter at

Digitized by Microsoft®

its ends. Under favorable conditions of preparation and light, the body of the fibre appears no longer homogeneous but distinctly fibrillated, the fibrils extending parallel with the long axis of the fibre, and being therefore of varying length (Fig. 3409). They are very fine and appear like a skein of thread, being in many superimposed layers, and not in a single layer, as is shown in Fig. 3409. These fibrils are supposed to be the true contractile parts of the fibre. Between them is a limited amount of clear intermediate substance. According to some authors, the fibrils are directly connected with the intranuclear network.

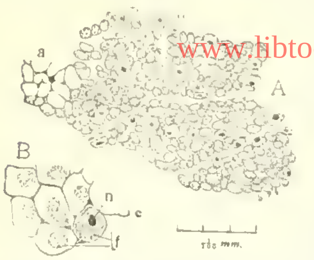

FIG. 3407. Transection of Part of the Circular Muscular Coat of the Human Duodenum. (Drawn by Mrs. Gage.) This shows the cut ends of the plain muscular fibres and their combination into fascicles. Magnified about 350 diameters. *A*, Camera lucida drawing; *a*, connective tissue between the fibres, the fibres having fallen out—it is a kind of endomysium; *n*, nucleus. A nucleus appears in only part of the cells as only a few are at the level of the section. Compare the longitudinal views in Figs. 3406, 3408, and 3409. *B*, Enlarged view to show the connective tissue between the cells and that the muscle fibres have shrunken considerably. The one at the left is shown unshrunken. *c*, connective tissue between the fibres; *f*, muscle fibres, one shrunken and one unshrunken; *n*, nucleus in the unshrunken fibre.

Sarcolemma. — A thin, homogeneous, elastic sheath or sarcolemma is described by some authors as enclosing the individual smooth muscular fibres (Fig. 3409, *B*). An equal, or greater, number of authors deny the presence of a special envelope or sarcolemma for the smooth muscular fibres of vertebrates.

Blood- and Lymph Vessels of Unstriated Muscular Tissue. —The blood-vessels are less numerous than those of the striated muscles, but they have the same general arrangement, the capillaries forming a network with square or parallelogrammic meshes. The lymphatic vessels have been most investigated in the muscular tissue of the uterus and intestine, where they are in the form of passages and lacunæ which anastomose between the fibres.

Nerves of Smooth or Unstriated Muscular Tissue.—These are abundant and consist of myelinic and amyelinic fibres, which are in many situations in the form of a plexus with ganglia. The special distribution to the individual muscular fibres, and the termination of the nerves, will be discussed under *Nerves* (*q.v.*).

FIG. 3408.—Smooth or Unstriated Muscular Fibres of the Vascular System, to show their Irregular Form and the Rod-shaped Nucleus. From the thyroid artery of man. Magnified 340 diameters. (Schaefer.) *n*, Nucleus.

HISTOGENESIS OF MUSCULAR TISSUE.—Muscular tissue of all forms in vertebrates is developed from cells of the mesoderm or middle germinal layer. The cells are at first rounded and indistinguishable from others of the mesoderm. It is only later, when approximately in the position of the future muscle, that they assume the characteristic form and appearance of the structural elements of the special kind of muscular tissue to which they give rise.

Histogenesis of Striated, Skeletal Muscular Tissue.—The muscles of the trunk are without doubt mainly or entirely derived from special masses of mesodermal cells—*muscle plates* or *myotomes* (*protovertebræ* of older writers). These appear on the dorsal aspect of the embryo, and give it the first appearance of being composed of a series of segments. According to some writers, all the skeletal muscles are derived from the muscle plates, those of the limbs being outgrowths or diverticula of the muscle plates; but working over an exceptionally large collection of human and mammalian embryos of all ages, Bardeen and Lewis[1] could in no case demonstrate definite processes of the myotomes growing into the limb buds. They do not deny the possibility of the entrance of scattered cells from the myotomes entering the limb protons, but the appearance is that the muscles of the limbs arise by a differentiation of a part of the mesenchyma, making up so large a part of the developing limbs.

Cellular Origin of the Muscular Fibres.—All are agreed that the muscular fibres are derived from mesodermal cells; but there are two views as to the number of cells entering into the formation of a single muscular fibre. These are: (A) That they are *multicellular in origin.* This view originated with Schwann,[15] and is at present held by a considerable number of investigators. It teaches that each striated muscular fibre arises by the fusion of several cells arranged in a row, the nuclei of the fused cells remaining as the muscle corpuscles. The entire fibre is therefore, according to this view, a multicellular structure or *cell complex.* (B) That they are *unicellular in origin.* This view originated with Remak,[15] and is the one adhered to by most later writers. It holds that each striated muscular fibre originates from a single cell, the nucleus of which divides repeatedly with the growth of the cell. According to this view, the muscle corpuscles are formed by the division of the original nucleus, and the entire fibre is an enormous *multinuclear cell.*

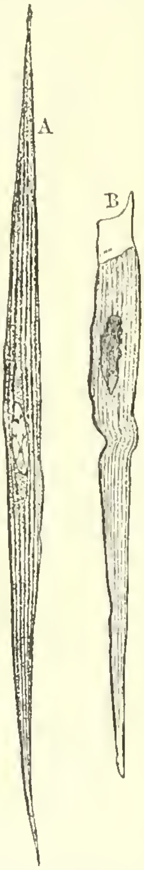

FIG. 3409.—Smooth, or Unstriated Muscular Fibres, to show the Fibrillated Structure and the Intranuclear Network. From the small intestine. Highly magnified. (Schaefer.) *A*, An entire cell or fibre, showing the fusiform shape, the longitudinal fibrillation, the oval nucleus with its intranuclear network, and the conical mass of granular protoplasm at each end of the nucleus. The fibrillæ appear coarse and as if in a single layer; in an actual specimen they are very fine and in many superimposed layers. *B*, A broken fibre, to show the presence of a sheath-like covering or sarcolemma projecting like a hollow sac from the broken end.

Whether the muscular fibres are of multicellular or unicellular origin, the later course of development is as follows: The elongated granular spindles, which are to become muscle fibres, show first a faint longitudinal striation at the entire periphery or at one side, and later a transverse striation; or the two striations appear simultaneously. The nuclei and the unstriated protoplasm occupy the centre or one side of the fibre (Fig. 3412). Gradually the entire protoplasm becomes striated, and in birds and mammals most of the nuclei reach the surface of the fibre; but in the cold-blooded vertebrates they are scattered throughout its entire thickness. Glycogen is very abundant during the later stages of development.

Sarcolemma.—According to Schwann, this is formed by a union of the cell walls of all the cells originating the fibre, the parts of the cell walls which originally came in contact in the interior having disappeared. Others hold that this is the cell wall of the single cell originating the fibre; and still others agree with Busk and Huxley that in the earlier stages of development nothing like a cell wall or

www.fibtool.com.cn
Digitized by Microsoft®

sarcolemma is present, but that it is an after development, and arises by a transformation of the protoplasm at the surface of the fibre into formed material or a kind of cuticula. The view of Busk and Huxley seems to be most in accordance with the general teachings of histogenesis and growth.

www.libtool.com.cn

Growth and Fluctuation in Size of Striated Muscular Fibres.—There are two marked changes in muscular fibres during their development in the embryo: (1) The cells pass from the ordinary reticulated condition of protoplasmic cells to the striated condition; (2) they increase in number until about the time of birth, and the sarcoplasm or undifferentiated part of the cell grows proportionally less, and the striated part gradually greater in amount, while the nuclei increase in number, and in mammals and birds gradually migrate to the surface.

Fig. 3410.—Sections of the Human Sartorius Muscle at Different Ages to Indicate the Change in Size. (Drawn by Mrs. Gage.) The sections were made through the proximal (upper) third in each case, and all were photographed at exactly the same scale. The drawings are from tracings directly from the photographs. The sections are placed with the corresponding edges looking in the same direction. Magnified about 4.5 diameters. *A*, Section from a fœtus 92 mm. long; *B*, section from a fœtus 140 mm. long; *C*, section from a female child at birth; *D*, section of the sartorius of a woman seventy-two years old; *ms*, muscle spindles. There are eight of these in this cross section. Their position is indicated in solid black (*cf*. Fig. 3382 and 3400).

The fibres at about the time of birth are more uniform in diameter than in earlier stages or in the adult (Fig. 3411, *A–D*).

Until recently investigations have not been made to determine whether the increase in the total size of a muscle from the new-born to the adult was due to an increase in the size only of the individual fibres or to an increase *both in size and in number*. That the size of the individual fibres is greatly increased (three to five times) is very evident to any one who examines new-born and adult muscle under the microscope (3411, *C–D*). But whether or not the fibres are increased in number as well as in size with the increase in bulk from the embryo to the adult (Fig. 3411), requires a most laborious investigation, and it is necessary in the investigation to keep in mind the possible difference in size of a fibre at different parts of its length, and to the fact that many fibres end by pointed or branched terminations wholly within the muscle, never reaching either tendon of origin or of insertion (Figs. 3388, 3389); also to the possible longitudinal shifting of fibres during the growth of the muscle in length. During the last five years careful investigations have been undertaken by Meek[13] and by MacCallum[12] to determine the changes taking place from birth to maturity. The work of Meek was directed to the lower animals with special reference to the elucidation of the principles underlying the most economical and satisfactory rearing of animals for food. He found that during growth there was an actual lessening, in a given cross section, of the number of fibres in a muscle, amounting in many cases to more than one-half.

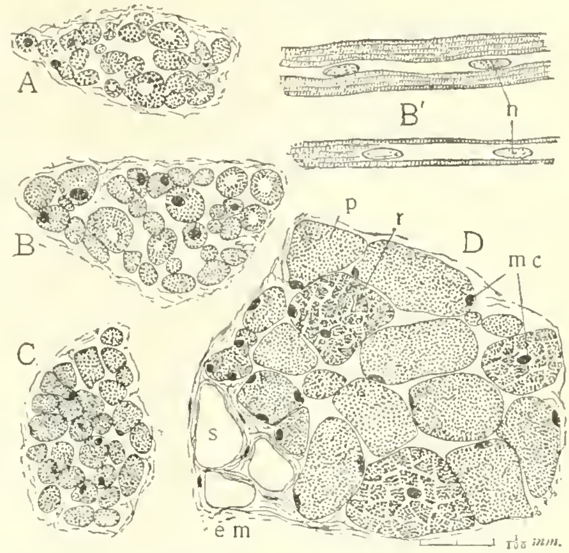

Fig. 3411.—Sections to show Fascicles of Striated Muscle at Different Stages of Development. (Drawn by Mrs. Gage.) Magnified about 350 diameters. *A*, Transection of a fascicle of the sartorius of a human fœtus 92 mm. long; *B*, fascicle of the sartorius of a human fœtus 140 mm. long; *B′*, two fibres from *B* in longitudinal section to show the striation of the fibrils and the central nuclei (*n*); *C*, transection of a fascicle of the sartorius muscle of a female child at birth. Here the nuclei are at the surface in most cases, and the fibres are more compact and more uniform in size than in *A*, *B*, or *D*; *D*, transection of a fascicle of the sartorius of a woman seventy-two years old. It will be noted that the fibres show great diversity in size. The drawing is diagrammatic only in showing some red fibres with abundant sarcoplasm. In the original the fibres were all of the pale variety. *em*, Endomysium surrounding the fibres; *mc*, muscle corpuscles; *p*, pale fibre with evenly distributed sarcoplasm and fibrils; *r*, red fibres with abundant sarcoplasm and evident muscle columns.

In the following table the kitten at nine days is taken as representing the normal number of fibres—one hundred per cent. It will be noticed that the number of fibres in a given cross section of a muscle decreases as the age increases, and that the mother possessed the smallest

Digitized by Microsoft®

number of fibres, although the sectional area of the muscle was very much greater than that in any of the kittens. The results obtained from the vole, rat, and sheep were equally striking.

Table of the Number of Striated Muscular Fibres in a Cross Section of the Biceps Brachii of the Cat (Felis domestica) at Different Ages. All from the Same Family. (Meek.[13])

Age.	Sex.	Area of section.	Number of fibres.	Percentage of fibres.
9 days	Male	8.4 mm.	83,514	100
20 days	Male	8.1 mm.	64,108	77
240 days	Female	22.8 mm.	37,830	45
3 years 5 months.	Female (mother of above).	41.5 mm.	32,039	38

In the investigations of MacCallum on human muscle, especially the *sartorius*, while a marked decrease in fibres was not noticed, it was brought out with great clearness that the increase in cross section of the muscle was due to the increase in size of the individual fibres, and not to an increase in number. Naturally an investigation of this kind is not so satisfactory on human beings as the same rigorous methods cannot be adopted as with the lower animals, where a whole family may be investigated. Individual variation within a single litter is considerable, but where specimens must be taken from different families, the variation would naturally be greater.

In the lower animals it was found that the decrease in number was greater with a muscle called upon for great exertion than in one less actively employed; and as a natural sequence, the muscles of the right side showed a greater decrease in fibres than the corresponding muscles of the left side, although the actual bulk of the muscles on the right is usually greater than that on the left.

The conclusions of Meek are as follows: "Up to the time of birth, in at any rate the higher mammals, perhaps in all *vertebrata*, hyperplasia characterizes the growth of muscle; while after or about birth hyperplasia ceases, and extra-uterine life brings about a selection of some of the fibres at the expense of their neighbors. In other words, during extra-uterine life muscle, according to its position, suffers more or less a reduction in the number of its fibres, the degree of which is expressive of its functional importance. The surviving elements are at the same time greatly hypertrophied, and the extent to which this takes place is also expressive of the work which the muscle performs, or of which it is capable."

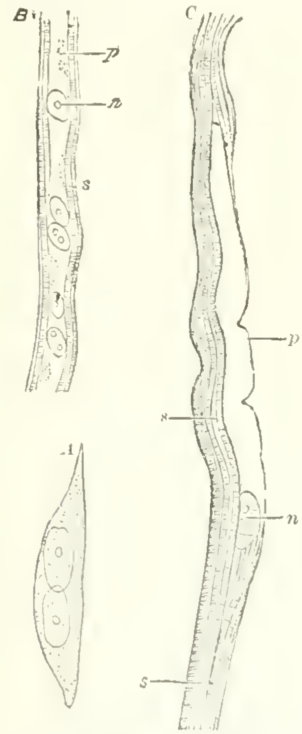

Fig. 3412.—Developing Striated Muscular Fibres, showing Different Stages of Development and Different Positions of the Unstriated Protoplasm. *A*, Elongated cell with two nuclei; the longitudinal striation is beginning to show on the right side. From a fœtal sheep. (Wilson Fox.) *B*, Developing muscular fibre, showing both longitudinal and transverse striations at the periphery, and a central unstriated cylinder of protoplasm containing several nuclei. From a human fœtus near the third month (Ranvier.) *n*, Nucleus (there is usually a mass of glycogen near each nucleus); *p*, central unstriated protoplasm; *s*, peripheral striated substance; *C*, developing muscular fibre, showing a lateral position of the unstriated protoplasm. From a three months' human fœtus. (Ranvier.) *n*, Nucleus; *p*, unstriated protoplasm at one side of the fibre; *s*, striated sarcous substance with longitudinal and transverse striations.

This figure is almost identical with the one of developing striated muscles published by Schwann[5] in 1839 (Pl. XIV., Fig. 3).

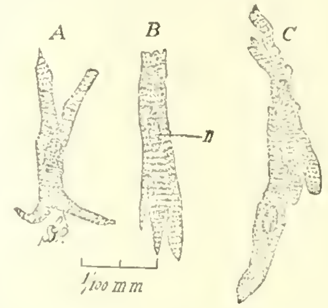

Fig. 3413.—Cardiac Muscle Cells of the Left Ventricle of a Newly Hatched Chick, to show the Form and Structure of the Cells, their General Appearance being like that of Adult Cold-blooded Vertebrates. *A*, Branched cell; *B*, cell with proportions nearly like those of the adult; *C*, two cells in their natural relations, the lower end is fusiform and the transverse striation obscure; *n*, nucleus. In all the cells the striations extend across the nucleus.

While the above investigations indicate clearly that in passing from birth to maturity the increase in size of the individual fibres determines the increase in size of the muscle as a whole, the decrease in number of the fibres in a given cross section may be due, in part at least, to a mechanical displacement along the long axis of the muscle as it increases in length. This mechanical displacement might also account for the fibres with two tapering ends (Fig. 3388, *B*). While it is conceivable that the decrease in number in a given cross section may be due to a longitudinal displacement, and not to an actual disappearance of fibres, the fact that in the more active muscles of the right side the apparent diminution in fibres is considerably greater than in the corresponding muscles of the left side, where the length is practically the same, can be explained only on the hypothesis that there is an actual decrease in the number of fibres during growth.

An elucidation of the processes involved in the disappearance of fibres during growth, and in the every-day occurrence of use-hypertrophy and disuse-atrophy, belongs to the domain of physiology and still awaits investigation, although Morpurgo and Schiefferdecker have made a beginning.

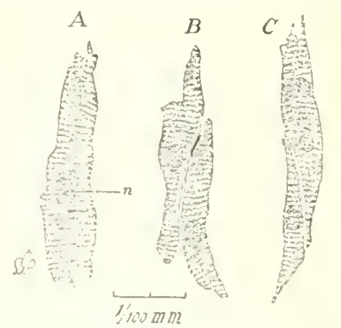

Fig. 3414.—Cardiac Muscle Cells from the Left Ventricle of a Kitten Three Weeks Old, to show the Form of the Cells, their Structural Details, and the Commencement of a Close Union between Two of them. *A*, Large cell possessing nearly the proportions of those of the adult; *B*, two cells in their natural relations; about opposite the nucleus of the upper one the cells are closely united as in the adult (compare Figs. 3397, 3403); *C*, two cells in their natural relations, the upper one has two nuclei; *n*, nucleus. The transverse striations cross the nucleus in all the cells.

Histogenesis of Cardiac Muscular Tissue.—This originates, like the other muscular tissue of the body, from mesodermic cells which are at first rounded and indistinguishable from the surrounding cells. These premuscle cells increase in size and elongate and become spindle-shaped. They contain a large nucleus and reticulated protoplasm. The reticulum is at first irregular, but later it becomes more regular; and when the cell has assumed a spindle shape, the appearance is given of clear bodies with rather definite outlines, arranged in somewhat regular longi-

Digitized by Microsoft®

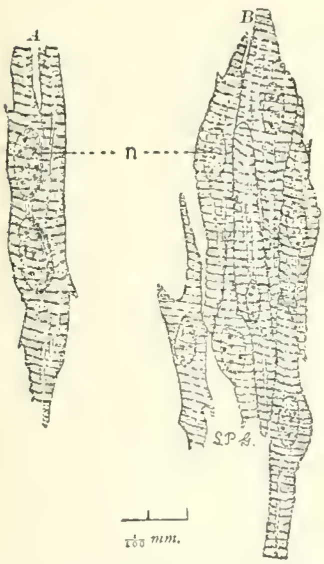
tudinal rows. These clear bodies are the sarcoplasmic discs of MacCallum.[12] As the cells continue to elongate, the striated fibrils so characteristic of striated muscular tissue appear in the cells, always appearing first near the periphery and gradually fill up the cell, so that finally the entire mass is pervaded by them (Figs. 3415, 3405).

www.libtool.com.cn

The further differentiation, besides the complete fibrillation of the cell body, consists in great increase in size, the production of branches or processes, and the fusion, apparent or real, of neighboring cells at various points to produce the anastomosing fibres of adult heart muscle. It is a very interesting fact that the heart beats rhythmically and vigorously for a considerable time before there is any sign of the striated fibrils in the cells.

Fibres of Purkinje.—In the heart of many adult animals (especially ruminants; also in the heart of the pig, horse, dog, cat, hedgehog, marten, and some birds; also, according to Gegenbaur, sometimes in the human heart) there appear, in the muscular substance next the endocardium, chains or groups of cells with a granular, nucleated central part and a striated periphery (Fig. 3417). These cells are supposed to be cardiac muscle cells in course of development into those of the ordinary, elongated, adult form, with branches and striation of the entire contents.

Histogenesis of Smooth or Unstriated Muscular Tissue.—The cells which develop into unstriated muscular tissue are derived mostly from the splanchnic layer of the mesoderm. The cells are at first rounded and granular; they elongate in two directions, thus forming the characteristic fusiform, smooth, or unstriated muscular fibres. The development of the longitudinal fibrillation has not yet been traced. The physiology of muscular tissue will form a separate article (*q.v.*).



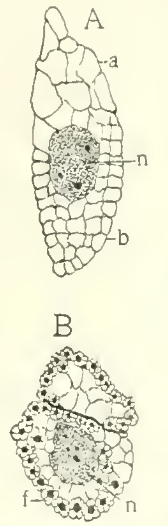


FIG. 3415. Cardiac Muscle Cells of the Left Ventricle of a Child at Birth (Full Term), to show the Form of the Cells, their Structural Details, and their Relations to One Another, and their General Agreement with those of Cold-blooded Vertebrates. *A*, Large cell with two nuclei; this cell has nearly the proportions of those of the adult; *B*, group of cells in their natural relations; at the right of the middle cell are two spaces or fissures (compare Fig. 3397). *n*, Nucleus. The transverse striations cross the nuclei in all the cells, and each nucleus possesses several nucleoli.

Figs. 3413 to 3415 are at a uniform magnification of 500 diameters. The drawings were made with a camera lucida, and the finer details of structure determined with a $\frac{1}{18}$ homogeneous immersion objective, and added free-hand. (Drawn by Mrs. Gage.)

FIG. 3416. Cardiac Muscle Cells from Embryo Pigs. (From MacCallum,[12] slightly modified.) *A*, Longitudinal section of a cardiac muscle cell from an embryo pig 10 mm. long. In the upper part of the figure the meshwork of the reticulum is irregular and represents a somewhat earlier stage of development. In the lower half of the figure the reticulum is regular and the sarcoplasm is arranged in rows of disc-like bodies. *a*, Irregular reticulum; *b*, regular reticulum; *n*, nucleus; *B*, cross section of two cardiac muscle cells from an embryo pig of 20 mm. The upper cell is cut above or below the level of the nucleus, while the lower cell is cut through the nucleus. *f*, Striated fibrils appearing at the periphery, the sarcoplasm forms kind of a mantle or coating for the fibrils; *n*, nucleus of the lower cell.

METHODS.—Isolation of the structural elements for all forms of muscular tissue is accomplished by soaking the tissue from one to three days in a mixture of 23 c.c. of

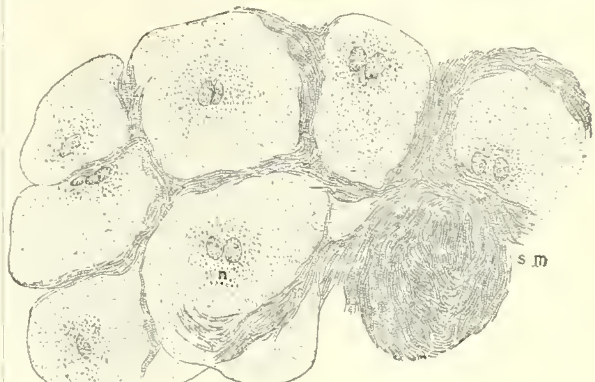

FIG. 3417.—Fibres or Cells of Purkinje from the Heart of a Sheep. Magnified about 300 diameters. (Modified from Ranvier.[14]) At the left the cells are shown in optical section with the peripheral striated fibrils between the cells. On the right is a cell viewed from the surface to show the striated mantle covering the whole cell. *n*, nucleus. Most of the cells contain two nuclei; *sm*, striated mantle at the surface of the cells.

concentrated nitric acid and 77 c.c. of water, and then for a day or more in a half-saturated solution of alum with five per cent. chloral hydrate. For cardiac muscle, soaking in a mixture of 40 gm. caustic potash and 60 c.c. water for fifteen to sixty minutes proved more satisfactory for isolation than the acid. Cardiac muscle must be perfectly fresh in order to obtain satisfactory results.

Acid specimens were mounted permanently in a mixture of glycerin, 75 c.c.; picrocarmine solution, 25 c.c. Permanent preparations of the caustic-potash specimens were obtained by washing away the caustic potash with a sixty-per-cent. solution of acetate of potash. The cells may be kept in this indefinitely, and mounted in this or in glycerin or glycerin jelly. For the fibrillation of the smooth muscular fibres, a piece of the perfectly fresh muscular coat of the small intestine of a cat was kept from one to three days in 100 c.c. of twenty-five-per-cent. alcohol, containing three-fourths of a gram of picric acid. Preparations were mounted in seventy-five-per-cent. glycerin. Serial sections were made to determine the relations of the striated muscular fibres to one another throughout the entire length of a muscle, and to determine the relative size and number of the fibres in a fascicle at different levels.

(For the general methods of histological investigation, the reader is referred to the article on *Histological Technique*, vol. iv.)

BIBLIOGRAPHY.—The bibliography of muscular tissue is so extensive that it would be out of place to give it all in a work of reference like the present. For a more complete discussion of special points, and for the bibliography, reference may be made to the following: *Human Anatomy:* Allen, Gerrish, Gray, Morris, Quain. *Histology and Histogenesis:* Böhm - Davidoff - Huber, Heitzmann, Klein, Kölliker, Leydig, Piersol, Prudden, Ranvier, Schaefer, Stricker. *Embryology:* Balfour, Hertwig, Kölliker, Kollmann, Minot. For monographs one is referred to special papers in the transactions of learned societies, and in the anatomical and embryological periodicals. The bibliography is given in the *Anatomischer Anzeiger, Bibliographie Anatomique;* "Ergebnisse

Simon Henry Gage.

MUSCLE, PATHOLOGY OF.—

I. Striated Voluntary Muscle.

From the pathological point of view, the important points to be considered in the structure of striated voluntary muscle are the amount of interstitial connective tissue, the size and shape of the muscle fibres, the striation, and the number and position of the nuclei. Normally the endomysium, or the connective tissue separating the individual fibres, is small in amount, while that separating the fasciculi is considerably larger in amount, varying in different portions of the muscle. The distinctness of the striation depends somewhat on the method of fixation and preparation of the tissue, but in well-fixed preparations the fibres show a distinct transverse striation, due to the difference of refraction of the fibrillar and interfibrillar substances of the fibres, the ultimate fibrils being anisotropic, while the sarcoplasm is isotropic. In cross sections, the muscle fibres present irregular lighter and darker areas, due to the arrangement of the fibrils in columns, known as muscle columns, with a larger amount of sarcoplasm between the columns than is found between the individual fibrils. The muscle fibres are large, showing normally in cross section a diameter of from 10 μ to 100 μ, while they often attain a length of 12 cm. Their free ends are usually pointed, while the end attached to tendon is rounded. The nuclei of white muscle fibres are situated immediately under the sarcolemma and are very numerous, a cross section of a muscle fibre presenting from one to four or five nuclei. The nuclei of red muscle are situated in the sarcoplasm between the muscle columns. Marked variations occur in the number of nuclei, however, as has been pointed out by Morpurgo and Bindi and others. In young muscles, the nuclei are more abundant and more uniformly distributed than in adult muscle. In small adult muscles the nuclei are more abundant than in the larger fibres, while in the large irregular fibres the number is very variable and much smaller than in the smaller fibres or the embryonic muscle. Hence growth of muscle is not accompanied by corresponding increase of nuclei, the small fibres with high coefficient of growth preserving the juvenile character of nuclear abundance. These are the fibres which change most in the process of activity hypertrophy, the abundance of nuclei corresponding to a greater reserve of growth energy.

Under different pathological conditions, any one of these factors may be materially altered. The connective tissue may be increased or diminished in amount. The muscle fibres may be larger or smaller than normal and may change their shape and their relation to each other. The striation may become indistinct or even be lost altogether, the fibres assuming a granular or homogeneous appearance, while the nuclei may be greatly increased in number and very irregularly grouped, so that some sections will contain large numbers of nuclei, while others contain none. The muscle fibres may segment into short discs, or may break up longitudinally into small slender fibrils, which may remain attached at one extremity, giving the appearance of a branching of the parent fibre. The pathology of striated muscle has recently been treated by Professor Warthin in the *American Journal of Pathology*, and with some modifications I have made use of his classification in the following discussion.

Congenital anomalies of muscle concern largely the realm of gross anatomy. Supernumerary muscles may be found or certain muscles may be lacking. Occasionally the origin or insertion of a muscle varies from the normal. Such anatomical variations are considered in a separate article. (See *Muscles, Anomalies of.*)

Circulatory Disturbances.—Voluntary striated muscle has a very rich blood supply; numerous arteries break up into rich, long-meshed plexuses of capillaries, which surround the muscle fibre, each cell being in contact with several capillaries. The free anastomoses of these vessels easily compensate for any local obstructions, thrombosis, or embolism, and prevent any deleterious results, unless an infective embolus is the cause of the obstruction, in which case an abscess results. "In cachectic conditions, fevers, etc., in which the nutrition of the muscle is lowered, an anæmic necrosis may result from arteriosclerosis, deficient heart action, local compression, infiltrations, etc. Such anæmic infarctions are seen in senile gangrene, decubitus, etc." (Warthin). Psoas infarcts, associated with bed-sores, may result from long continuance of the recumbent posture, in which case the main arteries of the muscle may contain obturating thrombi or may show a proliferating endarteritis. In this condition, the entire muscle may undergo Zenker's necrosis, appearing white and translucent, but usually hemorrhages are scattered through the muscle and the necrosed area is surrounded by an extensive extravasation of blood. Scar tissue may replace the necrosed tissue, attempts at regeneration of the muscle fibres being frequently found; if the area becomes infected, however, a psoas abscess may result.

Anæmia of muscle may result from general anæmia or it may be local in origin, being caused by obstruction in the nutrient arteries, compression or arteriosclerosis. The muscle is pale and either soft, as when the affection is local, or dry, when the process is part of a general anæmia. The muscle may, however, be brown from increase of pigment.

Hyperæmia usually disappears shortly after death, the passive hyperæmia occurring only in the rare cases of extreme vascular stasis, while the congestive form is found in the neighborhood of inflammatory areas. Œdematous muscle is softer and moister than normal muscle, and on microscopic examination clear vacuoles are seen in the protoplasm of the muscle cells, while the connective tissue is much looser than under normal conditions, the connective-tissue fibres being separated by accumulations of clear fluid. In severe cases, the muscle fibres may undergo liquefaction.

Hemorrhages in muscle are far from uncommon; they may result from trauma, from convulsive contractions of the muscle, from increased blood pressure, or from degenerative changes in the vessel walls or in the surrounding muscle. Such changes are common in typhoid or typhus fever, in septic conditions, pernicious anæmia, etc., while small hemorrhages are frequent in the acute infections, phosphorus poisoning, leukæmia, and pernicious anæmia. As a result of the hemorrhage, the muscle fibres are pushed apart and may be destroyed, if the hemorrhage is large. The muscle liquefies or undergoes a coagulation necrosis. Blood clot becomes organized and a pigmented scar remains, only a few regenerated muscle fibres usually replacing a portion of the connective tissue of the scar. The connective tissue

Digitized by Microsoft®

may, however, develop into cartilage and bone, as in some of the cases of traumatic myositis ossificans.

Retrogressive Changes.—Changes in size of the voluntary muscle fibres are among the commonest changes met. Under circumstances of increased nutrition, whether from the general condition or from systematic muscular exercise, the muscle fibres increase in size and we have a true *hypertrophy* of the muscle, while under the opposite conditions of disuse or diminished use of muscle, or when the general nutrition is lowered, the fibres undergo *atrophy*, the diminution in size varying with the degree of the unfavorable conditions. These conditions of true hypertrophy and of simple atrophy are usually transient, the fibre being restored to its normal appearance on the restoration of the normal conditions. If, however, the exercise be continued too long or be carried to an excess, the hypertrophied muscle may become atrophied, and simple atrophy may lead to degenerative changes. Simple atrophy, in its simplest form, occurs in old age, but it is also seen in cachectic states, such as tuberculosis, carcinoma, etc., and it may result from compression of the nutrient arteries. Macroscopically, atrophic muscles appear paler, dryer, and firmer than normal. A brown pigment, hæmofuscin, probably a product of the sarcoplasm of the muscle fibre, may develop in the fibres, giving them a brown color. In some cases, the fibres undergo *hydropic degeneration*, serous atrophy, in which the muscle appears moist and soft.

The clinical aspect of the muscular atrophies will be treated under a separate heading. Regarding the pathological aspect of the muscular atrophies, we may say that atrophic degenerations may be neuropathic, depending on lesions in the spinal cord, or they may be primary or myopathic. In the former case, some of the most interesting changes are those which occur in the spinal cord; the cells of the anterior horn are atrophied and show degenerative changes and the pyramidal tracts are involved. The degeneration may even be traced to cells in the medulla and motor cells of the cerebral cortex. In the myopathic form of muscular atrophy, or the so-called muscular dystrophy, the nervous system shows no essential changes, although varied and irregular alterations are described by certain authors, such as atrophy of the posterior root ganglion cells, some cytoplasmic changes in the ganglion cells of the spinal cord, etc. None of these changes, however, is found uniformly in all cases of muscular dystrophy, and the disease is therefore believed to originate in the voluntary muscle and is probably due to some congenital anomaly of development. Kollaritz describes atrophy of the motor cells and of the fibres of the substantia grisea centralis around the spinal canal, these changes occurring especially in the cervical and dorsal regions. The peripheral nerves were intact. He believes that the changes in the cord and in the muscle occur together and that both probably depend on faulty development. Atrophy of the motor cells is especially characteristic both in his cases and in those of Erb, Schultze, Preisz, Frohmeier and others. This may readily be explained as the result of faulty development, and the development of muscles might well stop if at a certain age the motor nerve cells thus atrophied, while it is not unreasonable to suppose that the motor nerve cells might undergo secondary atrophy, as the result of this degeneration of the muscle fibres. While it was formerly believed that the primary dystrophies could be distinguished microscopically from the neuropathic atrophies, it is now generally conceded that there is no essential difference in the pathological picture presented by the two classes of the disease. The idea that the dystrophies could be differentiated by the fact that the atrophy was uniformly preceded and accompanied by hypertrophy of the muscle fibres has been practically overthrown by the recognition of the fact that in both the neuropathic and myopathic atrophies the atrophy may be preceded by hypertrophy, the fibres being enlarged to a variable extent before the atrophy sets in, and even at the height of the atrophic process some enlarged fibres may be found among the many atrophic cells. In neuropathic atrophy, however, the localization of the degenerative process varies according to the localization of the lesion in the cord.

In a case of traumatic transverse myelitis resulting from an injury to the cord in the lower dorsal region, the psoas muscles showed the most extreme degree of degenerative changes, while the lumbar muscles and the leg muscles contained bundles of extremely atrophic fibres, and the muscle cells of other bundles were normal in size, appearing hypertrophied by contrast with the atrophied fibres. In the psoas muscles, most of the cells were very small, appearing scarcely larger in cross section than involuntary muscle cells. No transverse striation could be observed in any of the fibres and the cross sections appeared either homogeneous or finely granular. Some, however, were vacuolated, some showing very little of the protoplasmic substance of the fibre, appearing to consist of nucleus and sarcolemma, the intervening space being clear. A few of these fibres in cross section presented no nuclei; in the majority, however, one or two deeply stained, relatively large nuclei were seen near the end of the oval cell, while some showed a crescent or corona of nuclear substance at the periphery. Many cells were seen containing numerous nuclei, which were often hyperchromatic and appeared as a dense, fused mass of deeply stained chromatic substance. These giant cell forms or sarcolytes were especially numerous in some fields, while in others very few were found. In longitudinal sections, longitudinal and transverse cleavage could be observed, and in many areas long, narrow, spindle-shaped cells were seen, which contained long rows or chains of deeply stained nuclei. There was also a marked increase of connective tissue, often accompanied by a deposition of fat, especially in the increased connective tissue of the endomysium. This picture may be taken as the typical picture of muscular atrophy, varying in degree, but little in character. The increased connective tissue, the fibrillar forms mentioned, and the multinuclear, giant-cell forms have been the subjects of much discussion. Durante, Kroesing, and others, upholding the view of embryological development of muscle advocated by Hoffmann, Waldeyer and others, that the striated muscle cell is a syncytium developed by the fusion of numerous spindle-shaped cells of the mesoderm, describe the longitudinal cleavage or fibrillation of the muscle fibre as a return to the embryonic condition. They state that these fusiform fibres may form new muscle fibres, but usually degenerate and mingle with the connective tissue, acquiring all its characteristics. To this tissue Kroesing gives the name myogenous connective tissue or connective-tissue state of the muscle fibres. He states that the increase of connective tissue in muscular atrophy is due to the formation of this tissue rather than to an increase of true connective tissue. In preparations stained by Mallory's differential stain for connective tissue, however, it may be plainly seen that this tissue gives the reaction of true connective tissue, so that we may conclude that, if it be derived from muscular tissue, it has acquired, not only the morphological, but also the chemical characteristics of connective tissue. It seems more probable, however, that the muscle degenerates on account of the poor nutrition of the tissue, and that the increase of connective tissue is due to the well-known tendency of connective tissue to replace lost tissues and to fill spaces where it is needed. The fate and significance of the multinuclear forms have been considered by many authors and have been generally regarded as attempts at regeneration. Fujinami, however, believes that in purely degenerative processes, cells morphologically identical with the myoblasts of regenerating muscle may be found, and that in these cases they should not be interpreted as having a regenerative significance, but rather as degenerative forms. While this point seems to need further investigation, Fujinami's view receives confirmation from the fact that these multinuclear forms are quite as numerous in the most extreme degree of muscular degeneration, where no tendency to repair

Digitized by Microsoft®

seems to be present or is to be expected, as in areas less severely affected.

Progressive muscular dystrophy, in its simple form, presents a very similar pathologic picture to that described for neuropathic atrophy. The pseudohypertrophic form, however, is characterized by a marked formation of adipose tissue, formed probably from the proliferated cells of the endomysium, although Kroesing states that it arises from a metaplasia of the muscular tissue into adipose tissue. This myogenous adipose tissue is distinguished from true adipose tissue by the presence of fragments of muscle or by remains of muscle structure or arrangement. In this form of atrophy, as in the others, the muscle fibres are more or less atrophied. A true hypertrophy of the muscle may, however, accompany the increase of connective and adipose tissue, as in the case reported by Durante, in which many of the cells attained a diameter of 180 μ; the nuclei were greatly increased in number, being arranged either in long lines or in a circle surrounding the fibre. Vacuolation and granular degeneration were also noted in these fibres. Durante believes that the muscular hypertrophy in this case was congenital or was developed in early life, while the degenerations and elephantiasis were probably of much later growth.

Thomsen's Disease, or Myotonia Congenita, is a special form of muscular dystrophy, which is hereditary and congenital and affects numerous members of the same family. It is characterized clinically by the occurrence of tonic cramps, when the patient attempts to move. A case recently described by Koch may be taken as typical of the affection. The patient was twenty-one years old and his musculature was well developed. The principal symptom of the affection was stiffness, slowness, and difficulty of motion, especially when first beginning to move, but wearing off later as the effort was continued. This symptom had been noticed since early childhood. The cramps are usually painless and may affect the limb muscles, the eye muscles, and the muscles of mastication, but the extremities are the parts most involved. The involuntary muscles are spared. Cold and nervousness may cause an increase of the affection, while systematic muscular exercise is beneficial. The affection is rarely cured, although it does not endanger the life of the patient. Erb describes an increase of the interstitial connective tissue, with marked hypertrophy of the muscle fibres. The finer details of structure may also be slightly altered, the striations being less distinct than normal, the fibres appearing more homogeneous, but often vacuolated. Koch describes a longitudinal cleavage of the muscle fibres, causing an increased number of fibres. He states that amitotic division of the muscle nuclei was observed, resulting in the formation of the long, slender cells containing rows of nuclei, such as are observed in degenerative and regenerative processes.

DEGENERATIONS.—While the various forms of muscular degeneration have been variously classified, it may be

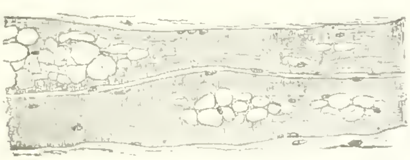

FIG. 3418. Hydropic Degeneration of Voluntary, Striated Muscle. (Ziegler.)

noted that they all tend to occur together, wherever the muscle is exposed to unfavorable conditions. Progressive muscular atrophy, whether of nervous or of muscular origin, may be accompanied by any or all of the degenerative processes, while inflammations, injuries of muscle and tumors are all, to a greater or less extent, surrounded by areas of degenerated muscle. One of the most common and at the same time the most serious degeneration affecting striated muscle is the *granular or proteid degeneration*, also known as *cloudy swelling*. The fibre is usually enlarged, the striations are less distinct, the cell appearing distinctly granular. The granules are not fatty, since they do not react to osmic acid nor dissolve in ether or chloroform; they dissolve in acetic acid. Durante distinguishes two forms of granular change—one, which we may regard as physiological, due to excessive activity of muscle, and analogous to the granular change in gland cells during secretion. The fibres are enlarged and the striations are indistinct on account of the thickened layer of granular sarcoplasm lying between the sarcolemma and the fibrils. This condition is usually transitory, the cell returning to its normal state as soon as the conditions which caused the change have been altered. If, however, the cause persists, the

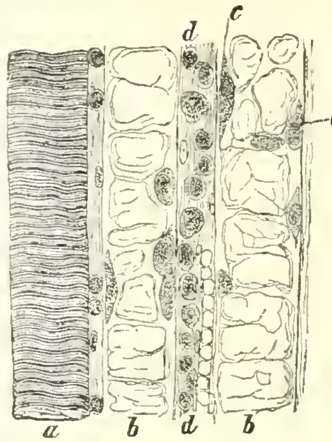

FIG. 3419.—Zenker's Waxy Necrosis. (Ziegler.)

cell may undergo fatty degeneration or liquefaction or coagulation necrosis. The second type is a true degeneration, leading to the death of the cell, and occurs in cachexias, infectious diseases, myositis, and other muscular affections.

Hydropic degeneration of voluntary muscle occurs especially in suppurative inflammations, chronic œdemas, etc., and is characterized by the presence of clear vacuoles in the protoplasm. Fresh muscle thus affected appears pale and watery. It may be distinguished microscopically from simple œdema of muscle by the fact that the muscle nuclei stain poorly in case of degeneration.

Fatty degeneration occurs in an extreme degree in cases of phosphorus poisoning and to a less degree in tuberculosis, in fevers, intoxications, etc. The muscle cells show fat globules in their protoplasm, which therefore appears peculiarly reticular. These may merge into larger fat droplets. These cells stain poorly in eosin, so that a fibre undergoing fatty degeneration appears hazy and mottled, while, after treatment with osmic acid, the droplets show the characteristic black reaction. The muscle nuclei may also show the characteristic degenerative changes.

In cases of inflammations, fevers, intoxications, and in the neighborhood of malignant tumors may be found fibres undergoing *simple necrosis*; these are larger than normal, show no transverse striations and no nuclei, and the entire fibre takes an indifferent bluish-red color, when stained with hæmatoxylin and eosin. In chronic œdema, suppurative inflammation, etc., the muscle fibres may undergo *liquefaction necrosis*. The fibres at first appear enlarged, vacuolated, or granular, and finally dissolve in the fluids in the surrounding tissues. Zenker has also described a *waxy or hyaline necrosis* of the muscle fibres, occurring in typhoid fever. It may also occur in any severe fever, in acute tuberculosis, in sepsis and variola, and also in wounds, inflammations, and to a limited degree in all the pathological processes which may result in the degeneration of voluntary muscle. If the degeneration is of wide extent, the affected muscle is soft, white and translucent, resembling fish-flesh. The softening may lead to more or less extensive hemorrhages in the muscle. The muscles most frequently severely affected are the psoas, the abdominal muscles, and the muscles of the thigh. The muscle fibres are of irregular size and form, many of them being swollen. The cross striation is lost, at least in many areas, and a peculiar

www.libtool.com.cn
Digitized by Microsoft®

hyaline or waxy mass appears in the protoplasm, the fibre finally breaking up into irregular hyaline masses, which are afterward absorbed. The hyaline mass usually stains poorly with the ordinary stains, but may resemble fibrin in its reaction to Weigert's fibrin stain, while in the Van Gieson stain it may react like colloid. The hyaline mass may fill the entire cell or occupy only certain areas, these peculiar homogeneous areas being surrounded by granular sarcoplasm, while some areas may appear striated and quite normal. The nuclei may entirely degenerate, while in milder cases they may proliferate and lead to the regeneration of the muscle fibre. A leucocytic infiltration of the intermuscular connective tissue may precede or accompany this degeneration. In senile gangrene, decubitus, infective inflammations, burns, freezing, and in lowered nutrition of the skin and subcutaneous tissues, the voluntary muscles may undergo gangrenous changes, the muscles becoming brownish, black, or greenish in color, breaking up into shreds or liquefying, or, if exposed to the air, undergoing mummification. Microscopically, the muscle fibres present the picture of liquefaction or coagulation necrosis, the fibres losing their form and striation. A marked leucocytic infiltration accompanies this process, while blood pigment and crystals of cholesterin and triple phosphate are often found. In mummification, the cells shrink and lose their form and nuclei and finally appear like horn. Not unlike a liquefaction gangrene is the degenerative process described by Hoen as occurring in the striated muscle fibres of the uvula. This is characterized by a bleb-like change, associated with pigment formation and nuclear proliferation. The sarcolemma is raised by the vesicles, each of which contains a nucleus, so that the liquefying process seems to begin in the undifferentiated sarcoplasm surrounding the nucleus. Cross striation can still be seen in places, but the longitudinal striation is replaced by wavy and undulating lines, due to the twisting of the fibrillæ. The final stage of the degenerative process shows masses of large blebs, containing small, large, and misshapen nuclei, with pigment, through the middle of some of which runs a shadow suggestive of a muscle fibre. Even in such a mass, some fibrils may be found which still show striæ.

Fragmentation and Fibrillation.—In necrosis and in most of the degenerative and other pathological states of muscle, fibres may be found which are breaking up either longitudinally into long fusiform fibrils, or transversely into irregular plates or discs of muscle substance. Often the fibril can be traced to the point where it joins the parent fibre. The process results in the atrophy of the main fibre, while the fibril which has been split off may either develop into a new muscle fibre, as in the regeneration of muscle by the proliferation of its nuclei, or it may still further degenerate, either shrinking into threads so that the tissue closely resembles fibrous connective tissue, or undergoing fatty degeneration and forming a tissue resembling adipose tissue. Warthin states that "*amyloid degeneration* of voluntary striated muscle is rare and occurs especially in the muscles of the tongue and larynx. The deposit begins in the capillary walls of the endomysium and may extend around the sarcolemma, causing an atrophy of the fibre. The atrophic fibre then appears as if surrounded by a glassy hyaline substance. Ultimately the fibre disappears and the confluence of the deposit leads to the formation of nodular masses." The presence of pigment in voluntary muscle fibres, in the so-called brown atrophy, has already been mentioned. The pigment, known as hæmofuscin, appears as brown or yellow granules in the neighborhood of the nuclei and it indicates a degeneration of the muscle substance. The degenerative processes in voluntary muscle caused by experimental section of the nerve have been well described by Ricker and Ellenbeck. Chromatin granules appeared in the nucleus on the twenty-third day. The nuclei appeared shorter and broader, even spherical, with loosening of the chromatic network. The muscle and nuclei showed œdematous changes. The division of the nuclei was by direct fragmentation, no mitotic figures being found. The authors regard this nuclear fragmentation as a degenerative process, not leading to the regeneration of the muscle. The muscle fibres showed atrophy, but very slowly developing, while the protoplasm showed vacuolation and transverse cleavage, with diminishing distinctness of striation. There was at first an increase in the amount of fat in the intermuscular connective tissue, followed by diminution. The muscle was at first hyperæmic and œdematous, but later became anæmic. There were also an increase of connective tissue and a narrowing and hyaline deposition in the intermuscular capillaries. The changes were believed to be due to disturbances of circulation rather than to direct influence of nerve section.

Schujeninoff has carefully studied the processes involved in the *calcification* of striated muscle, both experimentally in animals and by observation of men. He concludes that the lime salts are deposited in muscle under certain conditions, as after the suture of a wound in the muscle. The calcification takes place after the fibres have undergone a colloid degeneration. When the lime salts are absorbed, the calcified fibre disappears. The calcification of muscle is therefore a local, secondary process, which stands in relation with the local disturbance of circulation.

Regeneration of Voluntary Muscle.—In embryonic life, striated muscle fibres develop from mesodermic cells, each fibre being formed by endogenous proliferation of the nuclei of a single cell. This is the view advanced by Remak, Schultze, Kölliker, Zenker, and many others, who contend that the growth both in length and thickness takes place by this nuclear proliferation, while the protoplasm changes into the contractile substance of the muscle fibre. This view is opposed by Hoffmann, Waldeyer, Kroesing, Durante, and many others, who believe that the muscle increases in length only by endogenous division of the nuclei, while the increase in thickness is brought about by the apposition and fusion of numerous fusiform cells. Experimental degeneration of muscle has been brought about by tenotomy, by neurotomy, and by sectioning the muscle fibre itself. Numerous experiments have also been undertaken in the transplantation of portions of muscle taken both from the same animal and from other animals, even those of a different species. Salvia transplanted muscle from a rabbit to fill the space made by removing portions of a dog's muscle. He states that the result was perfectly satisfactory, as the new muscle replaced the old perfectly both anatomically and functionally. Others have claimed equal success in similar experiments, but Capurro, in a series of experiments recently reported, gained results which were only partially satisfactory. The result of transplanting free pieces of muscle was negative. By using only a portion and leaving a pedicle attached during the union, he was able to secure satisfactory functional results. He observed degenerative changes in the muscle, such as simple atrophy, Zenker's necrosis, fibrillation, increase of connective tissue, leucocytic infiltration, etc. In these cases, as well as in wounds of muscle, granulation tissue is first formed. The muscle nuclei proliferate, both by mitotic and by amitotic division, and buds of sarcoplasm containing the new nuclei grow out from the ends or body of the muscle fibre into the granulation tissue. These buds at first show no striation, but contain many large nuclei and appear like epithelioid cells. Then in the sarcoplasm, fibrils are formed and thus the fibre becomes striated. Several new fibres may be formed from one bud or myoblast. In addition to these myoblasts, free multinuclear cells are formed, known as sarcolytes. These are not in connection with the original fibre, and while some may form new fibres or unite either with the old fibre or with new ones, most of them probably undergo fatty degeneration or necrosis. The sarcolytes may resemble the myoblasts in section and give the appearance of regenerative effort, even when the conditions are so unfavorable that no attempt at regeneration is to be expected. A perfect regeneration of muscle appears to be possible only when the contrac-

Digitized by Microsoft®

tile substance is but slightly injured and the sarcolemma and muscle nuclei are intact, as after freezing, after the degenerative changes of typhoid fever, sepsis, and trivial traumatic injuries in which but little of the contractile substance is lost. In more severe injuries the regeneration is only partial, muscle fibres growing out from the

www.libtool.com.cn

FIG. 3420. — Regeneration of Muscles, Myoblasts, and Sarcolytes. (Ziegler.)

ends of the old fibres into the granulation tissue which at first replaces the destroyed muscle (Warthin). Volkmann states that regeneration is functionally important only after typhoid fever and freezing, while after injuries the regeneration is so slight that function is not restored unless the wounds are small. Larger wounds heal by the formation of scar tissue, which is muscularized from both sides and ends, but only for a short distance. Transplanted pieces of muscle degenerate and are replaced by scar tissue, which is in the same way muscularized for a short distance from the sides and ends. Kümmel, however, reports a case in which he sutured the ends of muscle which were from 8 to 10 cm. apart, and secured almost perfect restoration of function after six months. The differences in the reported results may depend upon different nutritive or nervous conditions, but it would seem from the majority of the reports that, while voluntary muscle does regenerate by both mitotic and to a limited extent amitotic division, its power of proliferation is extremely limited and does not extend to the complete restoration of large areas of destroyed muscle fibre.

CHANGES IN THE MUSCULAR NERVE ENDINGS.—The subject of degenerative changes in voluntary muscle can scarcely be fully treated without some consideration of the changes occurring in the motor and sensory nerve terminations in this muscle. I am not familiar with any work reporting the changes in the motor endings in human muscle occurring under pathological conditions, but Huber has recently reported the results of some experiments on rabbits, in which he crushed the posterior tibial nerves, afterward studying the motor and sensory nerve endings in the interossei muscles by means of the *intra-vitam* methylene blue method. Till the end of the first day after crushing the nerve, the motor endings presented a normal appearance and the muscle responded to electrical stimulation of the nerve applied below the point of injury. During the second day, changes began to appear in the motor endings, ushered in by relatively large, usually round or oval, deeply staining enlargements, or varicosities, varying in number, size, and shape, which were found on the arborizations of the motor endings. These changes did not affect all the motor endings at the same time; but when a majority of all the motor endings in the muscle showed the nodular enlargements, the muscle failed to respond to electrical stimulation. At the same time the nerve fibre showed degenerative changes at its distal end. Later, the arborizations disappeared or failed to stain differentially, although the so-called sole plate sometimes stained a faint blue. The regeneration of these endings was observed about thirty days after the experiment, beginning with the formation of fine, varicose fibres ending in a small granule, and passing through various transition stages to an ending which is in every respect like the original ending. Not until numerous regenerated motor endings were found, did the muscle again respond to electrical stimulation. The neuromuscular nerve end-organs are the most interesting of the sensory nerve endings found in voluntary muscle and have been subjected to the most careful investigation. Sherrington sectioned the sciatic nerve, causing degeneration of the nerve fibres and complete atrophy of the muscle fibres, but found the intrafusal muscle fibres of the spindle well preserved and the striation retained one hundred and fifty days after the section. Eichhorst reports the presence of fat globules in the intrafusal muscle fibres of neuromuscular spindles in a case of phosphorus poisoning. Grünbaum found the muscle fibres atrophied and surrounded by hyaline substance in some of the spindles in a case of pseudo-hypertrophic paralysis, while Gudden observed atrophy of the intrafusal fibres in a case of alcoholic neuritis. Batten examined the condition of the neuromuscular spindles in cases of infantile paralysis, tabes dorsalis, myopathy, progressive muscular atrophy, and peripheral neuritis, and found the muscle spindles normal, except in one of the three cases of tabes examined. After injury of the brachial plexus, however, which resulted in complete loss of motion and sensation, he found changes in the spindles one year after the traumatism. The spindles were small, the intrafusal fibres were atrophied and granular with indistinct striation, while the nerve fibres going to the spindles were poorly stained. Batten therefore concludes that after injury or section of the nerve the neuromuscular spindles undergo degenerative changes in time, but much later than the surrounding muscle fibres. Laslett and Warrington found the spindles unaltered in a case of lead paralysis examined by them. Batten, in a series of experiments upon animals, showed early degenerative changes in the nerve terminations within the neuromuscular end-organs, with later changes in the form, calibre, and arrangement of the intrafusal muscle fibres, but he was unable to reproduce the fatty change of the intrafusal muscle seen by him in the case of tabes dorsalis. Huber, in the experiments previously described, found that the myelin of the large sensory nerve fibres going to the neuromuscular and neurotendinous end-organs showed segmentation, and that the nerve fibres within the organs were broken up into irregular, deeply staining fragments, which gradually disappeared. The changes in the sensory nerve end-organs did not, however, take place until the third day after the crushing of the nerve. No degenerative changes in the muscle fibres of the spindle were mentioned by him. Regenerating sensory endings were seen by him on the forty-first day after the experiment, but it was not until the end of the second month or the beginning of the third month that the nerve endings in these organs presented an appearance similar to that found in the normal organs. In the case of transverse myelitis previously described, the neuromuscular nerve end-organs showed œdema, the layers of the capsule being widely separated by clear fluid, and the muscle fibres also being crowded apart. The muscle fibres of the spindle did not, however, show any marked pathological changes. In the neurotendinous nerve end-organs, also, Cattaneo and others have demonstrated early changes in the nerve endings.

INFLAMMATIONS.—The inflammatory processes in voluntary muscle may be acute, subacute, or chronic. The true inflammatory conditions are largely interstitial, involving the connective tissue of the endomysium and perimysium and the capillaries, while the muscle fibres undergo degenerative changes as a result of the changed nutritive conditions brought about by the presence of the inflammatory exudate. The inflammations may be the result of the extension of an inflammation from neighboring tissues, or germs may be carried into the muscular tissue through the blood current. Traumatism, disturb-

Digitized by Microsoft®

ance of nutrition, and vascular changes may also act as powerful indirect etiological factors. Myalgia or so-called rheumatic myositis or muscular rheumatism often affects the muscles of the back, neck, or the intercostal muscles. In most cases it is probably not a myositis but a neuralgia, due to slight twisting or laceration of some of the muscle fibres. Its one common symptom is pain in the muscles. It usually quickly subsides, often spontaneously. If necessary, anodynes or hot applications will generally give relief.

www.libtool.com.cn

In *acute parenchymatous myositis*, the muscle fibres show granular, hydropic, and fatty degeneration, Zenker's necrosis, fragmentation, fibrillation, etc. The endomysium contains large numbers of leucocytes and is œdematous, while the capillaries and blood-vessels are distended and filled with blood cells. If the degenerative changes in the muscle fibres are not too severe, recovery usually takes place with complete restoration of structure and function of the affected muscle. This comparatively mild form of inflammation occurs after slight injuries, in disturbances of circulation, in typhoid fever, and in the neighborhood of new growths. Trichina cysts, anthrax pustules and other irritating conditions may produce similar processes in neighboring muscles. A similar form of myositis has been called by Froriep *monomyositis*. It arises on a traumatic or infectious basis and may lead either to muscular abscess or to an indurative interstitial inflammation which ends either in repair or in the formation of a muscle tumor. The course may be acute, subacute, or chronic. The symptoms consist of extreme pain in the affected muscle, generally preceded by chill and slight rise of temperature. There are some swelling and œdema of the skin over the affected part, with swelling and extreme tenderness of the affected muscle, which soon becomes very hard. There is also contracture of the affected muscle, with some diminution of the electrical excitability. A more severe and generally fatal inflammatory affection is known as *primary acute polymyositis*. This is infectious in character and is accompanied by œdema and marked swelling of the overlying connective tissue and hyperæmia and even exanthema of the overlying skin. The clinical symptoms are fever, pain, tenderness, and loss of function in the affected muscles. These symptoms suggest trichinosis, and Hipp suggests the name pseudo-trichinosis. The resemblance indeed is at times so striking that a differentiation can be made only by removing portions of the affected muscle and subjecting them to microscopical investigation. This form of myositis is sometimes known as dermatomyositis, because of the simultaneous involvement of the skin and muscles. Polymyositis may also be hemorrhagic in character, since a marked extravasation of blood may be found between the muscle bundles. This usually runs a chronic course, death resulting from involvement of the heart. A case of this kind has been described by Bauer: The affection started with severe pains in the legs, after which swellings gradually developed in various regions of the body. The general condition was poor, sleep disturbed, appetite impaired; the patient had fever, and his face was reddened but not œdematous. The muscular swellings were painful, circumscribed, and surrounded by a doughy, indurated area. These showed areas of pigmentation surrounded by a violet zone. Death occurred from asthenia. At the autopsy, the muscle in places presented a brownish-red appearance, with punctate and linear pigmentation and in other places a waxy-yellow appearance. The muscle fibres were partly normal and partly degenerated with proliferation of the nuclei. These were separated by a hemorrhagic exudate, which in some places showed large numbers of leucocytes, so that a purulo-hemorrhagic effect was produced. In this case, the staphylococcus was found. In certain septic cases a diffuse, purulent infiltration of various muscles may occur, this condition being rarely regarded as primary and terminating in gangrene of the muscle. Ziegler describes a case of phlegmonous inflammation of the subcutaneous and intermuscular connective tissue near the pectoral muscle, resulting from an infected wound. Skin phlegmons, erysipelas, decubitus, and purulent arthritis may also cause similar suppurative muscular affections. The muscle is swollen and softened and may be mottled yellow, brown, red, and greenish in color. The pus infiltrates the endomysium and may burrow along the sheaths of the muscles for considerable distances. Small, circumscribed abscesses, either single or multiple, are found throughout the muscle in various regions in case of hæmatogenous infection. These small abscess cavities are filled with pus and tissue débris, and are surrounded by œdematous and degenerating muscle. These small abscesses may be absorbed or become encapsulated, while larger ones break and discharge their contents, being replaced by scar tissue, which gradually contracts and is partly replaced by new-formed muscle fibres. The scar tissue may undergo calcification, while the encapsulated forms may become either calcified or liquefied. On exposure to the air, this greenish-black, gangrenous muscle evaporates or undergoes mummification. Stierlin has described a case of septic total necrosis of muscles resulting from wound infection with obstruction of the artery and therefore interference with the nutrition of the part. The bacteria were gas-forming, putrefactive bacteria. Fragments of the necrotic muscle filled the abscess cavities. The entire process was limited to the musculature, the skin being unaffected. The connective tissue and lymph and blood capillaries were filled with innumerable cocci, forming a network around the muscle cells, which appeared in cross section as homogeneous red discs in which no nuclei could be seen. Very few cocci had penetrated the muscle cells. An *acute interstitial or productive myositis* may also be distinguished; it is progressive in character and generally passes into the chronic form. It

FIG. 3421.—Purulent Myositis, with Necrosis of Muscle. (Stierlin.)

occurs in typhoid fever, chronic irritations, etc. The primary changes are in the connective tissue, which proliferates and causes a secondary degeneration of the muscle fibres.

Chronic Myositis.—In progressive muscular atrophy, whether neuropathic or myopathic, there is a marked increase of the intermuscular connective tissue, so that the

Digitized by Microsoft®

small muscle bundles are separated by thick bands of connective tissue, or the muscle may be entirely replaced by connective tissue. This constitutes the condition known as chronic interstitial myositis or fibrous myositis. It may also occur in the neighborhood of chronic inflammatory or irritative processes, as ulcers, tumors, parasites, foreign bodies, etc. It may also affect the muscles in the neighborhood of inflamed joints, as in inflammatory rheumatism, gout, etc. Acute purulent myositis may be followed by a condition in which the abscesses are walled in by granulation tissue and we may speak of it as a chronic purulent myositis. This occurs most frequently in the psoas muscle. While the condition may follow an ordinary pyogenic infection, it is far more common after specific infections, such as tuberculosis, syphilis, actinomycosis, glanders, gonorrhœa, leprosy, etc.

www.libtool.com.cn

Tuberculous Myositis may and frequently does occur in muscles in the neighborhood of a tuberculous abscess or some focus of infection, the process extending directly into the muscle from the infected area, as in the muscles surrounding a psoas abscess or caseating lymph gland, or in the intercostal muscles in pyothorax and in miliary tuberculosis of the pleura. Primary or hæmatogenous tuberculosis of muscle is, however, rare—a fact which is explained by the bactericidal action of the muscular fluid, which, as Tria states, is more efficient in its action than the fluids of any other tissues. Cases of hæmatogenous tuberculosis of the muscles have, however, been described by Habermaas, Müller, Delorme, Reverdin, and Lanz and Quervain, and Steinthal, the latter having collected eight cases of primary tuberculosis of the abdominal muscles. The tuberculous nodules found in the intermuscular connective tissue present usually a caseated necrotic centre surrounded by a zone of lymphocytes and epithelioid cells with some giant cells, and this is surrounded by a zone of lymphocytes and connective tissue. Blood-vessels are poorly developed in these areas. The muscle in the neighborhood of one of these areas may be normal, but is usually atrophied, while the muscle nuclei are increased in number and surrounded by a clear zone; the protoplasm of the muscle diminishes as the nuclei increase in number, so that finally the sarcolemma appears filled with nuclear masses. As the muscle degenerates, it is replaced by connective tissue into which the tuberculous foci extend. Here they consist of lymphocytes mostly, with a few epithelioid cells. According to Petit and Guinard, the tuberculous process originates in the intermuscular connective tissue, the degeneration of the muscle resulting from the presence of cells called myophages, which send processes between the contractile fibrils and gradually destroy them. In none of these cases were the tubercle bacilli demonstrated microscopically, but the history of the case, the microscopic appearance of the tissue, and the positive results gained by injecting the contents into guinea-pigs made the diagnosis unquestionable. Tuberculous myositis must be differentiated from syphilitic myositis, interstitial myositis, actinomycosis, echinococcus, and benign and malignant tumors. A tuberculous abscess may also be found in muscle, consisting of muscular and cellular débris surrounded by a thin wall of granulation tissue poor in blood-vessels.

Syphilitic Myositis may be diffuse or circumscribed. In the former case there is a primary diffuse infiltration of the connective tissue with a secondary degeneration of the muscle fibres. It occurs especially in the later stages of syphilis and attacks by preference the muscles of the extremities. It is characterized by a painful, indurated swelling of the affected muscle, which is easily differentiated from other muscular affections by its prompt response to antisyphilitic treatment. Muscle gummata, while not infrequent in the later stages of syphilis, have not often been described. They may, as in the case reported by Eger, develop many years after the syphilitic infection. If no regressive changes have taken place, they are usually indolent in their course, causing no pain, no disturbance of function, and no alteration in electric excitability, unless by their excessive growth they press upon nerves or blood-vessels. They are influenced more or less readily by the potassium-iodide medication. The large tumors may caseate, forming deep ulcers or abscesses, which heal readily but leave indurated scars, which may disturb the function of the muscle. In the earlier stages, the gummas consist of very vascular granulation tissue which may be mistaken for sarcomatous tissue, but later the characteristic three zones develop, the outer consisting of vascular granulation tissue, the inner caseated zone, and the intermediate zone of mature connective tissue. Giant cells may be present or absent. The rich blood supply, the absence of tubercle bacilli, and the response to antisyphilitic medication will readily differentiate these nodules from those of tuberculosis.

A *Case of Gonorrheal Myositis* involving the latissimus dorsi has been described by Ware. The microscope revealed a picture of interstitial inflammation, with cloudy swelling of the muscle fibres, though in some places the striation was still distinct. There was some proliferation of the muscle nuclei, showing a possible tendency to regeneration of the muscle fibres. The connective tissue was so greatly increased that the muscle fibres were crowded apart and compressed. No germs were found except the diplococci. This form of myositis is characterized by the intense sclerotic process, which is so marked a feature of gonorrhœal inflammation in other localities. The process generally heals by the formation of connective tissue, which usually undergoes resolution, although cases have been reported of ossification of the affected muscles. If an abscess forms, it is probably due to a mixed infection. The localization of gonorrheal myositis is probably generally due to extension from neighboring joints and bones, though it may sometimes result from metastasis.

Leprous Myositis.—Fujinami describes the changes which take place in voluntary muscle in cases of leprosy. The muscle is crossed by white strands consisting of connective tissue containing many fat cells and numerous brown pigment granules arising from degenerated muscle fibres. The muscle fibres are atrophied, showing either a very irregular arrangement of the striation or a granular and pigment degeneration. The nuclei are increased in number, enlarged, and very irregularly arranged, while many of them take the stain intensely and show indistinct outlines, so that they appear as fused, hyperchromatic masses. The changes are similar to those observed in muscular atrophy, in the neighborhood of tumors, in inflammatory processes, and are probably due, not to the direct action of the bacilli, but to disturbance of the nutrition of the muscle, perhaps brought about by chemical changes in the lymph caused by the growth of the bacilli. Colonies of leprosy bacilli are seen between the atrophic muscle fibres and in the connective tissue, and they are sometimes seen within the connective-tissue cells or leucocytes.

Actinomycotic Myositis is not at all common, but in rare cases a focus infected with the ray fungus may, either by direct extension or by metastasis, lead to an infection of voluntary muscle. The infection results in the formation of nodules of granulation tissue, which may undergo fatty degeneration or suppurate and form abscesses. The healing of these nodules leaves areas of induration which are not easy to distinguish from the scars of syphilitic myositis. An inflammatory affection of muscle may also be due to an infection with the *glanders* bacillus. This leads to the formation of many small, grayish abscesses, containing a thin fluid in which the germs are found. The muscle may become infiltrated with pus and chronic ulceration or abscess may result.

Animal Parasites.—Varieties of chronic myositis may also result from the presence of certain animal parasites, one of the commonest of which is the *Trichina spiralis*. When found in muscle, it is in the encysted stage of its development, which is known as a measle. The poorly cooked measly pork is eaten, the capsules dissolve in the gastric juice, the embryos develop in the intestine six or seven days after the ingestion of the meat.

Digitized by Microsoft®

These pass into the muscles, showing a preference for the diaphragm, tongue, intercostal muscles, neck, larynx, and thigh muscles. The worm penetrates the muscle fibre, which degenerates, the fibrillæ appearing swollen, granular, and with indistinct striæ. The worm is soon surrounded by a clear, homogeneous capsule, which later becomes calcified. There are at first evidences of acute interstitial inflammation in the intermuscular connective tissue, which later disappear. The clinical symptoms consist of irregular fever, gastro-intestinal disturbances, typhoid symptoms, œdema of ankles, pain and tenderness in the muscles. Brown notes a marked leucocytosis in acute cases, the eosinophile cells being most markedly increased, reaching 68.2 per cent. of all the white blood cells present. Muscular changes take place similar to those in chronic myositis—increase of connective tissue, fibrillation and segmentation of the muscle fibres, with granular and hydropic degeneration of the muscle fibres, with proliferation of nuclei and thickening of the sarcolemma are the most marked changes noted. Death may result in the acute stage of trichinosis, or the worms may become encysted within calcified capsules and create no further disturbance, remaining innocuous during the life of the individual. The *Cysticercus cellulosæ* may sometimes be found encysted in muscle, the cyst being surrounded by a firm fibrous capsule, the whole being surrounded by a zone of inflamed muscle tissue. The *Echinococcus* may be encysted in muscle, although it is far more prevalent in the liver and lungs. The capsule is dissolved in the gastric juice, the embryo developing and making its way through the wall of the stomach or intestine and either passing through the portal circulation to the liver and thence to the heart and lungs, which are the regions infected in sixty-five to seventy-five per cent. of all cases, or wandering actively to the muscles and other regions. Gerulanos has recently collected from the literature two hundred and fourteen cases of muscle echinococcus, one hundred and ninety-five of which were single, while nineteen were multiple. Most of these were, however, very limited in number, while the cysts in the case described by Gerulanos were very numerous, varying in size from a pinhead to a man's head. Some of the largest had suppurated and contained masses of pus, while others showed the scolices and hooks, and others contained nothing except a clear yellowish fluid. The tumors were white, opaque, and either smooth or lobulated, surrounded by a fibrous capsule. The question of the origin of the multiple cysts is one of considerable importance. It is claimed by some that each cyst develops from a single embryo, by others that one cyst, containing an embryo is formed from which daughter cysts are given off; others believe that the rare cases of multiple echinococcus cysts are due to rupture of a fertile cyst and hence a reinfection of the surrounding tissues. Gerulanos, however, thinks that in his case at least the multiple infection was due to an active wandering of the embryos, which follow the paths of the loose connective tissue surrounding the large vessels, in the neighborhood of which these colonies were usually found. In the case reported by Scholtz, however, the hydatids were found on the outer side of the thigh, far removed from the great vessels. In several of the cases reported, trauma was described as an etiological factor, but probably, as Gerulanos suggests, the trauma has simply called attention of the patient to a latent tumor which has existed for a long time. The diagnosis of this condition must be based on the presence of an elastic, fluctuating, dense, slightly sensitive tumor. The sensitiveness will of course depend on the exact location of the hydatid. It must be differentiated from neoplasms and cold abscesses. The elasticity and fluctuation indicate fluid contents, while the lobulated, multilocular feeling and the history of the case will generally distinguish the echinococcus cyst from the cold abscess, although the cyst may also sometimes be smooth and spherical. The treatment consists in extirpation of the tumors.

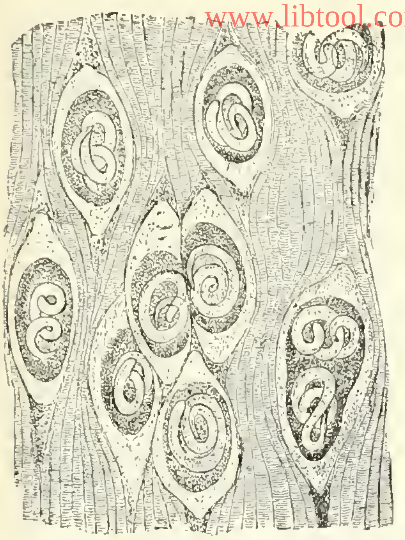

FIG. 3422.—Trichinæ Encysted in Voluntary Muscle. (Ziegler.)

MYOSITIS OSSIFICANS.—Myositis ossificans, as its name implies, is a disease in which an inflammatory affection of the muscles terminates in ossification. Long regarded as a pathological curiosity, it is still a comparatively rare disease, the character and etiology of which are not beyond controversy. Cases of pathological ossification naturally divide themselves into two great classes: those in which bone is formed in connection with bone, an abnormal activity of the cells of the periosteum being the apparent causative factor, and those in which bone is formed in the softer tissues, having no connection, primarily at least, with the skeletal bones or their periosteum. Myositis ossificans occupies a very prominent position in this second group of cases. Two types of this disease are sharply differentiated—a progressive and a stationary form. The progressive type, known as myositis ossificans progressiva, is distinguished from the localized form by the facts that many series of muscle groups are attacked, that it begins in youth and advances with occasional periods of apparent repose followed by exacerbations, which may or may not be attributable to any known exciting cause. This type is much more easily recognized than the second, so that most of the cases mentioned in the literature belong to it. The car-

liest cases of myositis ossificans progressiva were reported in the Philosophical Transactions of 1740. In the same journal in 1741, Copping gives the following graphic description of a case: "Das ganze Rückgrat war ein zusammenhängender Knochen, von dem sich ein scharfer Rand erhob, der wie eine Handhabe aussah, woran man das Skelet halten konnte. Es waren ihm jedes Jahr aus den Fersen Hörner gewachsen, wie die Sporen bei den Hähnen und die Ueberwüchse von Knochen waren in so grosser Menge da, dass es eben so schwer sein würde sie zu zählen als die Stalactiten in der Grotto der Calypso." In 1869, Münchmeyer, giving to the disease the name suggested by von Dusch, myositis ossificans progressiva, described the disease so accurately that little has been added to his description by later writers.

www.libtool.com.cn

He declares the disease to be a constitutional affection of slow course with periodical exacerbations followed by periods of apparent repose. The first disturbance of the muscle tissue begins with a marked infiltration of the intermuscular connective tissue, so that the name myositis ossificans interstitialis which has been suggested is not inappropriate; the second stage, that of connective-tissue induration, consists of an excessive growth of intermuscular connective tissue with destruction of the striated muscle as a result of pressure atrophy or fatty degeneration. The third stage is that of ossification, which begins in the centre of the affected muscle in the connective-tissue ground substance. The disease begins in youth with local swelling and later loss of function and ossification. Sometimes local and radiating pain is associated with it and also slight febrile reaction. The skin may be of higher temperature than normal and the connective tissue may be œdematous. The swelling may disappear after from two to four weeks, leaving the muscle hard and ossified, a condition which is sometimes temporary, but generally spreads to the origin and insertion of the muscle and remains permanent. With very few exceptions, the disease makes its appearance in the muscles of the back, especially in those of the upper portion of the back or of the neck. In connection with the neck muscles, the ligamentum nuchæ becomes ossified and the long muscles of the back generally form one mass of bone; later, the muscles of the scapulæ and the latissimus dorsi are involved; afterward the anterior muscles of the neck are attacked and then the deltoid and the muscles of the axial space. The final result is usually complete fixation of the head, immobility of the entire spinal column and ankylosis of the joints of both shoulders in the position of adduction, with fixation of the scapulæ. Still later, the muscles of the arm and forearm may become inflamed and the elbow-joint ankylosed; the muscles of the hand, however, possess almost complete immunity. In the further course of the disease the muscles of the pelvic girdle, the glutei, and then those of the lower limbs become involved; only at the last and in very severe cases does the disease extend to the muscles of the jaw and of the palate, while the face muscles usually remain intact. Münchmeyer notes the complete immunity of all muscles which are not attached to bone at both extremities, hence of heart muscle, of the diaphragm and sphincters, the muscles of the eye, of the tongue, the facial muscles, the muscles of the genital regions, and the muscles of the abdomen. This immunity is not, however, absolute, since Münchmeyer notes the occurrence of bony tumors in one case on either side of the chin, the location of which coincided with that of the triangularis menti. The disease rarely advances steadily; it is quite characteristic that there should be pauses which may last for years, the renewal of the process being either spontaneous or the result of some injurious influence. Deformities of a more or less severe degree, involving the position of the head, of the spine, and of the extremities result from the fixation of the joints, from the degeneration and loss of function of the muscles, and from the increase and subsequent contraction of the connective tissue. Münchmeyer closes his detailed description of this rare and terrible disease with the following vivid picture: "At first deprived of only a few not very necessary motions, the patient after a time can no longer carry food to his mouth, the hip and knee on one side become immovable, and finally walking becomes impossible. And during this whole long time, there is a constant alternation of hope, as each tumor disappears and as each pause occurs, and the sad feeling of bitterest disappointment as each new symptom appears, until finally all hope is gone, the mouth can no longer be opened, the food can be introduced only through an opening artificially made between the teeth; even swallowing and speaking become at times extremely difficult. The mental condition in a few cases indicates perfect resignation, but generally deep psychic depression prevails."

Although the disease is a comparatively rare one, a careful study of the literature has resulted in finding seventy-eight cases, most of which have followed the typical course which has been described. Exhaustive study of the literature of this disease has been made by Münchmeyer, Pinter, Pincus, Roth, and others, the results having been carefully tabulated by Pincus.

Little is known regarding the etiology of the affection. It occurs very generally in youth, with very few exceptions under fifteen, often in infancy, but Kronecker reports a case beginning at fifty-four. Males seem to exhibit a certain predisposition to the disease, nine of Münchmeyer's twelve cases being males and thirty of Roth's thirty-nine. Many factors are mentioned as predisposing to the disease, such as cold, damp, poor hygienic surroundings, insufficient nutrition, rheumatism, and other constitutional affections. A congenital predisposition is naturally suggested by the fact that it so universally occurs in early childhood, that it is so generally symmetrical in its development, and also by the fact that it is often accompanied by a curious congenital malformation. This is microdactylie, an ankylosis of the phalanges of the thumb, and a lack of one phalanx of the great toe on both sides. This malformation was first noted by Florschütz in 1873, since which time it has been observed in about seventy-five per cent. of all cases reported. While this is the most common abnormality noted in connection with this affection, other anomalies are mentioned, such as hallux valgus and other malpositions and incomplete development of the testis and other organs. Lexer has described quite minutely the microscopical appearance of sections taken from several tumors removed from two cases of myositis ossificans progressiva. Near the periphery of his preparations he finds quite normal muscle fibres. Nearer the centre, the muscle fibres are more or less degenerated, the cross striations lost, the muscle nuclei increased, so that the fibres in many cases resemble giant cells; the fibre is broken up, while the intermuscular connective tissue is increased and infiltrated with leucocytes, especially in the neighborhood of the capillaries. The connective tissue contains many cells of different forms, arising from division of the connective-tissue cells, which may be regarded as fibroblasts, while in some places may be seen cartilage cells with formation of hyaline cartilage. Nearer the centre the ground substance becomes denser, the former connective-tissue cells lie in small angular spaces, and the formative cells lie in rather regular rows on the dense tissue which comprises the osteoid trabeculæ. Later these become calcified and thus bone is formed. The fact that these tumors consist of true bone, often with all the structure of compact bone, is noted by many authors, who have not given so detailed a description of their findings as has Lexer. The degeneration of the muscle fibres, the increase of the connective tissue, and its infiltration with leucocytes are noted by all who have examined these tumors microscopically. Kissel, however, reports a case in which no osseous tissue was found, although the clinical picture was typical of the disease. The tumors showed only young connective tissue with remains of altered muscle. In his case some of the tumors disappeared, leaving no trace, while others broke down and a puriform liquid was discharged. This case improved somewhat under treatment and was regarded by Kissel as an incipient stage of the disease.

The *prognosis* in this disease is undeniably very bad. The course is, however, very slow, interrupted by many pauses of longer or shorter duration, and death directly assignable to the disease is very rare. As a usual thing, the disease drags its slow course along, the patient becoming more and more helpless, all vital functions unimpaired, until some pulmonary complication or some other intercurrent affection closes the scene.

www.libtool.com.cn

Treatment seems practically useless; yet, as in all hopeless diseases, many remedies are tried, partly in hope of relieving the most painful symptoms, and perhaps partly in the hope that the diagnosis may be wrong. Among the remedies suggested are thyroid extract, phosphoric acid, sodium salicylate. In a few cases, extirpation of the tumor was attempted in the earlier stages. So unanimous is the opinion regarding the bad prognosis in this disease that we may well be doubtful of the correctness of the diagnosis in those cases in which cure or permanent improvement is noted.

The disease has something in common with muscular rheumatism, with the muscular dystrophies, with polymyositis acuta, and with the multiple osteomata, but the history of the case, the order of advance of the disease from one series of muscles to another, the symmetrical nature of the affection, with the characteristic deformities resulting from the progress of the disease, make the diagnosis easy, especially in the later stages.

Cases of myositis ossificans confined to single muscles or groups of muscles are less frequently noted in the literature, either because the disease is less easily recognized or because it seems less striking and worthy of note. A careful study of the literature has resulted in finding thirty-five cases. Some of these cases followed a single severe injury, as in the four cases reported by Cahen, in which the growth resulted from the kick of a horse. Other cases resulted from repeated injury or strain, under which heading we may include the ossification of the deltoid and arm muscles in soldiers and of the thigh muscles in riders. This perhaps includes far the largest number of this class of cases. Then we have ossification of muscles occurring in the course of a chronic inflammatory process, which may be rheumatic, syphilitic, or tuberculous.

Cahen describes a case in which, six weeks after a kick had been received, a bony tumor was found about 12 cm. long on the left thigh, corresponding to the position of the biceps. After the failure of other modes of treatment, the tumor was excised; after a short time the tumor returned and was again removed, this time with the periosteum, to which it had become adherent. The sections from these two growths present somewhat different appearances. At the periphery of the section of the first tumor and crowded by connective tissue containing many blood-vessels and large spindle cells, he finds muscle fibres which have undergone many degenerative changes—hyaline degeneration, increase of nuclei of sarcolemma, loss of striation, etc. Near the centre of the tumor, he finds irregularly arranged trabeculæ of bone, with an epithelium-like lining of osteoblasts, with many lacunæ and giant cells, and the spaces filled with a marrow extraordinarily rich in blood-vessels and connective-tissue cells. All through the preparation are scattered bits of muscle, the relation being so intimate that single muscle fibres are completely embedded in bone. In the sections from the second tumor, no muscle fibres are seen. There are three distinct zones: a zone of greatly increased connective-tissue cells, then a zone of small-celled hyaline cartilage, which, by ingrowth of blood-vessels and giant cells, is changed into bone. There is no distinct boundary between the cartilage and bone, the cells becoming smaller and losing their capsules while the intercellular substance becomes denser, more opaque, and stains bluish-red in the hæmatoxylin-eosin double stain. The development of bone in all cases investigated stood in direct relation with an increase of the intermuscular connective tissue.

Lehman describes the case of a woman of thirty-six years, who presented herself with a tumor in the thigh which had been developing at irregular intervals since her seventeenth year. The tumor was extirpated and with it the greater part of the biceps, which was involved in the tumor mass. Microscopical examination showed

FIG. 3424.—Microscopic Appearance of Muscular and Osseous Tissue, Removed from one of the Tumors in a Case of Myositis Ossificans. (Cahen.)

a large amount of adipose tissue, permeated by bands of altered muscle. The changes in the muscle were as follows: 1. Indistinctness or entire loss of cross striation; this condition is called "streifige Degeneration des Muskels." 2. Loss of longitudinal striation—homogeneous appearance of muscle. No true fatty degeneration was however noted. 3. Increase of muscle nuclei, as is seen in atrophied muscle. These changes are accompanied by proliferation of connective-tissue cells. The young connective tissue, in the course of its maturing, undergoes manifold changes until from it peculiar fibrous or osseous tissue is developed. The osseous tissue is typical compact bone except that the lamellar systems are irregularly arranged and differ materially in the size and age of the systems. In some portions of the tumor bone was found, in others musculo-connective tissue, and in others a tissue which forms a transition between bone and connective tissue and might be called osteoid, since the structure of bone is distinct, but calcification is incomplete. This case is interesting on account of the large amount of fat tissue developed among the degenerated muscle fibres, so that Lehman has named this a case of myositis ossificans lipomatosa.

The author has recently reported two cases of myositis ossificans limitata, the autopsies on which were performed by Dr. Warthin. One of these cases was that of a young farmer, aged twenty-three years, the cause of whose

Digitized by Microsoft®

death was pulmonary and laryngeal tuberculosis. He died April 11th, 1897. His clinical history presents nothing of interest in this connection until March 1st, 1897, when he complained of pain in the left leg. On examination the left leg and foot were found swollen, soft, and œdematous. The thigh was also swollen, although less than the leg. On March 8th, 1897, examination showed the left leg only slightly œdematous and it was no longer painful. No tumor was detected, however, and a marasmic thrombus was believed to have caused the œdema. The autopsy showed a very general tuberculous process. Both lungs were infiltrated with tubercles and contained large cavities. Small tubercles were found in the spleen, liver, adrenals, and kidneys, and a tuberculous ulcer in the lower portion of the ileum. The bronchial glands contained many areas of caseation, the mesenteric glands were enlarged, many of them caseated, and all the lymph glands of the body were enlarged. In the left saphenous vein was found an old obturating thrombus, which extended through the femoral, the left external iliac, and into the left common iliac and the abdominal vena cava. Around the wall of the femoral vein there was an area of hyperæmia and infiltration, originating apparently from an enlarged lymph gland near by. This gland on section showed infiltration and caseation. The microscopical appearance was as follows: Both femoral vessels were nearly or quite filled by thrombi in various stages of organization. The entire section showed marked hyperæmia, all the smaller vessels and even the capillaries being distended and packed full of blood corpuscles. The connective tissue surrounding the large blood-vessels, as well as that around the smaller ones, was infiltrated with leucocytes, which were especially numerous in the tissue around the capillaries. This leucocytic infiltration was especially marked in the intermuscular connective tissue and around the capillaries of the endomysium. Many of the leucocytes showed degeneration and in some portions of the sections larger or smaller necrotic, abscess like areas were found. Surrounding these necrotic areas, and indeed in many portions of all the sections, attempts at repair were noticeable. The inflammatory tissue had been replaced by a new granulation tissue, rich in small, thin-walled blood vessels and in large plate-like cells with little fibrous tissue. The most marked changes, however, were in the muscular tissue. In addition to the alterations in the intermuscular connective tissue already noted, various degenerative changes in the muscle were observed.

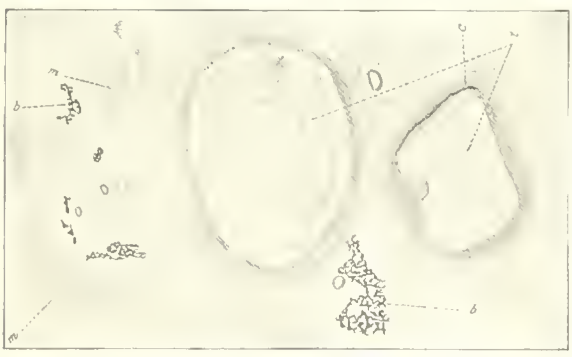

FIG. 3125. Section Through Both Thrombosed Femoral Vessels, Muscles, Fat, Connective Tissue, and Granulation Tissue Containing Plates of Bone. *m*, Muscle; *b*, bone; *c*, calcification; *t*, thrombus. Drawn under the dissecting microscope, with aid of camera lucida. Magnified about eight times. Reduced to one-half size of drawing. (DeWitt.)

In some portions of the sections, especially at a distance from the centre of the inflammatory area, the muscle appeared fairly normal, both in size and in the finer structure. Near the centre of the inflammatory area, however, the muscle fibres were much smaller, of very irregular contour, and either tapered to a point or divided into numerous bundles of finely fibrillar tissue resembling fibrous connective tissue. The cross striation was lost and in some even the longitudinal striation seemed lost or very indistinct, so that the fibre appeared finely granular or entirely homogeneous. In some places a muscle nucleus, with a fusiform fragment of sarcoplasm, was separated off from the rest of the cell. The nuclei may be absent from a considerable portion of the fibre and crowded together at one end or at one side, and often a small fragment of muscle containing many nuclei, or even a mass of nuclear substance in which the nuclear outlines were very indistinct was seen. Small, isolated, fragments of muscle could be seen in the granulation tissue and even in and near the inflammatory, necrotic areas, containing numerous nuclei embedded in homogeneous-appearing protoplasm, producing the appearance of giant cells. These may be interpreted as attempts at regeneration of the degenerated muscle fibre, although probably many of the forms, especially those in the necrotic areas, were degenerating sarcolytes. In addition to the simple atrophy, fatty degeneration and Zenker's waxy necrosis were noted.

In the granulation tissue, which seemed to have replaced the larger inflammatory areas, were irregularly branching and anastomosing trabeculæ of osteoid tissue consisting of a dense matrix, enclosing rather large cells usually not surrounded by a capsule. The spaces between the trabeculæ were filled with very vascular granulation tissue, somewhat resembling bone marrow. Many of the large cells of these areas were arranged on the trabeculæ, like the layer of osteoblasts on the trabeculæ of developing bone. Most of the osteoid tissue had undergone calcification, at least in the central portion, so that, according to Ziegler's definition, it represented a true ossification process. It may be added that some of the sections were stained by Schmorl's bone stain, and, while, as might be expected from the short duration of the process and the thinness of the trabeculæ, no structure of compact bone was to be seen and the cells did not show the processes so characteristic for adult bone cells, yet in each case a layer of greater or less width surrounding the trabeculæ gave the typical color reaction given by bone to that stain. In some of the sections these plates of bone formed a nearly continuous ring around the large blood-vessels. In others they were scattered throughout the section in smaller masses, always found in the granulation tissue, never in the old connective tissue, nor in the inflammatory tissue which was still undergoing retrograde changes. These ossified masses were found, not only immediately around the femoral vessels, but also extending out in all directions between the degenerating and regenerating muscle fibres, wherever a sufficiently large area of granulation tissue was found. The relation of the plates of bone to the other tissues in the section is represented in Fig. 3125. In the marrow spaces were often seen bits of degenerated muscle, atrophied, non nucleated, and appearing homogeneous.

By Unna's orcein differential stain and also by Weigert's stain for elastic tissue it was shown that a regeneration of the yellow elastic-tissue fibres was taking place in the granulation tissue. Although the patient was tuberculous, no tubercle bacilli were found in the enlarged lymph glands in the neighborhood of this inflammatory process, nor was the structure that of a tubercle, but rather that of a simple, necrotic abscess. The changes in the tissue indicate that the intermuscular inflammation, the changes in the muscle, and the bone formation antedated by a considerable period the thrombosis, which was probably secondary to the other changes.

In the second case, the clinical history presented nothing of interest except the fact that the femur was broken about five weeks before the death of the patient, but the fracture was not in the immediate neighborhood of the point of ossification of the muscle. The microscopical appearance of the two cases was identical and an obturating thrombus was found in the femoral vein in both. The fact that in these two cases the ossification was not discovered until the autopsy had been made and the

Digitized by Microsoft®

tissues examined microscopically is of interest as suggesting the possibility that pathological ossification of muscle after injury or inflammation may occur much more frequently than is generally supposed or than can be gathered from the literature, since such an ossification, if limited in extent, may not cause any symptoms that would lead to the diagnosis of myositis ossificans. When the diagnosis is made and the disturbance is sufficient to warrant it, operation seems to offer great hope of recovery. In the cases reported by Cahen, Lehmann, Munro, and others, entire extirpation of the tumor, with the periosteum in cases in which the bone had become adherent to the periosteum, resulted in perfect recovery. Much difference of opinion has arisen as to the true character of the bone formation. Virchow places the disease on the border line between inflammation and new growth and is supported by Lexer, Bollinger, and many others. Mays asserts that it is a true tumor and is supported by Kümmel, Pinter, Helferich, Pincus, Partsch, Cahen, and others. Cahen bases his assumption on the microscopical appearance, especially on the fact that new connective tissue, cartilage, osteoid tissue, and bone are found in the same section, thus showing the characteristics of an atypical growth. They consider the inflammatory phenomena and muscle degeneration to be secondary to the tumor formation. Pincus, after a most exhaustive study of the literature and of his own cases, arrives at the conclusion that myositis ossificans progressiva is not a disease, but undoubtedly a tumor belonging to the multiple osteomata and exostoses of Virchow. He states that the process begins in the periosteum, the muscle degenerating secondarily, and that an inborn, not hereditary, constitutional anomaly lies at the foundation, the constitutional anomaly consisting of an excessive productivity of the periosteum and connective tissue of the locomotor apparatus. The disease needs for its development an external cause, which may be trauma or rheumatism. The apparently spontaneous cases arising in early life are really of traumatic origin and due to intrapartum injuries. Nicoladoni advances the hypothesis that it is a trophoneurosis, comparable to progressive muscular atrophy and pseudohypertrophy of muscle. Electrical tests, however, indicate the absence of any neuropathic factor and the disease is probably myopathic, and either primarily inflammatory in character or having the primary characteristics of a neoplasm. In the progressive form of the disease many of the tumors are probably neoplasms, while others, as would seem to be indicated by Lexer's description, are developed on an inflammatory basis. In consequence of the diffuse interstitial myositis, an indifferent granulation tissue arises, which may change either into scar tissue or into cartilage and bone. In the myositis ossificans limited to single muscles or groups of muscles, the primary condition is an inflammatory process in the intermuscular connective tissue resulting in the degeneration of the muscle fibres, either from simple pressure atrophy or from fatty degeneration, so that the name myositis interstitialis ossificans seems not inappropriate. Processes of repair are then established, granulation tissue rich in fibroblasts and small blood-vessels, in which white fibrous and yellow elastic fibres are sparingly developed, is formed. Instead of changing to mature connective tissue, however, a portion of this granulation tissue changes to trabeculæ of osteoid tissue, and the rest into bone marrow which fills the spaces between the trabeculæ. This is not unusual since, as is well known, the different members of the connective-tissue group change with great readiness to other forms of connective tissue. Cold, unsanitary surroundings, trauma, either single or repeated, irritation, as in the exercise bones, or chronic pathological processes may act as the direct causes of the development of the disease. This might be satisfactory on the etiology of the affection, were it not that the exciting cause is often so slight and trivial that we cannot believe it sufficient to produce the disease in a normal individual.

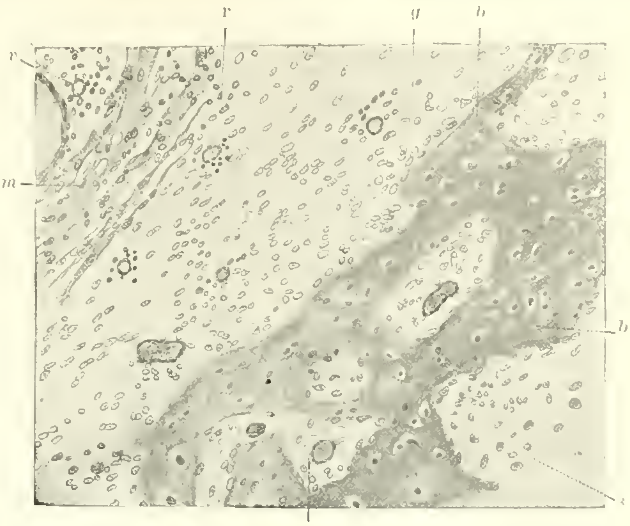

FIG. 3426.—Section Through a Few Trabeculæ of Pathological Bone Formation, with Marrow Spaces, Surrounding Granulation Tissue, and, at the Periphery, Degenerating Muscle Fibres. *b*, Bone; *m*, degenerating muscle; *g*, granulation tissue; *s*, marrow spaces; *r*, capillaries surrounded by connective tissue infiltrated with leucocytes. Drawn with the aid of the camera lucida. No. 2 eyepiece; one-sixth inch objective. Reduced to one-fourth. (DeWitt.)

This is especially true of the progressive type, while in the stationary form of the disease the irritant cause which has operated on hundreds of cases has produced ossification in very few. The explanation of these facts has opened a large field for conjecture and speculation. Virchow believes that in these individuals there is an ossifying predisposition, either hereditary or congenital, which he calls diathesis ossificata sive ossea. Mannz suggests as a predisposing causative factor a disturbance of embryonic development. He says: "In the 'Anlagen' of musculature, where in later life pathological bone formations occur, osteoblastic nuclei enter. These nuclei remain dormant so long as they are held in check by the physiological resistance of the neighboring tissues. If, however, this be weakened, the bone Anlagen develop into the pathological bone formation." He explains in a similar way the occurrence of exostoses and osteophytes which are so frequently found in conjunction with the muscular ossification. Those who favor the view of embryonic disturbance cite the frequent occurrence of microdactylie in this disease as an evidence in favor of their hypothesis. Atavistic influence, misplaced periosteal buds and osteoblasts, etc., have been suggested. Direct heredity, however, seems from the history of the cases reported to have very little influence. Atavistic influence seems to be contraindicated by the fact that in the hand and foot, where splint bones are most common in the lower animals, these osseous growths rarely occur. In the progressive myositis ossificans, beginning in early life, it may be necessary to admit the hypothesis of a congenital condition consisting of an abnormal activity of the osteoblastic, or, if we accept the Weismann theory of embryonic development, the persistence of indifferent, undifferentiated mesenchymal cells, which, under the requisite conditions of nutrition, develop abnormally into nodules of fibrous connective tissue, cartilage and bone, sometimes in connection with the skeletal bones, sometimes in fascia, tendons, ligaments, or intermuscular connective tissue. In the localized form of the disease, however, no such hypothesis seems to be necessary. In these cases granulation tissue is formed, a new connec-

Digitized by Microsoft®

www.libtool.com.cn

tive tissue, whose cells may therefore revert to the undifferentiated, indifferent, embryonal cell type, mesenchymal cells, which may develop into fibrous tissue, cartilage, or bone according to the prevalent nutritive conditions.

www.libtool.com.cn

WOUNDS AND INJURIES OF MUSCLE.—Injuries of muscle may be of the most varied degree of severity, from a slight strain or sprain, twisting, or laceration of a few fibres of the muscle, which results in the so-called myalgia, to complete severance of all the fibres of the muscle.

Myalgia is a temporary condition of pain in the muscle, which is usually neuralgic, and which is caused by a slight traumatism, with possibly an inflammation of the muscle, or may arise from an acute infectious disease, from syphilis, or from some toxic agent, as mercury, alcohol, or lead. The affection is usually but trivial, and is cured spontaneously, especially if the affected part is put at rest by the use of splints or strapping. Local applications of heat and anodyne solutions are useful, and the pain may at times be so severe that hypodermic injections of morphine may be necessary. If the muscle fibres are weakened by disease or degeneration, or if the strain upon the muscle is too great, either from an external force or from too violent and sudden contraction, the muscle may be fractured, either completely or partially. Fractures and lacerations of healthy muscle are rare except in cases of sudden, unexpected, or unusual contractions. Such accidents are more common among soldiers. Certain diseases, however, such as typhoid fever, yellow fever, scarlet fever, and other severe fevers weaken the resistant power of the muscle, which may undergo various degenerative changes which make it more brittle. The rectus abdominis, the rectus femoris, the adductors of the thigh, the calf muscles, the psoas, and the flexors of the forearm are the muscles most frequently fractured. The symptoms of fracture of muscle are quite characteristic, consisting of sudden sharp pain, with a sensation of giving way and powerlessness of the muscle. In case of complete rupture, a gap is immediately formed between the broken ends of the muscle by the contraction of the parts, and this gap, which can easily be palpated, is a characteristic feature of the affection. It is soon filled, however, by an extravasation of blood, which may form a hæmatoma of greater or less extent and hence a prominence in place of the depression. The skin becomes discolored usually from the extravasation of blood. Wherever muscle is lacerated, whether the tear is large or small, blood extravasates into the tissues, except in those cases in which the injury is very near the tendinous extremity of the muscle, where the vascular supply is poor. The interference with the function of the muscle depends upon the extent of the laceration, the use of the muscle being lost in cases of complete rupture. If only a few fibres of the muscle are broken, recovery is usually rapid and complete and the function of the muscle may be quite well restored even when the injury is quite extensive. In these milder cases the only treatment usually necessary is perfect rest of the affected part. If, however, the muscles are completely torn across, it is usually necessary to suture their ends; and where there is a considerable gap between the ends, it may be well to fill in the interval with the muscle from an animal (muscle grafting), or with sutures of chromicized catgut or kangaroo tendon to act as a framework for the reparative material. The interval is at first filled with granulation tissue, even the engrafted muscle undergoing degenerative changes, later a scar tissue is formed, penetrated in places by the regenerated muscle fibres. In spite of the experimental work on muscle grafting previously mentioned, the consensus of opinion among surgeons and pathologists seems to show that, while the function of the muscle may be fairly well restored, muscle fibres are not regenerated in sufficient numbers to fill the intervening space. At times the injury results in the formation of bone in the granulation tissue following the law of the metaplastic tendencies of the connective tissues. In some cases the muscle remains intact, while the overlying fascia is torn, generally as the result of the imperfect healing of some former wound. In these cases the muscle may protrude through the opening in the fascia, forming a muscle hernia. Féré collected thirty-one cases of muscle hernia in epileptics, fifteen of which were symmetrical, a finding which would seem to indicate a certain nervous influence as a possible etiological factor in these cases. The hernia is distinguished from a neoplasm in the muscle, from an aneurism, etc., by the fact that it disappears entirely or diminishes in size when the muscle is at rest, becoming prominent during the contraction of the muscle. Generally the opening in the fascia can be felt through the skin. The condition may often be attended by considerable inconvenience, pain and loss of function of the affected muscle. Rest and bandaging are usually sufficient to effect a cure in recent cases. In cases of long standing it may be necessary to freshen the edges of the rent and unite them by stitches. It is distinguished from fracture of muscle by the fact that the symptoms usually develop more gradually than those of fracture. It affects the adductor muscles by preference. Muscle may also be more or less completely crushed by external violence. The results of this as well as of other injuries of muscle depend upon several factors. Apparently identical injuries may in one case cause only temporary disturbance of function, in another ossification, and in another paralysis. Young tissues tend to heal more readily than old. The condition of the muscle at the time of the injury, whether at rest or contracted, has a marked influence on the effect of any traumatism. The nerve fibres which may be cut, injured, or compressed may have a vital bearing on the permanency and severity of the functional disturbance. Single or repeated injuries of muscle may have a real or fancied relation to the development of malignant tumors, a fact which may be explained by the assumption that embryonic tumor-tissue germs are latent in the muscle, which are either excited to activity by the irritation produced by the traumatism or permitted to grow because the normal resistance of the tissues is removed or diminished as an effect of the injury.

II. INVOLUNTARY MUSCLE.

Involuntary muscle has a wide distribution, occurring in the walls of the digestive tract, blood-vessels, skin, in the capsules of many organs, and making up the greater part of the structure of the uterus, bladder, and other organs. Its structure is far simpler than that of voluntary, striated muscle, and its pathological changes are therefore less complicated and have received less attention and research. It consists of mononuclear, fusiform cells, cemented together to form bundles or membranes, which are separated by a larger or smaller amount of connective tissue. The pathological processes in nonstriated, as in striated muscle, consist of inflammations, degenerations, and tumors. Certain abnormalities may be noted occasionally, such as the presence of striated muscle fibres among the involuntary muscle fibres of the uterus. These may be due to the metaplasia of nonstriated into striated muscle or to the misplacement of embryonal cells.

The pathological processes occurring in involuntary muscle have not attracted the attention of investigators as have those of voluntary muscle. This may be explained, in part at least, by the fact that any disturbance in the function of voluntary muscle causes unmistakable symptoms, while in most cases the symptoms of change in involuntary muscle are masked and indefinite and the pathological processes in it are often not recognized until after the death of the patient. In most cases of muscular atrophy, whether neuropathic or myopathic, and in other muscular degenerations the statement is made either that the involuntary muscle was normal or that it was not examined. Certain regressive changes, analogous to those which occur in striated muscle, are, however, observed, having been described especially in connection with inflammations and tumors of the myomatous type. Œdema of non-striped muscle is frequently

Digitized by Microsoft®

noted. Kenntmann described a case of myometritis œdematosa, in which the muscle fibres of the uterus became so soft and œdematous that the uterine wall was perforated by a sound. Microscopical examination of the myometrium in this case showed the muscle bundles separated by large clear spaces, equal in size to the muscle bundles themselves. This condition was especially marked in the vascular middle layer, in which the blood-vessels presented thickened walls, the connective tissue of the intima being especially thickened. The muscle cells appeared cloudy and in places atrophied. Near the vessels the muscle fibres appeared especially narrowed, even the nuclei being atrophied. Large areas were found in which the muscle had undergone pathological degeneration. No solid strands or bundles were found, and the single fibres were so small that they gave the impression of being reduced to fine fibrils, whose single thicker part, we might almost say whose single dimensional part, consisted of the degenerated and poorly stained nucleus. The connective tissue was probably somewhat increased, but not markedly so; still in places where the muscle was most degenerated, some increase of connective tissue could be observed. Similar degenerative changes are frequently observed and described in myomata of the uterus, which have undergone myxomatous or œdematous degenerative changes.

Atrophy of involuntary muscle occurs under conditions similar to those of atrophy of voluntary muscle. A neuropathic form of atrophy of involuntary muscle—although a form which may be considered neuropathic has been mentioned in connection with vitiligo and other skin diseases—has not so far as I have been able to find, been described. The atrophies are largely due to circulatory disturbances, as in the case above described, or to pressure of a fluid or cellular exudate, as in inflammations. No better picture of atrophy of involuntary muscle has been given than that by Kenntmann. Similar atrophy of the involuntary muscles of the skin in skin diseases has been described by Unna, Pospelow, and Lelois and Vidal.

Hypertrophy of non-striated muscle frequently occurs and may be physiological or pathological. The best example of the physiological hypertrophy is that found in the pregnant uterus. Pathological hypertrophy occurs as a result of stenosis or obstruction of the intestinal canal and other ducts. This is regarded by Herczel as a true hypertrophy, without increase of the number of cells, although many authors regard it rather as a hyperplasia accompanying the hypertrophy. Hypertrophy of the skin muscles was also described by Unna in keratosis suprafollicularis and in pityriasis rubra and other skin diseases. In elephantiasis streptogenes he found the non-striated muscles enlarged, but not increased in number. Calcification of involuntary muscle was noted by Meslay and Hyeme and others, and Brunings reports a case of fatty degeneration of a myoma, the process corresponding to that in progressive muscular atrophy. True ossification of uterine myomata has also been noted. Liquefaction necrosis of the dermal muscles was noted by Unna in abscesses and a collaginous degeneration of these muscles in erysipelas. Gangrene and other forms of necrosis have also been observed in myomatous tumors, as well as cystic degeneration. Nuclear degenerative changes have also been noted, such as atrophy, vacuolation, granulation, and karyolytic changes. The question of the *regeneration* of involuntary muscle is one which has been considerably discussed, and upon which authors are still at variance. Vignolo-Lutati, in his experimental study of the pathological conditions in the skin muscles, was never able to find karyokinetic division figures, but frequently, especially after the less severe injuries, he found appearances which he interpreted as direct nuclear division. Ziegler states that "there is a new formation of smooth muscle fibres and also a regeneration after traumatic, toxic and chemic injuries, as well as in the hypertrophic new formations of muscle, as in tumors; that this process begins with the karyokinetic division of the nucleus of the muscle cell. However, it is shown by experiment as well as by observation of men that there is very little reproduction of the non-striated muscle fibres, as in the healing of wounds and areas of degeneration, the regeneration soon ceases and the loss of substance in the muscular coats of stomach, intestine and bladder is replaced mostly by connective tissue. The new muscle tissue is formed probably entirely from preexisting muscle tissue." Moleschott and Piso Borne and Busachi support these conclusions, while Arnold, Aeby, Frey, Neumann, and Virchow favor the view that it may originate from connective-tissue cells, and Kölliker and Förster believe that it develops from embryonal germ cells or formative cells. Tizzoni also found a zone of proliferation near the diseased area in typhoid ulcer of the small intestine; and Baumgartner in cases of tuberculosis found mitoses in the muscle tissue of the arteries, veins, and bronchi near the affected area. Herczel and Baumgartner were unable to find signs of proliferation after their experiments, while Vignolo-Lutati found only direct nuclear division in the skin muscles in his experiments. From all this work we may conclude that regenerative changes occur in non-striped muscle as in striated muscle, both by mitotic and by amitotic nuclear division; but that the result is only a partial replacement of the destroyed muscle tissue, the main portion being replaced by scar tissue.

Inflammatory processes in smooth muscle are exceedingly common, although generally secondary to similar processes in the neighboring tissues. Vignolo-Lutati reports the development of inflammatory changes in the involuntary muscle of the skin as the result of the injection of bacria and also of chemical, thermic, and mechanical irritants. With some variations in degree, the pathological picture in all these experiments was essentially the same. The intermuscular connective tissue was infiltrated with leucocytes, which were either diffusely scattered through the tissue or formed small nodes. The blood-vessels were distended and filled with blood, while the whole tissue appeared œdematous. The muscle fibres were swollen, vacuolated and hydropic, and crowded apart by the exudate. The muscle nuclei were either granular or vacuolated and karyolytic figures were noted in some of the experiments. After the simpler mechanical injuries the nuclei showed direct division, which the authors regarded as preliminary to regeneration of the muscle fibres. Purulent inflammation of the non-striated muscle of the uterus is a very frequent occurrence, while Aristoff notes a case of syphilitic inflammation of the muscle coats of the stomach, extending from the mucosa. Tuberculous nodes have been noted in the non-striped muscle of myomas of the uterus, as well as in involuntary muscle in other localities.

Muscle Tumors.—Certain tumors composed largely of muscle are known as myomas, one class of which consists of striated muscle and are called rhabdomyomas, while the other and more common class of myomas consist of non-striated muscle and are called leiomyomas. The rhabdomyomas have a stroma of connective tissue in which cells and fibres are found which resemble striated muscle cells in various stages of development, degeneration, and regeneration. None of the cells appear as normal, mature striated muscle cells. Many of the cells are small, spindle-shaped cells with a single nucleus or with a few nuclei and with a very faint striation or even showing no transverse striation at all. Others are larger and the striation more distinct, but irregularly arranged, while the nuclei appear at the periphery of the fibre. Some appear granular, with undifferentiated hyperchromatic nuclear substance collected in the centre or near the periphery. Drops of glycogen may be seen in the protoplasm. Sarcomatous, myxomatous, fatty, cartilaginous, or osseous tissue may be mixed with the muscle tissue of these tumors, giving rise to the rhabdomyosarcomas, rhabdomyomyxomas, rhabdomyochondromas, etc. The teratomas also consist in part of muscle tissue closely resembling the atypical striated muscle tissue of the rhabdomyomas. The rhabdomyomas may occur in regions in which striated muscle is normally present, but

www.libtool.com.cn

Digitized by Microsoft®

are far more common in the kidney, testes, uterus, and other organs in which striated muscle is not normally found. They occur in childhood and even in the newborn, and it is generally conceded that they arise from misplaced embryonic muscle tissue. Fujinami, however, reports an interesting case of a so-called cylindroma and rhabdomyoma in a man of fifty, in the voluntary, skeletal muscle, the tumor showing a distinct endotheliomatous arrangement. There was a hyaline degeneration of certain tumor cells, as well as of the vessel walls and connective-tissue fibres, but especially of the fusiform sarcoma cells. Fujinami believes that the crosss-triped muscle cells arise from the fusiform sarcoma cells.

www.libtool.com.cn

Leiomyomas are far more common and occur usually in adult life and in the organs consisting of non striated muscle tissue, as the uterus, prostate and the muscular walls of the stomach and intestine. The tumors consist of strands of fibrous connective tissue, between which are found bundles of non-striated muscle, running in different directions. Although often hypertrophied, the muscle cells are fairly normal and yet sharply separated from the surrounding muscle tissue, either by a connective-tissue capsule or by a different arrangement of the muscle fibres. Blood-vessels run through the tumor mass, the arrangement of the muscle cells of the tumor having often a direct relation to the axis of the blood-vessel. These tumors are regarded as benign tumors, the seriousness of which depends upon the size which they may attain and the organs and tissues upon which they may press. When they occur in the intestine, however, especially in the internal coat, they cause an obstruction which is often fatal. They may also cause hemorrhage in the intestine, although this is not often seen in myoma of the stomach. If situated in the outer coat of the intestine, they may develop for a considerable time before causing any obstruction. Although the leiomyomas are generally regarded as purely benign tumors, Brodowski, Hansemann, and Schmorl describe multiple metastases in tumors which were regarded as pure myomas. Such observations are, however, so rare that the question naturally suggests itself whether some, possibly small, areas of the original muscle tumor may not have been sarcomatous. The occurrence of epithelial or glandular tissue within the muscular tissue of the myoma is noted by Schroeder and Ruge, Recklinghausen, and many

FIG. 3427. Degeneration of Muscle Fibre (a), and Penetration of Fibre by Carcinoma Cells (b). (Fujinami.)

others. This may give the tumor an adenomatous or even a carcinomatous character. These adenomatous appearances are found especially in the digestive tract, as in the case reported by Lubarsch, which he regarded as aberrant pancreatic tissue, which had excited the surrounding muscle to new growth. The muscle may undergo also all kinds of degenerative changes, such as calcification, gangrene, necrosis, œdema, inflammation, which may be tuberculous or simply purulent. It may also be so richly vascularized as to give it a telangiectatic or cavernous character. The sarcomatous and the rarer carcinomatous malignant degenerative changes in these tumors have already been mentioned. Steiner has collected from the literature and reported fifty-two cases of

FIG. 3428.—Muscle Forms Found in the Neighborhood of Malignant Tumors. (Fujinami.) a, b, c, h, Ampullar degeneration; d, e, f, g, giant-cell formation.

myoma of the stomach and intestine, while those of the uterus and prostate are much more numerous. The multiple dermatomyomas form a most interesting class of cases, in which numerous painful swellings arise in the dermis developed from the non-striated muscle of the blood-vessels, from the arrectores pilorum, or even from the involuntary muscle of the sweat glands. The etiology of the leiomyomas is still in dispute. Although they usually develop late in life, the theory is advanced by some that they are of embryonal origin, the tumor germs remaining latent, until they are excited to activity by some irritation. Others claim that they originate by a metaplasia of the connective tissue. Some claim that

FIG. 3429. Showing Twisting of Fibrils within the Sarcolemma. (Fujinami.)

the tumor tissue arises from the non-striated muscle of the blood-vessels and others say that the muscle tissue of the organ in which it develops is responsible for its growth. While all these theories have strong supporters, it seems reasonable to conclude that the muscle tissue of

Digitized by Microsoft®

these tumors usually originates from pre-existing muscle tissue, either of blood-vessels or of the organ involved, or from embryonal germs of such tissue which have re-

FIG. 3430.—Showing Irregular Contour of Muscle Fibres and Irregular Arrangement of Striation. (Fujinami.)

mained latent until some cause excited them to growth or removed the inhibition which was preventing their development.

Among the less important, because less frequent tumors arising in muscle are lipomas, angiomas, fibromas, chondromas, osteomas and myxomas. The structure of these tumors when found in muscle does not differ materially from their structure in other localities.

Carcinoma in muscle is a result of lymphogenous metastasis or of the infiltration of the muscle by the carcinomatous nodules in the neighborhood. The muscle fibres take no part in the formation of the tumor, although they undergo various degenerative changes, and the tumor cells may even penetrate the broken sarcolemma and fill the muscle fibre, as shown in Fig. 3427. From this fact it has been said that the carcinoma cells arise from the muscle cells, but although we recognize the atypical character of origin and growth of tumors, yet it seems unnecessary to assume in this case a mode of origin so remote from the normal type. Inflammatory processes may also be seen in the neighborhood of these tumors. *Sarcoma* is, however, the most common malignant tumor occurring in non-striated muscle. These may be very large and either consist of round cells or of spindle-shaped cells. The sarcoma may be mixed with fat, fibrous tissue, mucoid tissue, etc., forming the liposarcomas, fibro-sarcomas, and myxosarcomas. As in carcinoma, sarcoma cells may penetrate the broken sarcolemma, giving the impression of being formed from the muscle cells. The structure of these tumors does not differ materially from that of analogous tumors in other regions. We are therefore far more concerned at this place with the pathological changes produced in the muscle by the ingrowth of the tumors than with the structure of the tumors themselves, which will be fully treated in another place. Schaeffer, Fujinami, Anzinger, and others have investigated the changes which occur in voluntary striated muscle in the neighborhood of malignant tumors, and have found nearly every possible form of degenerative change. Fujinami asserts that the alterations in the muscle are essentially the same in sarcoma as in carcinoma, while Anzinger believes that degenerative changes are more marked in the neighborhood of carcinomas, while the so-called regenerative changes are seen in greater abundance near sarcomas. All agree that the distinctness of the striation may be greater or less than normal, varying much in different portions of the same preparation. Atrophy is the most frequent and constant change, due probably, at least in part, to a disturbance in the nutrition of the muscle, but partly also to the diminished functional activity of the muscle, and possibly also to nervous and trophic influences. Peculiar depressions, containing large numbers of muscle nuclei, are often found at the sides and ends of the fibres, giving an irregular contour to the fibre; this is known as lacunar erosion. The muscle fibres may also break up, either longitudinally into slender fibrils containing rows of nuclei, or transversely into segments containing groups of nuclei. Fujinami also notes a peculiar twisting of the muscle fibrils within the sarcolemma. Zenker's necrosis, cloudy swelling, vacuolation, proliferation of nuclei, both by mitotic and by amitotic processes, with marked alterations in the nuclear form, are frequently observed in the neighborhood of these tumors. Fujinami regards all these changes as essentially degenerative in character, in spite of the fact that certain multinuclear forms resembling the myoblasts of regenerating muscle are frequently seen. Anzinger and others regard these giant-cell forms as abortive attempts at regeneration. While more work is needed on this point, there seems little doubt that at certain stages of the process degenerative forms occur which closely resemble the regenerative forms of voluntary muscle, although the conditions are such that no attempt at regeneration is to be expected.

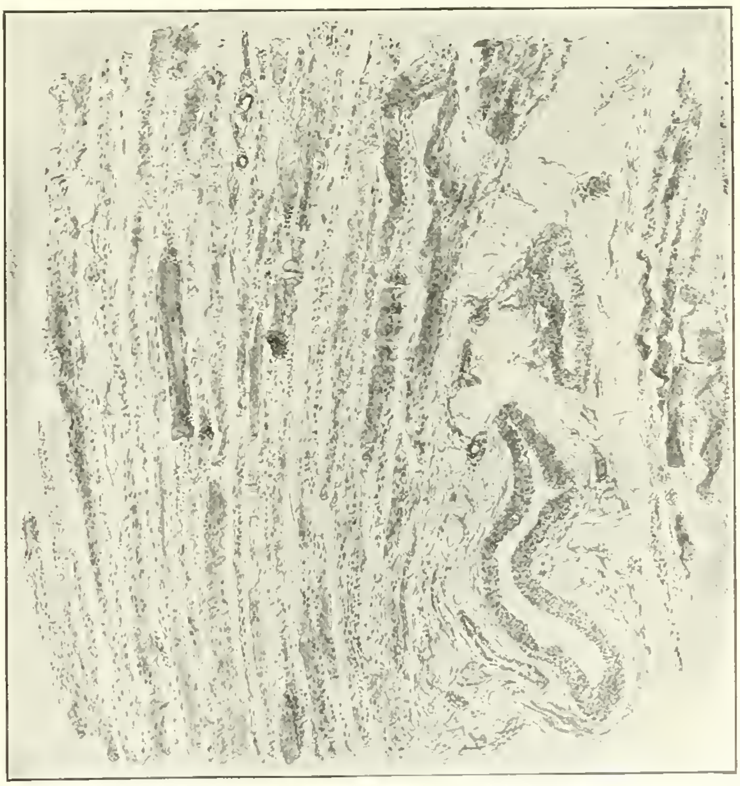

FIG. 3431.—This Figure Shows the Atrophy, Irregular Contour, Faint Striation, and other Degenerative Changes in the Muscle and the Inflammatory Process in the Intermuscular Connective Tissue in the Neighborhood of a Malignant Tumor. (Anzinger.)

The perimysium of the voluntary muscle in the neighborhood of these malignant growths is often hyperplastic and shows leucocytic infiltration, hemorrhage, œdema, fat infiltration. Endarteritis and periarteritis are frequent occurrences.

Digitized by Microsoft®

The penetration of mast cells and leucocytes and even of tumor cells into the muscle cells is one of the most interesting points mentioned in the study of these cases. Fujinami has figured a number of muscle cells containing a larger or smaller number of tumor cells and states that the tumor cells may be derived from the degenerating muscle cells. This idea is refuted by Schaeffer, although supported by Schroeder, Neumann, Bardeleben, and others. Schaeffer states that there may be a great similarity between the tumor tissue and the muscle tissue, which makes confusion possible, and that the tumor cells may penetrate the muscle fibres. The origin and etiology of these tumors in muscle, as in other tissues, are still obscure; but it seems more reasonable to regard the appearance of the tumor cells within the sarcolemma as a result of the passage of these cells through a broken sarcolemma, especially as they are accompanied in this position by leucocytes and mast cells, than to believe that the tumor cells are formed from the contractile substance of the muscle fibre by its degeneration.

MUSCLES, ANOMALIES OF.—The muscular system of man is subject to many variations, all of which are interesting from a morphological point of view, and many are important surgically. Not only do muscles vary as to form and attachment, but supernumerary and rudimentary muscles are not infrequent. Again, some may be absent in a certain number of individuals, *e.g.*, the pyramidalis, palmaris longus, etc.

Many muscles are mere rudiments of those which exist in a well-developed condition in the lower animals, and there is, in fact, no muscular variation in man which has not a corresponding normal condition in some animal lower in the scale.

In the present article space forbids the giving of any extended account of muscular variations, for it is a subject on which volumes have been written. It is intended to describe only the commoner and more important anomalies, especially mentioning those whose relation to arteries renders them of surgical interest. The reader who wishes to obtain a fuller knowledge of the subject is referred to Wood, Turner, and others, in the *Journal of Anatomy and Physiology*; J. Wood, "Proceedings of the Royal Society," 1864–69; "Guy's Hospital Reports"; "St. Thomas' Hospital Reports"; Macalister's "Catalogue of Muscular Anomalies," in Trans. Royal Irish Academy, 1872; W. Gruber, in the *Mém. of Acad.*, St. Petersburg, and Virchow's *Archiv f. klin. Med.*; Henle, "Handbuch, Muskellehre"; Hallett, *Edin. Med. Jour.*, 1845; Krause, "Handbuch," 1880; Testut, "Les Anomalies Musculaires chez l'Homme," Paris, 1884; also various papers in the *Journal of Anatomy and Physiology*.

MUSCLES OF THE HEAD AND NECK.—*Occipito-Frontalis* varies much as to size and position. The *occipitalis* occasionally approaches the median line, and may be divided into several portions. Some of its fibres may be continuous with the posterior auricular muscle.

The *Frontalis* may send slips to the nasal and superior maxillary bones. Theile says that it generally sends a bundle of fibres to the external angular process of the frontal bone. Its fibres have been described as normally continuous with the levator labii superioris alæque nasi.

Auricular Muscles.—Very various as to their development. The retrahens is very often of large size, and its tendon frequently arises from the neighborhood of the external occipital protuberance: in such cases its belly is

Digitized by Microsoft®

very fleshy, and may be divided into two portions. It is sometimes connected with the transversus nuchæ. Cruveilhier has described a deep *musculus auricularis anticus*, which goes beneath the superior from the zygoma to the outer surface of the tragus. The anterior auricular muscle is often very much diminished in size, and its fibres may be very indistinct.

www.libtool.com.cn

Muscles of the Nose.—Absence of the pyramidalis has been observed. The compressors and dilators are often so feebly developed as to be seen only with a magnifying glass.

The *Musculus Anomalus* (Albinus) is a slip described as being frequently present. Lying beneath the levator labii superioris alæque nasi, and arising with it from the nasal process of the superior maxillary bone, it is inserted into the same bone near the origin of the compressor naris.

Muscles of the Face.—*Zygomaticus Major.* Frequently double. The second head may arise in the neighborhood of the infra-orbital foramen or from the masseteric fascia below the zygoma. It is sometimes absent.

Zygomaticus Minor. Frequently absent. It may be inserted into the fascia of the cheek. It may be fused with the levator labii superioris proprius, zygomaticus major, or frontalis. It is not infrequently double; the second head may arise in common with the levator labii superioris proprius. Sometimes it arises from the orbicularis palpebrarum, and it may be inserted into the levator labii superioris proprius or levator labii superioris alæque nasi, or both.

Levator Labii Superioris Proprius occasionally sends a slip to the zygomaticus minor. The writer has twice seen this muscle arise by two heads, the extra head arising from the malar bone. In both these cases the zygomaticus minor was present.

Risorius (Santorini). Often absent. Santorini describes it as double, and even triple. It has been seen to arise from the zygoma, external ear, fascia over the mastoid process, and the skin over the upper portion of the sterno-mastoid.

Depressor Anguli Oris (triangularis menti). Santorini described a muscle, the *transversus menti*, which is sometimes found arising from the inner border of the depressor, and passing downward and inward across the mesial line below the chin to the corresponding part of the opposite side.

Muscles of the Orbit.—*Levator Palpebræ.* Sometimes absent or fused with the superior rectus. Budge describes the *tensor trochleæ*, which is a muscular slip given off from the levator to the trochlea.

The muscles of the eyeball are very constant. The two heads of the *rectus externus* have been seen separate to their insertion, forming a double muscle. Absence of the outer head has been noted by Macalister, and Curnow describes it as giving slips to the outer wall of the orbit and lower eyelid.

Transversus Orbita (Bochdalek). This is an arched slip of muscular fibres passing from the orbital plate of the ethmoid across the upper surface of the eyeball to the outer wall of the orbit (Quain). Macalister suggests that it is a deep, displaced slip of the palpebral fibres of the orbicularis.

Obliquus Inferior Accessorius is a slip going from the inferior rectus to the inferior oblique. The writer has seen a slip going from the inferior oblique to the superior rectus.

Muscles of Mastication.—*Masseter.* Monro has described a bursa as occasionally occurring between the two portions of this muscle, and Hyrtl has once seen a bursa between the masseter and the capsule of the inferior maxillary articulation.

Temporal. Henke says that sometimes the temporal muscle, and sometimes the deep portion of the masseter, is attached to the fore and back part of the interarticular fibro-cartilages of the lower jaw, or from the borders muscular fibres arise which are inserted into one or other of the afore-mentioned muscles. In many cases these fibres form a well-developed muscular belly, the *musculus temporalis minor*, which is inserted into the bottom of the sigmoid notch of the lower jaw (Henle). The writer has occasionally seen a deep slip from the temporal muscle attached to the pterygo-maxillary ligament. This slip is sometimes pierced by the internal maxillary artery.

Pterygoideus Externus. A considerable portion may be inserted into the capsule of the inferior maxillary articulation. When the pterygoideus proprius is present the upper head is of small size.

Pterygoideus Proprius. This is a muscle which is not infrequently seen arising from the infratemporal crest of the sphenoid and part of the great wing itself; it then passes over the external pterygoid to the lower part of the external pterygoid plate, or to the tuberosity of the palate and superior maxillary bones. It sometimes receives a slip from the upper head of the external pterygoid, and a portion of the upper head of the muscle may arise from it. The writer has occasionally seen the pterygoideus proprius inserted into the pterygo-maxillary ligament and alveolar process of the upper jaw (see Fig. 3433). In one case it sent a slip over the internal pterygoid to be inserted into the inferior maxilla near its angle. Externally this muscle is tendinous, and deep down, muscular; sometimes it is tendinous along the inner border only. When the pterygoideus proprius is present, the upper head of the external pterygoid is generally much diminished.

Pterygospinosus (Thane). This name is given to a muscular slip occasionally seen springing from the spine of the sphenoid and inserted into the hinder margin of the outer pterygoid plate, between the external and internal pterygoid muscles; the parts are frequently connected by fibrous tissue, and sometimes by bone.

MUSCLES OF THE NECK.—*Platysma Myoides.* This muscle varies considerably in its development. It is sometimes well developed, thick and red, and at other times its fibres are pale, thin, and hardly to be seen. It has been reported absent by Macalister. The platysma may reach over the clavicle as far as the fourth rib. It sometimes fails to reach as far as the clavicle; in such cases it is reduced in extent at other parts as well. It may have an insertion into the thyroid cartilage or the sternum. When well developed it has been seen attached to the lower jaw above and to the clavicle below. The upper part of the platysma is occasionally joined by a slip from the mastoid process, or from the occipital bone. The two muscles not infrequently cross each other in

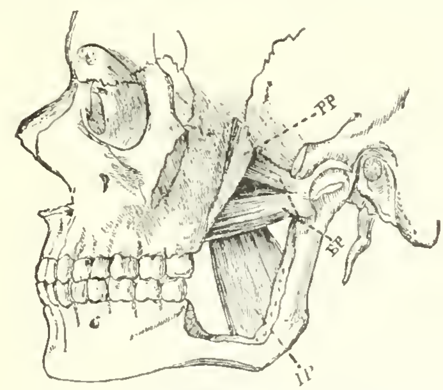

FIG. 3433.—*PP*, Pterygoideus proprius; *EP*, external, and *IP*, internal pterygoid muscle. (Shepherd.)

the median line. The writer has seen the lower fibres continuous with some fibres of the musculus sternalis. Fasciculi in connection with this muscle have been traced to the axilla. The platysma is the principal representative in man of the skin muscle (*panniculus carnosus*) of the lower animals. In most mammals with loose skins these tegumentary muscles are well developed; *e.g.*, in the hedgehog, porcupine, porpoise, etc.

Occipitalis Minor. This is the name given to a bundle of muscular fibres arising from the fascia over the upper

Digitized by Microsoft®

end of the trapezius and ending in the fascia over the upper end of the sterno mastoid. It is probably a modification of the slip which occasionally joins the platysma from the mastoid process or occipital bone.

Sternocleidomastoideus. This muscle is usually considered to be made up of two muscles, the sterno-mastoid

www.libtool.com.cn

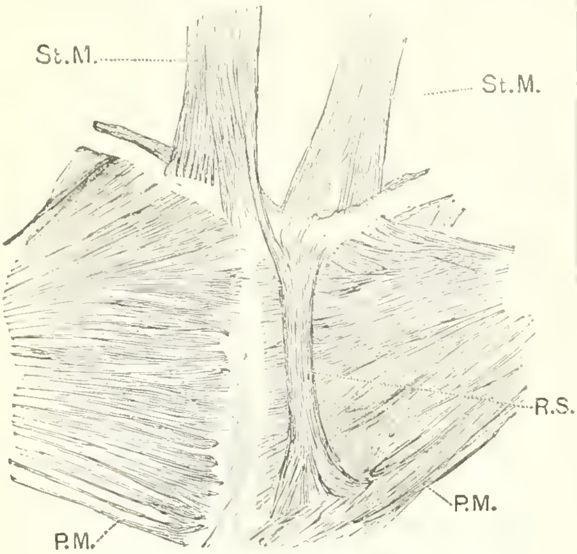

FIG. 3434.—*R.S.*, Rectus sternalis continuous with (*St M.*) sterno-mastoid of the opposite side. (Shepherd.)

and cleido mastoid. Krause, however, regards it as consisting of four muscles, viz.: (1) Sterno-mastoid, (2) sterno occipital, (3) cleido occipital, (4) cleido-mastoid. The spinal accessory nerve pierces the cleido-mastoid, or runs between the cleido-occipital and cleido-mastoid. Krause suggests the name *sternocleidomastoideooccipitalis*, or the *musculus quadrigeminus capitis*. He says that the ordinary varieties in man are readily explained by the isolation or absence of particular parts, or by the extension of the cleidooccipitalis to the occipital protuberance. Both the cleidooccipitalis and sternooccipitalis may be feebly developed, or both may be absent, as, indeed, may be the sterno-mastoid. Again, the cleido occipital or cliedo-mastoid may be developed as separate muscles. The views of Krause are supported both by human and comparative anatomy. However, for ordinary purposes it is sufficient to regard the sterno-mastoid as consisting of two muscles. These two portions may be completely separate, or may join together at a much higher point than usual. This separation of the muscles into two is the normal condition in the greater number of mammals; *e g.*, ruminants, solipeds, the majority of carnivora, and many of the anthropoid apes.

The sterno-mastoid and cleido-mastoid muscles may be completely fused—a condition which is not of great rarity.

Sternal attachment of the muscle may vary; the two sternal tendons may unite on the sternum or cross each other. The writer has seen the sternal tendon of one side continuous with a musculus sternalis of the opposite side (see Fig. 3434).

The sternal tendon may in rare cases be divided into two portions, inserted separately into the sternum. The sternal portion has been noted absent by Macalister. A sesamoid bone is sometimes seen in the tendon of the sterno-mastoid; this is looked upon as a rudiment of the episternal bone of monotremes and lizards.

The clavicular portion varies considerably as to the extent of its attachment to the clavicle; it not infrequently covers the space called the subclavian triangle, and this should be borne in mind when performing the operation of ligature of the subclavian artery in its third part. The writer once, when operating on the neck, found the clavicular portion absent. In animals without clavicles the cleido-mastoid forms part of the cephalo-humeral muscle, being continuous with the outer portion of the pectoralis major or deltoid.

Cleido-occipital (Cephalo-humeral of Flower). This is a muscle described by Wood and others as arising from the clavicle outside the cleido-mastoid and inserted into the superior curved line of the occipital bone close to the origin of the trapezius. It is usually separated by a distinct areolar interval from both the sternal and clavicular fibres of the sterno-cleido-mastoid (see Fig. 3435).

This muscle corresponds to the cleidooccipitalis of Krause. It exists as a separate muscle in the guinea-pig, hedgehog, etc. In apes and monkeys it is always present, but is in them continuous with the hinder border of the true sterno-cleido-mastoid. In many of the carnivora, as the dog and cat, it forms part of the cephalo-humeral muscle. Wood found this muscle thirty-seven times in one hundred and two subjects.

The sterno-mastoid has been described as sending slips to the angle of the lower jaw and hyoid bone (Gruber). The sterno-hyoid and omo-hyoid, and in rare cases the trapezius, may unite with the sterno-mastoid.

A tendinous intersection is sometimes seen near the lower end of the muscle; the same intersection is seen in the sterno-hyoid and sterno-thyroid muscles; it is probably the remains of one of the transverse septa of the primitive ventral muscle plate. These intersections are seen normally in the rectus abdominis.

Levator Claviculæ arises from the clavicle, and is inserted into the cervical vertebræ. A fuller description of this muscle will be given farther on, under Muscles of the Upper Limb.

Supraclavicularis is a small muscle behind the sterno-mastoid, which arises by a slender tendon from the first piece of the sternum, crosses above the sterno-clavicular articulation, and is inserted into the upper surface of the clavicle. When present on both sides the muscles may be continuous in the middle line.

Transversus Nuchæ. This is described by many anatomists as a normal muscle, which is always represented when absent by tendinous fibres. It arises from the external occipital protuberance, and is inserted into the aponeurosis of the sterno-mastoid (see Fig. 3436).

Sternohyoideus occasionally arises only from the clavicle. In such cases there is a wide interspace at the root of the neck devoid of muscle. The writer in one case saw, on both sides, the sterno-thyroid and sterno-hyoid arise altogether from the clavicle an inch outside the sterno clavicular articulation. On removing the skin and fascia the trachea and thyroid gland immediately came into view.

This muscle is occasionally double. There is sometimes an accessory muscle seen going from the clavicle to the hyoid bone (cleido hyoid). The sterno-hyoid has been described as occasionally arising from the sterno - clavicular ligament and first costal cartilage. It is sometimes fused with the muscle of the opposite side, as in the horse. The muscular fibres are not infrequently interrupted by a tendinous intersection, which is generally on a line with the tendon separating the two bellies of the omo hyoid. This intersection is seen

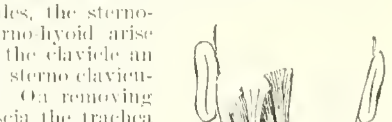

FIG. 3435. *C.h.*, Cephalo-humeral muscle; *Sp. Cap.*, splenius capitis; *D*, deltoid; *T*, trapezius. (After Flower, from the dissection of a Bushwoman, *Jour. of Anat. and Phys.*, vol. i.)

Digitized by Microsoft®

normally in some animals, as the chimpanzee, horse, etc. The muscle has been noted as absent on one side. It may be united by slips with the omo-hyoid, mylo-hyoid, or sterno-thyroid. All the anomalies above mentioned have their corresponding normal condition in the lower animals.

www.libtool.com.cn

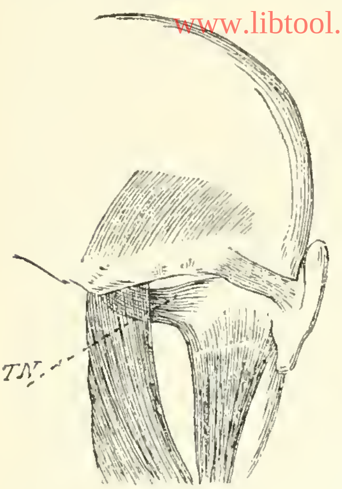

FIG. 3436. – *TN*, Transversus nuchæ. (After Henle.)

Sternothyroideus. Occasionally some of the fibres of this muscle continue on upward and are inserted into hyoid bone with the omo-hyoid, or are continuous with the hyo-glossus muscle. A few fibres may be continued into the thyro-hyoid or inferior constrictor of the pharynx. In one case the writer saw it, on both sides, arise, with the sterno-hyoid, entirely from the clavicle. Walsham reports a case ("St. Barth. Hosp. Rep.," 1880) in which the right sterno-thyroid arose from the left as well as the right side of the sternum and crossed the trachea. The left muscle was rudimentary. This muscle would be a source of embarrassment in performing tracheotomy.

In the gorilla and chimpanzee some fibres usually arise from the clavicle. The two sterno-thyroid muscles are often united at their origins across the middle line. Doubling of the muscle, as well as absence, has been observed. A tendinous intersection is sometimes seen opposite the tendon of the omo-hyoid. It may exist in both the sterno-hyoid and sterno-thyroid in the same line.

Costofascialis. Wood describes a slip arising with the sterno-thyroid from the hinder part of the first rib, which crosses the carotid vessels to be inserted into the cervical fascia as high as the thyroid cartilage.

Sternofascialis. This is a slip described by Gruber as arising from the first piece of the sternum behind the sterno-mastoid and passing upward to be inserted into the fascia of the subclavian triangle. It might be called the tensor fasciæ colli.

Thyrohyoideus. This muscle is often fused with the sterno-thyroid, and in such cases the sterno-thyroid is inserted into the hyoid bone. Absence of this muscle has been reported; this is generally due to a fusion of the sterno-thyroid and thyro-hyoid, so that they form one muscle, which is inserted into the hyoid bone. The muscle may be divided into two distinct slips.

Cricohyoid. Walsham first described this muscle as arising from the lower border of one side of the cricoid cartilage and inserted into the lower border of the hyoid bone. Gruber also mentions its occurrence.

Depressor Thyroideæ. A small muscle described by Bradley as arising from the first tracheal ring, passing over the cricoid cartilage and inserted into the lower border of the thyroid cartilage.

Omohyoideus. This muscle is frequently abnormal. In 250 subjects examined the writer found anomalies of the omo-hyoid in 39, or about 1 in 6. The muscle may be completely absent, and in rare cases it has been noted double. Again, one or other of its bellies may be wanting. When the anterior is absent, the posterior belly ends in the cervical fascia beneath the sterno-mastoid. In 250 subjects the writer has seen this arrangement twice. Sometimes the anterior belly arises from the clavicle and ascends the neck directly to its insertion into the hyoid bone without having any intermediate tendon or intersection. This has been regarded by some as absence of the posterior belly. The writer has only in one subject seen this anomaly; it occurred on both sides. This muscle has been called the *cleido hyoid.* In some rare cases, however, the posterior belly is altogether absent, the anterior arising from the fascia covering the subclavian triangle (*hyofascialis*).

The posterior belly not infrequently arises from the clavicle solely. In 120 subjects examined, the writer has seen this arrangement 8 times (1 in 15). The posterior belly may be double, the supernumerary portion arising from the clavicle. The writer has seen this occur 9 times in 120 subjects. In these cases the origin from the clavicle is generally extensive, and is from the middle third of the posterior border for a distance of two and sometimes three inches. In rare cases it may arise from the sternal end. The posterior belly of the omo hyoid may be so bound down by fascia to the clavicle that the subclavian triangle is obliterated. In ligaturing the subclavian, it would be well for surgeons to bear in mind this occasional arrangement. This condition is present more frequently when the posterior belly arises from the clavicle.

The omo-hyoid being originally fused with the sterno-hyoid, it would be natural to see the lower portion occasionally displaced and have its origin from any of the osseous points between the scapula and sternum, or to receive supernumerary heads from the various points.

The scapular head of the omo-hyoid, besides having an accession from the clavicle, may receive one from the coracoid process, the acromio-clavicular joint, the acromion process, and even the first rib.

The anterior belly of the omo-hyoid is occasionally double. The writer has seen this anomaly three times. In the first case the supernumerary belly was inserted into the superior cornu of the thyroid cartilage; in the second, into the great cornu of the hyoid; and in the third it blended with the sterno-hyoid.

The anterior belly not infrequently blends with the sterno-hyoid so as to form one broad muscle, which is occasionally bounded below by an arched tendon, as in the seal. This fusion is due to the non-differentiation of the primitive brachiocephalic sheet from which these two muscles are developed.

The writer has twice seen a portion of the omo-hyoid muscle pass over the hyoid bone and go up between the anterior bellies of the digastrics to be inserted into the lower jaw near the symphysis (see Fig. 3437).

The omo-hyoid may send slips to muscles in the neighborhood; *e.g.*, sterno-mastoid, sterno-hyoid, and the various muscles of the submaxillary region. A slip has been seen going from the posterior belly to the transverse process of the sixth cervical vertebra.

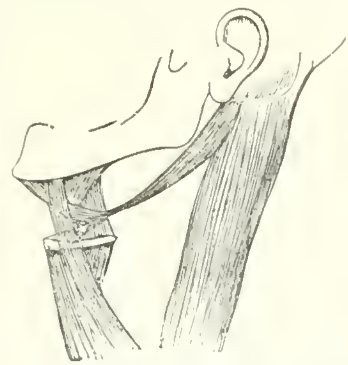

FIG. 3437. Shows the Omo-Hyoid Muscle Continuing up Over the Hyoid Bone to be Inserted into the Inferior Maxilla; also, the Muscular Belly going from the Tendon of the Digastric to be Inserted into the Body of the Hyoid Bone. (Shepherd.)

The intermediate tendon of the omo-hyoid may be absent or represented by a tendinous intersection.

Comparative Anatomy. The omo-hyoid is completely wanting in many animals, as the cat, dog, peccary, mole, and also in rodents without clavicles. The anterior belly is absent in the orang outang. The muscle arises from the clavicle in the scink and in some of the bats and the iguana. The intermediate tendon is absent in many mammals as the echidna, ornithorhynchus, the American black bear, and some of the quadrumana. In the seal

Digitized by Microsoft®

the anterior belly is fused with the sterno-hyoid and is bounded below by an arched tendon.

Levator Glandulæ Thyroideæ. This is a fibrous or muscular band which goes from the body of the hyoid bone to the isthmus or one of the lateral lobes of the thyroid gland. There may be two or three slips. The writer, in one subject, on both sides, saw this slip proceed from the oblique line of the thyroid cartilage and go to each lateral lobe of the gland. The levator thyroideæ is looked upon as an aberrant portion of the muscles between the sternum and hyoid bone (see Fig. 3438).

www.libtool.com.cn

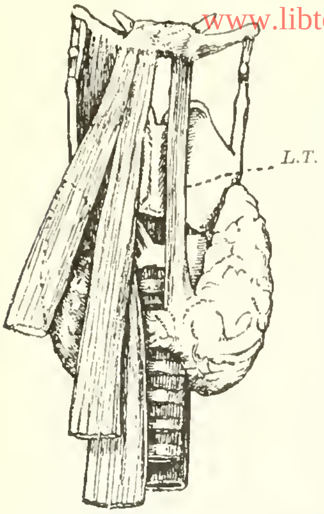

FIG. 3438.—*L.T.*, Levator thyroideæ, going from Hyoid Bone to Left Lateral Lobe of Thyroid Body. (Quain.)

Digastricus. The digastric muscle is subject to many variations. Occasionally its tendon fails to pierce the stylo-hyoid. The *anterior belly* is very often abnormal; not infrequently the two anterior bellies unite in the median line and completely shut out from view the mylo-hyoid muscles. The two bellies often decussate, as in the Norway rat and ruminants. It is not uncommon to find the anterior belly divided into two or more parts, one of which may cross the middle line of the neck and join the anterior belly of the opposite side. A slip from the anterior belly may join the mylo-hyoid, or decussate in the middle line with a similar slip from the opposite muscle. These slips may be looked upon as varieties of the mento-hyoid muscle, described below. In one subject the writer saw a well-marked muscular slip given off from the intermediate tendon and inserted into the body of the hyoid bone (see Fig. 3437). Also, in another subject there was complete absence of the anterior belly on the left side; the posterior belly ended in the deep cervical fascia attached between the hyoid bone and angle of the jaw. This might be regarded as a form of the monogastric muscle, which is well seen in the lower animals, as the carnivora. MacWinnie describes a case in which the muscle was monogastric and was inserted into the middle of the body of the lower jaw. In rare cases a muscular slip from the angle of the jaw joins the anterior or posterior belly. The writer once saw a well-marked tendinous slip going from the angle of the jaw to the posterior belly.

The *posterior belly* occasionally receives accessory slips from the styloid process. It has been seen arising entirely from the styloid process. It is sometimes connected by a muscular slip with one of the constrictors of the pharynx. Walsham describes a tendinous intersection, and in one case a distinct tendon, occurring in the posterior belly. The posterior belly has been seen to pass behind instead of in front of the carotid artery.

Occipito-hyoid. Perrin (*Jour. Anat. and Phys.*, vol. v.) first described this muscle as an additional digastric; he regarded it as homologous with the stylo hyoid of birds. The muscle is double bellied; its posterior belly arises from fascia covering the occipital bone, and its anterior belly is inserted into the hyoid bone beneath the hyoglossus. Humphry looks upon it as a superficial appendage to the stylo-hyoid and digastric muscles. There is a similar muscle in the seal.

Mento-hyoid (Macalister). This is the name given to a slip of muscle of variable size, and sometimes double, which is not infrequently seen passing, superficial to the mylo-hyoid, from the lower jaw near the symphysis to the body of the hyoid bone. Occasionally the muscle does not reach the hyoid bone, but ends in a fascia which covers the mylo-hyoid and is attached to the bone. It is sometimes triangular in shape. Macalister looks upon the mento-hyoid as a differentiated portion of platysma; but it is probably more closely related to the anterior belly of the digastric and the sterno-hyoid group, which are formed from the superficial brachiocephalic stratum of muscle (see Fig. 3439). The mento-hyoid exists normally in many animals, as the bat, hippopotamus, etc.

Stylohyoideus. Occasionally absent. Testut suggests that in cases of supposed absence of this muscle it is fused with the posterior belly of the digastric. A division of the muscle into three has been noticed. It may sometimes pass behind the carotid artery. It is occasionally inserted into the tendon of the digastric or lesser cornu of the hyoid bone. Its fibres may be continuous with the mylo-hyoid, thyro-hyoid, omo-hyoid, or, as in the ant-eater, with the muscles of the tongue. It sometimes arises from the lower jaw and goes to the hyoid bone (hyomaxillaris); again, it may not reach the hyoid bone, but go from the styloid process to the angle of the lower jaw, as in birds (stylomaxillaris). The writer has seen this muscle absent in two subjects, once on both sides.

Stylochondrohyoideus (Douglass); *Stylohyoideus alter* (Albinus). This is an additional muscle which occasionally replaces the normal stylo-hyoid and has the course of the stylo-hyoid ligament; in other words, it is the stylo-hyoid ligament become muscular. It is inserted into the lesser cornu of the hyoid bone and passes behind the carotid artery. In one case, noted by the writer, in which this muscle existed the normal muscle was represented by a thin tendinous slip. The normal stylo-hyoid and this muscle frequently are present together. The

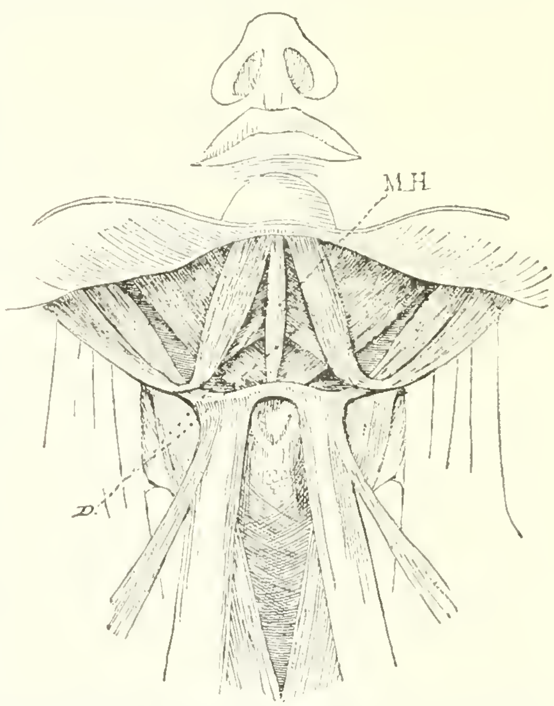

FIG. 3439.—Showing Mento-Hyoid Muscle (*MH*); also, the Anterior Bellies of the Digastric Muscles United in the Middle Line by Muscular Fibres (*D*). (Shepherd.)

stylohyoideus alter may receive a slip from the lower jaw. In one hundred and twenty subjects the writer has seen this muscle nine times; three times it occurred on both sides of the same subject.

Stylohyothyroideus. This is the name given by the

Digitized by Microsoft®

writer to a muscle seen by him in a female subject in the anatomical rooms of McGill University during the winter session 1885–86. On both sides of a thin female subject, in addition to the usual stylo-hyoid, a stylo-chondro-hyoid was present. On the left side this muscle gave off a slip to the middle constrictor of the pharynx. On the same side, arising in common with the stylo-chondro-hyoid, was another muscle of the same size, this had a well-developed belly, and passed down posterior but parallel to the above-mentioned muscle to a little above the hyoid bone; here it left its companion and developed a well-formed round tendon, which passed under the middle constrictor and was inserted into the tip of the superior cornu of the thyroid cartilage. The stylopharyngeus was of normal size and insertion.

Mylo-hyoid. The median raphe between the two muscles is sometimes absent. The mylo-hyoid is often closely united to the anterior belly of the digastric, and may be partially replaced by it. The sterno-hyoid, omo-hyoid, or stylo-hyoid may send slips to it. The muscle may be divided into two portions, an anterior and a posterior, separated by a considerable interval. This is the arrangement in some of the rodents. A deficiency of the fore part is of common occurrence, the origin not reaching farther than the canine tooth (Quain).

Geniohyoideus. The two muscles may be fused in the middle line. It occasionally receives a slip from the great cornu of the hyoid bone. It may be closely united with the geniohyoglossus or hyoglossus.

Geniohyoglossus. This muscle has been found united with the genio-hyoid. The two muscles may be fused together, no cellular interval separating them. Slips have been seen going from the geniohyoglossus to the epiglottis, stylo-hyoid ligament, and lesser cornu of the hyoid bone. An accessory muscle has been described by Henle, Luschka, and Bochdalek, going from the mental spine to the hyoid bone between the two geniohyoglossi muscles.

Hyoglossus. Sometimes pierced by the lingual artery. The middle portion of the muscle is occasionally absent, leaving a larger or smaller interval between the outer and inner portions, and exposing the lingual artery (see Fig. 3440). The lingual artery may lie on the muscle instead of beneath it.

Triticoglossus (Bochdalek). This is a small muscular slip which arises from a cartilaginous nodule in the thyro-hyoid ligament, and passes upward and outward to join the posterior part of the hyoglossus.

Chondroglossus. This has been described as a distinct muscle, occurring normally, separated from the hyoglossus by the pharyngeal fibres of the genioglossus. It arises from the base of the lesser cornu and, spreading out, is inserted into the dorsum of the tongue near the middle line.

Styloglossus. The styloglossus is occasionally absent. The writer once saw it absent on both sides of the same subject. There is sometimes an additional origin, from the angle of the lower jaw or the stylo-maxillary ligament. The whole muscle may arise from these points, the styloid origin being absent. When it arises from the angle of the jaw it is called the *myloglossus.* Gruber has described a rare origin of this muscle, from the external auditory meatus (*styloauricularis*). The muscle may be divided into two portions; one of which is inserted normally, the other into the pharynx (Sandifort). Macalister has reported this muscle as double. Henle has described a slip going from the styloglossus to the genioglossus near its origin.

Muscles of the Pharynx.—Constrictor Superior. The second portion may be distinct. Meckel describes an accessory slip, arising from the pharyngeal spine and becoming lost in the middle line of the posterior wall of the pharynx. The writer once, on both sides of the same subject, saw this muscle receive a slip from the Eustachian cartilage.

Constrictor Medius occasionally receives fibres from the stylo-hyoid ligament or hyoid bone; also from the tongue and hinder part of the mylo-hyoidean ridge. It is common to see a slip from the thyro-hyoid ligament (*syndesmopharyngeus*, Douglass). The upper fibres of the muscle may reach the occipital bone.

Constrictor Inferior. A few fibres of origin may come from the trachea. It is occasionally connected by muscular slips with the crico-thyroid, sterno-hyoid, or sterno-thyroid muscles.

Stylopharyngeus. Cleavage of this muscle into two or even three parts has been noted. Gruber has described a double-headed stylopharyngeus. The accessory head in his case arose from the mastoid process.

Supernumerary Muscles of the Pharynx are not infrequently present, proceeding from the lower part of the base of the skull and going to one of the constrictors or passing between these muscles and the fibrous layer of the pharynx. They may arise from the petrous portion of the temporal (*petropharyngeus*), spine of the sphenoid (*sphenopharyngeus*), hamular process (*pterygopharyngeus*), basilar process (*occipitopharyngeus*), or from the pharyngeal tubercle of the occipital bone (*azygopharyngeus*).

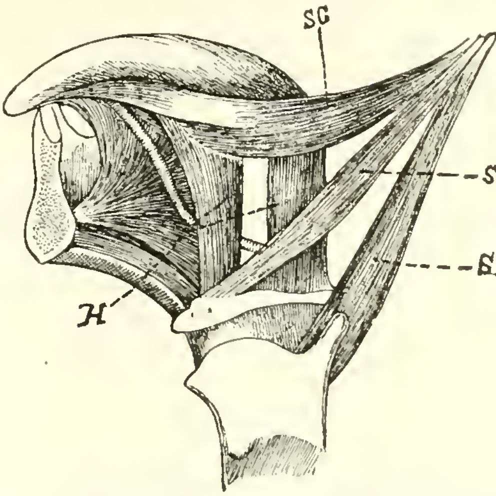

FIG. 3440.—*H*, Hyoglossus muscle deficient in its central portion; *SG*, styloglossus; *SH*, stylo-hyoid; *SP*, stylopharyngeus. (Walsham.)

PREVERTEBRAL MUSCLES.—*Scalenus Anticus.* Absence of the muscle has been reported by Macalister. In this case the subclavian vein was in direct contact with the artery. The attachment to the cervical vertebræ may vary in extent. The muscle may be divided into several distinct portions. It is sometimes pierced by the subclavian artery, and in rare cases lies behind the artery, or, more properly speaking, the artery passes in front of it.

Scalenus Medius and Posticus. These two muscles are so intimately united that French anatomists regard them as one muscle. They vary considerably as to the extent of their attachments to the transverse processes of the cervical vertebra; frequently the slips from the upper cervical are absent. In rare cases the posterior scalenus may be attached as far down as the third and even the fourth rib, as in many of the lower animals. In some animals, as the bear, it reaches as far as the seventh and eighth ribs. In man it is not infrequently absent. The scalenus medius is perforated by branches of the brachial plexus and frequently by the posterior scapular artery.

Scalenus Minimus (Albinus). This is a small slip of muscle, normal in apes, which is seen in man occasionally. It passes from the transverse processes of the lower cervical vertebræ to the first rib, behind the subclavian artery, and in front of the brachial plexus.

Transversalis Cervicis Medius (Törnblom). Under this name a muscle has been described as arising from the transverse processes of the second, third, and fourth cervical vertebræ, and inserted into the sixth and seventh cervical transverse processes.

www.libtool.com.cn
Digitized by Microsoft®

Rectus Capitis Anticus Major. Varies occasionally in the extent of its attachment to the cervical vertebræ. It is sometimes strengthened by a fasciculus from the transverse process of the axis, and has been noted as having

www.libtool.com.cn

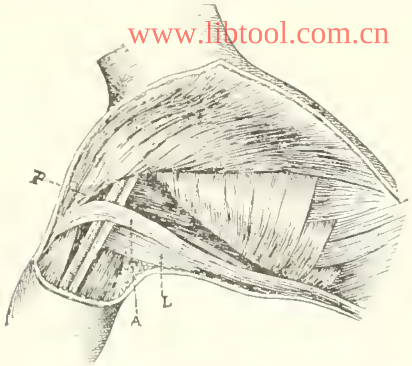

FIG. 3441.—*A*, Axillary band, between the latissimus dorsi (*L*) and the great pectoral (*P*).

no origin from the sixth cervical. It is frequently united with neighboring muscles, as the anterior scalenus, transversalis cervicis, etc.

Rectus Capitis Anticus Minor. Occasionally has a slip from the axis. Macalister has described a supernumerary muscle attached to the anterior portion of the atlas (M. rectus anterior medius of Gruber).

Longus Colli. The longus colli is subject to some variations in the number of its attachments and in the degree of separation of its constituent parts.

The lower oblique portion may send a slip to the head of the first rib. It is also sometimes prolonged to the rectus capitis anticus major, and has been seen sending a slip of insertion to the basilar portion of the occipital bone. A supernumerary longus colli (*M. transversalis cervicis anterior* Luschka) may arise by thin, tendinous slips from the anterior tubercles of the transverse processes of the lower four cervical vertebræ and be inserted by two tendons into the base of the transverse process of the atlas and the body of the axis (Henle).

MUSCLES OF THE UPPER LIMB.—*Trapezius* (Cucullaris). The attachments of this muscle are subject to considerable variation. The muscle may be much smaller than usual, and have no occipital origin or be attached to as few as six instead of twelve dorsal spines; it may be divided into a cervical and a dorsal portion. Again, its spinal attachments may be confined to the upper three or four dorsal, or lower three or four cervical spines, the other portions being absent. It is sometimes inserted into more of the clavicle than normal, being continuous with the insertion of the sterno-mastoid. Occasionally there is a slip passing forward across the subclavian triangle to reach the sterno-mastoid; this would be in front of the third part of the subclavian artery, and interferes somewhat with the operation of ligature of that artery. Again, it may be continuous with the deltoid, as is the case in animals without clavicles. In rare cases the portion attached to the clavicle is absent or very small. This arrangement is seen in some of the lower animals. A slip has been described going from the anterior border of the muscle near the clavicle to the sternum; this is a variety of the sterno-scapular muscle. Not infrequently slips of attachment unite the trapezius to the levator anguli scapulæ.

Latissimus Dorsi. The number of dorsal vertebræ to which this muscle is attached may vary considerably. It may be attached to as many as nine, and as few as four. The writer has seen it attached to all the dorsal vertebræ. Its attachments to the ribs also vary, the number being sometimes increased, sometimes diminished. It is occasionally attached to the lower angle of the scapula: the writer has twice seen it send slips to the spine of the scapula.

Axillary Band (Achselbogen). This is a muscular band which crosses the lower part of the axilla from the latissimus dorsi to the great pectoral muscle near its insertion (see Fig. 3441).

It may, instead of uniting with the great pectoral, be inserted into the coracobrachialis or fascia covering the biceps. In its course it usually crosses the axillary vessels, and hence it is well to bear this in mind in ligaturing the axillary artery in its third part. It is sometimes of large size, being as broad as 6.2 cm., and so may cover a considerable extent of the axillary vessels. More frequently it is a small slip, from 1 to 3 cm. broad. It occurs in about five per cent. of all subjects, and is frequently on both sides of the same subject. The writer has seen it in eleven subjects out of two hundred and fifty noted. This muscular band exists normally in many animals, as deer, etc., and is the remains of the continuity which previously existed between the latissimus dorsi and the pectoralis major.

Dorsoepitrochlearis. This is a muscle which is occasionally seen in man in a rudimentary form, but in many of the lower animals, as apes, lemurs, seals, bears, etc., is a well-developed muscle, and is the normal arrangement. It is a muscular slip which is given off from the lower border of the tendon of the latissimus dorsi, and is attached to various points in the arm. It may end in the long head of the triceps, some portion of the internal intermuscular septum, the epitrochlear process of the internal condyle, or the olecranon process (see Fig. 3442). In man the muscle is occasionally represented merely by a fibrous band, sometimes by a small, muscular slip ending in a fibrous cord, which is inserted into the internal condyle, or is continuous with the internal intermuscular septum.

Rhomboideus Minor and Major. Both these muscles are subject to variation as to extent of origin and insertion. They may be divided into two fasciculi, as in some animals.

Rhombo-occipital (occipito-scapular of Wood). This is a slip not infrequently seen in man, and occurs normally in many of the lower animals, *e.g.*, the deer, cat, tiger, etc., as a well-developed muscle immediately beneath the trapezius, and reaching from the occiput to the base of the spine of the scapula. In man it generally exists in an incomplete form, and varies considerably as to its upper and lower attachments. Instead of reaching the scapula it may be connected with either of the rhomboid muscles, serratus posticus superior, or levator anguli scapulæ. Its superior attachment may not reach the occiput, but be connected with the spines of the upper cervical vertebræ. Again, in man, this muscle may be represented by a slip from the aponeurosis covering the splenius capitis to the spine of the scapula, or by a slip from the levator anguli scapulæ to one of the rhomboids. In one case recorded by the writer it consisted of a well-developed muscular slip reaching from the transverse process of the atlas to the aponeurosis over the greater rhomboid (*rhombo-atloid* of Macalister). The many varieties of this muscle in man have been carefully described by Prof. J. Wood (Proceed. Roy. Soc., 1870—see Fig. 3443).

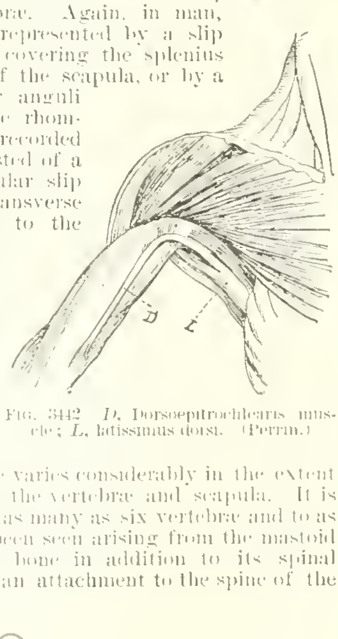

FIG. 3442.—*D*, Dorsoepitrochlearis muscle; *L*, latissimus dorsi. (Perrin.)

Levator Anguli Scapulæ. This muscle varies considerably in the extent of its attachments to the vertebræ and scapula. It is often seen attached to as many as six vertebræ and to as few as two. It has been seen arising from the mastoid process and occipital bone in addition to its spinal origin. It may have an attachment to the spine of the

Digitized by Microsoft®

scapula, and it sometimes sends slips of insertion to the first or second rib. Occasionally it is seen divided into two or more slips, the portions connected with the different vertebræ remaining separate. It is often connected with neighboring muscles by muscular slips. The writer has seen it thus connected with the serratus posticus superior, serratus magnus, deep surface of the trapezius, complexus, splenius capitis, rhomboideus minor, and scalenus posticus. These slips are regarded by Wood as varieties and modifications of the occipito-scapular muscle of the lower animals. In many of the lower animals the levator anguli scapulæ is merely the upper portion of the serratus magnus, forming with it a single muscle.

www.libtool.com.cn

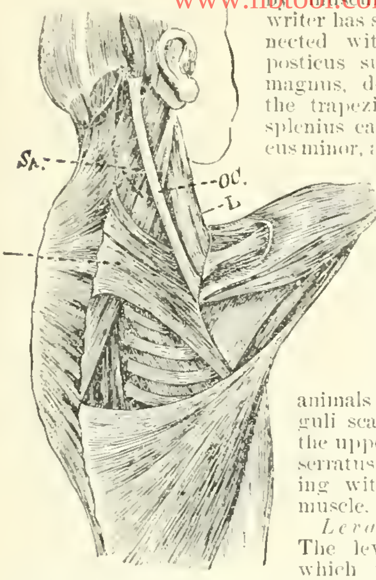

FIG. 3443.—*OC*, Occipito-scapular muscle; *L*, levator anguli scapulæ; *R*, rhomboid muscles; *Sp*, splenius. (Wood.)

Levator Claviculæ. The levator claviculæ, which normally exists in all mammals with the exception of man, is occasionally seen in him. It appears as a separate muscular slip arising from the transverse processes of one or two upper cervical vertebræ, and inserted into the outer end of the clavicle. Slips of muscle from the levator anguli scapulæ, or from the upper cervical spines, to the scalene muscles, serratus magnus, and ribs, are regarded as modifications of the levator claviculæ.

Cleidocervicalis (Gruber). This is a form of the above muscle arising from the transverse process of the sixth cervical and inserted into the outer end of the clavicle. Gruber looks upon it as a supernumerary scalene muscle attached to the clavicle.

Pectoralis Major. Many variations of this muscle have been observed. The more common varieties consist of a greater or less extent of attachment to ribs and sternum, and the separation of its clavicular from its costal attachment.

M. Testut divides the anomalies of this muscle into eight groups, viz.:

1. Fusion of the clavicular portion with the deltoid.
2. Fusion with the great pectoral of the opposite side.
3. Union with the rectus abdominis.
4. Union with the biceps brachii (see Fig. 3450).
5. Separation of the clavicular and sterno-costal portions by an interspace.
6. Division of the costo-sternal portion into two strata or layers.
7. Anomalies in the mode of insertion into the arm.
8. Complete or partial absence of the muscle.

Testut divides the anomalies of the brachial insertion into: (*a*) Insertion into the coracoid process and aponeurosis of the coracobrachialis. (*b*) Insertion into the capsule of the shoulder-joint. (*c*) Prolongation of the tendon of insertion into the capsule of the shoulder-joint. (*d*) Supernumerary insertion into the humerus. (*e*) Insertion into the brachial aponeurosis. (*f*) Insertion into the two lips of the bicipital groove.

Chondroepitrochlearis (Duvernoy). This is the name given by Duvernoy to a muscular slip which is sometimes seen arising from the cartilage of one or two ribs, the aponeurosis of the external abdominal oblique, the lower border of the great pectoral itself, or its tendon; from one of these origins it passes down and out, and is inserted in a variable way into the arm. It is often inserted into the internal intermuscular septum and occasionally reaches as far as the internal condyle of the humerus.

Mr. J. B. Perrin (*Jour. Anat. and Phys.*, vol. v.) has described under the name of epigastric slips a number of muscles connected with the lower border of the pectoralis major, or arising separately from the sixth or seventh rib and inserted into the tendon of the great pectoral, or into the fascia covering the coracobrachialis muscle (see Fig. 3444). They may also be connected with the latissimus dorsi. These muscles are developed to a high degree in many mammals, and are well seen in pigeons and fowls.

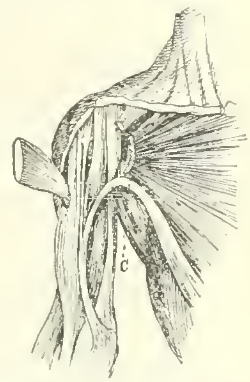

FIG. 3444.—Example of the Chondroepitrochlearis Muscle (*C*). (Perrin.)

Musculus sternalis. Syn.: Rectus sternalis, sternalis brutorum (Albinus), présternal (Testut). The musculus sternalis is a supernumerary muscle which has always excited a great deal of interest among anatomists; even yet its proper morphological significance is not fully determined. It is seen in about three or four per cent. of ordinary individuals, but in anencephalous monsters is nearly always present. Its fibres are generally at right angles, and superficial, to the great pectoral; it is often bilateral, but more frequently unilateral, and is subject to many variations. Frequently it has no attachment to bone but rests on the great pectoral, attached above and below to fascia (see Fig. 3445). It is often attached to the sternum and costal cartilages of one side or both, and is occasionally continuous above with the sternal origin of the sterno-mastoid, and below, with the external abdominal oblique (see Fig. 3433).

It usually arises from the first piece of the sternum, and is inserted into some of the ribs and costal cartilages, generally the fifth and sixth. It may be continuous in

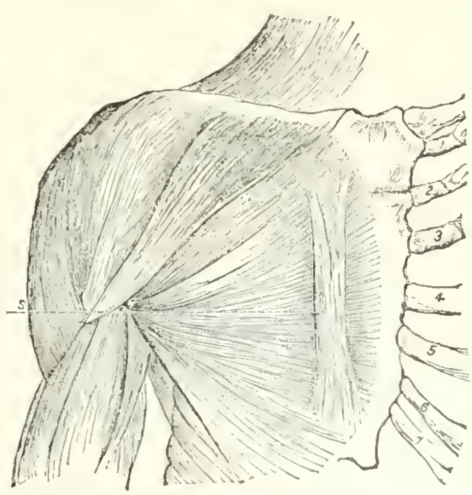

FIG. 3445.—*S*, Musculus sternalis, attached above and below to fascia. (Shepherd.)

part with the great pectoral itself and be associated with deficiency of that muscle. Sometimes it is of small size, but occasionally it is quite a large muscle, 8 to 10 cm. long, and 3 to 5 cm. broad. It has been recognized under the skin in the living. It derives its nerve supply from the same source as the pectoral muscles,

Digitized by Microsoft®

viz., the anterior thoracic. The muscle is regarded by Sir William Turner, Dr. Dobson, and others as a remnant of a skin muscle. Henle, Theile, Bourrienne, and others look upon it as a prolongation downward of the sterno-mastoid. Halbertsma thought it a muscle *sui generis* peculiar to man, having no animal representative. D. J. Cunningham thinks it a new inspiratory muscle appearing in man, and is of opinion that

www.libtool.com.cn

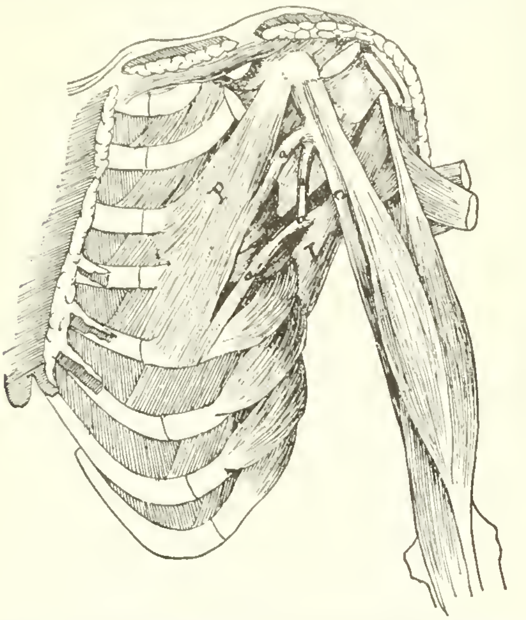

FIG. 3446.—*a, a, a,* Muscular slips connecting the pectoralis minor (*P*) with the coracobrachialis (*C*) and the latissimus dorsi (*L*). (Shepherd.)

it occurs more commonly in females, costal inspiration being more pronounced in them. In dissections of anencephalous monsters made by the writer the nerve supply was traced, in nearly all the specimens examined, to the anterior thoracic. These dissections convinced him that this muscle belongs to the pectoral and not the panniculus group (see *Jour. Anat. and Phys.*, vol. xix.).

Pectoralis Minor. The origin of this muscle varies considerably. It may arise from the second, third, and fourth ribs, instead of the third, fourth, and fifth. Not infrequently it arises from four ribs, and the writer has occasionally seen it arise by five digitations from the five upper ribs. It has been described as attached to only two ribs, and Testut, in his work on "Muscular Anomalies," describes a case in which it arose by a single digitation from the fourth rib, in this case the subclavius muscle was of large size. Sometimes the pectoralis minor is divided into a number of slips corresponding with the ribs from which it arises. It is occasionally connected with the great pectoral. In one case the writer saw it connected by muscular slips with the latissimus dorsi and coracobrachialis, and these two slips were connected together by a third (see Fig. 3446).

The variations of insertion of the pectoralis minor are numerous. The muscle not infrequently passes over the coracoid process and is inserted into the capsule of the shoulder-joint and great tuberosity of the humerus. It very frequently is united at its insertion to the coracobrachialis. In one case the writer saw it inserted into the coracobrachialis by a tendinous expansion, 5 cm. broad; in this case the coracoid process received no fibres of insertion. In many of the carnivora and quadrumana this muscle is normally inserted into the humerus. In rare cases the pectoralis minor is divided into two layers which have distinct insertions, and sometimes it is absent.

Pectoralis Minimus. Gruber has described a slip, to which he gives the above name, arising from the first piece of the sternum and cartilage of the first rib; from this origin it passes outward between the subclavius and lesser pectoral to be inserted into the coracoid process. Some regard it as a variety of the chondro-scapular muscle of Wood.

Subclavius. The subclavius is not infrequently inserted into the coracoid process as well as the clavicle; occasionally it has no clavicular attachment, but is wholly inserted into the root of the coracoid process. It has been described as double by some anatomists, but the supernumerary muscle will be described below as the sterno-scapular. Walsham describes a case in which the subclavius had an insertion into the humerus, as is normally seen in birds. The subclavius is sometimes absent, its place being taken by the sterno-scapular.

Sterno-chondro-scapular (Wood). Syn.: Scapulocostalis minor (Macalister), subclavius posticus (Rosenmüller). This is a supernumerary muscle of a somewhat cylindrical shape, which is attached externally to the root of the coracoid process or upper border of the scapula, passes inward over the subclavian artery and brachial plexus of nerves, beneath the clavicle and subclavius muscle, to be attached by a round tendon to the costal cartilage of the first rib, first piece of the sternum, or both (see Fig. 3447).

Sometimes this muscle passes over the clavicle in place of beneath it, and occasionally it does not reach as far as the coracoid, but may be inserted into the anterior

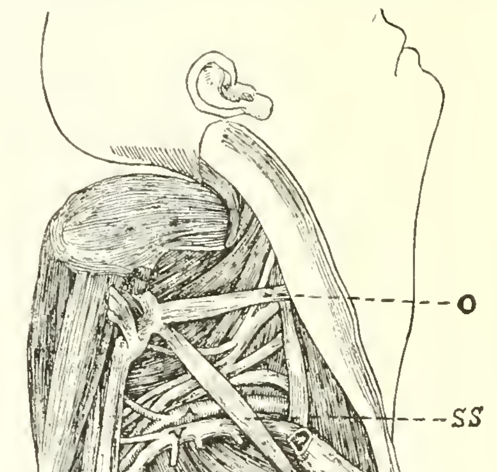

FIG. 3447.—*SS*, sterno-scapular muscle; *O*, omo-hyoid. (Wood.)

border of the clavicle (sterno-clavicular anterior). A variety of the sterno-clavicular muscle which the writer has seen is one which reaches from the sterno-clavicular articulation to the anterior border of the trapezius. In its course it passes over the clavicle and across the subclavian triangle, covering the third portion of the subclavian artery (see Trapezius). In ligature of the subclavian it is

Digitized by Microsoft®

well to bear this anomaly in mind. When the sterno-scapular muscle exists there is sometimes absence of the subclavius muscle; the writer has seen this occur once only out of seven cases; in three cases, however, the subclavius was much reduced in size. W. Gruber saw absence of the subclavius in seven out of eleven cases of sterno-scapular muscle.

www.libtool.com.cn

Comparative anatomy: In the Norway rat, guinea-pig, wombat, etc., the sterno-scapular muscle is normally present. In the horse it is a well-developed muscle. In animals without clavicles having a sterno-scapular muscle it is regarded as the homologue of the subclavius.

Chondro-coracoid is a small muscle described by Wood as arising from the first costal cartilage by a round tendon, and, passing outward below the subclavius, is inserted into the coracoid process superficial to the coracobrachialis.

Many other supernumerary clavicular muscles have been described, such as the scapulo-clavicular, coracoclavicular, supraclavicular, infraclavicular, etc., but they are so rare that it is only necessary to mention them and refer readers wishing to learn more about them to the special works on muscular anomalies mentioned in the introduction to this article.

Serratus Magnus. The serratus magnus may arise from nine ribs instead of eight, and occasionally it receives a slip from the tenth. Again, some of the highest or lowest digitations may be wanting, the muscle thus being attached to only six or seven ribs. Occasionally some of the central digitations are absent, and the muscle is then divided into two portions. Wood has described two large muscular bands, distinct from the serratus, arising from the ninth and tenth ribs, and inserted into the inferior angle of the scapula. He regards these bands as homologues of the depressor scapulæ of birds. Sometimes there is more or less complete fusion of the serratus with the levator anguli scapulæ. In many mammals it forms one muscle with the levator.

MUSCLES OF THE SHOULDER.—*Deltoid.* This muscle is not subject to many variations. It is sometimes divided into several distinct portions, viz., the clavicular, acromial, and spinal, as in carnivora. The clavicular and acromial portions are often separated by an interspace; not infrequently the clavicular portion is intimately connected with the contiguous part of the great pectoral, the division between them being determined only by the cephalic vein. The clavicular portion may also, in some cases, be continuous with the fibres of the trapezius, as in animals without clavicles.

The insertion of the deltoid varies in position and extent; in some cases it is inserted much lower than usual. Macalister has described a rare anomaly of this muscle, viz., the prolongation of its tendon as far as the lower end of the radius; he considers this to be the homologue of the extensor plicæ alaris of birds.

Testut has described a slip going from the clavicular portion of the deltoid to the internal condyle, crossing in its course the brachial vessels; he calls it the *cleido-epitrochlearis.* The deltoid not infrequently receives accessory slips from the axillary or vertebral borders of the scapula, and also from the spine and subspinous aponeurosis.

Supraspinatus. Variations of this muscle are extremely rare. It is very constant both as to its size and attachments. Occasionally fibres of the great pectoral are inserted into it. The writer once saw its tendon pass over the capsule of the shoulder-joint in a pulley-like depression, and become continuous with the deep portion of the insertion of the pectoralis major (see Fig. 3448).

Infraspinatus is occasionally fused with the teres minor. It may be connected with the deltoid by a strong fasciculus, and, again, it may be divided into several slips.

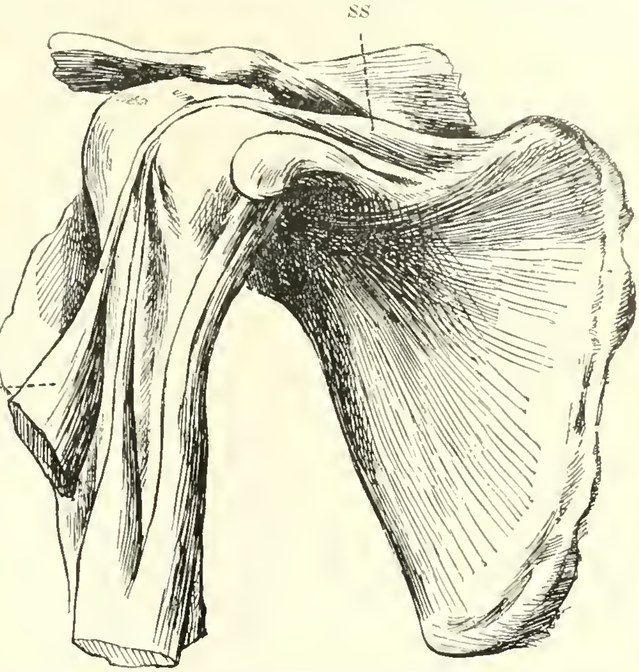

FIG. 3448.—*SS*, Tendon of the supraspinatus, continuous with the deep portion of the tendon of the pectoralis major (*PM*). (Shepherd.)

Teres minor is occasionally divided into two portions, the lower being called the teres minimus.

Teres major may be reduced to the size of the teres minor. It is sometimes inseparably connected with the latissimus dorsi, as in some of the lower animals. A fasciculus has been described descending on the fascia of the arm externally. It is analogous to the tensor fasciæ of the leg.

Subscapularis. Varies but little. A small accessory muscle (subscapulocapsularis, subscapularis minor) has been described by W. Gruber, Macalister, and others, which goes from the axillary border of the scapula to the capsule of the shoulder-joint or humerus. Knott describes some fibres given off from the lower border of the subscapularis and inserted into the aponeurosis and skin of the axilla. These are regarded as remnants of the panniculus carnosus muscle of the lower animals.

Curnow, Walsham, and others have described a muscle arising from the inner bicipital ridge, or the groove itself, and passing up to be inserted into the capsule of the shoulder-joint near the insertion of the coracobrachialis. Testut describes this muscle under the name of *brachiocapsularis.*

Coraco-brachialis. Professor Wood (*Jour. of Anat.*, vol. i.) considers that this muscle consists typically of three portions—superior, middle, and inferior. In man the middle and part of the inferior portion exist most constantly, the two portions being separated by the musculo-cutaneous nerve. Both the superior and inferior divisions are, however, occasionally seen in addition to the middle division (*coracobrachialis proprius*. The superior (*coracobrachialis superior vel brevis*), when it exists in man, arises from the coracoid process, passes over the subscapularis muscle, and is inserted below the lesser tuberosity, or more rarely into the capsule of the shoulder-joint (*coracocapsularis*). This is the normal arrangement in many animals, as the dog, cat, etc.

The inferior division (*coracobrachialis longus*) is also occasionally seen. It may be of large size and be in-

Digitized by Microsoft®

serted into the internal condyle or into a supracondyloid process when that anomaly exists. It is sometimes represented at its lower portion by a fibrous band; this is the internal brachial ligament of Struthers. As a rule, the inferior portion, when present, passes over the axillary artery, and must be kept in mind when ligaturing that vessel (see Fig. 3449).

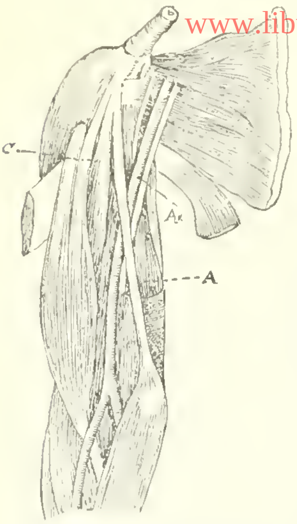

Fig. 3449. *A*, Coracobrachialis longus passing over the brachial vessels (*A c*) to reach the internal condyle; *C*, normal coracobrachialis. (After Wood.)

The coracobrachialis occasionally is not pierced by the musculo-cutaneous nerve.

Comparative Anatomy: In animals which swim or climb, as the beaver, bear, etc., the *coracobrachialis longus* is well developed. In most of the quadrumana there is a double insertion of the coracobrachialis, and, in the guinea-pig, the median variety only is present, as in man. In some animals, as the kangaroo, the muscle is absent altogether. It has once been found absent in a human monster. The coracocapsularis is present normally in many animals, *e.g.*, the dog, cat, etc.

Biceps Brachii. This muscle is rich in varieties. The most common is the presence of a third head, which arises near the insertion of the coracobrachialis, and in close connection with the brachialis anticus. The proportion of subjects having a third head is, in the writer's experience, one in seven; Theile makes it one in nine; Hallett, one in fifteen; Wood and Macalister, one in ten. In two hundred and fifty subjects examined the writer found it five times on both sides of the same subject. The third head generally soon joins the coracoid head about its middle, but it is occasionally seen quite separate as far as the bicipital fascia, into which it is inserted. The third head usually lies outside the vessels, but sometimes is seen covering them. It may arise from the bicipital groove, one of the ridges, or even from the great tuberosity. The writer has seen it arise from the lower edge of the great pectoral near its insertion (see Fig. 3450).

The third head is regarded by some as an offshoot from the brachialis anticus. Struthers has described a muscular slip which comes off from the inner border of the biceps, passes over the brachial vessels, and is inserted into the internal intermuscular septum or internal condyle.

The biceps has been seen with as many as four and even five heads. The supernumerary heads, as a rule, have their origin from the bicipital groove, body of humerus, coracoid process, capsule of shoulder joint, or tendon of the pectoralis major. The coracoid and glenoid portions of the biceps muscle may fail to unite, being completely separate to their insertion. The long head is occasionally absent, the muscle being uniceps instead of biceps, as in some animals. The *long* or *glenoid head* may not pierce the capsule, but arise from the capsule itself, the humerus, or the great pectoral tendon. The tendon of the biceps sometimes pierces the tendon of the pectoral (see Fig. 3450). This is a very rare anomaly. It is not uncommon in old joints that have become dry from rheumatic disease to find the long tendon worn through, and perhaps attached to the groove outside the capsule, or to the head of the humerus, or absent altogether. This pathological condition must not be confounded with the anomaly above described.

The *short* or *coracoid head* may also in rare cases be absent.

The biceps may send a slip of insertion to the coronoid process, capsule of the elbow-joint, or fascia of the forearm. It is sometimes connected with the pronator teres, supinator longus, brachialis anticus, and palmaris longus, by muscular slips. In one case, in which the muscular slip crossed the artery and went to the pronator teres, the bicipital fascia was given off from it.

The semilunar fascia is often of larger extent than usual, and may have a high origin. It may be developed into an almost true tendon. It not infrequently sends offshoots to neighboring parts.

Brachioradialis (Wood). The writer once saw this muscle. It arose from the supracondyloid ridge above the supinator longus, and between it and the deltoid; it coursed down the arm between the long supinator and biceps, and was inserted into the oblique line of the radius immediately above the insertion of the teres. Wood looks upon this muscle as a variety of a fourth head to the biceps.

Comparative Anatomy: A third head is the normal arrangement in many animals, *e.g.*, bat, seal, rhinoceros, etc. The long or glenoid head is absent in many animals, especially birds. The short or coracoid head is not present in many animals, as the seal, porcupine, paca, and the carnivora, as the dog, cat, bear, hyena, etc. The glenoid head in these comprises the whole muscle. In some, as the American bear, the coracoid head is represented by a very thin tendinous strand.

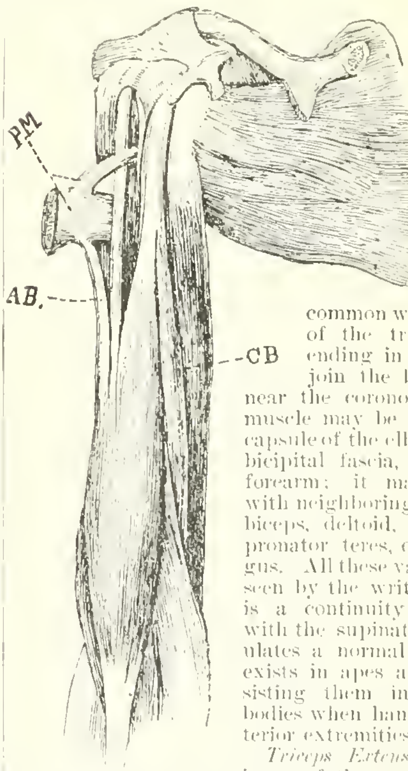

Fig. 3450. *AB*, Third head of biceps, arising from the pectoralis major (*PM*), which is perforated by the long tendon of the biceps; *CB*, coracobrachialis. (Shepherd.)

Brachialis Anticus. Subject to frequent variations. It may be divided into two or three portions. On one occasion the writer saw a slip arise in common with the outer head of the triceps, and after ending in a round tendon, join the brachialis anticus near the coronoid process. The muscle may be inserted into the capsule of the elbow-joint, radius, bicipital fascia, or fascia of the forearm; it may be connected with neighboring muscles, as the biceps, deltoid, coracobrachialis, pronator teres, or supinator longus. All these varieties have been seen by the writer. When there is a continuity of this muscle with the supinator longus it simulates a normal condition which exists in apes and monkeys, assisting them in twisting their bodies when hanging by their anterior extremities.

Triceps Extensor Cubiti. This is one of the most constant muscles in the body as to its insertion. One of the most common varieties is a fourth head arising from the inner side of the humerus. This fourth head may come from the axillary border of the scapula. The scapular head may have a more extensive origin than usual. The writer once saw a strong muscular slip, continuous with the deltoid and separated by a bursa from the teres minor, have a tendinous insertion into the scapular head near its origin.

Digitized by Microsoft®

In some animals, as the American black bear, the scapular head is of huge size, and arises from the whole axillary border of the scapula.

Gruber, Macalister, and Testut each report a case of a slip going from the coracoid process and capsule of the shoulder-joint to the triceps. In one instance the writer saw a fleshy slip between the triceps and teres major.

Dorsoepitrochlearis (accessorius tricipitis). Occasionally the muscle to which the above name is given, and which is common in quadrumana and other animals, is seen in man. It has already been described with the latissimus dorsi.

Epitrochleoanconeus. Exists frequently in man. Gruber found it in one in three; Macalister, one in four; and Wood, one in seventeen. It is triangular in shape, the apex being attached to the back of the internal condyle and the base to the olecranon process. The ulnar nerve passes beneath it and supplies it (see Fig. 3451). This muscle is exceedingly common in mammals. According to Galton, it is universally present in the edentata, less frequent among the primates, disappears among the anthropoid apes, and emerges again occasionally in man as an anomaly. Mr. Galton considers that it, like the supracondyloid process, is now "an almost functionally useless heirloom, which has descended to us from remote ancestors." Mr. J. B. Sutton (*Jour. of Anat. and Phys.*, April, 1885) says that when the epitrochleoanconeus is not represented as a muscle, its place is occupied by a collection of fibrous tissue having the exact shape and attachments of the muscle, and forming a bridge under which goes the ulnar nerve.

Subanconeus. This consists of a few muscular fibres, which are seen on removing the triceps from the lower part of the humerus; they extend from the lower end of the humerus to the capsule of the elbow-joint. It is homologous with the subcrureus muscle found in the lower limb beneath the quadriceps extensor. It is looked upon by many anatomists as a dependent of the triceps.

Anconeus. May vary as to the closeness of its connection with the triceps or extensor carpi ulnaris.

Pronator Radii Teres. The coronoid head is sometimes wanting, in most animals it does not exist. Occasionally there is a third head which arises from the internal intermuscular septum, or from a supracondyloid process when that variation is present; in such cases the direction of the brachial artery is often changed.

Sometimes the third, or supernumerary, head arises from the tendon of the biceps or brachialis anticus. The pronator teres may have its insertion lower down the radius than usual. It may also be divided into two portions, as in birds. The coronoid portion may be separated entirely from the condyloid, or there may be a doubling of each of these portions.

The pronator teres may be connected with the palmaris longus, carpi radialis flexor, or sublimis digitorum in the forearm and the biceps, brachialis anticus, and coracobrachialis in the arm.

Flexor Carpi Radialis. It may receive an additional slip of origin from the biceps tendon and fascia, the coronoid process, or the radius. It may have an insertion partly into the annular ligament, trapezium, scaphoid, or fourth metacarpal bone.

Palmaris Longus. This is one of the most variable muscles in the body. It is absent in about ten per cent. of individuals, and in rare cases is represented only by a tendinous band. It does not exist in the solipeds, ruminants, or pachyderms. The form varies considerably. There may be a central fleshy portion, with a long, slender tendon at each end; the muscular portion may be at the distal end. It has been seen muscular throughout, and again has been seen to consist of two bellies united by tendon. The palmaris longus is occasionally double; when a second muscle exists it generally arises by tendon, or is connected with the carpi ulnaris, or sublimis digitorum muscle. It may arise from the intermuscular septum between the two last-mentioned muscles, by a tendinous origin, and continue as part of the ulnaris as far as the middle of the forearm, then form a large belly which ends in a tendon near the wrist. The writer has seen it furnish the origin of the flexor brevis minimi digiti; a somewhat similar arrangement exists in the cebus and magot. Occasionally it receives an additional slip of origin from the coronoid process or radius. It sometimes terminates variously in the fascia of the forearm, muscles of the little finger, annular ligament, scaphoid, and pisiform bones, and tendon of the flexor carpi ulnaris. The writer once saw the tendon of this muscle near the wrist give off a broad muscular slip, which was inserted into the base of the first phalanx of the little finger. Most of the anomalies of this muscle correspond to the normal arrangement in some of the lower animals.

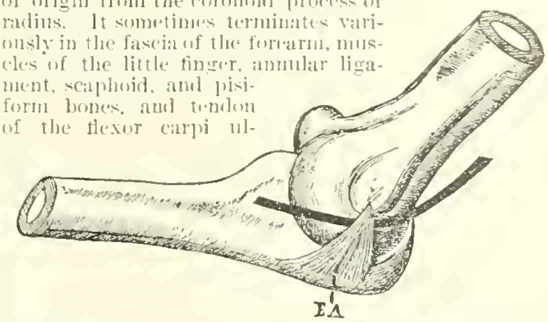

FIG. 3451.—*E.A*, Epitrochleoanconeus covering the ulnar nerve. (Sutton.)

Flexor Carpi Ulnaris. Is frequently inserted into the fifth metacarpal bone. It has been seen sending a slip of insertion to the fourth metacarpal. It sometimes gives off a slip to the annular ligament, but this is regarded as a supernumerary palmaris longus, as are also those cases in which a separate portion from the epicondyle passes down to be inserted into the pisiform bone. It is in rare cases double. I have once seen this muscle absent on the left side of a female subject.

Flexor Sublimis Digitorum. The radial origin of this muscle is sometimes wanting. The muscle is occasionally subdivided, each of the tendons being connected with a separate fleshy belly. This is more common with the index and little fingers, and may be classed among the anomalies called progressive. The tendon to the little finger may be absent, or the superficial flexor may be connected by slips with the deep flexor and the long flexor of the thumb. This is the arrangement in most mammals, and in man, and his order only, is seen the marked differentiation of the flexors. One of the lumbrical muscles occasionally arises from the sublimis digitorum. This muscle may send a muscular slip to the annular ligament and palmar fascia; this is the arrangement in the bear, and is supposed to represent the palmaris longus.

Flexor Profundus Digitorum. In many animals this muscle is intimately blended with the foregoing, but in man is generally quite distinct; not infrequently, however, it is connected with the sublimis digitorum and also with the flexor pollicis. It occasionally has an additional origin from the internal condyle and coronoid process (the *accessorius ad flexorem profundum* of Gantzer), which may join any one of the perforating tendons, commonly those going to the index and middle fingers (Wood). This is the normal arrangement in many mammals. The writer saw this coronoid slip very well developed on both sides of a negro subject. He also, some years ago, found a strange variety of the *accessorius* muscle occurring on both sides of the same subject. The muscle arose from both the internal condyle and inner side of the coronoid by fleshy fibres, developed into a large muscular belly which divided into two portions, each ending in a tendon, the innermost going to the terminal phalanx of the little finger, and the outermost to the terminal phalanx of the index, superficial to the tendon of the sublimis. On both sides, near the origin of this accessory muscle, a large slip went to the profundus digitorum.

The profundus digitorum may have an origin from the radius; when this occurs it joins the indicial portion of the muscle.

Flexor Indicis. The indicial portion of the profundus

Digitized by Microsoft®

may be quite distinct from the rest of the muscle. In one case the writer saw it connected with the flexor longus pollicis by a tendinous intersection. A flexor indicis is found in the gorilla and chimpanzee.

The tendon to the little and middle fingers may also be quite separate and distinct from the rest of the profundus. Accessory slips are not infrequently found going to join the various tendons of the muscle.

FIG. 3452. The Pronator Quadratus, *PQ*, consisting of two triangular portions with bases reversed. (Fenwick.)

Lumbricales. Varieties of these muscles are common; they may be diminished in number to three, or increased to five or six. Two may be inserted into one finger, or one into two by the bifurcation of a muscle. Occasionally the perforating tendons of the fourth and fifth fingers are furnished by lumbrical muscles. The third muscle is more frequently abnormal than the others. The writer has seen the lumbrical muscle of the little finger arise in the middle of the forearm from the sublimis digitorum by a round tendon, this, after passing under the annular ligament, developed a large fleshy belly which was inserted into the fifth finger. This might be regarded as a case of absence of the fourth lumbrical muscle, its place being taken by a slip from the sublimis.

Flexor Longus Pollicis. Has frequently a slip of origin from the coronoid process and internal condyle. This slip has been seen to pierce the radial nerve. The muscle may be connected by a slip with the superficial and deep flexors, and also with the pronator teres. It is sometimes fused with the profundus digitorum so as to form a single muscle, as is the case in nearly all mammals. It is sometimes fused with the indicial portion of the profundus, when that part forms a distinct flexor indicis, as in the gorilla. It has been observed sending a slip to the index finger and also to the first lumbricalis.

Pronator Quadratus. The pronator quadratus is sometimes entirely wanting; it may consist of two, three, and even four layers crossing each other. The attachment to the bones of the forearm may be greater than usual. It occasionally sends a muscular slip from its ulnar or radial attachment to the carpus. It may consist of two distinct triangular portions with the bases reversed; the anterior arising from the ulna by aponeurotic fibres and inserted into the radius by fleshy fibres, the deeper and inferior portion inserted into the ulna by fleshy fibres, and arising by aponeurosis from the radius (Fenwick, Sappey, and Macalister). (See Fig. 3452.)

The muscle may consist of a single triangle, as in some animals, *e. g.*, the macaque, seal, etc.

Flexor Carpi Radialis Brevis (Wood) (Radio-carpus of Fano). This is a small muscle occasionally seen. It arises from the anterior surface of the radius below the oblique line, and is inserted into the annular ligament, trapezium, os magnum, or other part of the carpus. It may also be inserted into one of the metacarpal bones. A variety of this muscle is, in rare cases, seen arising from the ulna (ulno carpus).

Supinator Longus. The varieties of this muscle are few in number. It sometimes has a higher attachment to the humerus than usual, and its insertion into the styloid process may be extended upward along the radius. It may have no attachment directly to the external condyle of the humerus, and in such a case it is closely connected with brachialis anticus. The writer once saw a slip from the supinator attached to the middle of the outer border of the shaft of the radius.

The tendon of the supinator may be divided into two or three slips. In cases of absence of the radius this muscle is wanting.

Occasionally it is double, the accessory portion (*brachio-radialis*) arising with it and being inserted into the radius in the neighborhood of the oblique line. It not infrequently is connected with neighboring muscles, viz., the deltoid, brachialis anticus (as in monkeys), flexor carpi radialis longior, and the abductor pollicis. The tendon may be pierced by the radial nerve.

Extensor Carpi Radialis Longior et Brevior. These muscles are sometimes completely fused. In many mammals (horse, pig, etc.) they form a single muscle, which ends in two tendons. In man the fusion may be only partial. The tendons of one or other of the muscles may be subdivided. The *radialis longior* may have an additional insertion into the second or third metacarpal bone. Wood has described a muscle which he calls the *extensor carpi radialis accessorius.* It arises from the humerus below the *radialis longior*, and is inserted into the first metacarpal bone, first dorsal interosseous muscle, abductor, or short flexor of the thumb. The writer has seen a digastric slip given off from the extensor carpi radialis longior, which joined the abductor pollicis. Testut has described an *abducteur huméral du pouce*, arising from the external condyle, and inserted into the first phalanx of the thumb. The long extensor is occasionally united with the supinator longus. Macalister has recorded absence of the short extensor.

Extensor Communis Digitorum. The varieties of this muscle relate chiefly to the increase or diminution of the tendons of insertion. The tendon going to the little finger may be absent, and also that going to the index finger. It is more common to have an increase than a diminution of tendons. Any one of the tendons may be subdivided, and as many as eleven have been observed by Perrin and Rüdinger, due to doubling of some tendons and tripling of others. Curnow in one case saw twelve tendons go to the inner four digits and five to the thumb, making seventeen in all. Five and six are commonly seen, the tendons of the little and index fingers being most often duplicated. The extensor communis occasionally sends a slip to the thumb.

The indicial portion of the muscle may be completely separated from the rest, and the extensor minimi digiti may be inseparably connected with the larger muscle.

Extensor Minimi Digiti. Sometimes fused with the common extensor or carpi ulnaris. It may be double, the additional tendon being inserted into the ring finger. It may have an ulnar attachment, and may be inserted into the annular ligament. Complete absence of the muscle has been observed.

Extensor Carpi Ulnaris. An accessory or short extensor, going from the lower end of the fourth and fifth metacarpal bone, has been described. The tendon is not unfrequently prolonged downward to the first phalanx of the little finger (*ulnaris quinti*). It is also frequently connected with the abductor minimi digiti. Sir William Turner has lately reported a case of absence of this muscle; its place was taken by a slender band of fibrous tissue. Curnow has also recorded absence of this muscle.

Supinator Brevis. An accessory supinator brevis has been observed going from the external condyle of the humerus to the radius or ulna. The extent of attachment to the radius may be much greater than usual. A sesamoid bone is sometimes found in the tendon of the muscle. This occurs normally in some animals, and is also seen in the popliteus, of which the short supinator is supposed to be the homologue.

Extensor Ossis Metacarpi Pollicis. The tendon of this muscle is frequently double, and sometimes is triple. When double, usually both are inserted into the meta-

Digitized by Microsoft®
www.libtool.com.cn

carpal bone, or one into this bone and the other into the trapezium, as is the normal arrangement in apes. The supernumerary tendon may be inserted into one of the short muscles of the thumb. The muscle may be double throughout, and Curnow has in one case seen it triple.

Extensor Primi Internodii Pollicis. Is sometimes absent, or is not differentiated from the extensor ossis metacarpi. Curnow describes a case of doubling of this muscle. It is found only in man.

www.libtool.com.cn

Extensor Secundi Internodii Pollicis. Doubling of the muscles is not uncommon. Additional muscles are occasionally present, and have been described by Curnow (*Jour. Anat. and Phys.*, vol. x., p. 596).

Extensor Primi Internodii Pollicis et Indicis. In some rare cases there is an accessory extensor present, which arises between the extensor indicis and the extensor secundi internodii pollicis; it divides into two tendons, one of which goes to the first phalanx of the thumb, and the other to the index finger. This muscle exists normally in the dog and many other carnivora.

Extensor Indicis. The tendon of this muscle is frequently divided into two portions, one going to each side of the index finger; sometimes one of the tendons goes to the middle finger. This latter is occasionally seen as a distinct muscle (*extensor proprius digiti medii*). It arises from the lower part of the ulna or posterior ligament of the wrist-joint, and is inserted into the base of the first phalanx of the middle finger. It exists normally in apes.

A short *extensor indicis* is occasionally seen taking its origin below the long extensor, from the back of the wrist or a carpal bone; it is inserted with the long extensor into the index finger. The writer has seen this accessory muscle arise from the radius, and pass through a separate compartment in the annular ligament to be inserted into the index finger. The extensor indicis may have a more extensive attachment to the radius than usual. The writer has seen it connected by a tendinous slip with the extensor secundi pollicis. Curnow describes one case in which the muscle divided into three tendons—one inserted normally, one with the secundi internodii, and one with the aponeurosis over the middle finger. A somewhat similar arrangement is seen in the hedgehog, kangaroo, and manis. It is rarely absent.

Extensor Pollicis and Indicis (see above).

Extensor Brevis Digitorum. Very rarely met with. It arises from the back of the wrist, post-annular ligament, from the carpus itself, or the bases of some of the metacarpal bones by fleshy fibres; it sends tendinous slips to one, two, or three fingers. The writer has seen them going to the ring and index fingers and to the middle finger. It is probable that the extensor brevis indicis and extensor medii digiti are varieties of this muscle. (See Fig. 3453.)

This muscle is common in reptiles, and survives only in a few anomalous mammals of the order Edentata (Curnow).

Muscles of the Hand.—*Palmaris Brevis.* Varies considerably as to its degree of development. It is occasionally altogether wanting.

Abductor Pollicis. Some anatomists describe the muscle as normally consisting of two portions—an outer and inner. It may receive a third belly from the opponens pollicis, or be connected with it by a muscular slip. It may also receive an accessory slip from the extensor carpi radialis longior, ossis metacarpi pollicis, palmaris longus, or from the radius. Not infrequently a thin, muscular slip is seen going from the skin of the ball of the thumb opposite the tuberosity of the trapezium to the abductor pollicis. Some regard this latter as a skin-muscle.

Flexor Brevis Pollicis. The deeper belly of the muscle is often with difficulty differentiated from the adductor pollicis.

Adductor Pollicis. This muscle is frequently blended with the deep portion of the short flexor of the thumb.

Abductor Minimi Digiti. Sometimes divided into two or even three slips. It is often united with the flexor brevis minimi digiti. It may have an accessory slip, arising from the tendon of the ulnar flexor, the annular ligament, fascia of the forearm, and tendon of the palmaris longus. The writer has seen an accessory head arise from the intermuscular fascia beneath the flexor radialis and ulnaris. The accessory slip may pass down and cover the ulnar artery.

Flexor Brevis Minimi Digiti. May be absent or replaced by a slip from the abductor minimi digiti or opponens. An accessory head may spring from the lower third of the inner border of the ulna, from the carpi ulnaris, or fascia of the forearm. A doubling of the muscle has been observed.

Opponens Minimi Digiti. May be closely connected with neighboring muscles, or receive a second head from the fascia of the forearm (Henle.)

M. Pisiuncinatus. This is a muscle described by Calori, and stretches between the pisiform bone and unciform process of the unciform bone.

Interosseous. These muscles do not vary to any great extent. They may be double in one or two interosseous spaces. Henle describes a *palmar interosseous* muscle of the thumb as normal. It arises from the metacarpal bone of the thumb, and joins the inner head of the flexor brevis pollicis. The arrangement of the interosseous muscles of the hand has been observed, in rare cases, to be similar to that of the foot.

Accessory Palmar Abductor Indicis. The writer once saw a small muscle arising from the third metacarpal bone, beneath the adductor pollicis and inner head of the flexor brevis pollicis. After ending in a round tendon, it was inserted into the base of the first phalanx of the index finger.

Muscles of the Lower Limb.—*Gluteus Maximus.* The great size of this muscle is peculiar to man, principally on account of his erect position. In the human species the muscle always covers the ischial tuberosity; in apes, this is uncovered. The variations are important. The muscle may be considerably reduced in size. Macalister reports a case in which the muscle was attached above to the last two sacral vertebræ only. The superficial portion of the muscle is often separated from the deep by a layer of cellular tissue. The lower edge of the muscle is sometimes quite distinct, and represents the *agitator caudæ* of the lower animals; it may be inserted into the femur or the femoral aponeurosis. The gluteus maximus is occasionally blended with the tensor fasciæ, as in the elephant and some monkeys.

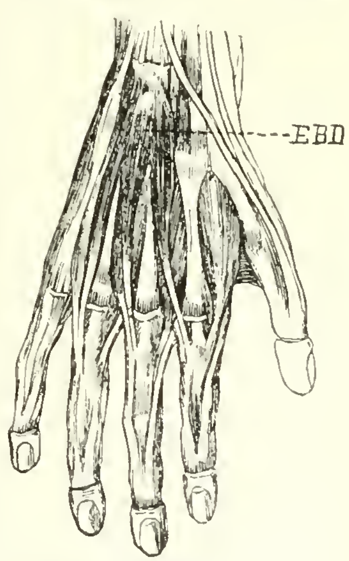

Fig. 3453.—*EBD*, Extensor brevis digitorum. (After Wood.)

Ischio-femoral. The writer has only once seen this muscle. It arose from the inner edge of the great tuberosity by a round tendon, which soon developed into a triangular-shaped muscle of considerable size; it was separated from the gluteus maximus by the great tuberosity, and joined it near the femur. It was inserted into the lower end of the gluteal ridge of the femur. The *ischio-femoral* muscle exists normally in the gorilla, certain apes, and other animals.

Gluteus Medius. The deeper fibres of this muscle may

Digitized by Microsoft®

end in a separate tendon, which is attached to the upper border of the great trochanter. Its upper or lower border may be separated from the rest of the muscle. Occasionally a bursa is interposed between the tendon of the gluteus medius and the pyriformis. Some of its fibres may be inserted into the pyriformis, or its posterior border may be completely fused with that muscle.

www.libtool.com.cn

Gluteus Minimus. Occasionally divided into anterior and posterior portions; may send slips to the hip-joint, to the pyriformis, gemelli, or vastus externus muscles.

Accessory Gluteus Minimus (fourth gluteal; scansorius). The fibres of the anterior border are in some cases separated from the muscle, and inserted variously into the anterior border of the great trochanter, into the capsule, or near the lesser trochanter, where it is connected with the iliacus tendon. It represents the scansorius muscle of apes. Testut looks upon it as representing the extrapelvic portion of the iliacus muscle.

Tensor Vaginæ Femoris (tensor fasciæ). Varies but little. May have a supernumerary origin from the abdominal fascia, iliac crest, and Poupart's ligament. It

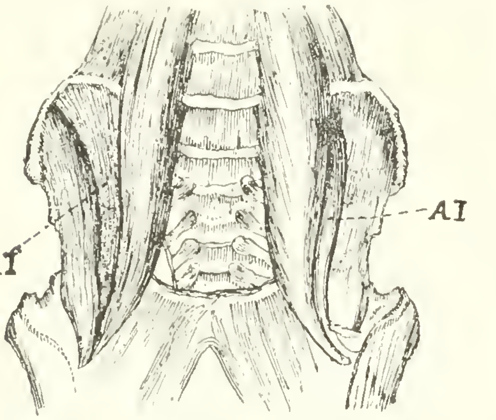

FIG. 3454.—*AI, AI.* Examples of double superficial iliacus muscles.

is sometimes fused with the gluteus maximus. A duplication of the muscle has been observed by Macalister and Testut.

Pyriformis. The most common variation of this muscle is its division into two portions by the great sciatic nerve or its external popliteal branch. It is occasionally fused with the gluteus medius more or less completely. It may be connected with the gluteus minimus by a few fibres. Its tendon is sometimes united with that of the obturator internus, or receives the gemellus superior. It may have its origin from as many as five sacral vertebræ, or as few as one. It frequently has no attachment to the first sacral vertebra. It may be inserted into the capsule of the hip-joint. Its complete absence has been noted by several observers.

Obturator Internus. The variations of this muscle are unimportant. It may receive supernumerary fasciculi from various parts in the pelvis, as the psoas minor muscle, ischial tuberosity, sacro-sciatic ligaments, third sacral vertebra, pubes, etc. A pubic portion is sometimes separated by the obturator nerve.

Obturator Externus. Wood has described a large fleshy slip going from the adductor brevis to join the tendon of this muscle, and Macalister has noted a separation of a pubic fasciculus by the obturator nerve.

Gemelli. The *superior gemellus* is not infrequently absent, or very small in size. The *inferior gemellus* has also been observed absent, but more rarely. Doubling of the *superior* has been noticed; it has also been seen fused with the pyriformis and gluteus minimus. The gemellus inferior and quadratus femoris are frequently inseparably united to the obturator internus.

Quadratus Femoris. This muscle may be much reduced in size, or absent altogether; in such a case, the inferior gemellus is larger. It has been described as sometimes double. It may be united above with the gemellus inferior, and below with the adductor magnus.

Biceps Flexor Cruris. The two heads may be quite separate, as in the orang and chimpanzee. The short head may be divided into several fasciculi, or, in rare cases, absent altogether. This latter arrangement is the usual one in a large number of mammals. There is sometimes a third head, which may arise from the femur, from the ischial tuberosity, coccyx, sacrum, fascia lata, or gluteal fascia. The third head generally joins the long head, though when it arises from the linea aspera, or inner condyloid ridge, it joins the short head. The third head has been looked upon as homologous with the caudal origin of the biceps in the lower animals. In rare cases a slip (*ischiocalcaneus*) has been seen going from the long head to the gastrocnemius, external tuberosity of the tibia, femoral aponeurosis, and even to the tendo Achillis. This arrangement is a modification of that seen in the lower animals, especially the bear.

I have seen a muscular slip arising from the biceps near its insertion and inserted by a tendinous expansion into the fascia covering the lower third of leg.

Semitendinosus and *Semimembranosus.* These two muscles may be fused into one. The *semimembranosus* may be absent altogether. It has been seen double. Occasionally, it derives its origin for the most part from the great sacro-sciatic ligament.

The *semitendinosus* may have a supernumerary origin from the coccyx, and sometimes gives off a muscular slip about its middle, which is inserted into the fascia of the leg. This arrangement is normal in some of the lower animals.

Psoas Magnus. Varies somewhat in volume, according as its origin is more or less extensive. It occasionally forms a muscle quite distinct from the iliacus. It may be divided into two portions, between which passes the anterior crural nerve. This is merely an exaggeration of the normal condition. An accessory psoas is sometimes seen arising from the transverse processes of some of the lumbar vertebræ. The writer, in a male subject, saw this accessory psoas of considerable size; it arose from the transverse process of the fourth lumbar, and as it descended widened out into a broad muscle, which joined the magnus in the middle of the iliac fossa.

Psoas Parvus. Frequently absent and occasionally fused with the magnus. It usually arises from the bodies of the last dorsal and first lumbar vertebræ, and soon becomes tendinous; it then passes down to the inner side of the magnus, and ends by being inserted into the ilio-pectineal line and pectineal eminence. It has been noted as having an insertion into the lesser trochanter, as in the seal, guinea-pig, etc.

Although inconstant in man, it is a large, well developed, and constant muscle in the lower animals. Gruber in 450 subjects found absence of this muscle on both sides in 183, and on one side in 69; Perrin in 112 subjects found it present in only 32; Theile found it in only 1 out of 20 subjects examined; and Testut, 6 out of 32.

It is occasionally double.

Iliacus. May be divided into several distinct portions. The deep portion is not infrequently separated from the superficial by a well-marked cellular interval, and thus constitutes a separate muscle.

Superficial Iliacus. Sometimes seen arising from the crest of the ilium, last lumbar vertebra, or upper border of the sacrum. In one subject, the writer saw this muscle on both sides: on the right side it was a broad, flat muscle, arising from the posterior third of the crest of the ilium, and on the left a fusiform muscle, which arose from the body of the last lumbar vertebra and upper border of the sacrum. Both muscles ended in strong tendons, which were pierced by the anterior crural nerve, and joined the iliacus below Poupart's ligament (Fig. 3454).

Iliocapsularis vel Iliacus Minor. Arises from the anterior inferior spine of the ilium and capsule of the hip-joint; it may be inserted into the lower part of the

Digitized by Microsoft®

anterior intertrochanteric line, lesser trochanter, or iliofemoral ligament. In one subject the writer saw a well-marked bursa separating it from the iliacus.

Sartorius. A case of absence of this muscle has been reported by Meckel. It is occasionally double in its whole course. An accessory portion has been seen having an insertion into the femur, patella, or tendon of the normal muscle.

www.libtool.com.cn

The sartorius, in addition to its tibial attachment, may have an insertion into the femoral aponeurosis, the capsule of the knee-joint, or the femur itself in the neighborhood of the internal condyle. All these various insertions are seen normally in mammalia. A tendinous inscription in rare cases is seen in this muscle. The writer has only once met with this anomaly.

Quadriceps Extensor Cruris. Not subject to many variations. Occasionally the acetabular origin of the *rectus* is wanting, or it may be reinforced by an additional origin from the anterior superior spine. The *vasti* muscles may be divided into two portions, superficial and deep; this bilaminar arrangement is the normal one in many birds. The two vasti muscles are often closely united.

The *Subcrureus* is a muscle which is very variable in volume. It is often divided into two or more separate muscular bundles.

Accessory Head to Quadriceps. The writer once saw, on the left side of a male subject, a supernumerary muscle which arose by a double tendinous origin from the anterior portion of the capsule of the hip-joint and the anterior border of the great trochanter. The two tendons soon united to form one strong tendon, which passed down the thigh between the iliacus and tensor fasciæ, lying on the vastus externus; about the middle of the thigh it developed into a strong muscular belly three inches long. After passing beneath the rectus it joined the common tendon of the quadriceps.

Gracilis. The variations are unimportant and consist chiefly of a greater or less extent of origin and insertion. An accessory head is sometimes seen.

Pectineus. May be occasionally divided into two portions, as in some of the lower animals, each portion supplied by a different nerve—the inner by the obturator, and the outer by the anterior crural. In one case the writer saw it divided into a superficial and a deep portion; the superficial arose from the pectineal line, two inches outside the pubic spine, and was inserted into the linea aspera, with the adductor magnus. The deep portion was the normal muscle.

The pectineus is not infrequently united with the adductor longus; this occurs normally among the Rodentia, Carnivora, and Quadrumana. It may be sometimes inserted into the capsule of the hip-joint.

Adductor Longus. May be divided into two portions by the passage of blood-vessels. It is often inserted low down on the femur, and its tendon is inseparable from the magnus. It is sometimes fused with the pectineus.

Adductor Brevis. Occasionally divided into two or three portions—may be continuous with the magnus. It has been reported as united to the tendon of the obturator externus.

Adductor Magnus. The upper part of this muscle is so often separated from the main portion that Henle, Macalister, and other anatomists describe it under the name *adductor minimus* or *quadratus.* Its upper border is occasionally completely united with the quadratus femoris. The different parts of the muscle are not infrequently separated; the portion inserted into the internal condyle is frequently quite distinct (*ischio-condyloid*).

Tibialis Anticus. This muscle has been seen arising from the femur, as occurs so generally in the higher mammals. In the case reported the leg was congenitally deformed. The tendon is occasionally double, the extra tendon being inserted into the astragalus or base of the first metatarsal, as in apes. The tendon has been seen divided into three portions, and occasionally a sesamoid bone is formed in it.

I have seen a muscular slip from the tibialis anticus end in a tendon which was inserted into the proximal phalanx of the fourth toe. I have also seen this slip inserted into the first phalanx of the great toe.

Tibiofascialis Anticus. A small muscle described by Wood, Macalister, and Humphry, which arises from the lower third of the anterior edge of the tibia, over the tibialis anticus, and is inserted into the annular ligament and deep fascia. It is sometimes represented by a tendinous slip from the tibialis anticus, which is inserted into the fascia of the dorsum of the foot. Gruber describes a *tibio-astragulus anticus* arising from the tibia and interosseous ligament behind the tibialis anticus, and inserted in the neck of the astragalus.

Extensor Proprius Hallucis. Is occasionally united with the extensor communis digitorum, or short extensor of the toes. The muscle or its tendons may be double, and have a supernumerary insertion into the metatarsal bone or first phalanx of great toe. It is sometimes inserted into the second toe. Its tendon may be divided into three portions (*extensor hallucis longus tricaudatus*).

Extensor Ossis Metatarsi Hallucis is a small muscle arising from the extensor hallucis, tibialis anticus, extensor communis digitorum, or as a separate muscle close to the extensor hallucis, going through the same compartment in the annular ligament as the hallucis; it is inserted into the metatarsal bone of the great toe.

Extensor Primi Internodii Hallucis. In one-half the subjects examined Professor Wood found this muscle; it is generally an offshoot from the extensor hallucis, but sometimes arises separately.

Extensor Longus Digitorum Pedis. Varies considerably in the mode of origin and the arrangement of its tendons. The number of tendons may be increased by the doubling of any one. It is not uncommon for the tendon going to one toe to give slips to adjacent toes. It may have an additional insertion into the metatarsus. Occasionally a supernumerary tendon is seen going to the great toe. The tendons may be united on the dorsum by slips, as in the hand. It may be united to a greater or less extent with the extensor proprius hallucis, or extensor brevis digitorum. Each of the tendons may have a separate muscular belly in connection with it. Wood reports a case in which the four tendons had each a separate muscular belly. All these abnormal arrangements have their corresponding normal conditions in the lower animals.

Peroneus Tertius. Sometimes of large size, and occasionally inserted entirely into the fourth metatarsal bone. Its tendon may unite with that of the extensor going to the fourth or fifth toe, or it may unite with the fourth dorsal interosseous. The muscle may be absent altogether or be double.

Peroneus Longus. Occasionally fused with the brevis. In one case it has been noted as arising from the femur, as in many lower animals, *e.g.* the bear, hyæna, etc. It may have a supernumerary insertion into one of the metatarsal or cuneiform bones, as occurs in some animals. The tendon sometimes gives origin to the flexor brevis minimi digiti and outermost plantar interosseous (Wood).

Peroneus Accessorius. This is a small muscle which arises from the fibula between the peroneus longus and peroneus brevis, and ends in a tendon which joins the long peroneal.

Peroneus Brevis. The tendon of this muscle is occasionally divided into two portions, the supernumerary one going to the fourth metatarsal or cuboid bone, or to the proximal phalanx of the fifth toe, joining the extensor tendon of that toe. It may also be inserted into the abductor minimi digiti.

Peroneus Quinti Digiti. It arises from the fibula beneath the peroneus brevis, and is inserted into the extensor aponeurosis of the little toe. It is seldom seen as a distinct muscle, being generally united with the peroneus brevis. It is seen normally in some animals, as the bear and the cat.

Peroneus Quartus. A muscle which is not infrequently seen arising from the back of the fibula, between the peroneus brevis and flexor hallucis, or from the fascia of the deep muscles of the calf; it is inserted into the external malleolus, peroneal tubercle of the os calcis, or the

Digitized by Microsoft®

ridges of the cuboid groove. This is looked upon by Testut as a variety of the peroneus quinti digiti.

In a male subject the writer saw, on both sides, the peroneus longus divided into two portions: the outer and larger passed down in the usual course of the long muscle, but the inner and smaller portion, which arose principally from the intermuscular septum, ended in a tendon which passed through the same compartment in the annular ligament as the outer portion, and immediately before it reached the peroneal tubercle it divided into two parts, one of which spread out and was inserted into the tubercle; the other crossed over the tendon of the peroneus brevis and was lost in the fascia covering the dorsum of the foot; between these two tendons passed the tendon of the peroneus brevis. This was probably a variety of the peroneus quinti digiti and peroneus quartus muscles.

www.libtool.com.cn

FIG. 3455. A. Example of a third head to the gastrocnemius. (Wood.)

Extensor Brevis Digitorum. The number and arrangement of the tendons vary considerably. Very frequently one or more of the tendons are doubled. A slip not infrequently goes to the little toe. The number of tendons may be reduced to two; occasionally a single tendon may have two muscular heads in connection with it. The innermost portion going to the great toe is often separated from the rest of the muscles, and is called the *extensor brevis hallucis.* Wood describes cases in which slips from the tendons of the extensor brevis joined the dorsal interosseous. There may be a special slip going to the second metatarsal bone or long extensor tendon of the second toe. This would be the homologue of the extensor indicis of the hand.

Gastrocnemius. The two bellies are sometimes more or less completely separated from each other, as in the marmot, unau, coati, etc. The most common anomaly is the existence of a third head (see Fig. 3455). This consists of a band of muscular fibres, which may arise from either condyloid ridge, the popliteal surface of the femur, or the posterior ligament of the knee-joint; passing down, it most frequently joins on the united muscle. This third head may pass between the popliteal artery and vein, or over both vessels and nerves. It is sometimes divided into two portions.

The writer has seen a third head arising from the inner side of the tendon of the biceps femoris, about three inches above the condyles. It passed down, and joined the external head about one inch above its junction with the internal one. This is the normal arrangement in the lion and some other animals.

FIG. 3456. Absence of the external head of gastrocnemius. (Shepherd.)

A slip may be given off from the biceps, semitendinosus, or adductor magnus to the gastrocnemius. The writer, in one female subject, saw complete absence of the external head. On removing the skin and fat, the first structure which came into view was the plantaris muscle (see Fig. 3456). Absence of the whole muscle has been observed.

Occasionally a sesamoid bone is developed in the tendon of the external head. A similar arrangement exists in many animals.

Soleus. An accessory soleus is occasionally seen which arises from the oblique line of the tibia and joins the inner side of the soleus; it covers the posterior tibial artery, and is often of large size.

The soleus has been observed of very small size, the fibular portion alone existing.

It is sometimes inserted into the os calcis separately from the gastrocnemius, an arrangement which is common in many animals. A muscular slip going from the tibia to the tendinous arch over the popliteal vessels has been occasionally seen.

Plantaris. The plantaris, which is rudimentary in man and gradually disappearing, is of large size in some animals, and in them is continuous with the plantar fascia or flexor brevis digitorum. In man it is frequently absent. It sometimes arises by two heads, the supernumerary one coming from the posterior ligament of the knee-joint or from one of the condyles. The writer has seen this supernumerary head arise from the outer head of the gastrocnemius and the middle of the outer surface of the soleus by a tendinous origin.

The plantaris has been seen to arise from the popliteal fascia and fibula. The writer on one occasion saw it arise solely from the posterior ligament of the knee-joint. The mode of its insertion varies, its tendon sometimes joins the tendo Achillis or internal annular ligament, or ends in the deep fascia of the leg. It may send a slip to the plantar fascia (*tensor fasciæ plantaris*). Its tendon may be enclosed in the lower part of the tendo Achillis.

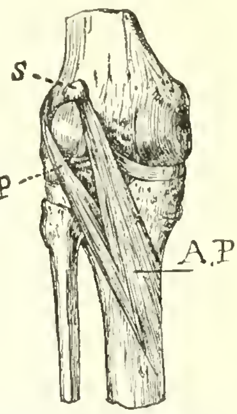

FIG. 3457.—AP, Accessory popliteus arising from a sesamoid bone (S); P, normal popliteus. (Wagstaffe.)

Popliteus. A sesamoid bone is sometimes developed in its tendon of origin. The muscle in rare cases is absent altogether.

Popliteus Minor. Is a small muscle, rarely seen, which arises from the femur internal to the plantaris and is inserted into the posterior ligament of the knee-joint. Wagstaffe has described an accessory popliteus which arose from a sesamoid bone developed in the external head of the gastrocnemius, and was inserted into the oblique line of the tibia superficial to the normal muscle (see Fig. 3457).

Peroneotibialis. This is a muscle described by Gruber, who met with it in one in seven subjects. It arises from the inner side of the head of the fibula, and is inserted into the upper end of the oblique line of the tibia. It is placed beneath the popliteus, and is looked upon as the homologue of the pronator teres in the arm. It is seen in many of the lower animals.

Flexor Longus Digitorum Pedis. This muscle varies somewhat as to its origin. It frequently receives extra slips of origin from the deep fascia and aponeurosis of the leg, the tibia, fibula, or flexor hallucis. The writer has several times seen muscular fibres originating extensively from the deep aponeurosis and flexor hallucis, and crossing the tibialis posticus to reach the flexor digitorum. In some cases the tibialis posticus was completely hidden from view by muscular fibres. A similar arrangement is seen in a great many of the apes. The tendon going to the second toe is sometimes absent; in these cases the second toe receives a slip from the flexor hallucis.

Flexor Accessorius Longus Digitorum Pedis. This muscle and its varieties have been described under various names, as *tibioaccessorius, accessorius ad accessorium* (Turner); *peroneocalcaneus internus* (Macalister); *pronator pedis* (Humphry). It may arise from the tibia or

Digitized by Microsoft®

fibula by a fleshy belly and in a well-marked tendon, which passes through a separate compartment in the annular ligament, either in front of or behind the flexor hallucis, and finally ending by joining the flexor accessorius or the tendon of the long flexor before it divides. It has been seen to replace the proper accessorius. In its course down to the foot, its fleshy fibres generally cover over the posterior tibial vessels and nerves. When it arises from the fibula and is inserted into the tubercle of the os calcis, it is called the *peroneocalcaneus internus*, and is looked upon as the homologue of the pronator quadratus of the forearm. The writer has several times seen this muscle arising from the tibia, and only once from the fibula. In one case it arose by two fleshy heads, one from the flexor hallucis, and the other for two inches from the inner border of the tibia immediately below the soleus; the two heads united to form a single belly which, after covering the posterior tibial vessels, ended in a tendon. This tendon passed beneath the annular ligament posterior to the vessels, and in the sole of the foot joined the tendon of the long flexor; the normal accessorius was inserted into this tendon instead of into that of the flexor.

www.libtool.com.cn

A *flexor proprius digiti secundi*, arising from the tibia and going to the second toe, has been described by Bahnsen.

Flexor Accessorius. The outer head is not infrequently absent. The muscle is sometimes much reduced in size and may even be absent. Its accessory long head has already been described under the name flexor accessorius longus digitorum pedis.

The number of digital tendons to which this muscle can be traced varies considerably. Offsets may be sent to the second, third, and fourth toes, and sometimes to the fifth. In rare cases it can be traced to only two tendons. The muscle has been observed going to the flexor hallucis tendon instead of the digitorum. It sometimes gives off a slip to the fifth toe (as in monkeys), when the slip to that toe from the brevis digitorum is absent.

Lumbricales. Absence of one or more of these muscles occasionally occurs. The writer once saw, on both sides of the same subject, the two outer ones absent. Two are sometimes seen going to one toe. The tendons are frequently inserted into the first phalanges of the toes.

Flexor Hallucis Longus. Seldom varies. The tendons of the digitorum longus and hallucis are seldom completely separated; they are generally united by a slip from the hallucis to the digitorum, and sometimes by one from the digitorum to the hallucis. The slip from the hallucis may generally be traced to the second or third toes, sometimes to all, and sometimes to the second only. In a subject dissected in 1879 by the writer, the tendon of this muscle divided into three tendons, which went to the great, second, and third toes. The longus digitorum divided into four tendons as usual; but those going to the second and third toes were of small size, and joined the ones from the hallucis. The lumbrical muscles were in connection with the digitorum tendons. In this case there was no connection between the tendons of the muscles before division. A slip may be given off from the flexor hallucis in the leg, and after passing under the annular ligament, may join the accessorius. This is a variety of the muscle described above—*flexor accessorius longus digitorum pedis.* In rare cases the tendons of the two long flexors are fused into one, as is seen in the lower animals. The writer once saw a sesamoid bone developed in the tendon of this muscle as it passed over the astragalus and os calcis.

Tibialis Posticus. Very seldom varies. Is occasionally blended more or less intimately with the flexor hallucis. A sesamoid bone is frequently developed in its tendon. It has been described as being inserted into the peroneus longus tendon, second, third, and fourth metatarsal bones, and cuboid. Wood has seen it combine with the flexor brevis hallucis muscles. It has been reported absent by Budge.

Tibialis Secundus. This is a muscle described by Bahnsen, Henle, and Linhart. Henle calls it the tensor of the capsule of the ankle-joint. It arises from the back of the tibia below the flexor digitorum longus, and is inserted into the posterior part of the capsule of the ankle-joint or annular ligament. A similar muscle has been described as being inserted into the anterior part of the capsule of the ankle-joint.

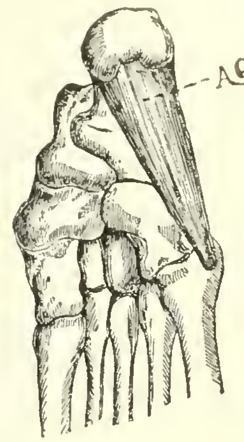

FIG. 3458.—*AQ.* Example of the abductor ossis metatarsi quinti arising from os calcis. (Bradley.)

Flexor Brevis Digitorum. The slip going to the fifth toe, which is usually of small size, and very often not perforated by the deep flexor, is sometimes absent altogether. Five tendons have been observed, two going to the second toe. The slip to the little toe, when absent, is occasionally replaced by a small muscle arising from the outer side of the long flexor tendon or flexor accessorius. This arrangement is seen in many of the apes.

The tendons of the short flexor may be united to those of the long flexor, and have a common insertion. Some portion of the short flexor may arise from the long flexor tendon. The writer, a few years ago, saw a very good example of this, an arrangement which is like that which exists in apes. The muscle consisted of two portions, superficial and deep; the superficial arose from the inner tuberosity of the os calcis, and divided into two tendons which went to the second and third toes; the deep portion, however, arose by a fleshy origin from the deep flexor tendon before it was joined by the accessorius; its tendons were distributed to the fourth and fifth toes.

Wood mentions a case in which the slip to the fifth toe was augmented by another from the long flexor tendon; they formed a single tendon, which was not perforated but blended with the tendon of the long flexor going to that toe.

Abductor Hallucis. Its tendon is sometimes joined by a muscular slip which comes from the skin in front of the inner ankle. Wood describes a muscular slip from the abductor to the base of the first phalanx of the second toe.

Abductor Minimi Digiti. The tendon is sometimes double.

Abductor Ossis Metatarsi Quinti. A portion of the above has been described, by Wood and Bradley, as a separate muscle arising from the outer tubercle of the os calcis, and inserted into the base of the fifth metatarsal bone; it occurs in about every other subject. Most anatomists look upon this as merely an insertion of the abductor minimi digiti, which fails to exist in about half the subjects examined. Occasionally it exists as quite a separate muscle (see Fig. 3458), having an extensive origin from under the surface of the os calcis. The interest attaching to this muscle lies in the fact that it is the true homologue of a muscle always present in the anthropoid apes.

Flexor Brevis Hallucis. A slip may be sent to the base of the first phalanx of the second toe (Wood). It sometimes receives fibres of origin from the os calcis or long plantar ligament. Occasionally it fails to be attached to the cuboid.

Adductor Hallucis. Occasionally a slip is seen going to the base of the first phalanx of the second toe; this may arise from the second metatarsal bone, or sheath of the tendon of the peroneus longus. Henle thinks it represents the *interosseus volaris primus* of the hand.

Opponens Hallucis (Macalister). Given off from the preceding muscle and inserted into the base of the metatarsal bone of the great toe, as in apes.

Digitized by Microsoft®

Adductor Indicis. The writer once saw a large muscle arise from the cuboid and sheath of the peroneus longus tendon, outside the adductor hallucis, and go to be inserted into the base of the first phalanx of the second toe. This, no doubt, is the homologue of the adductor indicis of quadrumana and other animals, as the sloth, elephant, etc.

www.libtool.com.cn

Transversus Pedis. The slip from the fifth toe is often wanting, and others may also be absent. The whole muscle is occasionally absent.

Superficial Transversus Pedis. In 1879 the writer saw, in the right foot of a male subject, immediately beneath the skin, a muscle which arose from the bases of the first phalanges of the second, third, and fifth toes, and was inserted into the base of the first phalanx of the great toe; deeper down the normal transversus pedis existed and was of the usual size.

Flexor Brevis Minimi Digiti. A slip of muscle is very frequently seen given off from the inner border of this muscle, and inserted separately into the anterior half of the lateral border of the fifth metatarsal bone. In some cases it is almost a distinct muscle. Henle calls it the *opponens minimi digiti*, and looks upon it as the normal arrangement. It is well developed in the orang-outang.

Interosseous. Seldom abnormal. May vary sometimes in size, according to the size and use of corresponding digit (Wood). A slip is occasionally seen arising from the base of the second metatarsal bone and sheath of the peroneus longus, and inserted into the base of the first phalanx of the second toe. Henle regards this as the homologue of the interosseus volaris primus of the hand.

MUSCLES OF THE TRUNK.—*Rectus Capitis Posticus Minor.* The writer has once seen this muscle absent on the right side. The left was of large size.

Serratus Posticus Inferior. Macalister has observed absence of this muscle. It may consist of only three slips, or in rare cases there may be as many as five or six from the first to the sixth rib. Slips may be received from the levator anguli scapulæ. I have, in two cases, seen a well-developed muscular slip arising from the mastoid process, beneath the sterno-mastoid, and inserted into the upper border of the serratus posticus superior. Once I noted a slip passing from the fifth cervical transverse process to this muscle.

Serratus Posticus Superior. In rare cases the whole muscle has been absent. Absence of one or more digitations is not infrequent. It is occasionally of larger size than normal. The writer once saw it arise from the four lower dorsal spines, and two upper lumbar, and go to be inserted into the five lower ribs.

Splenius. The extent of origin of the splenius varies. It not infrequently reaches as high as the middle of the ligamentum nuchæ; it may even be attached to the occipital protuberance (as in the bear). In one subject, on both sides, the writer saw the splenii attached to the whole length of the ligamentum nuchæ, the occipital protuberance, the superior curved line of the occipital bone, and the mastoid process. The two muscles presented the appearance of an inverted triangle.

The splenius colli may have a slip of attachment to the third cervical transverse process. The writer has seen it send slips to the second and third cervical, and in one case to the cervicalis ascendens. The splenius capitis may be quite distinct from the splenius colli, or these two portions may be fused together. The colli portion has been reported absent.

Rhombo-atloid (Macalister). Splenius accessorius, adjutor splenii (Walther). This muscle has already been described with the rhomboid. It is a muscular slip going from the transverse process of the atlas to the serratus magnus, rhomboid or serratus posticus superior, and is looked on by Wood as indicating the first degree of differentiation in man toward the formation of the occipito-scapular muscle of the lower animals.

Ligamentum Nuchæ Replaced by Muscle. The writer, in one case, saw the upper part of this ligament replaced by strong muscular fibres, which were attached to the external occipital protuberance, the whole length of the occipital crest, and the posterior tubercle of the atlas and axis. The external border of this muscle consisted of a thick, round tendon, continuous below with the ligamentum nuchæ, which was normal from the spine of the third cervical vertebra.

Sacrolumbalis. The inferior and superior accessory origins of the sacrolumbalis are infrequently absent. The *cervicalis ascendens* may arise as low as the tenth rib, and be inserted as high as the third cervical.

Spinalis Cervicis. This is described by Henle as a normal muscle. It is very inconstant, and arises from the spines of the fifth, sixth, and seventh cervical and upper two dorsal vertebræ, and is inserted into the spine of the axis, and sometimes the spines of the third and fourth cervical vertebræ.

Extensor Coccygis (sacrococcygeus posticus). This is the name given to some slender muscular fibres occasionally seen going from the lower end of the sacrum or the posterior inferior iliac spine to the coccyx. It is the homologue of the great caudal extensor of the lower animals.

Longissimus Dorsi. May vary somewhat as to the number and extent of its attachments. The writer once saw it receive accessory fibres from the spines of the third, fourth, fifth, and sixth dorsal vertebræ.

Spinalis Dorsi. The number of tendons of insertion may be reduced to three; one spine may receive two tendons.

Complexus. The biventer cervicis may be completely fused with this muscle. It may be fused with the trachelo-mastoid or longissimus dorsi. The number of vertebræ to which it is attached may vary from two to seven. A supernumerary fascia sometimes arises from the transverse process of the second dorsal vertebra, and is inserted into the occipital bone beneath the normal muscle. The biventer frequently receives accessory slips from some of the lower cervical or upper dorsal vertebral spines, or from the ligamentum nuchæ. Slips have been seen going to join it from the seventh cervical transverse process.

Multifidus Spinæ. The origin from the seventh cervical vertebra may fail. Muscular slips may run from the necks of the first and second ribs to the fifth and sixth cervical vertebræ, as well as between other ribs and vertebræ.

Interspinales. Longer interspinous bundles are sometimes found passing over one or two vertebræ. In the neck the bundles are broader.

The short *Rotatory* muscles of the neck may be occasionally doubled.

External Intercostals. The last ones are sometimes wanting. Not infrequently they extend as far as the sternum between the costal cartilages. The lower intercostals occasionally are continuous with the external abdominal oblique.

Internal Intercostals. These frequently extend to the vertebral column. The last two are sometimes absent, or so small that it requires a very careful dissection to discover them.

Supracostalis (Wood); *Rectus Thoracis* (Turner). This is a muscle which lies on the upper ribs in the antero-lateral part of the thorax, and generally extends from the first to the fourth rib.

It has been looked upon: (1) as the homologue of the thoracic extension of the rectus abdominis to the first rib, as is seen so often in mammalia, *e.g.*, cat, otter, beaver; (2) as a reproduction in man of the sterno-costal muscles of the lower animals, *e.g.*, dog, badger, etc.; (3) as belonging essentially to the scalene system of muscles, and corresponding to the condition seen in many animals. In the bear the scalene muscles extend back as far as the seventh or eighth ribs. The last view is probably the correct one.

Triangularis Sterni. This muscle varies much as to its extent and points of attachment. Absence of one or both muscles has been noticed. Theile reports a case

Digitized by Microsoft®

in which it extended to the clavicle. It is sometimes continuous with the transversalis abdominis, of which it is supposed to be a remnant or appendage.

Diaphragm. The sternal portion of the muscle is not infrequently wanting (Quain). Carruthers (*Lancet*, 1879) reports a case of absence of the left half of the diaphragm in a child which lived two days. In this case there was hernia of the small and part of the large intestine into the thorax. Absence of portions of the diaphragm is occasionally seen, and in these cases there is nearly always hernia of some of the contents of the abdomen into the thorax. At a post-mortem held at the Montreal General Hospital in 1885 on a man aged forty, a portion of the left half of the diaphragm was absent, and through the opening the greater portion of the stomach protruded into the thorax.

A fleshy fasciculus has been seen passing from the border of the œsophageal opening to the œsophagus. Knox has described a *musculus hepaticodiaphragmaticus* arising from the left side of the central tendon and passing over the œsophagus to the right, dividing into two slips, one of which went to the under surface of the liver and, becoming tendinous, joined the obliterated ductus venosus and umbilical vein; the other crossed the right crus and was lost in the peritoneum.

Henle and Bourgery describe a muscular slip going from the costal cartilage of the seventh rib partly to the costal cartilage of the ninth, and partly across the middle line of the diaphragm to the opposite border of the sternal portion.

Anomalous Muscle of the Thorax, Connected with the Diaphragm (Subvertebral Rectus of Humphry?) In a well-developed male subject in removing the lung and pleura the writer found a long, flat, ribbon-shaped muscle running down the left side of the bodies of the dorsal vertebræ. It arose from the anterior surface of the head of the sixth and seventh ribs. Becoming broader as it descended, it ended in two slips, one blending with the left arcuate ligament, and the other, which remained muscular with a tendinous intersection, united, by a blending of the two muscles, with the left crus of the diaphragm (*Jour. of Anat. and Phys.*, vol. xxx.).

External Abdominal Oblique (obliquus externus abdominis). According to Macalister, the number of attachments to the ribs varies from six to nine, and one or more slips may be doubled, generally those arising from the eighth and ninth ribs. It is not uncommon to see absence of the highest and lowest digitations. The two lowest may be rudimentary, and an additional fasciculus may come from the lumbar aponeurosis. This muscle may be connected with the serratus magnus, as well as with the pectoralis major, by continuous fibres. The musculus sternalis, when present, may be intimately associated with the external oblique.

A fasciculus has been described going from the ninth rib to the skin over that region (Flesch). This is no doubt a remnant of the dorso-abdominal skin muscle of mammals. Poland ("Guy's Hospital Reports," 1841) reports a case in which the external abdominal oblique became tendinous at a horizontal line on a level with the umbilicus. It was inserted as usual into the ilium and pubis, but had no connection with the linea alba or linea semilunaris; the internal edge of the muscle being external to the semilunar line, and leaving exposed the internal oblique. In this case the external oblique received a special fleshy fasciculus from the eighth rib, near its cartilage.

Internal Abdominal Oblique (obliquus internus abdominis). This muscle, like the preceding, is subject to variations in the extent of its attachments. Its upper or lower attachments may be reduced; it may have an additional slip of insertion into the ninth costal cartilage. A tendinous inscription in the upper part of this muscle has been described as not uncommon; it generally proceeds from the tenth or eleventh rib. Henle describes once finding in the anterior portion of this inscription a short, thin cartilage.

Accessory Abdominal Oblique (M. lateralis abdominis). This is a muscle situated between the two oblique muscles, which arises from the ninth, tenth, or eleventh rib, and passes down to be inserted into the crest of the ilium. The writer once saw this muscle on both sides of the same subject; on the right it arose from the tip of the twelfth, and on the left from the lower border of the eleventh, rib; this latter muscle was not inserted into the iliac crest directly, but blended with the aponeurosis of the external oblique behind and above the anterior superior spine of the ilium. Both muscles became broader as they reached their iliac attachment.

In some cases this muscle is attached to Poupart's ligament or to the sheath of the rectus.

Transversalis Abdominis. The extent of its attachments may vary. Cases are reported in which it was attached to the whole length of Poupart's ligament. The spermatic cord may sometimes pierce its lower border,

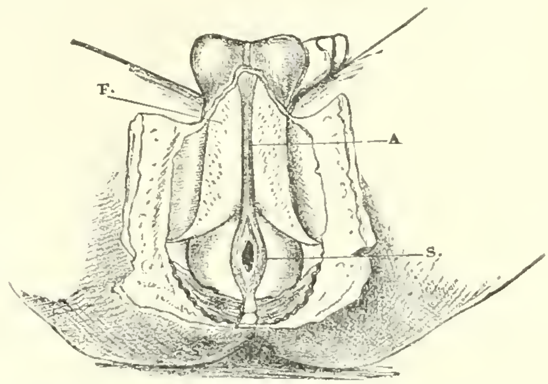

FIG. 3459.—*A*, Sphincter ani continued upward in the middle line and blending with the dartos of the scrotum; *F*, perinæal fascia; *S*, sphincter ani. (Shepherd.)

especially in those cases in which the attachment to Poupart's ligament is more extensive than usual. Fusion of the muscle with the internal oblique has been observed, and total absence has been noticed by Macalister. A tendinous intersection has also been seen.

Rectus Abdominis. In some cases this muscle has been seen extending as high as the third, and even the second, rib. It is not uncommon to see a supernumerary slip going to the fourth rib. In most animals the rectus abdominis extends higher than it does in man; in many it reaches as far as the first rib, *e.g.*, in the bear, otter, beaver, cat, porcupine, etc. The writer once saw a slip go from the upper part of the rectus to the middle of the lower border of the pectoralis major. The number of tendinous intersections may vary; as many as six have been noticed in the negro.

Pyramidalis. This muscle varies much as to size. It is very frequently absent, and is occasionally double. When absent the lower part of the rectus is increased in size. It is a muscle which is of no use in man, and is a mere rudiment of the larger muscle which exists in marsupials. It is absent in many of the lower animals, *e.g.*, solipeds, ruminants, and many of the carnivora, as the dog, cat, bear, etc.

Quadratus Lumborum. Is sometimes attached to the eleventh rib, and to the bodies and transverse processes of the tenth and eleventh dorsal vertebræ. Lange ("*Annals of Surgery*," vol. ii., p. 289) figures a quadratus muscle sending a slip to the fascia covering the pleura between the twelfth dorsal and first lumbar rib.

Muscles of the Perineum and Pelvis.—Sphincter Ani. The writer once saw the superficial fibres of this muscle continued up past the tendinous point of the perineum, as a flat muscular slip 6 mm. broad and 5 cm. long. This slip blended above in the middle line with the dartos of the scrotum (see Fig. 3459). Occasionally fibres of the transversus perinæi are inserted into this muscle.

Digitized by Microsoft®

Coccygeus. Is sometimes inserted wholly into the side of the sacrum (Quain).

Sacrococcygeus Anticus (curvator coccygis). This is the name given to a few fleshy and tendinous fibres passing from the lower part of the anterior portion of the sacrum and coccyx. It is well developed in animals with tails.

www.libtool.com.cn

Transversus Perinæi. This muscle is a very variable one. It is occasionally absent, or so small as to be with difficulty dissected out. It is sometimes inserted either partly or wholly into the accelerator urinæ (bulbocavernosus) muscle or sphincter ani. This muscle is not infrequently fan-shaped, covering the triangular space formed by the three perineal muscles. In these cases the ischiocavernosus forms one edge of the fan. The fibres are inserted into the accelerator urinæ, central tendinous point, and sphincter ani. The muscle is occasionally double, the extra slip joining the accelerator urinæ or levator ani. Henle describes a muscular slip springing from the fascia at the lower border of the gluteus maximus, and inserted into the lower surface of the triangular ligament. In one case of absence of this muscle, the writer found the deep transverse muscle of large size.

Ischiocavernosus (erector penis). Houston has described a variety of this muscle under the name *compressor venæ dorsalis penis.* It is a slip arising in front of the ischiocavernosus and crus penis, which passes upward and forward, and is inserted with its fellow into an aponeurosis above the dorsal vein. The writer once saw this extremely well developed. In the dog and some other animals it is quite a strong muscle.

Bulbocavernosus (accelerator urinæ). This muscle is occasionally joined by the transversus perinæi. Kobelt describes the fibres which cover the most prominent part of the bulb, and which are separated from the others by a more or less distinct interspace, as the *compressor hemisphericum bulbi.* *Francis J. Shepherd.*

MUSCULAR ATROPHIES, PROGRESSIVE.—The presence of muscular atrophy at once suggests to the clinician one of two possibilities, namely:

1. The atrophy is a *symptom.* As such it may indicate injury, hemorrhage, inflammation, or new growth, affecting more or less acutely the oblongata, the spinal cord, or a peripheral nerve; or it may be one expression of joint disease and then due to reflex trophic disturbance in the cord.

2. The atrophy is a *disease.* In other words, it is sufficiently regular in its evolution and constant in its associated symptoms to merit a definite place of its own in our nosology. The scope of the present article is limited to this second group of muscular atrophies, those of the first group being treated under appropriate headings elsewhere in this work.

Our knowledge of muscular atrophy as a clinical entity dates from 1850, when Aran [1] published the first account of what we now recognize as progressive spinal muscular atrophy, although he considered it a disease of the muscles primarily. The disease was elaborated upon by Duchenne a few years later, whence the name "Aran-Duchenne Disease." [10]

The muscular atrophies which are classed as distinct diseases are divisible pathologically into two types, namely:

1. The myopathies or progressive muscular dystrophies; also known as "idiopathic" muscular atrophies, which are characterized by slow premature dissolution of muscle fibres from inherent vital defect. This is a long-recognized tissue condition for which Gowers has recently given us the convenient and expressive term "abiotrophy." [2]

Abiotrophy of the myon would be a concise statement of the pathologico-anatomic status of this group.

2. The myelopathies or "spinal muscular atrophies," characterized pathologically by the same process (premature dissolution) in the spinal motor nerve elements (anterior horn cells or lower motor neurons). Since, however, these same changes often occur also in the cerebral motor neurons (pyramidal motor cells) or in other cases are apparently limited to the peripheral nerves, a more comprehensive designation would be *neuronic muscular atrophy. Abiotrophy of the motor neurons,* therefore, would express the pathologico-anatomic nature of this group.

While this classification serves to define the great majority of cases, a series of mixed forms or so-called "connecting links" between the two main groups is becoming numerous in the literature as experience in their recognition increases, *e.g.*, cases which present symptoms of myopathy and myelopathy combined. These serve to illustrate the anatomical and physiological fact now well recognized, that the entire motor tract from the cortex cerebri to cord and from cord to muscle fibre constitutes a continuous functionating unit, and cannot suffer long in one part without in some degree impairing others.

There seems no good reason, however, to the writer for the use of the term "connecting link" for these cases. The coincident or consecutive involvement of one more segment of the motor tract is all that is necessary to the evolution of these mixed forms, and this may be reasonably postulated in any given case.

Accepting the pathological grouping into myopathic and neuronic, therefore, as the best at present available, we proceed in the order mentioned to consider the individual diseases in each group. The accompanying diagram shows at a glance the anatomical location of the pathological process in the several clinical types (Fig. 3460).

The myopathies or primary atrophies are divided clinically into several "types," somewhat arbitrarily perhaps, since there are good reasons for the view held by many that they are all due to the same pathological processes, differing mainly in location. An exception to this statement, however, must be made in the case of the "pseudo-hypertrophy," which is a prominent feature in one form.

They are all characterized, moreover, by certain clinical features in common, of which the chief are:

1. Hereditary or familial tendency.
2. Onset before puberty.
3. Preponderance in the male sex.
4. Loss of myotatic irritability, and in consequence loss of "tendon reflexes."
5. Electrical changes of reaction of *quantitative* character (diminished response to galvanism and faradism), and absence of typical R. D.

The recognized types of myopathy are:

A. PSEUDO-HYPERTROPHIC MUSCULAR ATROPHY.—*Causation.* The disease begins in childhood; in two-thirds of the cases before the sixth year (Gowers). Heredity is traceable in three-fifths of the cases (Dana). The hereditary influence is strongest through the mother's side, though the *male members* of the family are more frequently affected. Church explains the transmission by the female members of affected families by the fact that the disease renders the males impotent.

The disease is frequently preceded by some acute infection—diphtheria for instance, which probably favors its onset in those already predisposed.

Symptoms.—Weakness in the legs of gradual onset, accompanied by a "waddling" gait and frequent stumbling without evident cause are the earliest symptoms. These are usually noticed about the fifth year and are often attributed to carelessness or stupidity on the part of the child. Later, a noticeable enlargement (pseudo-hypertrophy) of the leg muscles, especially of those of the calves, appears. This may extend to the thighs and gluteal muscles; and the infraspinati are also frequently enlarged. The enlargement of muscles may be slight in some cases, but even in these an undue firmness with lack of elasticity is noticeable on palpation. The shoulder girdle muscles are affected later, while those of the face, forearms, hands, and feet escape for a long time, but are probably affected eventually in most cases that survive a sufficient length of time. Thus in two cases, brothers, aged four-

EXPLANATION OF PLATE D.

Serial kinetographs illustrating the characteristic method of arising from the recumbent position in progressive muscular dystrophy, the patient "climbing up his own legs." (From Curschmann.)

Beginning at the top of left-hand column the figures are to be read downward; then begin at top of right-hand column. The successive utilization of the muscles of the upper extremities to assist the more atrophied ones of the legs and back is evident.

The weakness of the back muscles is also well indicated by the drooping head, counterbalanced by the lordosis. The figures represent a case of myopathy with little if any pseudo-hypertrophy.

Digitized by Microsoft®

teen and nineteen, seen recently by the writer, through the kindness of Dr. W. E. Lewis of Cincinnati, one presented marked weakness of facial muscles, and the occipitofrontalis could not be made to act at all, though the patient could frown at command. In this same patient as well as his brother, aged nineteen, the hands were markedly involved, the grasp registering by the dynamometer only nine (right hand) and ten (left) in the younger; and nineteen (right) and fifteen (left) in the elder, both showing a reduction in power estimated by me at seventy-five per cent. or more. Moreover, in the elder of these brothers there was marked wasting of the thenar group of right hand, as well as *fibrillary twitching*, though both cases were typical myopathies in their development and most other respects.

www.libtool.com.cn

Peculiarities of posture and gait due to the muscular weakness are developed in time. Lordosis is commonly present when the patient stands. The gait is waddling and clumsy. Frequent falls result from the lack of muscular power and irregular control of movements, so that contusions and abrasions are frequent accompaniments of the disease. Ascending stairs is particularly difficult, and the patient arises from the prone or supine position in a characteristic manner by pushing with his hands upon the front of each thigh, to steady the legs. Thus he is said to "climb up his own legs." (See Plate D.)

While the statement is commonly made that the face is unaffected, nevertheless the facies of most of these patients, according to the writer's observation, is characteristic in some degree of defective muscular action. A blank, expressionless countenance is the rule, or again a marked senile aspect is present after the disease has progressed for a few years. In one case this facial involvement notably affected the smile, the mouth extending horizontally in a straight line, without the usual curves, a pathological "*risus sardonicus.*"

In addition to lordosis, which is common, other forms of spinal curvature appear late in the disease. Contractures are also a feature in the extremities, talipes equinus often resulting therefrom.

Apparent lengthening of the neck, due to the drooping of the shoulders consequent upon weakening of the trapezii (Brissaud) is noted.

Fibrillary twitching in the affected muscles is commonly absent, but there are numerous exceptions to this rule. Notably in the two brothers just cited, the elder presents marked fibrillation in the lower portions of the pectoralis major, as well as in the thenar muscles of the right hand.

Sensation is usually unaffected. The writer has noted one case in which a constant "prickly" sensation was complained of throughout the trunk and limbs, but most accentuated on the anterior chest wall.

The tendon reflexes are progressively diminished and finally lost, as the muscular structure disappears.

The cases without pseudo-hypertrophy are separated from the preceding form by that circumstance and from each other mainly by differences in distribution of the atrophy. Two forms appear to require recognition, clinically speaking.

B. The Scapulo-humeral Form, Erb's "Juvenile Type" (Fig. 3462).—This begins as a rule between the ages of fifteen and thirty-five, though a range of from two to sixty years in ages of patients is recorded (Gowers).

The shoulder, scapular, and upper-arm muscles are first affected, though the deltoid often escapes (Gowers). The pectoralis and latissimus dorsi commonly waste in their lower portions. The supinator longus is commonly involved. As the disease progresses, the muscles generally are invaded.

Fibrillary contractions and R. D. are said to be absent.

C. The Facio-scapulo-humeral Form, or Landouzy-Dejerine Type.—Also called the "infantile variety." In this the face is the part first attacked, but the ocular muscles and those of mastication escape. The shoulder and upper arm are invaded later.

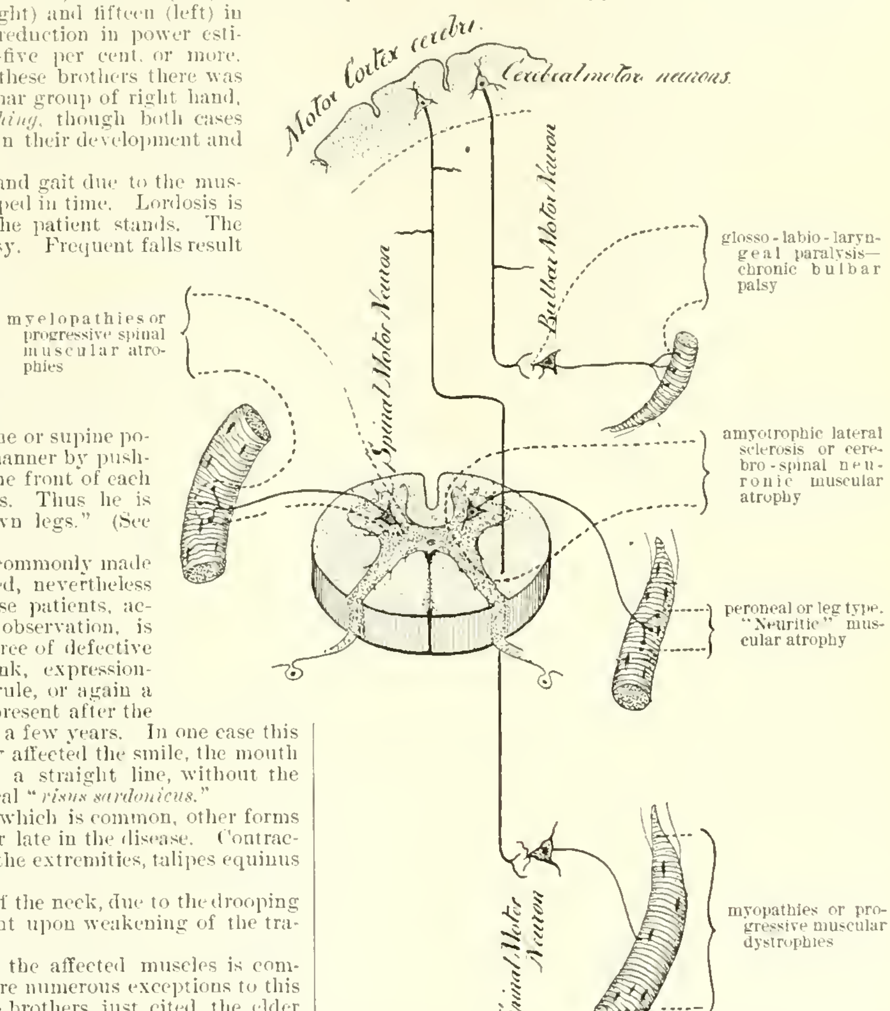

Fig. 3460.—Diagram of Motor Tract from Cortex Cerebri to Muscles, Showing Sites of Initial Degenerations in the Progressive Muscular Atrophies and Dystrophies.

The disease begins earlier as a rule than the two preceding forms, though marked exceptions to this statement are recorded.

For instance, in two cases reported by Hoppe,[3] one began at twenty-three, and was alive at fifty-five. In the other, a daughter of the first patient, the disease began at about the twenty-eighth year. These cases are also anomalous in the fact of R. D. being present as follows: In the mother's case, in the thenar and hypothenar muscles of both hands. In the daughter, in the *opponens pollicis and flexor brevis pollicis* only.

Fibrillation was not present in either case, and the mode of onset and distribution were regular in all respects.

D. Distal Form of Myopathy.—Gowers[7] applies this term to a case recently described by him, which dif-

Digitized by Microsoft®

fers from the other myopathies chiefly in the fact of the atrophy beginning in the hands and feet, although the sterno-mastoids and tongue were also involved.

www.libtool.com.cn

FIG. 3461. Pseudo-Hypertrophic Muscular Atrophy. (C. L. Dana.)

The disease began at ten or twelve, and at eighteen the patient still had good power in the peroneal groups and calf muscles as well as in the thighs.

The trunk muscles apparently escaped; of the shoulder-girdle muscles the trapezius only was affected, and that slightly.

Electrical response was diminished to both currents.

Another case referred to at the same time combined the features of this type with those of the scapulo humeral (form B).

As that author remarks, this is only another link in the chain of evidence which favors the essential unity of all types of myopathy.

Pathology and Morbid Anatomy.—These are practically the same in all forms of myopathy.

The process is a degenerative atrophy, with irritation and swelling of muscle fibres and proliferation of nuclei in the early stages. Later, there is atrophy of the muscle fibres with disappearance of their transverse striæ. Increase of connective-tissue elements follows the disappearance of muscle fibres, causing a "myosclerosis" with, in the pseudo-hypertrophic forms, a lipomatosis in addition. Along with the atrophy and pseudo-hypertrophy a number of observers have noted an apparent *true* hypertrophy in some fibres.

The spinal cord and nerves are normal with rare exceptions, which are found in the "irregular forms" of the disease.

The *diagnosis* of the myopathies in general is simple. The age of onset (usually under puberty), the slowly increasing weakness, the waddling, stumbling gait, the muscular atrophy without R. D., and the absence of fibrillary twitching sufficiently separate the myopathies from the neuronic or "spinal muscular atrophies." The diagnosis of the different "*types*" of myopathy from each other is mainly a question of the place of beginning and order of distribution of the muscular atrophy, as already noted. (See Fig. 3461.)

Prognosis and Treatment.—The disease being dependent on inherent defect in tissue vitality, the most that can be hoped for from treatment is to retard its progress and promote the comfort and general well-being of the patient. As already seen from some of the cases cited, the disease is not always incompatible with a moderately prolonged life. From ten to twenty-five years, however, expresses the usual range of duration in ordinary cases.

The usual treatment recommended consists of nutritional and tonic measures. Strychnine is spoken highly of by Gowers.

The glycerino phosphates of lime and soda and other phosphorous compounds would seem indicated in young and developing patients.

Exercise, massage, and electricity have been recommended by most authors. Overuse of these agents may do harm. Orthopedic measures, such as division of tendons, are useful in the contractural disabilities.

THE SPINAL PROGRESSIVE MUSCULAR ATROPHIES OR MYELOPATHIES.

These are the atrophies of neuronic origin, and imply primary degenerative disease of motor neurons of the cord, or cord and brain combined.

A. PROGRESSIVE MUSCULAR ATROPHY PROPER, OR ARAN-DUCHENNE DISEASE, "WASTING PALSY."—*Definition.*—A chronic progressive disease of the spinal motor neurons (ventral horn cells), characterized by fibrillary contractions, slow atrophy, and gradually increasing weakness of voluntary muscles, with R. D.

Causation.—Direct heredity is rare. The neuropathic diathesis is presumably the chief predisposing factor. Adult age (twenty-five to forty-five), the male sex, exposure and fatigue, typhoid fever, rheumatism, gout, syphilis, and lead poisoning are credited as additional causes. The actual exciting cause, if such exists, is unknown. Why certain "systems" of neurons should die in some persons and not in others, after the operation of the preceding causes, is a problem which can be solved at present only by assuming a "potential insufficiency" in the nerve elements, an "abiotrophy" (Gowers), only fully developed by the action of some profound and persistent nutritional drain.

FIG. 3462.—Juvenile Type of Scapulo-Humeral Muscular Atrophy. (C. L. Dana.)

Pathology and Morbid Anatomy.— Degenerative atrophy of peripheral motor neurons (ventral horn cells) is the essential lesion. As a result of this, sections of the cord in affected areas show shrinkage and disappearance of cell bodies, with corresponding degeneration and diminution in their processes (dendrites and anterior root fibres). These changes are naturally most marked in the cervical enlargement, since the disease begins in the upper extremity in typical cases.

The posterior horns, together with the columns of Goll and Burdach, as well as the direct cerebellar tracts are normal, excepting in the rare cases of muscular atrophy supervening upon tabes dorsalis, of which the writer has seen two well-marked instances. In this case two dis-

Digitized by Microsoft®

Muscular Atrophies.

eases are present, according to our present nosology. It is probable that the first actual destructive changes occur in the neuron endings (muscle plates) of the affected

www.libtool.com.cn

FIG. 3463.—Pathological Histology of Pseudo-Hypertrophic Muscular Dystrophy. (Partly diagrammatic; after Erb.) *A*, Hypertrophied fibres; *B*, mixture of hypertrophy and atrophy; *C*, *D*, atrophy and fatty deposit; *v*, vacuolization; *s*, splitting of fibres; *h*, hypertrophy of fibres; *g*, thickened blood-vessel.

muscles (see diagram, Fig. 3460). Following closely upon this impairment of their neurotrophic organs the muscles degenerate, fibre by fibre, into granular and fatty material, the transverse striæ disappear, while the adjacent connective tissue at first proliferates and later undergoes fibroid changes and contraction. Distention of blood-vessels is also described.

The pyramidal tracts of the cord are usually affected in some degree. In fact, so experienced an observer as Gowers[4] remarks that he has not seen a single case in which they were unaffected.

This, as the same writer aptly puts it, is "the visible expression of a tendency to decay of the whole motor path from the cortex of the brain to the muscles."

Clinical History.—The disease begins with weakness and wasting of the thenar and hypothenar muscles of one hand, usually the right. This may be preceded by dull aching pains in the corresponding limb and cervical region. Otherwise sensory changes are absent. The nutrition of the bones and skin is not affected. The wasting advances slowly to other muscle groups, notably the interossei and lumbricales, producing the characteristic longitudinal furrows between the metacarpals, especially noticeable on the back of the hand. The wrist flexors and extensors may go next, or the deltoid and biceps may be affected before the forearm. In this case, as the writer has seen, the patient may present the anomaly of a powerful grasp, with inability to abduct the arm to a right angle.

The spinal extensors are commonly affected early, producing lordosis and allowing the head to droop forward in extreme cases.

The upper portion of the trapezius escapes, which may be a diagnostic sign of importance, as between this disease and the myopathies.

The disease extending downward involves the hips and thighs, impairing locomotion. Marked weakness of the legs proper also exists, often without atrophy, but with more or less spasm and heightened muscle jerks. The explanation of this is the involvement of the upper neuron for the legs, with escape of the lower. In those cases in which the lower leg is atrophied, however, the peroneal group suffers most, thus corresponding to the same process in the "peroneal" type (to be considered later); and also to the atrophy in multiple neuritis.

This distribution contrasts with the myopathies, which affect more markedly the calf muscles.

If the disease extends upward, the upper cervical segments and the oblongata may be invaded, giving rise to respiratory and bulbar symptoms of grave import, such as dyspnœa, dysphagia, dysphonia, dysarthria, irregular heart action, glycosuria, etc. The facial muscles usually escape, but not always.

Fibrillary tremor is a characteristic symptom and is almost continuous in the affected muscles so long as any contractile substance remains. The mechanical irritability of the muscles is increased, light taps producing marked contractions.

The deep reflexes diminish gradually and finally disappear.

Electrical changes in the affected muscles are marked and constant. Early a quantitative reduction (diminished response) to both faradism and galvanism may be noted. Later, reaction of degeneration in varying degrees from simple sluggish response to complete polar reversal, *i.e.*, the muscle contracts more readily (or to a weaker current) with the anodal (positive) closure than with the cathodal (negative) closure.

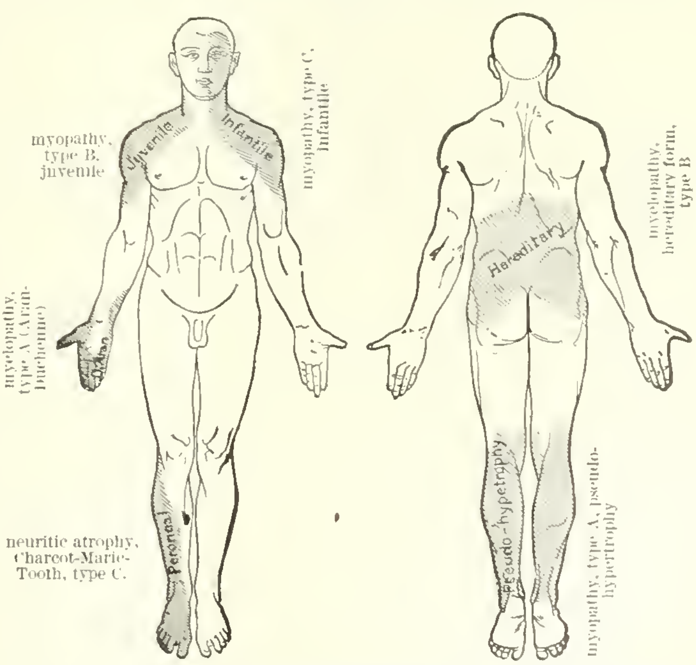

FIG. 3464.—Clinical Chart of Distribution of Muscular Atrophies. The shaded portions indicate the initial locations of muscular wasting in the different forms. (From C. L. Dana.)

Digitized by Microsoft®

The presence of this R. D. is an important diagnostic sign in excluding the myopathies or "idiopathic" atrophies.

Contractions and deformities due to unequal wasting of opposing muscles are common. The "claw-hand" or "main en griffe," lordosis, and talipes equinus are examples.

The sphincters www.libtool.com.cn

Sexual power is commonly lost.

Eventually the patient presents an extreme degree of generalized emaciation, the "living skeleton" type.

Pulmonary complications, bulbar palsies, bedsores, and septic infection are of serious import.

Diagnosis.—The myopathies, the age (adult) at time of onset, the initial affection of the hands, the presence of

FIG. 3465.—Case of Spinal Progressive Muscular Atrophy of the Aran-Duchenne Type. (From the Neurological Department of the Cincinnati Hospital.)

fibrillary tremor and the R. D. are sufficiently distinctive. The onset in one hand and the extremely slow progress separate this from other neuron diseases, such as multiple neuritis, lead neuritis, and poliomyelitis, acute or chronic. The absence of pains and cervical deformity distinguish the affection from pachymeningitis cervicalis hypertrophica. Syringomyelia is excluded by absence of the "dissociation" sensory symptoms and of cutaneous trophic lesions.

Prognosis.—Arrest is said to be possible in rare cases. Remissions are more likely to occur. To retard the progress of the disease and improve the "compensation" in the remaining muscle tissue is as much as can be reasonably expected from treatment.

The duration is commonly prolonged, varying from two to thirty years (Dana). The fatal outcome is due to complications, pulmonary or laryngeal, resulting from involvement of the respiratory muscles.

Treatment.—Strychnine nitrate, administered hypodermically in doses gradually increased from gr. $\frac{1}{80}$ to gr. $\frac{1}{15}$, is highly commended by Gowers, who has seen the disease apparently arrested by its use.

General hygienic measures, careful diet, avoidance of fatigue are important. The phosphorus compounds should be tried.

Electricity, massage, and gymnastics should be used with caution, and any excess or fatigue should be avoided.

Mercurials and iodides are *never* indicated and may do harm.

B. HEREDITARY OR FAMILIAL TYPE OF PROGRESSIVE SPINAL MUSCULAR ATROPHY.—This is a rare form of neuronic atrophy described by Werding[5] and Hoffman.[6] It is characterized by heredity, by early onset (under two years), beginning in the hips and back; by rapid progress to complete helplessness and a fatal termination at or before the sixth year. R. D. is present, and wasting of the ventral horn cells has been found. Beevor[7] records one case which began in utero.

Diagnosis.—This is distinguished from the ordinary spinal atrophies (Aran-Duchenne type) by the hereditary element, early age, rapid progress, and absence of fibrillary twitching; from the myopathies, by the absence of hypertrophy, the presence of R. D. and the early termination.

Treatment has not influenced these cases appreciably.

C. AMYOTROPHIC LATERAL SCLEROSIS.—This is practically a progressive spinal muscular atrophy (type A) plus involvement of the upper neuron (pyramidal tracts of cord) to a marked degree (see Fig. 3460). The clinical difference consists in the marked spasticity, causing a stiff-legged gait, with toes tending to dig into the ground. There is also a rather more marked tendency to bulbar involvement, and the lower half of the face may be affected. The affection does not differ materially from type A as regards the prognosis and treatment.

D. GLOSSO-LABIO-LARYNGEAL PARALYSIS. — *Chronic Progressive Bulbar Palsy.*—This may occur primarily, or may indicate an extension upward of ordinary spinal muscular atrophy (type A). As a primary affection the degenerative process is limited to the bulbar neurons.

Patients are usually at the degenerative period of life. In many respects the disease appears to indicate a localized presenile change.

The chief *symptoms* are hoarseness, aphonia, dysarthria, dysphagia, sialorrhœa, atrophy, and fibrillation of the tongue, glycosuria, cardiac arrhythmia, and dyspnœa.

Pseudo-emotional symptoms, as causeless weeping or laughter, are frequent accompaniments. The palate reflex is absent in advanced cases.

The *diagnosis* must be made from bulbar apoplexy (small hemorrhage, thrombosis) by the sudden onset of the latter, with sensory defects of face frequently present; from cerebral lesions in the bulbar motor path (pseudobulbar palsy) by the sudden onset of the latter, with absence of sensory defects, of atrophy of the tongue, and also of accompanying hemiplegic symptoms; from asthenic bulbar palsy (bulbar palsy without anatomical findings) by the absence in the latter of muscular atrophy and twitching and by the frequent remissions which occur.

The progress is toward a fatal termination from inanition or respiratory complications in from one to seven years. Treatment is similar to that of other neuronic muscular atrophies—viz., rest and attention to hygiene and nutrition. Electrical treatment may add to the comfort of the patient and prolong life.

E. NEURITIC OR LEG TYPE OF PROGRESSIVE MUSCULAR ATROPHY, CHARCOT-MARIE-TOOTH DISEASE.—This variety of the "neuronic atrophies" differs from the typical (spinal) form (type A):

(1) In its hereditary character.

(2) In its onset in the legs and feet (peroneal group of muscles).

(3) In its slower course.

(4) In the circumstance that the prospects of prolonged life are better.

It is a rare disease in this country, Burr[8] recording but

Digitized by Microsoft®

five known cases up to 1897, including one reported by himself.

Pathologically a degenerative neuritis has been found. The disease therefore affects the distal extremities of the lower motor neurons.

Treatment is similar to that of the other neuronic forms.

This work contains a digest of the French literature on the subject, with especial reference to the clinical and pathological distinctness of the Duchenne-Aran form (type A), and the amyotrophic lateral sclerosis form (type C), which Charcot (the younger) considers well established. The work is beautifully illustrated.

MUSK.—MOSCHUS. "The dried secretion from the preputial follicles of *Moschus moschiferus* L.; Order, *Ruminantia*," U. S. P. This little animal, the so-called musk-deer, is a slender-limbed, active, and very timid inhabitant of the mountain regions of Central and Northern Asia. In its general shape it resembles a young deer. It is 60 or 80 cm. long (from two to three feet), from 40 to 60 cm. in height, with the rump higher than the shoulders, of a grayish or blackish-brown color, with long, slender ears, large dark eyes, and two long, curved tusks projecting downward from the upper jaw. The secreting organ containing musk is a large, simple sac, situated in the median line just beneath the skin of the abdomen, in front of the preputial canal (of the male; it does not exist in the female), with which its posterior wall is connected. It is of a round or oval, plano-convex shape, 6 or 7 cm. in its longest diameter, and 1 or 2 cm. or more thick. Internally, it is incompletely divided by folds and partial partitions reflected from the wall. The orifice, often double, is situated over the middle portion of the sac, and is 1 or 2 mm. in diameter. Its position is easily determined from the outside, because the hairs converge toward it and fairly grow within it. In the living animal the secretion contained in the gland is a soft solid, not much thicker than honey, of a brownish-red color, and of a most intense, offensive smell. As it dries it darkens, becomes greasily brittle, and less odorous.

The musk-deer is laboriously hunted in the central and northern provinces of China, in the countries to the north of India, and in Siberia,—in short, over a very extensive portion of Central Asia,—for its skin and musk glands. These "pods," as they are called, are cut out as soon as the animal is killed, and dried, often with the aid of artificial heat, when they are ready for the market. In this condition they are flattish, shrivelled pouches, covered on one side with hairy skin, in the centre of which is the orifice; the other side has the black appearance of dried meat. As now usually marketed, they are prepared so as quite closely to resemble a large fowl's gizzard. The contents are dryish, crumbly, breaking as they are turned out into coarse fragments (called grains), of an almost black color and penetrating odor. The very high cost of musk has led to numerous ingenious methods of adulteration. Thus, stones and other heavy minerals, hair, dried blood, fæces, etc., are sometimes introduced through the natural opening; occasionally, also, the sac is split and emptied, and then filled and dextrously sewed up again, with a mixture containing but little musk, or that of an inferior quality—Siberian musk, for example, instead of that from Tonquin. Or the musk itself, when sold in grains, may be tampered with in similar ways. Sometimes artificial pods are made and filled—the scrotum of some animal is used, or a bag is made entirely *de novo* from skin, with a bladder, or some other membrane, for the back. The geographical source is important in determining the quality of musk; that of China and its tributaries is the most fragrant and best. Its pods are rounder, of more uniform shape, and its grains more odorous and larger. That from the north of India comes in irregular sacs, and that from Siberia in larger and longer ones. The following are the characters of musk as given by the Pharmacopœia: "In irregular, crumbly, somewhat unctuous grains, dark reddish-brown, of a peculiar, penetrating, and persistent odor, and bitterish taste. It is contained in oval or roundish sacs, about one and a half to two inches (4 to 5 cm.) in diameter, on one side invested with a smoothish membrane, on the other side covered with stiff, appressed, grayish hairs, concentrically arranged around two orifices near the centre. About ten per cent. of musk is soluble in alcohol, the tincture being light brownish-yellow, and on the addition of water becoming slightly turbid. About fifty per cent. of musk is soluble in water, the solution being deep brown, faintly acid, and strongly odorous.

"When ignited with free access of air, musk gives off a peculiar, somewhat urinous odor, and leaves behind not more than eight per cent. of a grayish ash."

COMPOSITION.—Musk is a very complex substance, and consists chiefly of common animal tissues and secretions. The following synopsis is from Hager's "Pharmaceutische Praxis": *Fats, cholesterin, wax, biliary matters, mucus, albumin*; besides traces of *lactic, butyric, phosphatic, sulphuric*, etc., *acids*; traces also of *ammonia* and a *volatile oil*. The odorous principle has never been separated. It is supposed to be formed by the gradual decomposition of some of the other constituents.

ACTION AND USE.—This substance was for centuries the leading antispasmodic, and was, during most of this time, much more highly esteemed in medicine than it is at present, and it was given for numerous diseases involving disturbance of the nervous or mental faculties—*e.g.*, hysteria, epilepsy, mania, etc. In a similar manner several other odorous animal secretions—civet, castor, etc.—have been employed, but of them all musk is by far the least disgusting. Its high cost and impressive odor made it well adapted to hysterical outbreaks, for the relief of which it undoubtedly has some real value. As it is, however, it acts in these cases merely as a palliative, and as there are now a dozen or more remedies which are more certain and far cheaper (a single dose of musk, which might be repeated several times a day, costs two dollars or more), musk as a medicine may be considered as fairly out of use. It can, however, be given, if desired, in doses of about 1 gm. (gr. xv.) in pill or emulsion. A tincture (*Tinctura Moschi*, U. S. P., strength one-tenth) is official and may be used, but is mostly employed as a basis of perfumery, where the persistent or "staying" qualities of musk make it of the greatest value.

The odor of musk is considerably diminished by fennel, ergot, tannin, sour fruit juices, and some other things. Mixed with sugar it keeps very well.

W. P. Bolles.

MUSTARD.—BLACK MUSTARD, or SINAPIS NIGRA, "the seed of *Brassica nigra* (L.) Koch," and WHITE MUSTARD, or SINAPIS ALBA, "the seed of *Brassica alba* (L.) Hooker fil. (fam. *Cruciferæ*)," are thus separately official in our Pharmacopœia. Since they agree in most respects, they may be discussed together, and their differences pointed out in passing. Both are natives of Europe and Western Asia, cultivated and naturalized in most countries. Both are slender, tall, and widely spreading, weedy-looking herbs, with coarsely pinnatifid or pinnate leaves, the upper entire, and yellow flowers. The two are best distinguishable by the habit of their pods. In the black mustard these are erect on spreading

Digitized by Microsoft®

www.libtool.com.cn

pedicels; in the white, both the pedicel and the pods are spreading. White mustard is also a rougher and smaller plant. The herbage of both is reputed antiscorbutic, and is used as a salad, also for poultices. The relationship of these plants to some of the forms of turnip, rape, cabbage, and colza is close and confusing, so that in India, where mustard is largely cultivated, a number of ill-defined forms exist. This condition—partly the result of natural causes and partly effected by design—results in much admixture in some lots of seeds. The following are the descriptions of the Pharmacopœia:

White Mustard.—"About 2 mm. in diameter, almost globular, with a circular hilum; testa yellowish, finely pitted, hard; embryo oily, with a curved radicle, and two cotyledons, one folded over the other; free from starch; inodorous; taste pungent and acrid."

Black Mustard.—"About 1 mm. in diameter, almost globular, with a circular hilum; testa blackish-brown or grayish-brown, finely pitted, hard; embryo oily, with a curved radicle, and two cotyledons, one folded over the other; free from starch; inodorous when dry, but when triturated with water, of a pungent, penetrating, irritating odor; taste pungent and acrid."

The principal adulterant of whole black mustard is rape seed, which can readily be distinguished by its slightly larger size and its peculiar bluish tinge. In the ground condition, white mustard is often mixed with it. This addition, if kept within moderate limits, only adds value to the product, for reasons stated below. Most other adulterants either contain starch—which may be determined by the iodine test—or, like curcuma, the most common of these, they contain resins, which may readily be indicated by the use of sulphuric acid.

Pure ground black mustard is almost too strong for safe use upon the table, and curcuma is usually added to dilute it. Advantage is taken of this to use excessive quantities of the substance selected for admixture. Hence the importance of the preparation of black mustard for medicinal purposes by purely pharmaceutical agencies.

Composition.—The constituents of the two varieties of mustard, although presenting close relationships, are not exactly identical. They both agree, however, in containing a considerable amount of a bland, light-colored non-drying *fixed oil*—a mixture of the glycerin combinations of *oleic, stearic*, and *erucic acids*; in white mustard oil *benic acid* is also found. This oil amounts to about twenty-two or twenty-three per cent. of the seeds. The most remarkable constituent of black mustard is the crystalline, bitter-tasting, inodorous glucoside, *myronate of potassium*, or *sinigrin*; soluble in water, but not in alcohol or ether, and in its watery solution decomposing, in the presence of various ferments, especially of one to be mentioned below, into glucose, bisulphate of potassium, and the horribly acrid, sulphureted, *essential oil of mustard* (isosulphocyanate of allyl, etc.), to which mustard is indebted in part for its medicinal value, and which is described below. This oil is not present in the dry seeds or their powder, but is produced only when they are moistened. The development of the odor upon wetting mustard flour is very evident, and distinguishes this from that of white mustard. The albuminous ferment which assists in this decomposition is called *myrosin*, and is common to both kinds of mustard.

The glucoside in white mustard, resembling the sinigrin of the black, has been correspondingly named *sinalbin*, a neutral crystalline substance, soluble in cold water, and decomposed in a similar way as sinigrin into *sugar*, *sulphate of sinapin*, and *sulphocyanate of acrinyl*, the latter corresponding to the essential oil of the black mustard. It is an acrid and vesicating substance, but much milder than the glucoside of the black variety, and not volatile.

To bring out the full percentage of the black mustard oil, a certain amount of myrosin, additional to that contained in this drug, is desirable, and is obtained by judiciously adding a certain quantity of the white mustard. The flour from this mixture is the strongest and best that can be made. That obtainable in our market is often the flour of white mustard only, and is generally more or less adulterated besides.

An oil exactly resembling that of black mustard has been made synthetically and is in the market.

Action and Use.—Both sorts of mustard seeds possess the same qualities; they vary only as regards the degree of pungency, the black being the stronger. Swallowed whole they do not disintegrate much, but pass through the digestive tract. In this way white mustard seed, particularly, is now and then given, in doses of a teaspoonful (3 or 4 gm.), for dyspepsia, constipation, etc.; like nearly everything else, it has also been employed in chronic cases of bronchitis, rheumatism, and some skin diseases, without any rational indication for such employment. Its rare use at present for these purposes shows its slight value.

Ground mustard, white, black, or mixed, is an active local irritant as soon as wet with water so as to produce the acrid decomposition products of the drug. Applied to the skin, it is quickly and painfully rubefacient; and if allowed to remain in contact with it for a long time, it is vesicant—producing a crop of fine, deep, eczematous blisters, easily ruptured, very painful, and rather slow to heal after rupture takes place. Internally, mustard, in small doses of 2 or 3 dgm., is an aromatic stimulant, and as such is in every-day use at the table. In larger quantities, 10 or 15 gm., it is a prompt and valuable emetic, usually coming up in from two to five minutes after being swallowed. On this account, and because it is almost always at hand in the house, it is the most valuable emergency emetic at our command. For poisoning by opium or by other narcotics it is a remedy almost without an equal.

Administration.—The employment of whole mustard has been noticed sufficiently above. The ground mustard in use in this country is that sold by grocers for family use, and is seldom, if ever, a plain mixture of the two sorts of seeds and nothing else, which gives the most perfect product. It is oftener ground white mustard alone, and oftener still mustard diluted with a varying amount (generally considerable) of inert yellow powder. It is therefore subject to considerable variation in strength. This is used both internally and externally—internally, as a stimulant (condiment) and emetic; externally, always as a rubefacient. For an emetic, from a dessert- to a tablespoonful should be given, as a less amount may fail to produce vomiting but still cause considerable gastric distress. Externally, it is chiefly employed in foot-baths and sinapisms—for the former, from one to two tablespoonfuls may be added to a small tubful or bucketful of warm water; for the latter, the mustard meal is simply mixed with a little water and spread upon a cloth, or it may be diluted with meal or flour to reduce its strength. In this way mustard is the most widely used local remedy for the sudden and intense pain or distress of pleurisy, colic, some neuralgias, etc. It is also used as a derivative in nervous vomiting, cerebral and spinal inflammations, etc., and in many other conditions when acute attacks of pain are present. Both kinds of mustard are greatly damaged, or even spoiled, if mixed with hot water, as this destroys the ferment which brings out the active decomposition principles. The following preparations are official: *Charta Sinapis*, U. S. P., made by taking ground black mustard, exhausting it of its fatty oil by percolation with benzin, then mixing it with enough solution of india rubber to make a paste, and spreading it upon paper. This mustard paper is almost never made by the dispensing apothecaries, since several manufacturers here and in France make excellent substitutes for it that can be easily obtained and carried everywhere. The activity of the mustard paper is not developed until it is moistened in cold or merely warm water.

Oleum Sinapis Volatile, U. S. P. The oil of black mustard is also official. It is obtained by grinding and macerating black mustard, or a mixture of both kinds, in water and distilling. It is "a colorless or pale yellow

Digitized by Microsoft®

www.libtool.com.cn

liquid, having a very pungent and acrid odor and taste, and a neutral reaction. Sp. gr., 1.017 to 1.021. It boils at 148° C. (298.4° F.). It is freely soluble in alcohol and in ether." Its vapor when concentrated is intensely disagreeable, causing lachrymation and severe pain in the nose. Applied to the skin, it blisters severely. Diluted with nine parts of alcohol, or three parts of olive oil, it causes, when rubbed upon the temples or forehead, a sharp temporary tingling that occasionally relieves mild headache. The compound liniment of mustard (*Linimentum Sinapis Compositum*, U. S. P.) contains:

Volatile oil of mustard	3	parts.
Fluid extract of mezereum	20	"
Camphor	6	"
Castor oil	15	"
Alcohol q. s. to make	100	"

It is a good stimulating liniment. *Henry H. Rusby.*

MYCOSIS FUNGOIDES.—Mycosis fungoides, while one of the rare diseases of the skin, its real nature being still in dispute, has been sufficiently observed since 1860 to establish for it a sharply defined clinical evolution. Alibert first described it in 1814. The symptoms, for convenience of description, have been grouped in three stages, which, however, do not always occur in regular succession. The third or fungoid stage, for example, appears at times without antecedent lesions, this giving rise to the erroneous belief that two forms of the disease exist. There is but one form. The earliest phenomena vary greatly in the first or so-called premycotic stage, the only characteristic and constant symptom being intense itching. Eczema, urticaria, pityriasis rubra, erythema exudativum, or psoriasis may be simulated in this stage, the eczematous form being, however, the most common. Kaposi says that nearly every case of mycosis fungoides starts with the characteristics of an eczema. The lesions manifest themselves upon the trunk, folds of the articulations, the face, more particularly the forehead, or, indeed, any part of the body, by more or less sharply defined erythematous patches, varying from the size of a silver dollar to that of the palm of the hand and even larger. Upon these patches the epidermis presents a fine desquamation, and it is but rarely and only in places here and there that a slight exudation occurs with the formation of thin crusts. The alteration in the skin corresponds perfectly to the well-known picture of squamous eczema which occurs in patches of a pale red color with but slight tendency to become moist. The itching is intense at this stage, and insomnia is often a troublesome feature of the disease. This "eczema" may persist for several months or for one or two years (French authors denominate this the eczematous stage of mycosis fungoides), and while certain areas fade out and disappear, others make their appearance. Some of the lesions persist, extending peripherally over quite large areas of the body to unite with neighboring lesions. Hence, in some cases, although rarely, almost a completely generalized eczema, with interspersed areas of normal skin, will be established. Some of the lesions fade in the centre while they extend peripherally, giving rise to circinate lesions. Besides the desquamation and the slight occasional moisture, no lesions except those secondary to scratching supervene.

After a more or less extended period the second stage, or stage of infiltration, sets in. This is marked by a thickening of the skin consequent upon an inflammatory œdematous infiltration of the chorion, more particularly appreciable at the periphery of the eczematous areas, the borders of which appear tense, smooth, and shining. From this time on appear various circinate, sharply defined, more or less elevated plaques and nodules of a brownish-red or bright pink color, situated at the centre or upon the irregular borders of the eczematous parts of the skin. These nodules, plaques, and elevations vary in size and may appear upon regions of the skin which are free from eczema, which are located at the most diverse points, and which manifest no particular regularity in their disposition. A certain number of these lesions disappear completely after an existence of several days or weeks, leaving no trace other than a slight pigmentation, while others start up at new points. This spontaneous disappearance is quite as characteristic as is that of the lesions of the first stage. The two periods together may last many years (fourteen in one case) before the appearance of tumors.

In the so-called third or fungoid stage, which in some instances is the first and only stage, the characteristic tumors of the disease appear upon different portions of the body. They vary in size from a bean to an orange or even a larger object, and their coloring likewise varies from a pink to a dull red hue. As regards their shape they are either sessile or pedunculated, well rounded or lobulated, and distinctly circumscribed. When developing from the plaques they may be quite flat. They may develop from previously existing lesions or from the sound skin. They are usually painful. Like the other lesions of this disorder, the tumors may disappear spontaneously, while at the same time others make their appearance; or they may all disappear to return after uncertain intervals without known cause. As a rule, they leave no trace behind them of their previous existence, though they may be followed by pigmentation or slight atrophy of the skin. Sooner or later some of the tumors degenerate and lead to superficial ulceration, usually followed by papillary excrescences and mushroom-like growths of varying sizes, from which the disease obtains its name. At times they may be the seat of much more destructive ulceration, though with but few exceptions this destruction is limited to the new growths; and even large fungoid and apparently deeply ulcerated tumors may completely disappear and leave no trace of their previous existence, further than pigmentation and possibly a small atrophic scar.

The general condition of the patient at first seems unaltered; later, when the tumors ulcerate, exhaustion occurs and the victim usually dies as the result of febrile processes, of intercurrent disorders, of cachexia, or of pyæmia. Extirpation of the tumors is usually followed by recurrence, frequently with added malignancy. The duration of the tumor stage is brief compared with the others, death frequently occurring within a few months, though it may be postponed for two or three years.

Although the cause of the disease is not definitely known, there can be little question to-day as to its infectious character. It is probably produced by specific micro-organisms, but direct evidence of contagion and successful culture and inoculation experiments are wanting. The disease is more frequent in men than in women, and usually occurs after the fortieth year, though in a few recorded instances it began earlier.

Diagnosis.—At the beginning, when apparently simple eruptions precede the formation of the tumors, the diagnosis may be very difficult, even Hebra having once diagnosed a case as eczema; and it may also be mistaken for an exudative erythema, a psoriasis, or a pityriasis rubra. The irregularity of distribution, the sharply defined border, and the greater thickening than in any of those diseases might excite suspicion. There is generally not so much discharge as in eczema with the same amount of hyperæmia; the heaping of silvery scales is decidedly less than it is in psoriasis; and, finally, there is too much scaliness and it persists for too long a time for exudative erythema. The itching, also, is generally more severe than it would be in any skin affection except eczema. Besnier says: "In all cases of ambiguous pruritic dermatoses which are prolonged and rebellious to ordinary methods of treatment, the possibility of the affection being the premycotic period of mycosis fungoides should be borne in mind." When the bright red gives way to a deeper or more coppery red, and the infiltration increases, a suspicion of tubercular leprosy may be aroused, but there would be no anæsthesia and the scaliness would be much greater than that which leprous infiltrations present; moreover, the characteristic bacilli of that disease would be absent. When the fungating tumor

Digitized by Microsoft®

stage is reached there can be no difficulty in making diagnosis. In the more localized forms in which there is no preceding eruption, the disease may be mistaken for sarcoma or carcinoma cutis. Against this diagnosis, however, there would be the absence of early implication of the lymphatic glands (although tumors in the groin may simulate them), and the comparative painlessness; and besides, as a rule, the course would be slower than in cancer and the internal organs would never be implicated.

www.libtool.com.cn

With possibly two recorded exceptions, the disease has invariably terminated fatally, the extremes of duration being nine weeks (a case of Gaillard's) and fifteen years. The widespread cases, which commence as apparently simple inflammations, are much less malignant in their course than those which begin at once as tumors.

PATHOLOGY.—While the main facts as to the morbid anatomy of mycosis fungoides are generally agreed upon, much difference of opinion exists as to the interpretation to be placed upon these facts. Anatomically, the tumors consist of round cells supported by a scanty, delicate reticulum, which replace the normal tissue of the cutis. The new growth is somewhat scantily provided with vessels, and as it spreads it destroys the cutaneous capillaries. The boundary between the healthy and diseased tissues is ill defined. Ranvier and most French observers have classed it with lymphadenoma, but Sireday thought it was lymphosarcoma, and until recently all German authors have considered it to be a sarcoma. There is a growing tendency among observers at the present time to class the disease with the infectious granulomata. Various micro-organisms have been seen in the tissues by different observers and some have been cultivated, but none have as yet been demonstrated to have any pathogenic relation to the disease.

TREATMENT, so far as a cure is concerned, seems to be of little avail. Arsenic has been used hypodermically with apparent temporary benefit. Large doses of quinine are recommended. Resorcin subcutaneously has failed. The *x*-ray has of late been tried, but not with sufficient thoroughness to determine its value. Pyrogallic acid, aristol, iodoform, ichthyol have been used for the relief of local symptoms. It should, of course, be the physician's endeavor to make the patient as comfortable as possible by treating the various distressing symptoms as they arise. *Charles Townshend Dade.*

MYCOSIS INTESTINALIS. See *Anthrax*.

MYDRIATICS AND MYOTICS.—The opposing forces which maintain the iris in a state of equilibrium are controlled by two sets of nerves; the contracting muscle, the *sphincter pupillæ*, and the ciliary muscle being supplied by the third, while the dilating muscles are under the influence of the sympathetic nerve. The action of the third nerve has been very clearly demonstrated, but that of the sympathetic is not so evident, as the presence of radiating muscle fibres in the iris is a matter of dispute. Paralysis, or section of the third nerve, is followed by a relaxation of the sphincter muscle and dilatation of the pupil, and stimulation of the nerve produces contraction of the muscle and myosis. If the sympathetic nerve is stimulated there follows a dilatation of the pupil, and that the nerve exercises a positive dilating influence is shown by the greater degree of dilatation that takes place when a mydriatic is placed in an eye in which the third nerve has been paralyzed. This action of the sympathetic has generally been explained by the direct effect of the nerve upon the dilating muscles; but, since the presence of these latter has been called in question, a further explanation is necessary, and it has been suggested that the dilating nerve acts through the muscular tissue in the walls of the blood vessels of the iris (see article on *Cocaine*).

Alterations in the size of the pupil may be due to ordinary physiological action, to some pathological change, or to the effect of certain drugs. Exposure to a strong light or to darkness, efforts at accommodation, the influence of fear or of shock, will produce an enlargement or a narrowing of the pupil, according as one or other set of muscles is reflexly irritated. So also diseases of the central nervous system, which interfere with the integrity of the third nerve, cause dilatation, as is seen in meningitis, hydrocephalus, brain tumors, etc., while any profound effect upon the basal ganglia or depression of the sympathetic will be followed by contraction of the pupil.

MYDRIATICS.—Mydriatic drugs produce their effect either by paralyzing the motor oculi or by stimulating the sympathetic nerve. Belladonna and its allies are examples of the first group, and cocaine belongs to the second.

In the first group are belladonna, hyoscyamus, stramonium, and duboisia, the alkaloids of which—atropine, hyoscyamine, daturine, and duboisine—are active mydriatics and are almost identical chemically. Many other plants, not employed therapeutically, are members of the order Solanaceæ and possess the same physiological action. Hyoscine and scopolamine are closely allied to atropine, yet differ from it to some extent and form another group.

Belladonna is the best-known mydriatic and has been longest employed. Whether administered internally or applied directly to the eye, one of its earliest and most marked symptoms is the dilatation of the pupil. This persists for several days, the length of time depending upon the dosage. In some cases of poisoning the pupil has remained under the influence of the drug for three or four weeks. When it is employed as a mydriatic, a solution of the alkaloid is applied directly to the eye in order to obtain a purely local action. Formerly the extract was painted around the eye or upon the temple, or an infusion of the leaves was applied as a poultice over the eye. The pupil is extremely sensitive to the effects of atropine. It will be influenced by gr. $\frac{1}{130000}$, and a solution of the strength of 1 to 80,000 will enlarge the pupil within an hour. Accommodation is not affected by solutions below a strength of from one-thirtieth to one-tenth per cent. Generally a one-per-cent. solution is selected, which, instilled into the eye, begins to act in fifteen minutes and fully dilates the pupil in half an hour, accommodation being lost in one hour. The paralysis lasts for three or four days and is accompanied by annoying disturbance of vision caused by the enlarged pupil and loss of accommodation. Minor disturbances may persist for several days. For convenience of use gelatin discs are prepared which contain gr. $\frac{1}{5000}$, and which are easily inserted beneath the lid. If paralysis of accommodation is required, discs containing gr. $\frac{1}{500}$ must be used. A solution of salicylate of atropine is to be preferred to the sulphate, as it forms an antiseptic solution which remains free from any fungoid growth such as forms in solutions of the sulphate.

Homatropine is replacing atropine when dilatation is required for the purpose of examination. The advantage is a more rapid and less prolonged action. The pupil begins to dilate in the course of a few minutes and accommodation fails in thirty or forty minutes. Its effect begins to subside in three or four hours, and the eyesight is quite recovered within twenty-four hours. The drug is also less irritating to the conjunctiva and is devoid of constitutional effects when used with ordinary care. For the purpose of simply dilating the pupil, a one-per-cent. solution is employed; when accommodation is to be paralyzed, a two-per cent. solution is to be preferred. If mydriasis is required for a prolonged period, atropine is selected in preference to homatropine.

Hyoscyamine and *daturine* are rarely or never employed for their mydriatic action. Their action is the same as that of atropine, but they are less to be depended upon and offer no advantages.

Hyoscine exercises a much less marked influence upon the pupil, and is never used.

Duboisine.—This alkaloid has recently been extolled as possessing a more powerful action than atropine and as producing effects which are of shorter duration. As it is chemically identical with atropine, it will probably be found to have the same mydriatic action. The solu-

Digitized by Microsoft®

tion employed has a strength of one per cent., and produces dilatation within an hour.

Cocaine.—As a mydriatic cocaine differs from atropine and possesses many advantages. It is much less intense in its action, the pupil is not dilated to so great an extent, and a certain degree of reaction to light or other stimulus may be retained. Its effect is accomplished in half an hour and passes off in a few hours. There is little or no influence exerted on the power of accommodation. As before stated, it acts through the sympathetic nerves, either by stimulating the dilating muscle of the iris (if these exist) or by contracting the arteries of the iris.

www.libtool.com.cn

When it is combined with atropine a very powerful mydriatic is obtained, as both a paralysis of the sphincter and a stimulation of the dilators are obtained. Koller uses a mixture of equal parts of a one-per-cent. solution of atropine sulphate and a five-per-cent. solution of cocaine hydrochlorate. This is applied every ten minutes until dilatation is secured, and if a prolonged action is required it is maintained by applying the solution three times a day. In inflammatory conditions much benefit is also obtained from the anæmia and blanching of the parts which the cocaine produces.

Mydriatics are employed to dilate the pupil for the purpose of an efficient intraocular examination and to facilitate cataract operations; also to remove the iris from the danger of adhesions in many inflammatory conditions. The dilatation of the pupil will also lessen the probability of prolapse of the iris in wounds of the eye.

For ophthalmic examinations and for simple dilatation of the pupil, homatropine and cocaine are now employed almost to the exclusion of atropine on account of their transient action. In examinations in which it is necessary to paralyze accommodation homatropine must be employed, as the action of cocaine upon the ciliary muscle is insufficient. In inflammatory states where a prolonged effect is required, atropine, with or without cocaine, is to be preferred. It is also indicated in all forms of iritis and in wounds or injuries accompanied by inflammatory action. When there is much ciliary spasm, it lessens the pain and photophobia by paralyzing the muscle.

The employment of mydriatics is not unaccompanied by dangers. For example, the alkaloid may be absorbed to such an extent as to cause severe constitutional disturbances, or some of the solution may pass into the nasopharynx and its local action be extended into the throat. Mydriatics may also, by continued use, prove so irritating as to produce a conjunctivitis. The most serious danger is the possibility of aggravating an incipient glaucoma—a result which has frequently followed their careless employment. This is due to the increased intraocular tension which accompanies the paralysis of the ciliary muscle, and, although cocaine is thought to have but little effect in increasing this tension, many cases are reported in which it has aggravated a glaucomatous condition of the eye. Certain signs of glaucoma, which readily distinguish it from iritis, are very marked and should never be overlooked. In iritis the iris is contracted and fixed, while in glaucoma it is dilated and also fixed; in iritis the eye is hypersensitive, in glaucoma it is almost insensitive. In glaucoma there are also the early symptoms of vomiting, with inflammation of the eye, and the prodromal disturbances of vision, with haziness of the cornea, color rings, etc.

MYOTICS.—The action of myotics is quite the opposite to that of mydriatics, the contracting muscles being stimulated and the dilating muscles depressed. With the contraction of the sphincter pupillæ there is also a contraction of the ciliary muscle which lessens intraocular tension. The action of myotic drugs is not well understood. It is probable that they act upon both sets of muscles, but even in the case of physostigmine, the best known of these drugs, many authorities consider that its action as a stimulant of the motor oculi is the most important, while others claim that its influence is directed chiefly as a depressor of the sympathetic. Myotics are of less therapeutic value than are mydriatics, and were it not for the lessened intraocular tension that accompanies the narrowing of the pupil, they would very rarely be employed. They are recommended in cases of paralysis of the third nerve, but are rarely of any service, except in the paralysis following diphtheria. In glaucoma they are of undoubted value. The great tension is overcome and the eye is relieved, and in many instances their employment has apparently rendered an operation unnecessary. In wounds of the surface of the eye and in corneal ulcers the tendency to rupture of the coat is lessened by their use.

Physostigmine or *Eserine* is the drug always selected. Pilocarpine exercises the same effect, but it is mild and uncertain. A solution of the sulphate or salicylate of eserine is employed, of the strength of one-quarter grain to the ounce. This will begin to act in fifteen minutes, its full effect will be reached in an hour and will continue for two or three hours, and in twenty-four hours the myosis will have disappeared. In glaucoma myosis is more difficult to obtain, and a solution of two per cent. may be required. The condition of myosis is not so intense as is that of mydriasis, and if atropine has been applied to the eye eserine will have no effect until the action of the atropine has begun to pass off. On the other hand, atropine rapidly dilates a pupil under the influence of eserine.

Beaumont Small.

MYDRIN is a colorless powder composed of ephedrine hydrochloride, 100 parts, and homatropine hydrochloride, 1 part. It is used in ten per-cent. solution as an evanescent mydriatic.

W. A. Bastedo.

MYELOMA.—Under the greatest variety of names there have been described in recent years cases of an affection of the bones which have in common certain features so distinctive as to justify their union under one name. Briefly stated, these cases show as a rule evidence of the presence of multiple new growths developing simultaneously in the most widely separated bones. Pain is often felt in these tumor-like masses, and from the destructive influence which they exert upon the bony structure fractures with dislocation and deformity soon appear as the result of the most trifling traumatism. A cachectic condition supervenes in the later stages and is associated with the occurrence of a peculiar urinary condition, — one in which the urine contains albumoses. Various paræsthesias and pareses may occur, and with the great increase in the deformities produced by the tumor masses the patient finally dies of exhaustion or succumbs to some intercurrent affection.

As early as 1847 a case of this sort was observed by Bence Jones[1] and Macintyre. Their attention was particularly attracted to the condition of the urine, in which a peculiar proteid could be demonstrated. The patient after a long and very painful illness died, and at the autopsy there were found red gelatinous masses replacing in large part the vertebræ, sternum, ribs, etc. They designated the condition "osteomalacia fragilis rubra."

Rustizky[2] first gave the name multiple myeloma to the condition in a paper published in 1873. He considered it a simple hypertrophy of the bone marrow, because, although the tumors were multiple, they were present only in the bones and did not give rise to metastases.

Since then a number of cases have been described under this name, while many others obviously of the same nature have been designated "osteomalacia," medullary pseudoleukæmia, sarcomatous osteitis, malignant osteomyelitis, lymphosarcoma, etc. Good summaries of the literature with descriptions of cases have recently been given by Hammer,[3] Winkler,[4] Wieland,[5] and Paltauf,[6] from which it appears that there is really a well-defined condition, easily distinguishable from the endotheliomata and sarcomata of bone, and for which the name myeloma is most fitting,—a condition which Virchow prophesied, although at that time no case had been published.

The disease may perhaps be made clear most easily by the description of a case which occurred recently at the

Digitized by Microsoft®

Johns Hopkins Hospital and which has been reported in its clinical and pathological aspects by Dr. Hamburger and myself. For the clinical description I quote from his paper in the *Johns Hopkins Hospital Bulletin* (vol. xii., 1901, p. 38).

The patient was a colored woman, fifty years of age, who entered the hospital complaining of "rheumatism" and a "sprained wrist." Her personal and family history were unimportant, but for about a year she had had pain in the region of the right groin and hip. One night about six months ago, while picking up a bucket of coal, she experienced a remarkable sense of lengthening in the left arm, and next morning found that she could not raise it to her head because of pain and a feeling of weight. A week later the right arm became affected. She had pains in the shoulders, neck, and chest. About this time she noticed a swelling the size of a hen's egg on the back of her head. Pain and stiffness in the arms continued, so that after two months she could not feed herself. Six days before admission to the hospital, while walking, the right leg "gave way" without apparent cause. She fell to the ground and since then had not been able to stand or walk. She suffered great pain in the right hip.

She became much emaciated and very weak and anæmic. On admission to the hospital, any movement of the body was found to produce great pain. Over the occipital region there was a round, soft, fluctuating mass about 10 cm. in diameter, not adherent to the skin, not movable on the deeper tissues, not tender. A nodule, 3 to 4 cm. in diameter, was visible on either clavicle over its inner third, the one on the left being a little larger and evidently eroding the bone, for manipulation caused pain and crepitus. There was another tumor in the left supraspinous region, about 4 cm. in diameter, connected with the acromion process of the scapula. The right leg was rotated outward and abducted, the upper third of the thigh being markedly enlarged and deformed by the presence of a tumor about the size of a child's head, projecting from its postero-external aspect. It was firm and tender on pressure and any attempt to move the limb caused intense pain.

Physical examination was otherwise negative. There was no glandular enlargement and examination of the blood showed only a diminution in the number of red corpuscles with a corresponding diminution in the percentage of hæmoglobin. The urine was turbid, light yellow, and usually alkaline; from 600 to 800 c.c. were voided daily, of a specific gravity varying from 1.012 to 1.030. Heller's reaction was positive. When the urine was acidified and heated to a temperature of 56° C., a heavy white precipitate appeared. It redissolved in part on boiling and returned on cooling. The nitric-acid precipitate disappeared on boiling, to reappear on cooling. The mixture assumed a darker color and particles of the precipitate adhering to the tube became pink. The biuret reaction was marked. The proteid content measured by the Esbach albuminometer varied from 0.3 to 0.6 per cent.

This case illustrates well the symptoms which have been spoken of as fairly constant, viz., the emaciation and anæmia, the simultaneous occurrence, over the bones, of soft, almost fluctuant masses, and the erosion of these bones with fracture and deformity associated with great pain. Particularly well, however, is the albumosuria illustrated. Acute transitory or slight albumosuria has been observed in many acute febrile diseases, and similarly slight peptonuria has been described in the greatest variety of conditions. The work of Kühne and Chittenden renders it probable that all of these are instances of albumosuria, the proteid substance found in the urine being very closely related to, but not exactly identical with, the products of partial digestion described by those authors. These cases, however, are without difficulty distinguished from those in which the quantity of albumoses is large and its occurrence persistent throughout a long time. It has been found (Hamburger) that in the great majority of cases of definite albumosuria multiple myelomata have been found at autopsy, although as yet the evidence is not sufficient to prove that in all cases of myeloma albumosuria is found.

The origin and exact nature of this proteid substance are as yet quite obscure, but when it is present in considerable quantities it is easily recognized by the reactions described above, and especially by its property of redissolving at boiling temperature in acidified solution, from which it was precipitated by a temperature of 56° C.

The pathological anatomy of the multiple myeloma may be made clear by a further reference to the case above mentioned.[7] The patient died after a stay of some months in the hospital, and at the autopsy multiple tumor masses were found involving various bones. The right leg was shorter than the left by about 3 cm., and in the trochanteric region, where there was a large tumor mass, there was excessive mobility of the femur. The organs in general showed only the evidences of senile atrophy and in the lungs a few old tuberculous scars. On removal of the sternum it was found to contain, at the points of insertion of the second and third costal cartilages, a tumor mass, which, being very soft, allowed free movement of the two parts of the sternum upon each other. The left clavicle was much enlarged at its sternal end, the bone being apparently distended by the tumor mass within, for the cortical portion was very thin and could be compressed by the fingers. On sawing through the bone lengthwise the cancellous bone was found to be much rarefied and the cortical portion very much thinned; the marrow was almost entirely replaced by the tumor mass, which extended quite to the acromial end.

The right clavicle showed evidences of a healed fracture, the portions having united in a somewhat abnormal position, so that a slight angular deformity existed. The marrow of this bone also showed tumor masses, which did not, however, cause any extensive erosion of the bone.

From the spinous process of the left scapula there arose a soft tumor mass which on section was found to have eroded and replaced a considerable portion of the bony process. None of the cortex or cancellous bone tissue was to be discovered in this one. The ribs were not involved. Unfortunately, the vertebral column was not sawn through, but there were no evident tumor masses visible from without. The right ilium was completely eroded through in its median portion by a large soft mass, which had destroyed the whole thickness of the bone and which projected both ways—inward into the pelvis under the iliacus muscle, and outward under the muscles covering the outer surface of the ilium. The hip-joint on this side showed no abnormality, but in the intertrochanteric region a large tumor mass sprang from the marrow of the femur. At the upper end of the shaft of the femur there was a fracture, the shaft being displaced upward. On sawing through the bone at this point the intertrochanteric region was found to be extensively involved in the new growth, which extended into the adjacent tissues. The cancellous bone was almost entirely destroyed and the cortex much atrophied and roughened internally. For a distance of about 5 cm. the cavity of the shaft of the femur was invaded, the yellow marrow being pushed ahead and fairly sharply limited from the dark purple new growth. The bone marrow was atrophic and œdematous, grayish-pink and moist in appearance, and sunken below the level of the cut surface of the invading tumor. The left femur showed no evidence of tumor formation.

Removal of the large mass at the vertex of the skull revealed a large aperture in the skull, the edges of which were very ragged, as if gnawed away, with here and there loose spicules of bone lying in the soft tumor mass which evidently sprang from the marrow cavity. This tumor mass spread itself between the cranium and the dura for a short distance, and, completely filling the aperture in the skull, projected outward to form the large soft mass felt under the scalp.

No other tumor nodules were to be found so far as it was possible to examine the bones.

These growths presented everywhere the same appear-

Digitized by Microsoft®

ance. Everywhere they evidently sprang from the marrow of the bone, from which they were not by any means sharply demarcated. Only where the tumor seemed to invade the yellow marrow of the shaft of the femur was the outline sharp, but even there the microscopical examination showed evidences of the presence of tumor elements far past this outline. Where the red marrow of the short bones formed the point of origin, the outline was not nearly so sharp. The well-defined tumor masses were perhaps somewhat firmer than such a mass of bone marrow would be. They varied somewhat in consistency, however. In general they were soft; some of the larger ones were almost diffluent, and they flattened out when they were cut and laid out on a pan. Others were less soft, and in some parts the gelatinous pulpy consistency gave way to a fair degree of firmness. In color there was also considerable variation. The greater part of the masses was of a deep red color, perhaps even darker than that of the normal red bone marrow, but showing everywhere a grayish tint. Usually lines and streaks of gray were to be seen throughout this deep red, and in nearly all the masses definite nodules of firmer consistency and of grayish-white color were found. At some points there was a slight yellow opacity.

Microscopically, the various authors have emphasized the regularity in form and size of the cells, and Wieland has adduced this as a distinction from the myelocytes. Nearly all writers have thought the tumor cells to be derived from some cell or other of the bone marrow. Wright alone considers them to be plasma cells or closely related cells at least, to explain which he states that plasma cells are present in the bone marrow. The results of attempts to determine the histogenesis of the cells in this case will appear from the following description of the microscopical appearances:

The tumor masses present in sections a remarkably homogeneous appearance. There is, as described in practically all of the other cases, a delicate stroma with rather wide meshes in which lie innumerable rather large round cells. These are not in intimate connection with one another, but lie singly and loose; sometimes, where their number is very great, they are somewhat compressed into a polygonal form, but in general they are quite regularly rounded; they vary slightly and may be elongated or pear-shaped or even notched. The nucleus is large, round, and vesicular, sometimes lying eccentrically. The protoplasm presents a rather ragged granular appearance. Blood-vessels exist throughout the tumor and are indeed rather numerous. The smaller ones lie in very intimate contact with the tumor cells, their walls being merely a single layer of endothelium. Connected with these and the coarser strands of the stroma are exceedingly fine filaments of connective tissue which run in between the cells. Everywhere, scattered quite without order through the tumor mass and among the tumor cells, are numerous red blood corpuscles, which are quite well preserved. These evidently give the dark red color to the tumor masses, being absent or present in only very small quantity in the translucent grayish-white nodules described above.

More careful examination of the characteristic cells of the tumor shows them to be distinctly of one type, although certain variations in size occur. They measure from 13 to 21 μ in diameter, and thus approach very closely the myelocytes, while they exceed considerably the plasma cells in size. The nucleus is provided with a definite nucleolus, which shows especial avidity for certain aniline dyes. In smears from the tumor the nuclear structure is shown clearly. The nuclei appear large and flattened out, and in the general pale blue stain there appear irregular spaces which do not stain or take only the tint of the cell protoplasm. In this respect they resemble closely the myelocytes as described by H. F. Müller. The protoplasm is rather ragged and granular-looking, but the granules are not sharply outlined and with specific stains they take on no different coloration from the rest of the protoplasm. These are, therefore, not specific granulations. In sections as well as on smears stained with the polychrome methylene blue of Unna or the alkaline methylene blue, the protoplasm takes on only the palest greenish-gray coloration; there is nothing of the specific staining described by Unna and others for the plasma cells. With polychrome methylene blue and eosin the protoplasm stains with eosin.

The relation of these cells to the other normal cells from which they might possibly arise is therefore about as follows: In size they greatly exceed the plasma cells, but agree fairly well with the myelocytes and non-granular cells resembling myelocytes found in the bone marrow. With polychrome methylene blue, etc., they do not show the reaction typical of the plasma cells; on the other hand, their protoplasm, although in its raggedness it does resemble the "granoplasma" described by Unna for the plasma cells, shows none of the specific granulations characteristic of the myelocytes. The presence of a nucleolus must be admitted for all these various types of cells, so that it is of no help in determining such relations. The cells of the myeloma and the myelocytes and non-granular cells of the bone marrow have in common, however, the peculiar lacunar structure of the nucleus, as seen in dried smears, which H. F. Müller[8] describes as follows: "With adequate magnification one sees in the myelocytes a remarkable nuclear structure; one finds often nuclei in which definite clear fields are visible. These may be in part nuclear substance, but in many such nuclei these fields seem to represent the cell substance which stretches itself into pre-existent holes or pores in the nucleus." And then again: "There is a large round or oval nucleus limited by a thin chromatin wall which shows frequently more or less numerous larger and smaller clear areas, which are often plainly seen to be definite apertures in the nucleus through which the cell substance extends into the interior of the nuclear body."

This structure seems so peculiar that its occurrence in these various cells at least indicates their close relation to one another. The descriptions and figures of plasma cells in the papers of Unna,[9] Jadassohn,[10] Marschalko,[11] Justi,[12] Krompecher,[13] and Councilman[14] give no hint of such a structure in the nuclei of these cells.

The myeloma cells are apparently separated from the myelocytes by the absence of the characteristic neutrophile granulations. An examination of a bone-marrow smear, and more especially of a smear from actively proliferating bone marrow, will convince one of the great variations in the abundance of the granules which occur in these cells. In a recent paper on the relation of the myelocytes to leucocytosis, Rubinstein[15] describes the transitions which take place in the development of myelocytes from smaller cells whose protoplasm is quite free from granules. These young myelocytes reach quite the size of the adult myelocytes before the granules appear, which they do gradually a few at a time. The resemblance then between these non-granular myelocytes, as they may perhaps be called, and the myeloma cells is most striking, and suggests most strongly the origin of the myeloma from these characteristic cells of the bone marrow in one or other stage of their development.

Further evidence of this close relation is given in the abundant presence of the tumor cells in the marrow adjacent to the tumor masses, where they take on exactly the arrangement of the myelocytes among the fat cells and are intermingled with the occasional eosinophile cells. Indeed, if, in a large section, we pass gradually from the relatively normal marrow toward the tumor, we find a gradual and insensible transition, the myelocytes being replaced entirely in time by the tumor cells, which become more and more densely arranged, forming finally definite nodules. Among the trabeculæ of the cancellous bone this consolidation of the cells which have the position and form of myelocytes into solid strands in direct continuity with the tumor mass is very convincing evidence of the direct relation between the tumor and bone-marrow cells.

Various alterations in the appearance of the tumor cells, such as fragmentation and partial division of the

Digitized by Microsoft®

nucleus, occur. Indeed, one sometimes finds large cells containing numerous nuclei and a vacuolated protoplasm in which irregular or rounded cellular inclusions are present. These are perhaps best interpreted as evidences of degeneration.

The tumor mass as described above contains in the interstices between the cells very numerous red blood corpuscles in a very well-preserved condition. There is very little evidence of any breaking down of the red corpuscles,—hardly any deposit of hæmatoidin in the tissues, which would certainly be present if the presence of the blood were due to actual hemorrhage. Red corpuscles are found scattered in considerable numbers among the myelocytes and other cells in the normal bone marrow, however, and it seems probable that the condition here is analogous. The walls of the blood-vessels in the tumor are nevertheless of extreme thinness and extravasations might readily occur. So also tumor cells are quite frequently found inside these blood-vessels lying among the red corpuscles, although an examination of the circulating blood a few days before the death of the woman showed only one or two doubtful myelocyte-like cells among a great number of leucocytes, the varieties of which were those of the blood in practically normal relations.

www.libtool.com.cn

From this description, then, it is seen that in this condition we have multiple new growths from the bone marrow, not very sharply delimited from the marrow and showing very gradual transitions into it. The cells have the form and general characters of the bone-marrow cells, lacking the specific granules of the myelocytes, but possessing the peculiar nuclear structure found in the myelocytes and their formative antecedents. They differ in essential particulars from the plasma cells, and in view of these facts and of the fact that they largely replace the myelocytes in the marrow in the neighborhood of the tumor, there being no sharp boundary between the myeloma-like marrow and the myelocyte marrow, we may consider them directly related to these cells and probably derived from the large non-granular forerunners of the myelocytes.

The exact relations of this condition to others with which we are familiar are difficult to determine. On the one hand, there are none of the anatomical features of the ordinary forms of chronic inflammation, while on the other hand the process differs from that which characterizes the majority of tumors in its simultaneous origin in many bones and in its mode of growth, which while destructive is not of such a nature as to give rise to metastases. We are quite ignorant of any etiological factors, but on the whole the condition seems most analogous to those forms of lymphosarcoma which, arising often simultaneously from many lymphoid structures, invade and destroy the adjacent tissues.

MYOMA.—The myoma is a tumor composed chiefly of muscle tissue, therefore of mesoblastic origin, and belonging in the connective-tissue group. According to the type of muscle tissue of which myomata are composed, they are divided into leiomyoma (Zenker) or myoma lævicellulare (Virchow), containing smooth muscle fibres, and rhabdomyoma or myoma striocellulare, containing striated muscle fibres.

In general, the term myoma, without further distinction, is used for leiomyoma.

Leiomyoma.—Of the two varieties, the tumor composed of smooth muscular fibres is by far the most frequent and of the most importance clinically.

HISTOLOGY.—The physiological type of the tissue, the smooth muscular fibre, is widely distributed over the body, and is best seen in the intestinal canal and in the uterus. The smooth muscular fibres are long, fusiform cells, which are connected by a small amount of cement substance. The nucleus is a long rod-shaped body situated in the middle of the cell. The tumor is composed for the most part of such muscular fibre cells, which are arranged in bundles, closely packed together, frequently interlacing, and separated from one another by a small amount of connective tissue which carries the blood-vessels. On section of the tumor these bundles are cut at various angles, and when the nuclei are brightly stained the section often appears peculiar. When a bundle of fibes is cut exactly across, the section of the muscular fibres, with the brightly stained nuclei in the centre, may be mistaken for round cells with a central nucleus, or, still more readily, for a section of a nerve. The nuclei may be mistaken for connective-tissue nuclei and the tumor for a fibroma. In the myoma the nuclei are longer, narrower, and more refractive than connective-tissue nuclei, and in the fibroma the arrangement of the fibres in bands is never so characteristic as in the myoma. In cross-section of the fibres the muscle substance around the nucleus is seen to be denser, more homogeneous, and more refractive than the protoplasm of other cells. When fresh unstained sections are examined the tumor may be mistaken for a sarcoma, in which the cells are often arranged in bundles in the same way, but a careful study of the nuclei will reveal its true character. The separate cells which compose the tumor may be isolated by macerating small portions in a twenty-per-cent. nitric-acid solution or in a thirty-per-cent. solution of caustic potash. This dissolves the cement substance between the muscular fibres, and they can then readily be teased apart. There is often a considerable difference in size between the tumor cells and the cells of the analogous physiological tissue. The cells may be very much larger or very much smaller than these. Sometimes cells as large as the muscle cells in the rapidly growing pregnant uterus are found. There is always with the muscular tissue a variable amount of connective tissue which is principally found between the larger muscle bundles. From this, smaller septa are given off which run between the smaller bundles of cells. White (*Johns Hopkins Hospital Bulletin*, xi., 111, 1900) has demonstrated that this connective tissue is of the white fibrous and reticular types, and that each muscle cell is surrounded by a connective-tissue capsule. He could demonstrate no elastic fibres. In this connective tissue run the blood-vessels. In some cases the connective tissue is so abundant that it forms a considerable part of the tumor, and in others there is scarcely any present, except around the larger vessels. The amount seems to vary with the age of the growth, being always less in small tumors of recent for-

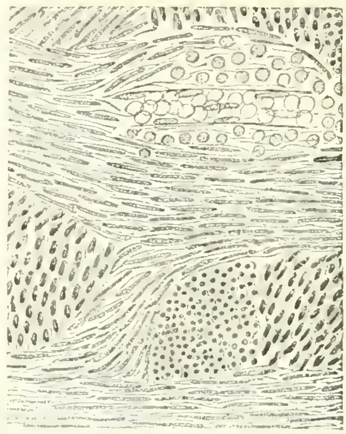

FIG. 3466.—Section of a very Small Myoma of the Uterus, Hardened in Müller's Fluid and Stained with Hæmatoxylin. Bands of muscular fibres are seen cut in various directions. (× 175.) (After W. T. Councilman.)

mation. When there is much connective tissue present the tumor is generally firm and fibrous, but in some places it may have more the character of loose areolar tissue and contain numerous lymphoid cells. In some of the very large myomata of the uterus the development of connective tissue is so great that the tumor appears to be principally composed of this, and it is only after considerable search that the muscular tissue is found. To this form the term *fibro-myoma* is given. In almost every tumor some places will be found where neither muscular tissue nor connective tissue can be made out. There are larger or smaller areas of firm, highly refractive, homogeneous tissue, in which a few rod-shaped nuclei are scattered. Such areas are most abundant in the larger tumors, and represent a hyaline transformation of the tissue. As a rule the myomas have a very poor vascular supply, but cases are sometimes seen in which the blood supply is so abundant that the tumor almost resembles a cavernous tissue. This variety of tumor will be considered more fully in speaking of myoma of the uterus.

Gross Appearance.—Macroscopically the myoma resembles most the hard fibroma or one of the sarcomas. It is always sharply circumscribed, and generally surrounded by a firm capsule of connective tissue. On section of the tumor it can always be easily separated from the tissue surrounding it. The cut surface has a whitish or yellowish color and glistens. It is not homogeneous, but marked by fissures and lines which represent the spaces between the muscular bundles, and which often have a concentric or spiral direction. Whiter and darker patches are sometimes seen on the surface; these generally depend on degenerative processes in the tumor.

Origin.—The tumor always develops from non-striated muscular tissue. Unlike the rhabdomyoma, it never develops in any locality where this tissue is not found; it is never heterologous. Although its origin from smooth fibres has long been generally accepted, it is interesting to note that Kölliker and his followers believed its origin to be from the connective tissue. The exact histogenesis, however, is not always clear. Keifer (*La Presse médicale*, 1899, No. 10, p. 49) has demonstrated by injection methods small islands of non-vascular tissue in the uterus, which increase peripherally by the addition of smooth muscle tibres. In the centres of these masses was frequently seen an arrangement of cells suggesting obliterated vessels. From these masses about obliterated vascular trunks he believes myomata take their origin. Cohen (Virchow's *Archiv*, 1899, clviii., 524), in a study of the histogenesis of myomata of the uterus and stomach, concludes that in many cases it is impossible to determine the origin. He examined by serial section small tumors, and in many but not in all he found a central blood-vessel without an adventitia, whose muscular coat could not be differentiated from the newly formed muscular fibres.

In myomata of the skin the origin of the new growth is supposed to be the muscular coat of the blood-vessels and the erector muscles of the hair shaft (Jadassohn).

Nature.—The leiomyoma is a benign tumor, distinctly encapsulated and of slow growth. Although not in itself a dangerous tumor, it may, mechanically, cause serious complications; thus submucous myomata of the uterus may become eroded and be the source of a serious hemorrhage. Pedunculated tumors may be forced into the cervix uteri, causing a spurious labor; or if of large size they may perhaps produce prolapse of the uterus. Similar tumors beneath the peritoneum may exert pressure on the rectum or bladder, or by their weight bring about displacement of the uterus and other pelvic organs. They may form adhesions to other organs and thus induce strangulation; or they may themselves, if pedunculated, become strangulated and form free masses in the peritoneal cavity. Myomata of the digestive tract may cause occlusion or serious results may follow the traction superinduced by their mere weight.

Etiology.—Little is known in regard to the etiology of the myomata. In the uterus they are found most frequently after middle life and are much more frequent in blacks than in whites. On the other hand, the analogous tumor of the prostate in man is much more common in the white race than in the black. It cannot be shown that irritation exerts any influence. Some uterine tumors containing glandular acini suggest a congenital origin, the result of misplaced uterine fragments, thus supporting Cohnheim's theory.

Seats.—The more common situations are the uterus, gastro-intestinal tract, and prostate; the less common are the bladder, skin, nipple, and walls of blood-vessels.

Uterus.—The most frequent place of the formation of the tumor is the uterus. Every variety of the tumor is found, and it can be studied best here. The new growth may spring from any part of the uterine wall, but usually from the portion above the cervix; and it may vary in size from a microscopic nodule to a mass or masses weighing over a hundred pounds and entirely filling the abdominal cavity. The chief mass of these tumors is composed of muscle fibres, which are generally much larger than those of the normal uterus. The increase in size affects principally the width of the cell and the nucleus. Cells are often seen which are wider than the diameter of a red blood corpuscle. The muscle fibres are arranged in bundles, which are surrounded by wide capillary vessels. The walls of these vessels consist of a single layer of endothelial cells with large nuclei, supported by a thin layer of connective tissue. Both between the muscle bundles, and between these and the connective tissue of the vessels, are small spaces which contain white corpuscles and are surrounded by a fine tissue in which here and there nuclei are enclosed. In this way a cavernous structure is formed, which is not present in the normal uterus. Klebs supposed that these spaces represent lymphatic cavities, in which the whole tissue, muscular fibres, and blood-vessels are suspended by the small bands of connective tissue. Larger blood-vessels, with thick walls and a wide adventitia, are but seldom found, and then in the broad partitions between the larger bundles of muscular fibres.

The tumors may increase in size by the joining together of the neighboring growths, but this mode of increase is rare. Generally it appears that the same process of new formation, in consequence of which the smallest and most simple myoma was formed, repeats itself. Every single vessel, with the muscular and connective tissue belonging to it, proliferates again and forms a second generation of nodules, which are situated in the original tumor. These different centres of growth can, as a rule, be easily made out, and sometimes the arrangement is such that the tumor appears to be composed of triangular masses, the apices of which point to the centre and the base is along the periphery of the tumors. In other cases, the formation of secondary nodules takes place only in certain parts of the tumor, and in this way very irregular, uneven masses arise. This peculiar process of growth leads to the displacement of the tumor, which originally is enclosed in the walls of the uterus. If the growth takes place most rapidly in the part of the tumor nearest the mucous or the serous membrane, that part escapes from the muscular tissue and projects into the uterine cavity or on the surface of the organ, and finally the whole tumor becomes separated from the uterine walls. In this way the submucous and subserous varieties of the tumors arise, which are either connected with the uterus by a narrow pedicle or have a wider attachment. This attachment often contains dilated venous vessels in the loose connective tissue. The tumors which remain within the muscular coat are termed interstitial or intramural. When the connective tissue is much developed the tumor is denser and harder, and on section the lines and fissures are not so evident. The lymph spaces and blood vessels become narrower and partly obliterated. The smooth muscular fibres remain preserved, but the single fibre cells can no longer be recognized, and in place of them small, long, rod-shaped nuclei are found embedded in a substance which appears more or less fibrillar (fibromyoma). The

Digitized by Microsoft®

best conditions of nutrition are found in the small tumors of the uterus, which sometimes are composed entirely of muscle fibres and blood-vessels. Such tumors have the grayish-red, dull appearance which the uterus shows on section, and microscopically they cannot be distinguished from the uterine tissue. The small lymph spaces which were spoken of may become widened to form large cysts filled with a clear fluid analogous to serum and coagulating spontaneously on exposure to air. Often these do not seem to have a special lining membrane. Small processes of connective tissue sometimes grow from the walls of these cysts, which penetrate between the adjoining bands of muscular tissue, and in this way a series of smaller cysts may arise. These *cystomyomata* of the uterus may attain a large size, especially when, as often happens, heterologous formations of a myxomatous or sarcomatous character arise in them. Single cysts of large size, entirely surrounded by muscular tissue, are sometimes found. Their contents are fluid, generally more or less colored with blood pigment from numerous hemorrhages which have taken place into them. The contents of all of these cysts will usually coagulate spontaneously. The walls often contain a layer of fibrin of variable thickness, and the cysts may be traversed by bundles of muscle tissue. Dilated blood-vessels are often found in the neighborhood of the tumor, and in the extramural forms they run in the loose connective tissue of the attachment. These are the most frequent source of the hemorrhages which so often accompany this form of tumor, they being often torn across by the traction of the tumor. The dilatation of these vessels is nothing but a passive process, but in some cases there is a very abundant formation of vessels in the tumor itself. Virchow distinguishes this variety under the name *telangiectatic myoma* or *cavernous myoma*. There is little or no development of connective tissue, and the vessels are immediately in contact with the muscular bundles. It is in such tumors that marked variations in size are seen, the tumor appearing sometimes double its usual size. It is probable that this variability in size may be due both to changes in the amount of blood in the dilated vessels and to different degrees of contraction of the muscle cells.

There may be mixed forms of myomata. The most frequent combinations are with myxomatous and sarcomatous tissue. The myxomatous degeneration occurs when much fibrous tissue is present. Sarcomatous change is much less frequent. Such tissue develops around the vessels in the septa between the bundles of muscles. The myxomatous tissue in the tumor can be recognized as patches of grayish, gelatinous material, while the sarcomatous portions are whiter and less refractive than other parts. Combinations with other forms of tumors do not take place. In the uterus carcinoma may coexist with myoma, and the carcinoma may erode and grow into the myoma in the same way that it grows into the muscle tissue of the uterus itself.

Of the degenerative processes the most frequent is calcification, which may affect the whole tumor or only parts of it. When the calcification is complete the whole tumor may be changed into a hard, stony substance, in which no tissue or blood-vessels can be made out. Generally the process is not so complete as this, and a network of calcified tissue traverses the tumor, in the meshes of which small bands of muscle tissue and vessels are seen. In some cases a true formation of osseous tissue has been made out in the tumor, and in one tumor the writer has observed areas of adipose or true fat-bearing connective tissue. Occasionally complete gangrene may result from interference with the blood supply of large areas. Suppuration is rare but may occur. After the menopause these growths are said to undergo atrophy.

An interesting form which occasionally occurs is one which contains glandular structure of the type of the uterine mucosa and is known as adenomyoma. It is distinctly a benign tumor, though its growth may be diffuse. It is usually situated in the inner layers of the muscular wall. Opinions vary as to the origin of this growth. Von Recklinghausen believes that it develops from remnants of the Wolffian body, but admits the possibility of its origin from the uterine mucosa. Cullen (Johns Hopkins Hospital Reports, vol. vi., 1897), who has studied carefully two cases, believes the latter to be the only possible origin.

The presence of a myoma usually produces more or less hypertrophy of the muscular coat. This is especially true of the mucous form. Distortion of the uterus is common. The mucosa is usually atrophied over submucous myomata, but elsewhere is unaltered (Cullen).

Broad Ligament.—It is very doubtful if myomata ever arise in the broad ligament. Tumors found there are in reality subserous forms which have developed in the lateral wall of the uterus, and have finally become separated from it.

Prostate.—The myomata of the prostate come next in importance to those of the uterus, and are most frequently found in advanced age. Some of these enlargements of the prostate depend on an actual hypertrophy, in which all parts of the gland participate. In others, the enlargement is principally due to hyperplasia of the glandular elements, and this form passes most readily into adenoma. In the third class Virchow has shown that the enlargement is principally due to a hyperplasia of the smooth muscle fibres, which make up a large part of the gland.

This new formation is sometimes diffuse, but more often is in the form of distinct nodules. The favorite seat for their formation is on the posterior upper portion of the gland, and this distinct tumor formation is generally spoken of as hypertrophy of the third lobe of the prostate. The lateral halves of the gland are the next most frequent seat of this formation. It is rather rare that the anterior part of the gland is affected, although Thompson has described a tumor here as large as a walnut.

Digestive Tract.—The myomata of the digestive tract are, next in order, most frequent. Their microscopic characters do not present any differences from those of the uterine myomata. Cyst-formation and degenerative processes are not commonly found. They occur in the œsophagus, generally near the cardiac end, in the stomach, and in the intestine. Myoma of the appendix has also been reported. They are comparatively rare in all these localities, they seldom attain a large size, and usually do not give rise to symptoms, unless of sufficient size to produce obstruction or invagination. In the duodenum such tumors may obstruct the common bile duct (Delafield and Prudden). These tumors develop from the muscular coats of the canal, soon project into the lumen, are covered only by the mucous membrane, and may become pedunculated. Less frequently they project outward beneath the peritoneum.

Skin.—Myomata in this location are divided by Besnier (Hyde) into two groups: simple and dartoic. The former are rare, less than a dozen cases having been reported. They are generally multiple, occurring chiefly on the upper extremities and in old people, especially men. They are supposed to arise from the erector pili muscles.

The dartoic type is more common, generally occurs singly, and is found most frequently in the skin of the mammæ, scrotum, and labia majora. They may be sessile or pedunculated, and vary from the size of a nut to that of an orange. Mixed forms may occur, as fibromyoma, angiomyoma, and lymphangiomyoma.

Bladder.—Myoma of this organ is rare. It was first described by Virchow, who supposed it to be an outgrowth of the prostate; but a myoma of the bladder pure and simple, arising from the muscularis and extending beneath the peritoneum, has since been described by Belfield (*Wien. klin. Woch.*, 1881, 329), and a somewhat similar one by Verhoogen (Kelly, "Operative Gynæcology"). These tumors may be sessile, but are usually pedunculated. They may be submucous or subserous, and vary greatly in size. In Verhoogen's case it was the size of a child's head. They are usually quite vascular.

Urethra.—Myoma in this location is rare. Büttner

Digitized by Microsoft®

(quoted by Kelly) found an ulcerated myoma the size of a hen's egg in a woman of forty years of age.

Veins.—Small leiomyomata have been found in the saphenous and ulnar veins. A large myosarcoma of the inferior vena cava has been reported.

Kidney.—Minute myomata, usually multiple, are occasionally found in the kidney. They are generally found in the cortex, close beneath the capsule, and may arise either from the capsule or from blood-vessels (Lartigau and Larkin, *Journal of Medical Research*, N. S., vol. l., No. 1, 1901). They give rise to no symptoms during life.

Other locations in which leiomyoma is occasionally found are the spermatic cord (the growth occurring here sometimes as a myolipoma), the liver (where these growths are of slight significance), the Fallopian tubes, ovaries, vagina, and vulva; in all of which locations the type is generally that of a fibromyoma. In mixed tumors of the mammary gland small masses of both smooth and striated fibres are occasionally seen.

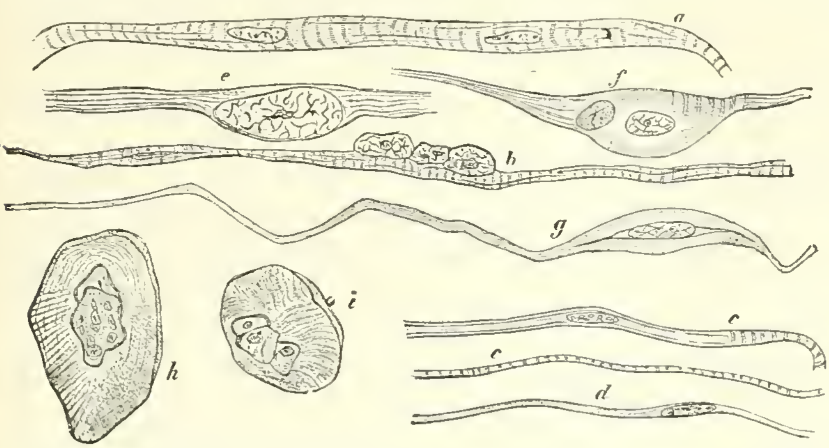

FIG. 3467.—Cells from a Rhabdomyoma. (From Ribbert and Wolfensberger.) *a, b, c,* Fibres of various sizes with transverse striation; *d,* small nucleated fibre without striæ; *e,* spindle cell with longitudinal striæ; *f,* spindle cell with longitudinal and transverse striæ; *g,* spindle cells, non-striated, with elongated processes; *h, i,* round cells with concentric and radial striation.

Rhabdomyoma.—This form of myoma, into whose structure striated muscle fibres enter, must be considered one of the rarest of tumors. The first of these tumors was described by Rokitansky, and since then not more than thirty or forty cases have been reported. Von Recklinghausen found in the hearts of newly born children, in a few instances, small tumor masses which contained striated muscle fibres. Generally the tumors are not pure forms, but are mixed with sarcoma. The muscle fibres are, as a rule, not straight and arranged in masses, but are separated from one another and irregularly distributed in the tumor. The character of the fibres varies. The well-developed fibres appear as nuclear bands of varying width and may have both longitudinal and transverse striations. The poorly developed forms are narrow bands without transverse striations, or spindle cells with long processes and imperfect or no striations; also there may be seen irregular round or oval cells, varying in size, with radial or concentric striation. Associated with these are numerous cells of indefinite origin. (See Fig. 3467.) A sarcolemma is not always demonstrable, but has been described.

The most frequent place of formation of these tumors is in the genito-urinary system, especially in the kidney or testicle, and frequently in the uterus, vagina, bladder, or ovaries. They occur occasionally, however, in other locations, as in the skeletal muscles, parotid gland (Prudden), subcutaneous tissues, mediastinum, and œsophagus. They are found almost exclusively in children, and may reach a very large size; as in the case described by Marchand, in which such a tumor of the left kidney extended from the diaphragm to the pelvis and weighed 2,770 gm. Most probably the explanation given by Cohnheim of their origin, which refers them to unused embryonic material, is the correct one. Their presence in such parts where complications in the embryonic formations take place, and where there is a mingling of the germinal layers, speaks in favor of this. *Richard Mills Pearce.*

MYOPIA—**M**—(μυωπία, μυωπίασις, also μυωπός, μύωψ—from μύω and ὤψ, signifying winking or contracting the eyelids—German, *Kurzsichtigkeit;* French, *vue courte;* English, short- or near-sightedness)—is mentioned by Aristotle, in the Galenical writings, and by the Byzantine medical authors—Oribasius, Aëtius, Paulus Ægineta, and Actuarius. It is described as a congenital condition, in which small near objects are seen distinctly, but distant objects imperfectly or not at all; also as the opposite condition to that occurring in old persons who distinguish small near objects, such as written characters, imperfectly, but see well at a distance. It is further recognized as incurable.

These brief statements, which comprehend practically the sum of the teaching of the earlier writers on medicine, and which were not seriously questioned until after the middle of the last century, include, nevertheless, two fundamental errors: (*a*) M, although very common in children, and dependent in many cases on inherited tendencies or conditions, is very rarely congenital; and (*b*) M is not the opposite condition to presbyopia—which is a disability resulting from impairment of the function of accommodation incident to advancing age—but is really the opposite of hypermetropia—H—(see *Hypermetropia*), which is a congenital condition, and which, like M, consists essentially in a faulty proportion between the radii of curvature of the refracting surfaces of the eye and the length of the antero-posterior axis of the eyeball.

As in H the axis of the eyeball is, as a rule, actually shorter than in the normally proportioned (emmetropic) eye, so in M the axis of the eye is, as a rule, longer than in the emmetropic eye. These two opposite anatomical conditions constitute, in fact, the essential variations from the normal in typical H and M respectively, namely, *axial* H and *axial* M.

Fig. 3468 represents, in section, a myopic eye, the dotted outline indicating the section of the emmetropic eye (*cf.* Fig. 2758, vol. iv., p. 796). It has been explained (see *Accommodation and Refraction*, vol. i., p. 56) that the sum of the successive refractions at the cornea and the two surfaces of the crystalline lens is just sufficient to focus pencils of parallel rays upon the retina at its normal position *E*, and that, through the exercise of its accommodation, the emmetropic eye is able to focus, upon its retina, pencils of divergent rays, such as are received from near objects (*cf.* Fig. 2762, vol. iv., p. 797). In the myopic eye the principal focus—*i.e.*, the focus for pencils of parallel rays—is in front of the actual position of the retina, so that the retinal image of any distant object is made up of overlapping circles of confusion and is, therefore, imperfectly defined.

The unaccommodated myopic eye is, however, adapted for the correct focussing of pencils of divergent rays emanating from an object at some particular short distance, as shown in Fig. 3469, in which a pencil of rays

Digitized by Microsoft®

diverging from r is represented as refracted to a focus on the retina of the myopic eye at M. The distance of this *far-point* of distinct vision (*punctum remotissimum*—r), measured from the eye in metres or fractional parts of a metre, is the reciprocal of the grade of the myopia expressed in dioptries. Representing this distance by R, and the grade of the myopia by M, we have:

www.libtool.com.cn

$$R = \frac{1}{M} \text{ metre} \quad . \quad . \quad . \quad . \quad [1]$$

By the exercise of its accommodation the myopic eye is able to adjust itself for distinct vision at any distance

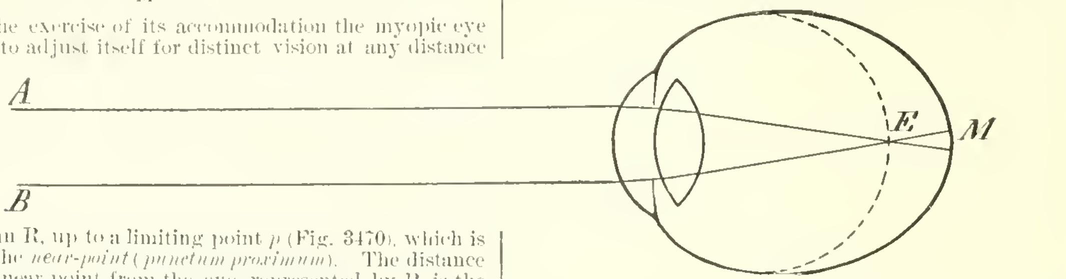

FIG. 3468.

less than R, up to a limiting point p (Fig. 3470), which is called the *near-point* (*punctum proximum*). The distance of the near-point from the eye, represented by P, is the reciprocal of the grade of the myopia plus the range of accommodation, both expressed in dioptries. Representing the range of accommodation by A, we have:

$$P = \frac{1}{M + A} \text{ metre} \quad . \quad . \quad . \quad . \quad [2]$$

From the form of equations [1] and [2], it is evident that, for increasing values of M, both R and P decrease, but that R decreases at a greater rate than P. It follows that for higher grades of myopia, both r and p fall nearer

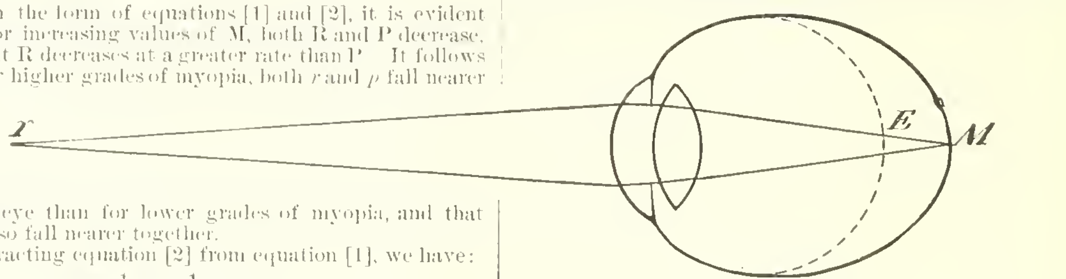

FIG. 3469.

to the eye than for lower grades of myopia, and that they also fall nearer together.

Subtracting equation [2] from equation [1], we have:

$$R - P = \frac{1}{M} - \frac{1}{M + A} \text{ metre} \quad . \quad . \quad . \quad . \quad [3]$$

The linear measure R — P, which represents the difference in the distance of the far-point (r) and the near-point (p) from the eye, and which represents, therefore, the linear distance through which the myopic eye is able to adjust itself for distinct vision by the full exercise of its accommodation (A), is its *region of accommodation*. As R is the reciprocal of M, the region of accommodation, R — P, is at its maximum (infinity) when M = zero (emmetropia). Table I. shows the measure of R, of P, and

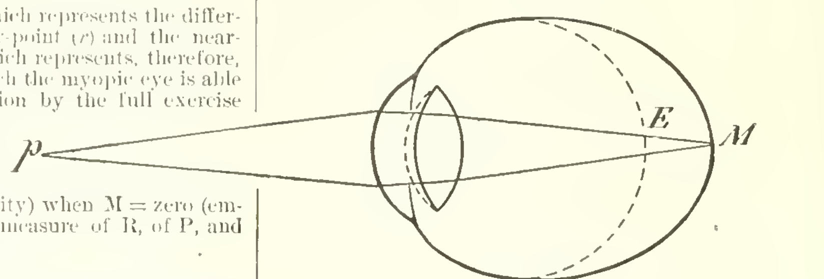

FIG. 3470.

of R — P, respectively, for progressively increasing grades of myopia, from 1. D to 10. D, in a young person with an unimpaired range of accommodation of 10. D.

Inspecting Table I., it will be observed that in high grades of myopia both the near-point (p) and the far-point (r) are very near to the eye, and that the region of accommodation (R — P), although extended, by a few centimetres, in the direction toward the eye, is so greatly contracted, as a whole, as practically to annul the part played by the accommodation in seeing at short range; only in the lower grades of myopia, in which r lies farther from the eye than the reading distance, is there a limited field for a partial exercise of the accommodation to meet the restricted requirements of near vision.

As a consequence of the displacement and contraction of the region of accommodation in myopia, the interrelation of accommodation and convergence, as it exists in emmetropia (see *Accommodation and Refraction*, vol. i., pp. 55–58), is materially altered. Thus, in myopia of M dioptries, the farthest point of distinct vision—r—(under full relaxation of the accommodation) is at a distance of $\frac{1}{M}$ metre from the eye; but, in order to see an object at this distance with the two eyes, the axes of the two eyes must converge to an amount represented by M metre-angles (see vol. i., p. 583, note). It follows that for perfect binocular vision, at or within the distance of the far-point, a normal exercise of the convergence, corresponding to the distance of the (near) object, must be associated either with full relaxation or with less than the normal exercise (relative relaxation) of the accommodation; in other words, there is an essential change in the relation between accommodation and convergence from that which obtains in emmetropia, in which (normal) condition an exercise of the convergence measured by any number of metre-angles goes hand-in-hand with the

Digitized by Microsoft®

exercise of an equal number of dioptries of accommodation.

As a fact, a notable readjustment of the physiological bond by which the two functions of accommodation and convergence are linked together follows closely upon the progressive change in the refraction in most cases of myopia; and this readjustment is often so nearly perfect as to admit of the easy and sustained use of the two eyes together in near work. Thus in most cases of stationary or slowly progressive myopia, up to a grade of about 3. D, no difficulty is experienced in reading ordinary print, with the two eyes, at approximately the normal reading distance of about ⅓ metre; also, in notably higher grades of myopia, very fine print may be read, easily and without fatigue, at some shorter distance corresponding to the distance of the point of intersection of the visual axes. Hence the very old and widely disseminated belief that myopes, as a class, enjoy a substantial advantage in respect of strong and fine vision in near work, and that this advantage, together with the further advantage of partial or complete exemption from the ordinary disabilities incident to presbyopia, may be held to outweigh the single recognized disadvantage of imperfect vision at a distance. That this old belief is, in the main, erroneous, and founded in ignorance or imperfect appreciation of the pathology of myopia as the visual expression of distention of the eyeball from disease, is proved by the anatomical demonstration of extensive and characteristic lesions in the fundus and coats of the eye in high grades of myopia; by the study of these lesions in the living eye in their successive stages of development, as revealed by the ophthalmoscope; by extended statistical researches on the refractive conditions existing in the eyes of school children in the lower and higher classes and grades; and by clinical experience based on successive examinations of the eyes of individual myopes, extending often over many years.

Two fundamental facts, based on exhaustive studies of myopia during the past half-century, are definitively established:

(*a*) Myopia is ordinarily the optical expression of an elongation of the antero-posterior axis of the eyeball, dependent on a pathological distention of the globe. Furthermore, this distention is in many cases rapidly progressive, and not infrequently attains to so high a grade as to become a grave menace to the integrity of the eye as an organ of vision.

(*b*) In many cases of myopia, especially when it is of high grade or of rapid development, the compensatory readjustment of the convergence to the displaced region of accommodation is in so far incomplete as to give rise to a state of persistent conflict between accommodation and convergence. As alternative issues of this conflict there may result either an habitual exercise of the accommodation in excess of that which is required for perfect vision at the distance of the point of intersection of the visual axes, or accurate accommodation for the actual reading distance accompanied by fatigue or insufficiency of the recti interni muscles—muscular asthenopia, or relative or actual strabismus divergens (see *Asthenopia* and *Strabismus*).

A myopic eye looking through a concave lens of any (negative) power up to the measure of its myopia is rendered virtually less myopic. With a concave lens of N dioptries, taking N < M, the uncorrected part of the myopia is M — N dioptries.

If we take N = M (Fig. 3471), we have M — N = zero, in which case the myopia is completely corrected (neutralized) by the concave lens, and the eye is rendered virtually emmetropic, *i.e.*, the far-point (*r*) is carried off to an infinite distance. At the same time the near-point (*p*) is removed farther from the eye, to a distance, $\frac{1}{A}$, determined by the magnitude of the range of accommodation (see *Accommodation and Refraction*, vol. i., p. 57).

The effect of a concave lens added to a myopic eye is, then, to remove both the far-point (*r*) and the near-point (*p*) to a greater distance from the eye; but the recession of *r* is greater than that of *p*. The region of accommodation (R — P) is therefore enlarged, attaining its maximum (infinity) when the (negative) power of the lens is numerically equal, in dioptries, to the grade of the myopia.*

As a result of this re-establishment of a normal region of accommodation, with the far-point (*r*) at infinity, the requirements for the conjoined exercise of the accommodation and the convergence in binocular vision become identical with those which obtain in emmetropia—the distance of the near-point, as determined by the exercise of a certain number of dioptries of accommodation, now coinciding with that of the point of intersection of the visual axes, as determined by an exercise of the convergence measured by the same number of metre-angles. As a rule, in uncomplicated myopia of low or medium grade, with unimpaired range of accommodation and normal acuity of visual perception, little or no inconvenience is experienced in utilizing fully the enlarged region of accommodation and, at the same time, re-adjusting the convergence to the changed optical conditions imposed by the wearing of neutralizing concave glasses. In the higher grades of myopia, especially if concave glasses are to be given for the first time, only a partial optical correction may be accepted in the beginning, and the full correction may have to be reached by a later change, or perhaps through one or more changes, to glasses of greater power.

With advancing years, as the crystalline lens becomes progressively harder and less capable of undergoing changes in form (see *Accommodation and Refraction*, vol. i., p. 59), the range of accommodation (A) diminishes in myopia just as in emmetropia and in hypermetropia. With decreasing A, approaching zero in old age, $P = \frac{1}{M + A}$ . . [2] increases, approaching $R = \frac{1}{M}$ . . [1] as a limit; the region of accommodation (R — P) being then reduced to zero through the recession of *p* to *r*. At the practically unchanged distance of *r*, the vision of the myopic eye is still perfect, and whenever *r* lies within a convenient reading distance from the eyes, as in myopia of not less than 3. D or 4. D, convex glasses are not needed for reading. In myopia of less than 3. D the need of convex reading glasses is first experienced later in life than in emmetropia, and relatively weak glasses then suffice. Similarly, in the higher grades of myopia, concave glasses weaker than those which completely correct the eyes for distant vision must be given for reading at the best distance from the eyes.

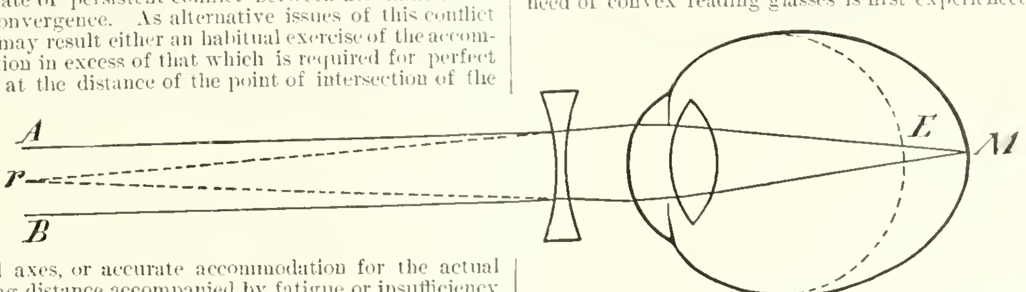

FIG. 3471.

*If we take N > M, the effect of the concave lens will be to overcorrect the myopia, and the eye will be rendered virtually hypermetropic (see *Hypermetropia*.)

www.libtool.com.cn
Digitized by Microsoft®

Although the tendency in axial myopia is, as a rule, in the direction of a progressive increase in grade as a result of progressively increasing distention of the eyeball, in a notably large proportion of all cases of myopia this tendency becomes arrested sooner or later, and the length of the axis of the eye may then continue stationary for many years or during the remainder of life. In such cases a small decrease in the grade of the myopia, amounting to a dioptrie or two, or perhaps a little more, may generally be detected in old age, as a result of a physiological decrease in the refractive power of the crystalline lens (see *Hypermetropia Acquisita*, vol. iv., p. 800). On the other hand, an increase of a few dioptries in the refractive power of the crystalline lens is not infrequently observed as an incident of beginning senile cataract, and from this cause a true lenticular myopia may make its appearance in old age, or a pre-existing myopia may develop a considerable increase. Thus certain elderly persons, who have used convex glasses in reading for perhaps many years, discover that they can read as well or better without glasses (so-called second sight), and in certain cases of myopia it is found that the concave glasses which have been habitually worn are no longer perfectly satisfactory in distant vision. A revision of the glasses worn by myopes, whether for distance or in reading, is therefore generally indicated in advanced life, changing oftenest to somewhat weaker concave glasses, but occasionally to stronger, according as the lenticular refraction is found to have diminished or to have undergone a pathological increase.

The size of the retinal image of any object situated at or within the distance of the far-point of the myopic eye is greater than in the case of the same object focussed by an emmetropic eye through the exercise of its accommodation, in the ratio of the respective distances of the second nodal point of the eye (k'') from the retina. The size of the retinal image increases, therefore, for every increase in the length of the eyeball, so that a young person, with uncomplicated myopia of high grade, may enjoy, for a time at least, exquisitely fine sight for small near objects. With the correction of the myopia by concave spectacles, the nodal point is moved nearer to the retina, and, in the case of a neutralizing concave glass worn at the anterior principal focus of the eye (about 13 mm. in front of the cornea), the distance of the nodal point from the retina, consequently the size of the retinal image, becomes the same as in emmetropia. Owing to this diminution in the apparent size of small near objects, it not infrequently happens that a myope of high grade, although accepting neutralizing concave glasses for distance, is disinclined, or, in the case of subnormal visual acuity, is unable to use them in reading. This may become a source of grave embarrassment to the ophthalmic practitioner, who recognizes the dangers attendant upon the habitual use of the uncorrected eyes in fine near work, but may find it difficult to persuade a young patient to abandon such work as a means to the conservation of his sight.

Origin and Development of Myopia.—In young children hypermetropia is the typical refractive condition. Of 100 eyes of infants from one to four weeks old, measured, under atropine, with the ophthalmoscope, by Horstmann,[1] 88 (aggregating 244. D) were hypermetropic, 10 were emmetropic, and 2 (aggregating 4. D) were myopic. Of 100 eyes of children between one and two years of age, similarly examined under atropine, 84 (aggregating 188. D) were hypermetropic, 10 were emmetropic, and 6 (aggregating 8. D) were myopic. Of 100 eyes of children between four and five years of age, 74 (aggregating 188. D) were hypermetropic, 13 were emmetropic, and 13 (aggregating 22. D.) were myopic.

Of 10,060 pupils of public schools in Breslau (including 1,486 children in five village schools) examined subjectively by H. Cohn,[2] the percentage of cases of myopia increased progressively from an average of 6.7 per cent. in twenty elementary schools, to an average of 26.2 per cent in two gymnasia (colleges). The grade of myopia also increased from an average of 1.8 D. in the elementary schools, to 2. D in the gymnasia.

Erismann[3] measured the refraction in 4,338 pupils of schools in St. Petersburg; he found: Of hypermetropes, 43.54 per cent.; of emmetropes, 26.10 per cent.; of myopes, 30.36 per cent. Tabulated in percentages for successive years of school life, Erismann's statistics show, for seven consecutive school grades, a progressive decrease in hypermetropia from 55.6 per cent. in the lowest to 36.2 per cent. in the highest grade, and an increase in myopia from 15.8 per cent. in the lowest grade to 42.8 per cent. in the highest. The percentage of emmetropic is given as 28 per cent. in the lowest grade, 25.1 per cent. in the sixth grade, and 21 per cent. in the seventh (highest) grade; in grades I. to VI. it fluctuates between 28 per cent. and 25.1 per cent., averaging 26.1 per cent. Studied as a whole, the numbers show (*a*) a progressive increase in the percentage of cases of myopia, (*b*) a concomitant progressive decrease in the percentage of cases of hypermetropia, and (*c*) a nearly constant percentage of cases of emmetropia. They thus emphasize the fact, previously suspected, but denied by Donders, that the ranks of myopia are recruited, through emmetropia as a transient condition, from eyes originally hypermetropic. It follows that a condition of emmetropic or even of hypermetropic refraction may be present in an eye which has already undergone notable distention, and that the beginning of the pathological process typical of myopia must be dated back, in many cases, to a period possibly long antecedent to the development of myopic refraction. In this fact is found an explanation of the cases in which pathological conditions characteristic of myopia of high grade are seen in eyes of relatively low myopic refraction, or, more rarely and less highly developed, in eyes which are optically emmetropic or hypermetropic.

An enormous mass of statistical material gathered by many observers in many lands shows conclusively that with moderate and easily explicable variations in the percentages, the conclusions based on the original researches of Cohn and Erismann are essentially true for all highly civilized communities.

Distribution of Myopia.—Myopia is pre-eminently a disease of the higher ranks of society, and of highly cultured peoples. It is widely prevalent in Germany, where its causes may be referred, in part, to the national "studious habit"; partly to long hours of school work, supplemented by protracted study hours at home, by artificial light; partly to the general use of the old German text, in which the differentiation of certain letters is especially difficult; and possibly to racial predisposition.

In a relatively small proportion of cases, myopia of high grade and of malignantly progressive type is observed in laborers or other persons who have never been subjected to the conditions generally recognized as especially causative of myopia; in these cases an inherited predisposition to myopia may be suspected. Myopia often occurs in certain families, appearing in several children of a myopic parent or parents, and sparing others. Soldiers and sailors are, as a rule, exempt; but this is mainly a result of selection. Savage races are largely exempt from myopia; Furnari[4] found no cases among the Kabyles. "Survival of the fittest" and the absence of exciting causes of myopia afford an obvious explanation.

Myopia as Related to Age.—The statistics of myopia show that it is essentially an acquired condition; also that, in school or college, myopia of high grade occurs almost exclusively in the more advanced classes. Every case of myopia must, therefore, be regarded as having passed through a progressive change from a lower to a higher grade, and, especially in the case of a young person, as, possibly or probably, still in a stage of continuous or remittent progression. The study of the refraction of individual young moypes, examined from year to year, enforces the same conclusion. The age at which a more rapid increase is ordinarily first noticed follows very closely upon that at which considerably increased

Digitized by Microsoft®

demands are made upon the eyes in study, namely, about fourteen years. From about the fifteenth to about the twenty-fifth year the increase is generally most rapid. This corresponds, in a general way, to the years of advanced preparatory and collegiate study, with some added years in the university or in a professional school. It also includes the ordinary period of apprenticeship to trades which may demand close and continuous application. Furthermore, a somewhat rapid rate of increase may be expected to go on, for a time, after the special determining conditions have been mitigated or have ceased to be actively operative.

www.libtool.com.cn

In considering the influence of age in its relation to the development of myopia, the greater extensibility of the scleral tissue in children may be assumed to play an important part. Also, in older subjects, the stretched and thinned sclera of the highly myopic eye may oppose inadequate resistance to continuing distending forces to which it has already yielded. As a fact, myopia is seldom developed, in a previously healthy emmetropic eye, after the term of youth has been passed; the apparent exceptions are almost always instances of increase in the grade of pre-existent, but unrecognized or unacknowledged, short-sightedness.

Myopia of high grade (10. D or more) is occasionally observed in a child of eight or nine years, and should then be contemplated with great solicitude in view both of the disability incident to the high grade to which it may be expected to attain and the fear that, later in life, the integrity of the eyes may be endangered.

It has been erroneously assumed that myopia tends to diminish with advancing age. On the contrary, it is always either progressive or, at the best, stationary. An apparent exception, based on certain cases in which a myopia of low grade disappears as a result of a decrease in the refractive power of the crystalline lens in old age, also the occasional late occurrence of a lenticular type of myopia dependent on a pathological increase in the refractive power of the crystalline, have been already mentioned.

Classification of Myopia.—Donders[5] has divided myopia into three categories, basing them on the course and progress of the disease, namely: (1) stationary M; (2) temporarily progressive M; (3) permanently progressive M.

(1) The type of the stationary class is represented mainly by cases of myopia of low grade, which increase slowly up to a limit not much exceeding 2.5 D to 3. D at the age of twenty-five years; after the twenty-fifth year the increase is insignificant. In this category are included certain cases of myopia of higher grade, which follow a similar course of slow and limited progression. After the age of about fifty years, distant vision often improves, owing in part to the smaller pupils, in elderly people, lessening the diameter of the circles of confusion in the retinal image, and in part to the slight physiological decrease in the refractive power of the crystalline lens.

(2) The temporarily progressive class includes those cases which increase rapidly up to about the twenty-fifth year, and become stationary, generally before the thirtieth year, after having attained a grade averaging about 8. D. At this grade the myopia remains practically stationary during the remainder of life, but with a tendency, in certain cases, to recrudescence, which may bring the case under the category of—

(3) Permanently progressive myopia. In this class a myopia of 6. D or more, at the age of twelve years, develops continuously, but generally at a decreasing rate, up to a limit which may reach or exceed 20. D at the age of sixty years. "The worst is then to be feared. It is rare at sixty years of age to find a tolerably useful eye with myopia of 16. D or even of 13. D" (Donders).

Ophthalmoscopic Appearances.—The region of the fundus about the entrance of the optic nerve (optic disc) is the seat of certain very characteristic changes which, although occasionally seen in eyes of emmetropic or even of hypermetropic refraction, are so constant in myopia that they are justly regarded as typical of this disease.

Especially characteristic is an alteration in the choroid which, from its general configuration, is known as the "crescent" or "sickle" (Figs. 3472, 3473, and 3474).

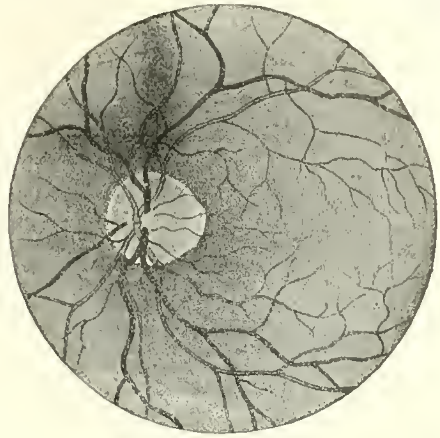

Fig. 3472.—Left Eye.

Fig. 3473.—Left Eye.

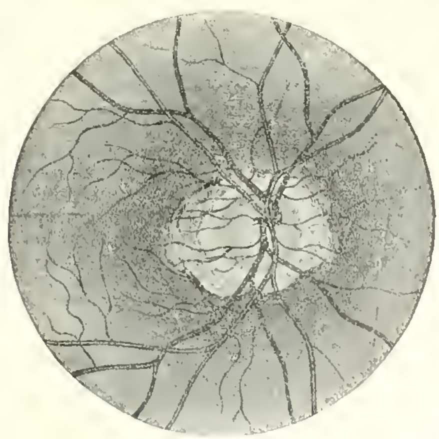

Fig. 3474.—Right Eye.

Figs. 3472, 3473, and 3474.—Represent Different Types of Crescents as seen in the erect image. (From Jaeger.)

This appears, ordinarily, as a whitish or grayish-white area, crescentic in outline, the concavity of the crescent closely hugging the outer margin of the disc, the con-

Digitized by Microsoft®

vexity either sharply outlined by a more or less conspicuously pigmented border or shading gradually into the normal choroidal tissue in the general direction of the fovea. Traversing this area the finer retinal vessels, which supply the region about the macula, are seen somewhat straightened in their course, as if stretched longitudinally. The crescent may vary in width from a thin sickle shaped band at the disc-margin, from which it is with difficulty to be distinguished, to a large area, approximately parabolic in outline, which, from its resemblance to a conic section, has been named "conus." In other cases, especially in myopia of high grade, the approximately regular curvilinear outline is lost, the altered area taking on irregular and often bizarre shapes.

The myopic crescent is essentially the expression of a localized atrophy of the choroid, accompanied in many cases by a stretching and thinning of the sclera adjacent to and mainly at the temporal side of the optic disc. It then becomes an area of least resistance which may be the seat of a gradually increasing protuberance or, in extreme cases, of a deforming boss, at the posterior pole of the eye (*staphyloma posticum*).

The pathological processes leading to the development of the crescent are still imperfectly understood. In general, the ophthalmoscopic appearances are such as to suggest a sliding of the choroid on the sclera, with attendant stretching of the choroidal tissue at the temporal side of the disc. As a result of this stretching, a localized choroidal inflammation of low grade, passing into atrophy, may be invoked as offering the best explanation of the origin and subsequent enlargement of the crescentic area. The irregular extension of the conus in advanced stages of the disease is clearly the expression of atrophy following choroiditis. Atrophic spots in different parts of the fundus, indicating areas of previous circumscribed inflammation of the choroid, are of not infrequent occurrence in high grades of myopia.

The optic disc in myopic eyes often presents an oval contour, as if shortened in its horizontal diameter. This appearance may be simply the effect of foreshortening due to an oblique position of the disc with reference to the direction from which it is viewed. In many cases, however, there is almost certainly an actual variation from the typical circular form.

Capillary hyperæmia of the disc is a frequent condition, especially in young myopes whose myopia is in the progressive stage; it may be regarded as the local expression of general ocular hyperæmia. At a later period, after the congestion has disappeared, the disc often assumes a pallid tint indicative of anæmia, and may even present the appearance of a shallow excavation.

Liquefaction of the vitreous, with the presence of finer or coarser floating specks or shreds, is very common in myopia of high grade and long standing. Myopic eyes are also especially subject to detachment of the retina,

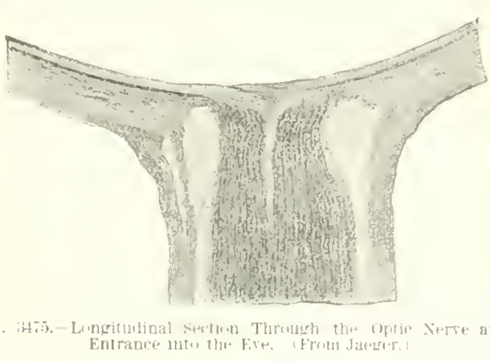

FIG. 3475.—Longitudinal Section Through the Optic Nerve at its Entrance into the Eye. (From Jaeger.)

a disaster which has been attributed to a dragging of the vitreous upon the retina. A bow shaped reflex concentric with the disc (best seen through a concave lens, a little weaker than the measure of the myopia, behind the hole in the mirror of the ophthalmoscope) has been described by Weiss[6] as a sign of posterior separation of the vitreous from the retina.

Pathological Anatomy.—A meridional section through the fovea and the distal end of the optic nerve (Fig. 3475) shows, in cases of highly developed conus, a wide separation of the inner and outer nerve sheaths where the nerve joins the globe. Beyond the limits of the conus the outer sheath becomes continuous with and reinforces the sclera, but within the area corresponding to the conus, where the reinforcing fibres of the outer sheath are absent, the outer coat of the eye appears very much thinner than in its normal condition or than at the posterior region of the globe generally.

A general thinning of the sclera, the decrease in thickness becoming gradually more marked posteriorly, is characteristic of the higher grades of myopia.

A typical change in the form of the ciliary body, as shown in a meridional section of the anterior segment of the eyeball, conjoined with an appearance as of an increased development of the radiating fibres and a decrease in the number of the circular fibres of the ciliary muscle, as first described by Iwanoff,[7] may be regarded as an expression of the general stretching of the choroid.

Causes of Myopia.—The causes leading to the typical pathological changes in myopia are but imperfectly understood. Donders[8] laid much stress on the hypothesis of an inherited predisposition, and this opinion is supported by many clinical facts. Certain families show a very large proportion of myopes, others comparatively few. The inheritance of a special anatomical condition of the sclera or optic nerve, implying less than normal resistance to the operation of distending forces, is not more improbable than the inheritance of a hypermetropic configuration of the eyes. Corneal asymmetry, the ordinary cause of astigmatism, is distinctly transmissible from parent to offspring, and astigmatic refraction is too frequently associated with myopia to admit of reasonable doubt that the former stands in a causal relation to the latter. The general distention of the globe, mainly in its posterior half and especially about the posterior pole, corresponds to the thinner and presumably less resistant scleral region posterior to the insertions of the recti muscles. The immediate causes of the distention, whether they are to be sought in original structural weakness of the tissues or in increased intraocular pressure, or both, are matters of dispute. Continuous close application to fine near work, in which strong accommodation and convergence go hand-in-hand, is a most important etiological factor. After elongation of the globe has begun, convergence for the ordinary reading or working distance tends to evoke accommodation for some shorter distance; but reading or working at this shorter distance implies an increase in convergence, which in turn incites to increased exercise of the accommodation. As a result of this inter-action of convergence and accommodation, the tendency is to a progressive shortening of the reading distance, and, *pari passu*, to an increase in the grade of the myopia.

Weiss[9] has suggested that a short optic nerve, dragging on the sclera in inward rotation of the eyes, may be a factor in the development of posterior staphyloma. Stilling[10] has called attention to a particular conformation of the orbit, giving rise to an alteration in the direction of the pull of the reflected tendon of the superior oblique muscle, as a supposed cause of injurious traction upon the globe.

Treatment of Myopia.—"The cure of myopia belongs to the *pia vota*" (Donders). Erroneous assumptions regarding the causes of short-sightedness have led in the past to the proposal of a variety of futile or harmful plans of treatment. Thus attempts have been made to diminish the convexity of the cornea by the prolonged application of pressure, or by corneal paracentesis repeated at short intervals. Practice in reading at progressively increasing distances from the eye has been strongly advocated, in the belief that a supposed excessive lenticular refraction might thus be gradually lessened. Division of one or more of the recti, or of the

Digitized by Microsoft®

oblique, muscles, in order to diminish a supposedly injurious muscular pressure on the globe, has also been advised and practised.

Therapeutic measures directed to the removal of conditions of irritation which not infrequently appear in connection with rapidly progressive myopia, belong to the realm of rational therapeutics. Rest of the eyes from near work, protection from exposure to excessive light, regulation of the general physical condition, and, in some cases, the local abstraction of blood from the temples—preferably by means of the artificial leech of Heurteloup—are all of value. The so-called atropine cure is also employed, with good effect, in certain cases of rapidly increasing myopia; the eyes are kept under the full influence of atropine for about two weeks, in a moderately darkened room, after which the patient is permitted to go about with the eyes well protected by dark glasses; the use of the eyes in near work is forbidden for another fortnight.

Use of Concave Glasses.—The wearing of concave glasses to improve the distant vision of myopes is first mentioned by writers of the latter half of the sixteenth century; but the intelligent prescribing of such glasses, with a view to their effect upon myopia considered as a disease, belongs exclusively to modern ophthalmology; and even now there is notable divergence of opinion on certain points. In general, it may be accepted as a well-established principle that in uncomplicated myopia of low or medium grade, with normal acuity of visual perception and unimpaired range of accommodation, concave glasses should be chosen of such strength as to correct the vision accurately for distance, and that the same glasses should be worn for near work. Furthermore, it should be the aim to raise the vision, as controlled by tests made at a distance, to the highest point of acuity of which the eyes are capable; and to this end even low grades of astigmatism should be carefully investigated and corrected. The distance at which the glasses are worn, their proper centration before the two eyes, and the direction of the plane of the glasses with reference to the line of sight should all be definitely prescribed and controlled. Inasmuch as the same glasses are worn both for distance and in reading, they should be tilted so that the angle made by the visual axes to the plane of the lenses shall be as nearly equal as practicable in looking forward at distant objects and downward on the book ("pantoscopic" position). The effect of the tilting of the glasses in increasing their effective refractive power in the vertical meridian, and to a less degree in the horizontal meridian, should, in every case in which glasses of high power are required, be considered and allowed for in deciding upon the formula for the lens. The eyes should, further, be reexamined, at first at short intervals and later at intervals of a few months, in order that any change in the grade of the myopia may be promptly discovered and corrected. Explicit instruction should be given as to the kind and amount of work which may be permitted; reading or sewing without glasses, and especially the use of the eyes in near work by failing daylight or by insufficient artificial illumination, should be absolutely forbidden. The glasses (ordinarily spectacles made with elastic sides curved to fit accurately behind the ears*) should be worn continuously during the waking hours.

The wearing of neutralizing concave spectacles is ordinarily attended with great comfort to the patient, and the progress of the disease is, as a rule, either greatly retarded or wholly checked. Every renewal or change of glasses should be rigorously controlled, and it should be fully explained to the patient or, in the case of a child, to the parents, that the condition is one that must be kept under continuous observation for years.

Cases of myopia complicated by low acuity of vision, whether dependent on impaired perceptive power of the retina or on irregularity or imperfect transparency of the cornea or crystalline lens, present especial difficulties which militate against the best results from wearing glasses. In general, such patients cannot see small objects unless they are brought very near to the eye, a condition unfavorable to binocular vision. Accordingly, they often form the habit of using only one eye in reading. By this, perhaps unconscious, neglect of the retinal image in one of the eyes, the conditions which ordinarily give rise to a state of conflict between accommodation and convergence are eliminated, so that reading to a limited extent without glasses may be practically innocuous. Concave glasses may, however, be accepted in distant vision, although not in all cases.

Operation for the Removal of the Transparent Crystalline Lens.—The proposal to lower the grade of myopia in extreme cases, or to render a strongly myopic eye either moderately hypermetropic or possibly emmetropic, by the removal of the transparent crystalline lens, has been frequently discussed, although generally rejected by ophthalmic surgeons, to be revived and somewhat extensively practised in recent years.[11] Simple discission of the lens capsule, discission followed by removal of the swollen lens through a small corneal incision, and, in older subjects, extraction combined with iridectomy are the methods which have been recommended and employed. Apart from the immediate risks incident to the operation, and the uncertainty as regards its possible effect in arresting or retarding the progressive distention of the globe, the possibility of later adverse complications, such as not infrequently occur in patients upon whom an apparently ideal operation has been performed for cataract, would seem to forbid resort to an operation on the transparent lens except in extreme cases, and even then only after an exhaustive study of the particular case in all its aspects. In addition to the ordinary chances of disaster following operations for cataract, it is probable that the removal of the lens increases the tendency to retinal detachment, which is always to be feared in the higher grades of myopia. On the other hand, the fact that in the highest grades of myopia the ordinarily beneficial effect of concave glasses, in sharpening the definition of the retinal images, is largely neutralized by the diminution in the size of the images may afford an argument in favor of the operation. The incidental sacrifice of the accommodation should not be accorded undue weight in the exceptional cases in which alone the operation may be regarded as permissible.

Effect of the Removal of the Lens on the Refraction of Highly Myopic Eyes.—The average focal length of the crystalline lens, *in situ*, is estimated at 43.707 mm., which represents a power equal to 22.877 D. But the removal of the crystalline lens changes the eye from a compound dioptric system, of three refracting surfaces, to one in which the entire refraction is effected at the surface of the cornea, and in which a single principal point at the vertex of the cornea and a single nodal point at the centre of curvature of the cornea replace the two principal points and the two nodal points of the complete eye.

In the case of a previously emmetropic eye of average dimensions, the refractive insufficiency caused by the removal of the crystalline lens is exactly corrected by an addition of 13.428 D at the cornea, which may be represented by an effectively equivalent meniscus, of negligible thickness, assumed to be worn in contact with the cornea. But a convex spectacle lens, of a thickness such as is ordinarily required after an operation for cataract, is necessarily worn at a distance of approximately 15 mm. in front of the cornea, in which position it becomes a part of a new compound system in which a convex lens of 11.177 D suffices to correct the aphakial eye for distant vision.

A myopic eye whose length of axis is equal to the posterior focal length of the cornea (31.692 mm.) has a focal length (measured from the second principal point, h'') of 29.336 mm., and the distance of the concave spectacle lens which is worn to correct the myopia, measured from the first principal point, h', is about 2 mm. greater than its distance from the cornea. In the case which we have assumed, the myopia is measured by a thin concave lens

* So much of a concession to fashion may often be made as to permit the occasional use of a carefully adjusted *pince-nez*, instead of the spectacles, in distant vision.

Digitized by Microsoft®

of −16.326 D, supposed to be placed at the position of the second principal point of the eye, but a stronger concave lens, of no less than −21.234 D, is required for distinct distant vision when worn 15 mm. in front of the first principal point, or 13 mm. in front of the cornea.* It follows that in a case of axial myopia measured by a spectacle lens of −21.234 D, the eye, after the removal of its crystalline lens, will be adapted for distinct distant vision without a glass; and a spectacle lens of + 3. D or + 4. D will then suffice for reading.

K. Bjerke[12] has collected, from different sources, 93 reported cases of myopia in which emmetropic refraction is said to have followed the removal of the crystalline lens by operation. In 29 of these cases (31 per cent.) the pre-existent myopia, as measured by a concave spectacle lens, is given as 20. D. In 44 cases (47.3 per cent.) it is given as between 20. D and 26. D, and in 44 cases (47.3 per cent.) it is given as between 14. D and 19. D. The tabulated figures would seem to point to about 19.5 D as the mean grade of myopia in which emmetropic refraction may be expected to follow the removal of the crystalline lens from the eye. The difference of about −1.7 D, between the mean of the observed results and that calculated from the dimensions and corneal curvature of the schematic (average) eye, may be explained, in part at least, by errors of observation incident to the employment of collections of trial lenses of insufficient range and with too great intervals between the higher numbers. The very large number of cases (thirty-one per cent.) given as of 20. D, which corresponds to the strongest concave lens in the trial cases in ordinary use, points to a probable higher grade of myopia than that reported for these especially typical cases.† If we could assume a slightly greater radius of corneal curvature in the average highly myopic eye as compared with the emmetropic eye, the discrepancy between the mean observed grade and the calculated grade of myopia corresponding to emmetropic aphakial refraction would practically disappear. The assumption of an exceptionally short radius of corneal curvature in the higher grades of observed myopia, and of a curvature of exceptionally long radius in the lower grades, as tabulated, would similarly explain the comparatively few aberrant cases in which a very wide departure from the mean has been observed. As regards possible or probable differences in the focal length of the crystalline lens or differences in its effective power due to variations in its distance from the cornea, in individual eyes or as related to ametropia, trustworthy data are as yet almost wholly wanting.

Prevention and Control of Myopia.—In the evolution of the race the eyes have become admirably adapted to the requirements of binocular vision both at long and at short range. But the demands upon the eyes, incident to higher civilization, have doubtless been always in excess of the ability of certain eyes to withstand assiduous and prolonged application to near work. Certain myopes must always have had a notable advantage over emmetropes in many kinds of exceptionally fine work, such as engraving gems, embroidery, writing and illuminating manuscripts, etc.; and even now it is said that only myopes are successful in the production of the finest needle-wrought lace. In view of the fact that the gravest disabilities of the myope appear somewhat late in life, it is hardly conceivable that the predisposing causes, of myopia can ever be appreciably lessened through the operation of natural or artificial selection. It remains to consider some of the more common exciting causes, incident to the lives of children, with reference to the possible amelioration of existing harmful conditions.

In civilized communities the school is an all-important factor in the life of the child, and it is during school life that myopia ordinarily develops and attains to a notably high grade. So striking is the observed relation of myopia to the grade of the pupil in school, that the designation *Schulmyopie* (school myopia) has been widely adopted by German writers. As regards ocular hygiene, the prevalent methods in teaching and the conditions under which they are carried out are radically faulty. As a rule, there is an excessive amount of book-work, required of all pupils alike and relegated in great part to hours of study at home by uncontrolled and often badly arranged or insufficient light; many of the best hours of daylight, during the school sessions, being too often given up to exercises or occupations unrelated or remotely related to the curriculum of studies. School-rooms, especially in large school-buildings, are often inadequately or unequally lighted, and the desks are not always so placed with reference to the windows as to afford the best illumination to the greatest number of pupils. Preliminary investigation of the vision of children entering upon school life, and periodical examination of the eyes from year to year, with a view to the early detection of possible visual defects, are scarcely thought of. Indifference, on the part of teachers, to recognized symptoms of beginning myopia; inciting children with known ocular defects to perform tasks which are necessarily attended with danger to the eyes; and, in general, sacrificing individual pupils to inflexible arrangements of class work are some of the besetting faults of routine wherever children are brought together in large classes.

A general recognition, on the part of physicians, that myopia is essentially a progressive and often a dangerous disease; that it may be prevented in certain cases and arrested in its progress in other cases, but never cured; that prompt attention and careful and continuous hygienic control, together with the exercise of the highest professional skill in the adaptation and renewal of glasses, are necessary in order to check its progress and guard against possibly grave pathological changes later in life; and that the haphazard resort for glasses to venders who offer advice gratuitously, and make their profit by selling a possibly badly selected *pince-nez* or pair of spectacles, is an unintelligent evasion of a serious problem in therapeutics, will go far toward creating and disseminating juster views than now prevail.

The not uncommon habit, with children, of reading an interesting book by failing daylight or by insufficient or badly arranged artificial illumination, is especially harmful in the early stages, as indeed in any stage, of myopia; fine sewing or embroidery, as an habitual occupation for leisure hours, and long-continued application to fine work of whatever kind are also to be deprecated.

Imperfect vision at a distance, as demonstrated by easily available visual tests such as the test-letters of Snellen or as revealed by inability to follow blackboard exercises at school, should be promptly reported by the teacher, and the child excluded from school until an investigation of the condition of the eyes has been made by

* The assumption of a shorter distance from the cornea, in the case of a strong concave as compared with a strong convex spectacle lens, is justified by the fact that a concave lens, however strong, is very thin at its centre. But a double-convex spectacle lens of 11. D has a thickness of about 4 mm. at its centre; a plano-convex lens, and still more a meniscus, is even thicker.

As the optical distance of a spectacle lens from the eye is measured to the second principal (= nodal) point of the lens, which in the case of a double-convex lens lies nearly half the thickness of the lens within its substance, the optical distance of a double-convex lens from the eye is greater, by nearly half its thickness, than its distance, or that of a double-concave lens, as measured from the surface of the cornea to the back of the lens. In the case of a plano-convex lens, worn with its plane surface toward the eye, the optical distance exceeds the measured distance by about the thickness of the lens, and in the case of a meniscus, worn as a periscopic lens, the difference is still greater. Conversely, a concavo-convex lens, worn with its concave surface toward the eye, has its principal (= nodal) points outside of, and behind the lens, so that the optical distance of such a lens is less than its measured distance, and still less than the measured distance of any convex spectacle lens.

In all cases in which lenses of high power are worn, and especially when a thick convex lens is given in aphakia, or a very strong concave lens in myopia of high grade, the form of the lens becomes a factor of too great importance to be neglected.

† The appearance, in the table, of 11 cases of M = 16. D and 14 cases of M = 18. D, with only a single case of M = 17. D and 5 cases of M = 19. D, has been explained by Bjerke as resulting probably from the general omission of the numbers − 17. D and − 19. D from the series of trial-lenses in common use. The occurrence of 29 cases of M = 20. D, with only 2 cases of M = 21. D and 5 cases of M = 22. D, may be interpreted as indicating a similar source of error growing out of the general omission, from the series, of trial-lenses of higher power than − 20. D.

MYOTICS. See *Mydriatics and Myotics.*

MYRONIN is a mixture of potash soap, carnauba wax, and doegling oil (chenocoeti), and is employed as a very stable ointment base. *W. A. Bastedo.*

MYRRH.—*Myrrha.* *Gum Myrrh.* "A gum resin obtained from *Commifera Myrrha* (Nees) Engler (*Balsamodendron M.* Nees.—fam., *Burseraceæ*)." The variety of myrrh thus defined is that known in commerce as Somali or Herabol myrrh. It is official in all pharmacopœias, though these are much at variance as to the species named as its source. There appears no good reason to believe that it is derived from any other than the species named in our definition, though the inferior varieties (Arabian and Yemen) and various spurious substances often sold for it are—some of them certainly, others probably—obtained from other species of *Commifera.* This plant is a spiny, large shrub or small tree of northeastern Africa. The myrrh exudes as a thick milky juice from natural and artificial fissures, and slowly hardens to a red-brown mass, which is then collected by the Somali natives, either from the plant or from the ground where it has fallen. "Drossy myrrh," containing a large amount of earthy matter, may result from the accidental entrance of dirt into these fallen masses or from its intentional admixture. The substance is chiefly carried to Aden, whence it is exported to Europe and America, either directly or, as was formerly usual, viâ Bombay. The "Turkish myrrh," which a generation ago was a favorite brand, was simply a carefully selected quality exported viâ Turkey. Either at Aden or in Bombay the myrrh is picked and assorted, yet when it leaves those places it commonly contains a considerable percentage of spurious or inferior fragments.

Description.—In irregular, more or less rounded nodules or tears, from 2.5 to 10 cm. (1 to 4 in.) in diameter, the surface more or less roughened by nodules and small cavities, as though eroded, red-brown, dull, and more or less gray from adhering powder; heavy, hard, and rather tough-splintery in fracture, the freshly fractured surface of a waxy lustre and oily feel, red-brown, usually variegated by gray crescent-shaped spots and intersecting lines; thin fragments translucent, usually strongly so; strongly and agreeably aromatic, the odor characteristic; the taste bitter and somewhat acrid, and producing a hardening and slight wrinkling of the mucous membrane of the mouth, though different from the astringency of tannin; readily powdered when cold and dry, but with difficulty when warm and damp; the freshly fractured surface, moistened with alcohol, colored purplish, as is the brownish-yellow alcoholic tincture, by nitric acid (distinction from bdellium); yielding a brownish-yellow emulsion with water; the ten-per-cent. ethereal extract acquiring a violet color in the presence of bromine vapor; if six drops of a seven-per-cent. petroleum ether extract be mixed with 3 c.c. of acetic acid, and 3 c.c. of sulphuric acid be then added, forming a heavy lower layer, the latter takes only a light rose color, which does not deepen (*distinction from Bissabol myrrh*); not more than seventy per cent. should be insoluble in alcohol, and the ash should not exceed six per cent.

Constituents.—Good myrrh consists of from two to five per cent., or occasionally more, of the volatile oil *myrrhol*, and from twenty-five to forty per cent., rarely nearly fifty per cent., of resin, the remainder being mostly gum, with a very small amount of a bitter principle, and from two to six per cent. of ash. In "drossy myrrh," the earthy matter increases the ash, frequently to fifteen per cent. or more. In the poorer grades of myrrh the amount of gum is larger, at the expense of the resin. Myrrh resin is a complex substance, the composition of which is not fully understood. Myrrh oil, which is sold for use in perfumery, is yellow or greenish-yellow, thick and viscid, and almost as heavy as, rarely appreciably heavier than, water.

Action and Uses.—Myrrh is essentially an aromatic stimulant, with slightly bitter properties, and a mild disinfectant. Its stimulant properties are especially active on mucous or raw cutaneous surfaces with which it comes into contact, so that it is a favorite ingredient of mouth washes, hardening the gums and acting like a mild astringent, and an excellent cleansing and stimulating application to ill-conditioned sores, for which purpose the tincture is diluted to about one-fourth strength. Combined with cathartics, it enhances their activity and is at the same time somewhat carminative. When administered internally it acts as a mild stimulating expectorant and diuretic, through its respiratory and renal excretion. In connection with the latter mode of elimination, it acts as a stimulating emmenagogue. It has from ancient times been credited with specific emmenagogue properties, but these effects have probably been largely imaginary. In all its internal uses it is almost invariably combined with other drugs, as in the pills and the tincture of aloes and myrrh, the pills of iron and myrrh, the compound iron mixture, etc.

The principal preparation of myrrh is the official twenty-per-cent. tincture, the dose of which is 1 to 4 c.c. (fl. ʒ ¼ to i.). The Tinctura aloes et myrrhæ contains ten per cent. each of aloes, myrrh, and liquorice root, and the dose is 4 to 8 c.c. (fl. ʒ i. to ij.). The Pilulæ aloes et myrrhæ each contain 0.13 gm. (gr. ij.) of aloes, about half as much myrrh, and one-third as much aromatic powder, the dose being from two to eight pills. The Mistura ferri composita contains 1.8 per cent. of myrrh, 0.6 per cent. of ferrous sulphate, 0.8 per cent. of potassium carbonate, and 6 per cent. of spirit of lavender, with sugar, etc.

Allied Substances.—*Bdellium* (elsewhere considered) is very similar in composition and properties to myrrh, but is very inferior, being less aromatic and one of its varieties being devoid of bitterness. The myrrh of the Bible is not our myrrh, but the Balm of Gilead or Mecca balsam, from *Commifera* ("*Balsamodendron*") *Opobalsamum* (Kunth.) Engler, now rarely seen in commerce. *Henry H. Rusby.*

MYRRHOLIN—a solution of equal parts of tincture of myrrh and castor oil, is used as a vehicle for creosote in tuberculosis. *W. A. Bastedo.*

MYRTOL.—A constituent part of the essential oil, derived by distillation, from the leaves of *Myrtus communis* L. It is supposed closely to resemble eucalyptol. It is a clear liquid with a powerful but not unpleasant aromatic odor. It is recommended as a disinfectant and deodorant, but has no bactericidal action. In medicine it is used to replace the balsams in bronchitis, blennorrhagia, and vaginitis. In small doses it improves the digestion and stimulates the appetite, but in larger doses it irritates the stomach. Dr. Solomon Solis-Cohen has reported favorably of its use in subacute and chronic affections of the respiratory tract. It is administered in doses of from two to five minims, in capsules, repeated two or three times a day. *Beaumont Small.*

www.libtool.com.cn

MYXŒDEMA.—A chronic disturbance of nutrition characterized by accumulation of mucin in the subcutaneous tissue and caused by loss of function of the thyroid gland. Abundant evidence has proven that myxœdema of adults, cretinism, and the cachectic condition following removal of the thyroid gland for goitre represent the same morbid process occurring under different circumstances. Numerous experiments have demonstrated that similar conditions can be produced in lower animals by removal of the thyroid gland.

Removal of the Thyroid Gland in Lower Animals.—That the thyroid gland is essential to normal metabolism and even to life was shown by Schiff as early as 1859. Its removal is followed either by the acute symptoms known as tetany or by a chronic disturbance of nutrition, myxœdema. Within a few days, often a few hours, after extirpation of the gland in dogs, the animal is seized with tetanic contractions of the voluntary muscles accompanied by active tremor, and death follows, often caused by interference with respiration. In sheep, goats, and monkeys, rarely in dogs, death does not follow these acute symptoms, though this may occur, but a chronic condition supervenes; the animal becomes dull and apathetic, nutrition suffers, and the skin is dry and the hair falls out. The subcutaneous tissue becomes swollen and by chemical examination has been found to contain mucin in greatly increased quantity. Horsley has performed numerous experiments on monkeys; these animals survive the symptoms of tetany which frequently follows the operation, and within a few weeks or months develop in typical form the chronic condition described. The temperature becomes subnormal and exposure to cold hastens the progress of the disease.

Extirpation of the thyroid gland in young animals has a remarkable effect, observed by von Eiselsberg in sheep and goats and by Hofmeister in rabbits. Development is retarded and the animal remains small and stunted in appearance. The growth of the long bones is hindered by interference with the normal transformation of cartilage into bone. The undeveloped animal, like the adult, after extirpation of the gland becomes dull and inert and mucinous material accumulates, particularly in the subcutaneous tissue.

Extirpation of one half of the thyroid gland does not cause the conditions described, but if considerably more than half is destroyed nutrition may suffer, though in some instances little effect has followed when only a sixth of the gland was retained. After partial removal that part which remains, together with accessory thyroid bodies which are not infrequently present, undergoes hypertrophy and replaces the extirpated parenchyma. Schiff first showed that if thyroid tissue were successfully transplanted into the peritoneal cavity of a dog, the thyroid gland of the animal might be removed without fatal effect. Numerous experiments have shown that both tetany and myxœdema may be prevented by transplantation of thyroid tissue. Vessale, moreover, demonstrated that injurious consequences of the operation could be retarded or prevented by the intravenous or subcutaneous injection of an extract made from the gland obtained from other animals, and it was subsequently found that equally beneficial results could be produced by feeding animals with the raw gland or with dried extracts made from it.

Removal of the Thyroid Gland in Man: Operative Myxœdema.—In 1882 Reverdin described certain changes which follow total removal of the thyroid gland for goitre, and the following year, under the name cachexia strumipriva, Kocher described a chronic condition following thyroidectomy. The results which follow loss of thyroid function in man do not differ from those observed in lower animals. Symptoms do not follow partial removal of a goitre if a considerable mass of parenchyma still remains, while in some instances their absence is due to the presence of an accessory thyroid gland which undergoes hypertrophy. In some cases acute symptoms almost immediately follow the operation. The muscles, particularly those of the upper extremity, undergo tonic contractions accompanied by tremor; such attacks may be of mild intensity, but at times are of great severity, causing opisthotonos and death by implication of the diaphragm. More frequently, however, extirpation of the gland is followed by chronic symptoms which sometimes appear shortly after operation, but may not manifest themselves for months. The patient becomes apathetic and indisposed to exert himself, mental actions are slow, and voluntary movements are performed languidly. The temperature is subnormal and the patient feels cold. The subcutaneous tissue of the face and extremities becomes swollen and œdematous in appearance, but does not pit on pressure. The skin is dry, the hair falls out, and the physiognomy assumes the appearance which, as will be pointed out, is observed in cases of myxœdema occurring idiopathically. The symptoms are analogous to those which follow thyroidectomy in lower animals.

In a case described by von Brunn a goitrous thyroid gland had been removed at the age of ten years, eighteen years before death. Development had been arrested and the dwarfed individual, who presented the appearance of a cretin, had the mental characters of an imbecile. Similar cases have been observed.

Myxœdema of Adults.—In 1873 Sir William Gull, in a paper "On a Cretinoid State Supervening in Adult Life in Women," described the symptoms of a disease to which Ord, several years later, gave the name myxœdema, since its most conspicuous feature is an œdema-like swelling of the skin caused by accumulation of mucin in the subcutaneous tissue. The resemblance between myxœdema, cretinism, and the cachectic condition following extirpation of the thyroid gland was soon recognized and was fully elaborated in the exhaustive report upon myxœdema published in 1888 by the Clinical Society of London. Numerous experiments upon animals, already referred to, have been undertaken in order to explain the pathogenesis of this disease, and have been so successful that an efficient therapy has been established within thirty years following its recognition.

Myxœdema of adults may occur at any age, but most frequently affects individuals between the ages of thirty and fifty years. The disease is much more common in women than in men, the ratio being about five to one. Heredity plays a part in its occurrence and several cases have been observed in the same family. Occasionally myxœdema has followed exophthalmic goitre, a disease in many respects the antithesis of myxœdema, while in one instance myxœdema has been observed in a woman whose daughter suffered with exophthalmic goitre.

Pathological investigation has shown the constant occurrence of a destructive lesion of the thyroid gland. The organ is diminished to one-half or even to one-fourth of its normal size; the tissue is pale and tough. By microscopic examination the interstitial tissue is found increased at the expense of the glandular alveoli, which are atrophied and in part destroyed; the gland is the seat of chronic interstitial inflammation comparable to cirrhosis of the liver or to chronic interstitial nephritis. Carcinoma and actinomycosis affecting the gland have in rare instances been associated with the disease. The subcutaneous tissue is distended and spaces occasionally occur

Digitized by Microsoft®

between the bundles of connective-tissue fibres, while late in the disease there is evidence of proliferation of fibrous tissue associated with atrophy of the sebaceous glands and hair follicles. The amount of mucin present in the subcutaneous tissue varies in different cases, and at a late stage of the disease may diminish in amount. In a case studied by Cranston Charles it exceeded the normal fifty times. The parotid gland and certain other tissues have been found to contain an increased quantity of mucin.

www.libtool.com.cn

The symptoms of myxœdema are characteristic and in most cases the condition can be readily diagnosed. The onset of the disease is usually very gradual, but occasionally within a few weeks it is recognizable. There are at first languor and disinclination to exertion, associated with slowness in the performance of voluntary movements. The patient feels cold readily and may suffer much in winter. Myxœdematous swelling of the subcutaneous tissue is observable first in the face, the physiognomy assuming a characteristic appearance which produces a certain likeness among those affected with the disease. The features become coarse and broad, the lines of the face are smoothed out, and the face assumes a stolid expression. The lower eyelids are puffy, the lower lip is thickened and often everted, the nostrils are broadened. Subcutaneous swelling occurs in other parts of the body, the extremities being at times most markedly affected; the hands and feet are broad and clumsy. This œdema-like swelling has a solid character, and, unlike ordinary œdema, does not pit on pressure. The body weight increases in proportion to the gradual swelling. The skin is dry and the nutrition of its appendages suffers; the hair becomes dry and brittle and falls out and the nails are stunted.

The subjective sense of coldness is associated with a subnormal temperature, which not infrequently falls to 95° F. or even lower. The disease is said to progress more rapidly in winter than in summer, and an important factor in its treatment is exposure to a warm temperature. Slowness of mental action is a constant feature of myxœdema and memory becomes defective. The temper is usually remarkably placid, but is occasionally irritable, and dementia is by no means uncommon. Hemorrhages from the gums or nose or from the uterus during menstruation or after pregnancy are not rare. The circulatory, the digestive, and the urinary systems exhibit no characteristic alterations, though albuminuria often occurs. The functions of the sexual organs undergo no constant change, and the greater frequency of myxœdema in women has not been referable to changes in the female organs of generation. Patients with myxœdema seldom become pregnant, but in exceptional instances the myxœdematous condition has been found to improve during pregnancy.

The progress of the disease is very slow and the patient may survive ten, occasionally even thirty years. Death usually occurs with some intercurrent affection, not infrequently tuberculosis or nephritis.

Cretinism or Myxœdema of Childhood.—No essential difference exists between the disease myxœdema and the condition known as cretinism, save that the latter occurring during the early years of life is associated with arrest of development. Endemic cretinism occurs in Switzerland and in certain other countries, particularly in the deep valleys of high mountains where goitre is prevalent. Sporadic cases occur in the United States and elsewhere. The disease, affecting females more frequently than males, usually develops before the fifth year. Lesions of the thyroid gland which cause destruction of its parenchyma and which are analogous to those of myxœdema in adults, occur. In cases of sporadic cretinism the gland is undeveloped or atrophied. In about two-thirds of the cases of endemic cretinism there is a goitre-like enlargement, but doubtless the functional ability of the gland is much diminished; in one-third of the cases the organ has been found absent or atrophic.

The condition of the affected child is analogous to that produced in lower animals and in young children by the operative removal of the thyroid gland. The stature is dwarfed and the limbs are short and thick. There is a corresponding arrest of mental development, so that the intelligence may not be greater than that of a child three years of age, while in many instances there is complete idiocy. The subcutaneous tissue is the seat of solid œdema, giving the features a coarse, repulsive aspect. Not infrequently cretins live to adult age or even to middle life, retaining their dwarfed condition of body and mind.

Treatment.—Experimental pathology and pathological anatomy, having demonstrated the identity of so-called idiopathic myxœdema and cretinism with the disturbance of nutrition which follows operative removal of the thyroid gland, have at the same time furnished an efficient method of treatment. The thyroid gland performs some function essential to normal metabolism. The effects which follow removal or destruction of the gland can be prevented by supplying to the body thyroid tissue or its products derived from another individual not necessarily of the same species. It has been found possible to transplant thyroid tissue, preferably that of the sheep, into the subcutaneous tissue of patients suffering with myxœdema, occurring spontaneously or as the result of operation for goitre, and well-marked improvement lasting for several months has followed. The transplanted tissue undergoes partial vascularization and functions like the normal gland, but atrophy occurs and the improvement is only temporary. Subcutaneous injection of extracts made from the thyroid gland was introduced by Murray, who employed with success a glycerin extract made from the thyroid gland of the sheep. Products of the gland administered by mouth have been found equally efficient, and the effects differ little whether the gland is ingested raw, partially cooked, dried and powdered, or in the form of a glycerin extract. The glycerin extract or the dried powder prepared as tablets is most conveniently used, the dose varying with different preparations. Toxic symptoms may follow the administration of too large quantities.

The effects of treatment in cases both of spontaneous and of operative myxœdema are remarkable. Within a few weeks subcutaneous swelling disappears, the face loses its stolid expression, and there is a rapid diminution of body weight. The mental condition improves and the temperature becomes normal. The treatment of cretinism has proved almost equally successful. With administration of thyroid extract the skin soon becomes normal in appearance and intelligence improves; growth occurs with surprising activity and the height may increase several inches during the first year. When treatment is begun at an advanced age its effects, as might be expected, are less satisfactory. In the treatment of all forms of myxœdema it is necessary to continue the administration of thyroid products after the disappearance of all symptoms, since throughout the remainder of life it is necessary to supply the deficiency caused by the absence or destruction of the thyroid gland.

Eugene L. Opie.

MYXOMA.—The name myxoma, or tumor composed of mucous tissue, was first used by Virchow, who separated from the other connective-tissue tumors a special class of formations to which he gave this name. Before this they had been described under various names, which generally had reference to the soft and jelly-like character of the growth. Laënnec gave them the name colloid, because the soft, trembling, gelatinous character of the tissue reminded him of partially solidified gelatin. Those tumors described by Johannes Müller under the name gelatinous tumor, or collonema, belong in this category, although the latter name seems also to have been used for soft tumors of other sorts, as the soft fibromas, etc. Paget has described them under the name fibrocellular tumors.

Virchow distinguished as a separate variety of the connective tissue, *mucous tissue*, which was characterized by containing in the intercellular substance a quantity of mucin. This tissue was most developed in the fœtus,

Digitized by Microsoft®

where it formed the jelly of Wharton in the umbilical cord, and was also abundant in the subcutaneous tissue. In the subcutaneous tissue it afterward became converted into fat, and when it was found elsewhere in the body Virchow regarded it generally as an antecedent to fat formation. Its cells either take up fat directly, and so become changed into fat cells, or they proliferate and the young cells so formed become fat cells. In the adult tissues it occupies but a small field, being found only in the vitreous body of the eye and in the subcutaneous tissue in a few places, here principally over the pubes. Histologically the tissue consists of cells embedded in a homogeneous matrix. The cells may be of various shapes, round, spindle-, or star-shaped. Generally they have the latter form, and are abundantly provided with processes which freely anastomose with the processes of neighboring cells, and form a fine meshwork through the tissue. On section of the tissue abundant fluid escapes, which has the same properties as those fluids which contain mucus. The mucin in the ordinary secretions of mucous surfaces is the result of the action of the epithelial cells, and is formed in them; but in the mucous tissue it is not found in the cells, but in the intercellular substance. The mucin contained in the fluid has some of the chemical properties of albumin, but can be distinguished from it in various ways. On the addition of alcohol to fluids containing mucin, there is formed an abundant precipitate, which can be distinguished from the albuminous precipitate, formed in like manner, by the fact that it swells up and dissolves on the addition of water. The albuminous precipitate is not affected by water. Mucin is not dissolved by an excess of the organic acids, but is readily soluble in an excess of mineral acids.

The result of later investigations has been to throw much doubt on the existence of mucous tissue as a distinct type of tissue, such as Virchow has described it. Even in the place where he supposed it to be most typical, *i.e.*, in the umbilical cord, it has been shown that this is only ordinary connective tissue with an abundance of fluid in its meshes. A tissue almost analogous to mucous tissue is found in every subcutaneous œdema, and can be produced artificially by puncturing the skin with a fine hypodermic needle and injecting salt solution. A doughy swelling is so produced, and on section the injected fluid will not flow out again, but is held in the meshes of the tissue and along the fibres. On microscopic examination of sections, made by clipping out a piece of the swollen tissue with a pair of sharp scissors, the cells are found separated from one another, often anastomosing, and the fibres of the connective tissue do not appear so prominent. The fact that the supposed mucous tissue of Virchow contains mucin cannot be held as peculiar to it, and as distinguishing it from other forms of connective tissue. Mucin is found in all the connective tissues, and the gelatinous œdematous tissue does not contain any greater proportion of it than do other tissues of its class. The fatty tissue which Virchow supposed to be developed from the mucous tissue does not stand in any immediate connection with this, but, according to Ranvier, takes its origin from cells which from the beginning are destined to form fat cells

Following this, Rumler and Koster have taken the ground that the myxoma is not to be considered a special type or class of tumors, but that it simply represents conditions which might arise in any of the tumors which contain connective tissue. This myxomatous condition of the connective tissue consists in its saturation with serum in consequence of circulatory disturbances in the tumors, passive congestion, etc. They regard this tissue, wherever found, simply as ordinary connective tissue infiltrated with fluid, or œdematous. In every tumor there can be numerous conditions which might give rise to this. The veins can easily be compressed by the growth of certain parts of the tumor, and we cannot suppose that the vessels of a tumor of any sort are less prone to allow of transudation, in case of passive congestion, than those of any other tissues. On the contrary, it seems probable, from the numerous areas of small-cell infiltration in tumors of every description, and from the frequency with which red corpuscles are found in the tissues, that the vessels are easily traversed by the corpuscular elements of the blood, and where this is the case the fluid elements pass through also. The serum would be most readily taken up in the meshes of the connective tissue, enlarging these, and the connective-tissue fibres would be forced apart and rendered less distinct. The fact that we scarcely ever find a pure myxoma, such as Virchow has described, but almost always this so-called myxomatous tissue in connection with some variety of the tumors which contain connective tissue, as fibroma, sarcoma, carcinoma, etc., speaks much in favor of the correctness of this view of Koster. Still the term myxoma or myxomatous tissue, to denote this swollen and œdematous connective tissue, is a convenient one and will be retained, although the myxoma, in the light of these recent investigations, should occupy no place in the category of tumors. The myxoma was first described by Virchow, and his descriptions of it are in all respects so full that they have undergone but little modification by subsequent writers on the subject. The writer has thought it best after this preface, which sheds a clearer light on what has been a complicated subject in *onkology*, to give, in the main, Virchow's description of the tumor.

The cells in the tumor vary in shape and in numbers, this variation depending chiefly on the stage of development of the tissue. The younger the tissue is, the more the cells are inclined to be round and the more numerous they are. In the older portions the cells are rather star- or spindle-shaped, and have numerous processes which communicate freely with one another, producing a reticular or areolar tissue, in the meshes of which round cells are frequently enclosed. When these cellular elements are fewer in number, the whole tissue has a transparent, gelatinous appearance, and is similar to the vitreous body of the eye. This forms the variety *myxoma hyalinum*. Virchow has described several other varieties, which depend on various, for the most part minor, differences in the structure of the tumor.

Myxoma Medullare.—In this the cells are more abundant, and this gives the tumor a whitish, opaque, medullary appearance.

Myxoma Fibrosum.—In this the tumor contains a considerable amount of fibrous tissue, especially elastic fibres, which often form dense bands which appear on the cut surface.

Myxoma Lipomatodes or Myxo-lipoma.—In this the tumor contains a considerable amount of fat, either in the shape of small drops contained in the cells or as fully formed fat cells. There may be so much fat present that the tumor has most of the characteristics of lipoma.

Myxoma Cartilagineum or Myxo-chondroma.—A large proportion of the myxomata contain islands of cartilage. This is especially the case in the compound tumors of the parotid gland and of the testicle.

Myxoma Cystoides.—In some cases the cells of the tumor enclosed in the mucous tissue undergo mucous or fatty degeneration, and there are formed large cavities filled with viscid fluid.

Myxoma Telangiectodes.—As is the case with most tumors, the vessels here also may be enormously developed, and this name has been given to the condition.

Mucin is found in numerous other tumors, as a result of the physiological activity or of a degeneration of the tumor cells. It is found, for instance, in the cystic tumors of the ovary and in most other epithelial cysts. Virchow excludes these from the myxomata, and has limited this term to those tumors in which the mucin is contained in the interstices of the tissue and forms an integral part of the tumor. Billroth has included with the myxomata all such tumors, among them goitre. Just as the most typical formation of mucous tissue is found in the fœtus, the most typical examples of myxomata are found in tissues belonging to the fœtus. The myxoma of the chorion, forming what has been termed mole pregnancy, is the most typical example of this myxoma. Abortion takes place in this case at an early period, and

Digitized by Microsoft®

the chorion will be found covered with transparent, gelatinous vesicles, which are connected with the membrane by a narrow pedicle. Sometimes several of these vesicles are connected with the same pedicle, and are strung along it like rows of beads. The vesicles vary in size from a pin's head to a nut. On microscopic examination they are found to be covered with epithelium, and composed of a tissue similar to that of the umbilical cord, *i.e.*, branched cells lying in a homogeneous matrix. Other parts of the fœtal appendages may be the

www.libtool.com.cn

FIG. 3476.—Section of a Myxoma of the Subcutaneous Tissue of the Thigh. × 300.

seat of similar formations. Cases have been seen in which the umbilical cord contained along its course a series of such vesicles. Also in the placenta itself there may be an abundant formation of mucous tissue in the form of circumscribed tumor masses. Retained portions of the placenta may form the starting-point of tumors which reach a considerable size.

In the adult the subcutaneous cellular tissue is the most frequent seat of the myxomata. Here they are principally found on the thigh, on the buttocks, on the labia majora, and on the lower lip. The fat in the orbit may be a point of origin for the tumor. Such tumors may reach considerable size; those of the size of a child's head have repeatedly been seen. These large myxomata have a distinctly lobular structure, and when they break through the skin they become ulcerated and often very foul. They may have a deeper origin, as from the intermuscular tissue. In some localities, where the skin covering them is not tense, they become distinctly pedunculated.

The long bones are often the seat of this tumor. In this place it seems to originate in the bone marrow. In these tumors various combinations, as with sarcoma and enchondroma, are seen. The spongy osteomata, with soft cellular marrow, may be confounded with them. The pure myxoma of the bones is a soft, spongy tumor, which ordinarily originates in the bone marrow, and in the course of its growth becomes covered with a thin shell of bone. At a later stage it breaks through this and grows as a soft mass. It is always accompanied by a new growth of bone, is generally lobulated, and here and there portions of the old bone may be enclosed in its substance. The tumor is soft and grayish-white or yellow. Virchow compares its tissue to the flesh of oysters. An abundant formation of blood-vessels may give a reddish tint to the tumor.

The myxomata often have a heteroplastic origin, and in these cases the starting-point is most frequently located in the central nervous system. A considerable proportion of the brain tumors belong in this category, especially those of the cerebral hemispheres. The dura mater of the brain and cord may also be the place of origin.

When seated on the peripheral nerves the tumor does not originate in the neurilemma, but in the interstitial tissue. Such tumors along the nerves are often mistaken for neuromata. They give rise to severe neuralgic pains, and are often multiple. All the nerves of an extremity may be affected, in some cases several being seated on a single nerve trunk. In many cases the nerve does not pass into the substance of the tumor, but over it, and is generally flattened from pressure. It is often possible to dissect out the nerve from such a tumor and remove the tumor, leaving the nerve intact. The consistence of these tumors is so soft that they may be easily mistaken for cysts. They have a tendency to return after removal.

Myxomata may also be found in the glandular organs, where they arise from the interstitial tissue. Such tumors are found in the female breast. The tissue of the tumor grows into the milk ducts in the form of polypoid masses. The duct becomes dilated into a cyst, which is filled with the branching growth. The whole tumor may in this way be enclosed in one large duct, and may be removed from it, leaving a cavity with smooth walls. On microscopic examination the section often appears to be composed of small islands of myxomatous tissue surrounded by epithelium. The islands of tissue are the cross sections of the branching dendrate growth in the duct. This manner of growth is not peculiar to the myxomas of the mamma, but is seen also in fibromas and sarcomas in the same locality. The tumor finds the least resistance to its growth in the milk ducts, and grows into and dilates these. Jungst has recently described one of these tumors in which a great part of the tissue had undergone hyaline degeneration. When the superficial ducts are the seat of this growth, the tumor may project as a nodular mass from the breast. This is particularly apt to take place in the region of the nipple. The skin covering the tumor becomes thin and finally breaks, and a soft, fungous, often gangrenous mass appears. This may have an appearance very similar to that of an ulcerated cancer. If it is closely examined, spaces may be found in which a probe may be pushed deeply down between the single masses of which the tumor is composed.

The mixed forms of the tumor deserve especial attention, for they are much more common than the pure forms. They are most apt to be seen with tumors of the connective-tissue type, as the fibroma and sarcoma, but may be found with any tumors which contain connective tissue. In the spindle-cell sarcoma the tissue may be seen to pass into myxoma. The cells become separated from one another by an increase in the interstitial tissue and lose their spindle shape. In carcinoma the most typical mucous tissue may be found between the masses of epithelial cells. These mixed forms have been given special names, as carcinoma myxomatodes, etc. The fact of the presence of such tissue in a carcinoma or sarcoma does not influence the growth of the tumor, nor its prognosis, but may lead to errors in diagnosis. Wherever this tissue is present the tumor is softer. The mixed tumors of the parotid gland always contain a considerable quantity of myxomatous tissue.

In general the tumors described as myxomata are not malignant. Some, however, are. Those of the central nervous system are malignant from their position, and those of the peripheral nerves have a tendency to multiple formation and to return after extirpation.

The best and most typical pictures of this tissue are to be obtained by examining fresh sections made by the freezing microtome in salt solutions. After the tumor has been hardened in almost any of the hardening agents, the tissue loses its fluid and shrinks very much.

W. T. Councilman.

NÆVUS.[1] — (Greek, *σπίλος*, *σπίλωμα*; French, *næve*, *couenne*, *envie*, *signe*, *tache congenitale*, *ou pigmentaire*, *ou de naissance*; German, *Mal*, *Muttermal*, *Muttermahl*, *Mutterflecken*; Italian, *neo* [*materno*], *nevo*; Spanish, *nevo*, *lunar*.) (Synonyms: Mother's mark, birthmark, etc.)

DEFINITION.—A nævus is a congenital alteration of the skin, confined to a limited area and characterized by an increase in the amount of pigment deposit, and by a certain amount of hypertrophy of one or more of the other elements of the skin, especially the vascular and connective tissues, as well as the hair, fat, nerves, and

Digitized by Microsoft®

lymphatics. Unna[2] aptly describes nævi as: "Circumscribed, small malformations of the skin, which have a hereditary basis, or have their foundations laid in embryonic life, become evident at different periods of life, develop very slowly, and are distinguishable by their color or the form of their surface."

www.libtool.com.cn

The following varieties of nævi may be distinguished: *Nævus fibromatosus; N. lipomatodes; N. pigmentosus; N. pilaris* or *pilosus; N. unius lateris* (*N. linearis*)*; N. vascularis; N. verrucosus.*

Nævus fibromatosus is marked by excessive connective-tissue development; it varies in size and involves the skin in different parts of the body. As subdivisions may be mentioned: N. foliaceus, in which the central portions are fibrous, while the circumference is vascular; N. mollusciformis, a protuberant pedunculated form (Fig. 3477); and N. sarcomatodes, which at first is a simple congenital nævus, but afterward undergoes sarcomatous degeneration.

Nævus lipomatodes is a congenital fatty tumor (lipoma), usually more or less fibromatous.

Nævus pigmentosus, the commonest form of nævus, is characterized by an excessive deposit of pigment in a circumscribed area of the skin. The discoloration thus produced varies from pale yellow to purple or even black. The lesion, which is usually level with the skin, occurs especially on the face, hands, neck, arms, and back. This variety of nævus is often verrucose, or elevated; at times it is more or less covered with hair and is then designated as *Nævus pilosus* or *N. pilaris*.

Fig. 3477.—Case of Angio-Fibroma of Congenital Origin. (Case of Dr. Isadore Dyer.)

Nævus vascularis, N. sanguineus—"mother's mark," includes a large number of forms, among which are now classed varieties of angiomata, which embrace tumors of embryonic rudimentary vessels.

The vascular nævus may involve the capillaries, the smaller veins, or the terminal arterial branches.

The capillary nævus is distinctly cutaneous and in size varies from a pin's head to the palm of the hand or even a larger area; at times it involves whole regions of the body. This is the form of nævus most commonly met with. It is usually only slightly elevated, or it may even be level with the surface of the skin. It is often seen as a tiny red spot with lines (dilated capillaries) radiating from a central point of vascular hypertrophy, and to it are applied the terms "spider nævus," or "spider cancer," or *nævus araneus*.

Vascular nævi often begin indistinctly and spread gradually until they cover large surfaces. On the other hand, nævi, present at birth, may within a few months entirely disappear spontaneously.

The venous nævus is apt to be more elevated than the capillary. It is smooth, stands at a higher level than the surrounding surface of the skin, is soft and compressible, and often is lobulated. The thin-walled veins of which it is composed communicate directly with one another and are bound together by delicate bands of connective tissue, thus constituting a network of intercommunicating venous sinuses. Such a formation should be called a nævus cavernosus or an angioma, for such in reality it is. These tumors are markedly irregular in form, reddish or bluish in color, and at times erectile (in women this is especially noticeable at the time of menstruation).

Although there have been reported many instances of congenital nævi which seem to confirm the belief that prenatal events, through the impressions which they make upon the mother, sometimes play a part in the causation of these tumors, the best modern authorities are opposed to this view.

Nævus Verrucosus.—A warty nævus, often having a hairy growth, and at times highly vascular and erectile.

Nævus unius lateris is excluded, by Unna, from the nævi, but only provisionally. I am disposed to believe that this type of growth may properly be classed among the nævi. It embraces a number of types of nævus, in which the essential feature is the arrangement in a linear way following the distribution of the superficial nerves. Some attempts have been made to show the association of this form of nævus with previous neurotic influence, injury, shock, etc. The terms N. neuroticus, N. linearis, papilloma neuropathicum (neuroticum), etc., have been applied to this type. That the term *unius lateris* is a misnomer is evident from the fact that the author has had two cases of bilateral distribution. To these he has given, by preference, the name "linear nævus."

It is certain that there is a distinct difference in the arrangement of the lesions between this variety and the ordinary nævi. The arrangement is in sprays and clusters of lesions, which vary in character, some of them having a pale yellow pigmentation, while others are black. Then again there are also differences in structure, some of the growths being clearly vascular nævi while others

Digitized by Microsoft®

are mere papillomatous growths. In some cases there is even involvement of the lymph vessels (lymphangioma) (see Figs. 3479 and 3480).

www.libtool.com.cn

FIG. 3478.—Vascular and Verrucose Linear Nævus of the Cheek. (Case of Dr. Isadore Dyer.)

The PATHOLOGY of nævi is of only indirect importance, as the condition is not difficult of diagnosis and the treatment is essentially radical.

Unna (*op. cit.*) quite exhaustively reviews the histological evidence in regard to the different types of nævus, and discursively argues the embryonic origin and course of the several varieties classed by him under the term nævus. Soft nævi, or the warty, epithelial types, are recognized as embryonic deposits in the upper part of the cutis, while the hard nævi are either of prickle-cell layer origin or else are found chiefly in the horny layer. The more complicated nævi are also considered by him in their complex pathology.

TREATMENT.—The necessity for treatment of nævi must depend upon the character, the location, and the size of the lesion or lesions. Simple pigmentary moles are of little serious importance, and, on account of their harmless character, they need not be removed. In exceptional cases the melanotic mole calls for early operative interference. Even the simple moles, when there are several of them, often cause sufficient disfigurement to warrant their removal by surgical interference. Hairy moles are especially disfiguring. In the case of vascular nævi, on the other hand, the danger of accidental hemorrhage must also be taken into consideration.

There are not a few different ways in which nævi may be treated. For the simple pigmentary moles and also for those of a verrucose character the employment of escharotics will often suffice. Of these we might name carbolic acid, chromic acid, glacial acetic acid, picric acid, acid nitrate of mercury, corrosive sublimate, cantharides (in collodion or in ether), pyrozone, sodium ethylate, nitrate of silver, nitric acid, salicylic acid (alcoholic solution or in collodion), chrysarobin, chrysophanic acid, pyrogallic acid, liquor potassæ, etc.

In the case of large lesions, or where the location forbids the use of caustic applications, the actual cautery —the Paquelin or the galvanic—should be used.

In small pigmentary nævi electrolysis is preferable. To the negative pole of a galvanic battery a small needle (steel, platinum, or gold) is attached. The positive pole carries the sponge, which is customarily held in the patient's hand. The needle is introduced beneath the pigmented mole and the current is gradually increased until the lesion blisters. To accomplish this a current of about 8 or 10 milliampères is required, or, if cells with switch-board are used, there should be as many as from twelve to twenty cells. Where the moles are hairy, a blunted broach or needle should be employed. The hairs are removed first by electrolysis, and then the mole itself is removed by the ordinary operative procedures. In removing the hairs the needle should be gently introduced into the hair follicle, the hair shaft serving as a guide and care being taken not to pierce the follicle. The current is gradually applied until there is frothing at the orifice of the follicle, when the hair is ready to come away. If there is resistance on the part of the hair, the operation is not complete. Not more than from 3 to 5 milliampères is needed in this operation; in fact, in some instances a single milliampère will be found sufficient. The negative pole of course must be used here.

In the treatment of vascular nævi, electrolysis is likewise of service, but more particularly in those in which the area of skin involved is small, and the vessels forming the growth are simply capillaries. The object of the treatment here is either to cause the absorption and atrophy of the blood-vessels or to effect their destruction. Various procedures, all of them more or less inefficient, have been suggested for the accomplishment of these objects, but as the space at our command is limited, we shall describe only those which have stood well the test of time.

There are two methods for using the ligature. First of all, it is a good plan in smaller nævi to circumscribe the growth with a single or double silk ligature, drawing tightly and tying on opposite sides of the growth, when the double ligature is used. In the case of the larger nævi, the ligature is applied at a point a little remote from the growth. An incision is made above the vein, or small artery, a catgut ligature is applied, and the wound closed. In either instance the growth begins to pale after several days. In superficial nævi the whole patch grows bluish in color. Here and there a spot grows white where the blood has been absorbed, and finally, in the successful cases, the whole patch grows whiter and whiter. When it is thought best to resort to excision, as in the case of deep-seated nævi, it will often be found advisable to ligate a few days or weeks before the excision. When the cautery is employed, several methods may be followed. A fine platinum needle may be attached to the galvano-cautery, raised to a red heat, and then introduced into the growth several times in succession. Linear cauterization may equally well be carried out by means of the needle or with the small plat-

Digitized by Microsoft®

inum knife. The Paquelin cautery will serve the same purpose.

Caustic pastes (Bougard, Felix, Marsden, etc.) act as the cautery does, by producing an eschar, and finally a slough. With caustics, however, the slough is apt to be more extensive than when the cautery is used. Hence the need for caution in using them.

www.libtool.com.cn

Vaccination has been used in locations where an irregular scar is no objection. The slight bleeding need not be stopped, except by a temporary compress.

The injection of pure carbolic acid or the tincture of iodine is followed quite often by gratifying results. Little scarring remains, plugging of the vessels is rapidly obtained, and the operation is less painful and of shorter duration than when other methods are employed. The injection of a one-per-cent. solution of chloride of zinc is used for the same purpose. The perchloride of iron may be used by injection, or, as is frequently indicated in the more elevated growths, silk threads, saturated with the perchloride solution, should be passed in several directions through the nævus, and be allowed to remain until they are absorbed in the contraction, or else slough out.

Except in the case of small nævi, the treatment is never highly satisfactory, and the methods employed may have to be changed several times before the whole of the growth is removed. It is always well to impress upon the patient the necessity of perseverance in the matter.

Where the patient will submit, the use of repeated ignipuncture with the Paquelin cautery under a general anæsthetic will effect good results; otherwise the electric needle is of most service. A number of cures have been reported after long use of electrolysis. For extensive nævi of the capillary variety, multiple needles (as many as a dozen) attached to the negative pole of the galvanic current may be employed. This does not answer so well as the single needle frequently introduced. The amount of current required varies with the patient and should be regulated accordingly, a mild current being used at the start.

The technique of this operation is as follows: The patient should hold the sponge electrode and should turn on the current when the needle is introduced and turn it off when the needle is withdrawn; or, if he does not mind the greater painfulness of the procedure, he should keep the sponge constantly applied. The needle may be pushed in to a depth of at least half an inch below the surface of the skin and parallel with it, and it should be allowed to remain until a distinct eschar, in the form of shrivelled skin, shows itself along the line of the needle. This procedure is to be repeated at each sitting as often as the patient will permit. As this linear operation almost always leaves ridges as the ultimate result, it is probably better to introduce the needle simply at a right angle to the surface of the skin, leaving it in position until a small blister forms. Several such punctures should be made at each sitting, and they should be located as closely together as possible. At each sitting, for a few succeeding days, a new area should be selected, and then each area in turn, beginning with the one first selected, should be gone over a second or even a third time, until finally the region so treated presents the appearance of a white superficial scar.

For the cavernous variety of nævus the electrolytic method is not so well adapted. In the treatment of this condition by electricity the positive pole is supplied with a platinum and the negative pole with a gold needle, or *vice versa*, and both are introduced at once, deeply. The strength of the current is gradually increased to the limit of the patient's endurance, and is kept applied as long as possible.

In both varieties of nævus it requires months of treatment before any result is obtained, but usually the patient's endurance is finally rewarded.

Isadore Dyer.

[2] Unna: Histopathology of Diseases of the Skin, Walker's translation, p. 1128.

NAFTALAN is a greenish-black, soft, gelatinous material, with a slight empyreumatic odor, and consists of 96 to 97.5 per cent. of a peculiar Russian naphtha, purified and mixed with anhydrous soap. It is readily miscible with oils, fats, ether, and chloroform, and is insoluble in water, alcohol, and glycerin. Kolbl found it of distinct value in minor skin lesions such as urticaria, scabies, psoriasis, burns, and bee stings. Bloch considers it almost specific in burns, but in psoriasis not so good as chrysarobin. Several authors report good results from its use in chronic eczema, though it is not recommended in acute eczema, or when the skin is moist. Skin parasites are destroyed. It is applied as a thick coat and does not melt at body temperature (melting point, 70° C. or 158° F.).

W. A. Bastedo.

NAILS, DISEASES OF THE.—TERMINOLOGY.—As the study of the nails demands its own vocabulary, it is necessary to define clearly the various terms which will be employed in this article.

The root or matrix is that part of the finger under the lunula from which the nail substance is formed.

The bed is that portion of the finger lying directly anterior to the matrix, which forms the floor on which the nail rests, but which plays no part in the formation of the nail.

The plate is what is commonly termed the nail. The lunula is the white, opaque, rounded part of the plate which lies over the matrix and under the eponychium.

The walls of the nail are those parts of the finger which lie along the sides of the plate.

The eponychium or "quick" is the horny layer which forms a selvage to the skin over the bed of the nail.

Pterygium is a forward growth of the eponychium over the plate.

Transverse or horizontal will signify the direction across the plate, while vertical will mean the direction from eponychium to free or distal border of plate, *i.e.*, the line in which the nail grows.

ANATOMY.—The normal shape of the plate is convex both horizontally and vertically. The vertical ridges which appear on many nails in youth and adult life, and which increase markedly in old age, are due to the presence of the papillæ in the underlying bed of the nail. The color of the nails should be a delicate pink, due to the subjacent capillaries which transmit their color through the normal, translucent plates above. The plate is composed of flat, polygonal, keratinized, nucleated cells between which are air spaces. Wherever these air spaces exceed their normal size the plate becomes opaque and white, a condition which is called leuconychia. The lunula is white in color because the underlying matrix is not supplied with vessels. On the thumb the lunula appears distinctly anterior to the eponychium, but on the other fingers it does not extend so far forward.

The nail bed is not sharply marked off from the adjacent parts of the finger, there is never a clearly defined boundary, and the contiguous parts blend into each other. The lower layer of the bed merges gradually into the periosteum of the last phalanx without the interposition of the panniculus adiposus. The blood-vessels are arranged in an upper and a lower layer as in other parts of the skin, and the lymph vessels are well marked.

EMBRYOLOGY.—The nail arises from the ectoderm and makes its first appearance between the third and fourth months of fœtal life.

GENERAL PATHOLOGY.—Disorders of the nail may be symptomatic of general infections of the skin or of the body, or may be simply local affections.

Inheritance.—Diabetes, tuberculosis, cretinism, eczema, psoriasis, or epidermolysis in the parents have been known to cause marked disturbances in the nails of the child, while serious disturbances in the nails and hair have been a family dyscrasia for several generations (*vide* observations of Nicolle and Halipré in France and of the present writer in America).

Psychic disturbances are frequently the cause of nail

Digitized by Microsoft®

derangements. Such examples have been recorded after "apparitions," severe lightning, hysteria, delirium, mania, overwork, or worry.

Disturbances of the nutrition are common causes, among which Heller mentions typhoid fever, gastric disorders, icterus gravis, infantile atrophy, pneumonia, anæmia, phthisis pulmonalis, erysipelas, epididymitis, severe angina, parotitis suppurativa, scarlatina, measles, influenza, gout, rheumatism, accidents, and childbed. These conditions are often followed by the appearance of transverse furrows in the nail plate.

www.libtool.com.cn

Localized Nail Affections.

Anonychia or absence of nails may be congenital or acquired. The former origin is rare, but the latter is not uncommon, and loss of the nails is frequently observed after syphilis, injuries, chemical irritants, burns from *x*-rays, constitutional diseases, eczema, psoriasis, pus under the nail, ringworm, felon, paronychia, shock, hydroa æstivale, and ichthyosis.

Onychatrophia almost always results from the separation of the plate from the bed of the nail, a condition which usually follows any hyperkeratosis of the bed itself. Another source of separation is the invasion of blood after trauma or in connection with certain nerve diseases—for example, cerebral paralysis, multiple sclerosis, or tabes dorsalis.

Onychorrhexis.—This term is applied to the condition of the brittleness of the nail which follows decreased production of nail substance, and is usually associated with some trophic disturbance.

Onychauxis.—An increased growth of nail substance, and when associated with curving or hooking of the nail the word *onychogryphosis* is used. The etiology of this condition is somewhat obscure, but the deformity has been observed in connection with wounds, pressure of shoes, old age, deformities of toes, especially hallux valgus, syphilis, tinea tricophytina, central or peripheral nerve disorders, old tuberculosis, circulatory disturbances, such as thrombosis and aneurism, leprosy and confinement to bed.

The pathology of onychogryphosis was carefully studied by Virchow in 1855, and his description which follows remains the best to-day. There are three gradations in the formation of a truly gryphotic nail: First, the flat or plate shape; second, the conical form; and third, the perfected claw. At first the bed becomes shortened and the pulp of the last phalanx diminishes in size; the subungual vessels dilate and the stratum spinosum proliferates with the formation of abnormally high, transverse ridges, and an accompanying hypertrophy of the stratum corneum. These changes separate the plate from the bed, especially at the distal border, and the plate itself thickens, becomes yellow or dark brown in color, and shows on its surface overlapping transverse ridges. These ridges, of course, denote an intermittent process. The second or conical stage results from a continuation of the previous changes. The bed becomes deeper and forms a distinct transverse ridge, behind which the plate is almost perpendicular, yellow, translucent, and very hard; while in front it is opaque. The cells of the plate are no longer nucleated and apparently lose their boundaries. In the deeper portions of the bed the cells soften and blood finds its way into the intercellular spaces as in cutaneous horns. The third stage shows a still further advance from the normal. The downward pressure of the plate has caused an almost total disappearance of the bed. The ridge noted in the second stage has widened and the distal portion of the plate has become smaller; in fact, the last stage is one of atrophy. The resulting claw may grow simply downward or downward and backward, or in rare cases may assume the spiral curves of a ram's horn.

Leuconychia (leukopathia unguium, canities unguium).—The appearance of white areas in the nails follows three types, the punctate, the striate, and the total. Pathologically, we find this normal color due to the faulty production of nail cells with subsequent imbibition of air. This abnormality has been observed following wounds, trophic disturbances, relapsing and typhoid fevers, stimulation of nerves by electricity, and, rarely, congenital examples have been recorded.

Koilonychia, or spoon-nail, is the concave appearance which the plate assumes at times. This condition is usually the result of an underlying eczema, but may appear after other diseases, or without any apparent etiological cause.

Agnail, or hangnail, is caused by the drying up of the eponychium after insufficient nourishment. With the formation of the hangnail an easy entrance is afforded to bacteria, and in this way arise many of the syphilitic chancres and the more numerous cases of paronychia and of panaritium.

Hemorrhage.—The invasion of blood below the nail is usually traumatic in origin. A squeeze or a blow is followed by the bursting of a vessel in the bed or in the matrix; and when in the latter, the plate is sure to fall. The blood forms a clot between bed and plate, and if small, is usually absorbed while a large hemorrhage will often lift up the plate and produce subsequent atrophy or possible loss of the nail. Cases of vicarious subungual menstruation have been recorded, while other etiological factors in hemorrhage of the nail are scorbutus, morbus maculosus Werlhofii, tabes dorsalis, or the introduction of foreign bodies below the nail plate.

Trauma.—Wounds of the plate mean nothing serious to the nail, while similar injuries to the matrix always lead to scars which produce permanent deformities.

Unguis incarnatus.—Ingrowing of the nail is most commonly met with in males between the ages of fifteen and twenty, and is usually coincident with lack of care of the feet and the wearing of ill fitting shoes, but flatfoot, wounds of the nail walls, and great convexity of the nail are other possible etiological factors. The first symptom is pain, followed by swelling and the formation of pus, and finally a granulating sore is produced, which shows no tendency to heal. Constitutional symptoms sometimes make their appearance, and finally the disease may result in necrosis; but this event is fortunately rare.

Subungual Tumors.—The presence of new growths under the nail is distinctly uncommon, but, according to Heller, cases of subungual corns or horns, fibroma, papilloma, leiomyoma, angiosarcoma, angioma, colloid sarcoma, exostoses, cancer, and enchondroma have been recorded.

Symptomatic Pathological Involvement of the Nails.

Onychomycosis tricophytina.—Ringworm of the nail is a rare condition, and is usually caused by the megalosporon. The disease first appears at the distal end of the nail and gradually spreads backward. The plant first attacks the bed, producing an opacity and discoloration of the plate, which usually assumes a whitish-yellow tint. As the disease progresses, the color darkens even to a brown, but never reaches black, as is so often the case in favus. Coincident with the progressive color changes the bed becomes more and more hyperkeratosic, the plate is raised more and more from the bed and shows transverse depressions, transverse elevations, or vertical ridges, and finally the plate itself is attacked and becomes rough on the surface, exfoliates in lamellæ, atrophies or splits, and is finally cast off. The disease is essentially a very chronic one, and even when properly treated requires at least two years for its thorough eradication. If left to itself, the plant has been known to remain active in the nail substance, even up to thirty years. The diagnosis is extremely difficult, for even although we have to our satisfaction excluded all other possibilities, the spores may elude the most diligent microscopical investigation—in fact, it is only when one has demonstrated conclusively the glistening, rectangular spores with rounded corners, five to seven micromil-

Digitized by Microsoft®

limetres in diameter, growing in chain formation that one can positively state that the disease present is ringworm of the nail. On the other hand, if the nail presents the clinical characteristics above enumerated and ringworm is present elsewhere on the patient's body, we have a certain right to assume that the nail is similarly infected. The treatment, although tedious, always triumphs in the end. It consists in the bi-weekly or tri-weekly cutting of the nail, and, in case the plate has been cast off, the curetting of the bed and subsequent painting with Lugol's solution or with acetic or pyrogallic acid.

Onychomycosis favosa.—Nails are apparently much more susceptible to tinea favosa than to tinea tricophytina. The clinical appearances of the diseases are quite similar. The plant attacks the distal end of the bed and produces an opacity and discoloration of the plate. The hyperkeratosis spreads backward and the plate is raised from its bed, becomes darker and darker in color, even to blackness, and its surface shows transverse depressions or ridges. Often the substance of the plate is attacked and assumes a honeycombed appearance, which soon leads to crumbling and splitting and final loss of the nail; or else the hyperkeratosic granules are extruded from the bed, leaving, as sometimes occurs in ringworm, a hollow space underneath the somewhat atrophied and brittle nail plate. The disease may be caught from domestic animals or from one's neighbors, and often occurs in two or more members of the same household. The Russian Jews seem to be particularly liable to infection, and in the writer's four hundred and eighty-five tabulated cases of nail diseases occurring during the last three years, his eight examples of onychomycosis occurred in this race. Histologically, one finds a thickened prickle layer of the bed, elongated papillæ, and an enormously hypertrophic horny layer in which the achorion Schönleinii appears. The fungus is not so abundant at the distal end of the plate as farther back, and its mycelium grows parallel with the cells of the stratum corneum. The process is much more chronic than in the scalp, and follows closely the characteristics of ringworm, both in its life history and in its treatment.

Diseases Caused by Animal Parasites.—This forms a class about which there is little to state beyond the fact that in extremely chronic cases the nail plates show slight changes. The chief diseases in this group are scabies, myosis, pulex penetrans, and plica polonica.

Ichthyosis and Xeroderma.—At birth, in severe cases, nails have appeared small, soft, and easily detached, with poorly developed nail walls. In older children and adults nails may show transverse depressions or vertical ridges, or may appear dull, very convex, or even gryphotic. Hyperkeratosis of the bed with gray or greenish discoloration of the plate and final loss are still further conditions which have been observed.

Elephantiasis Arabum.—The changes of nails in this disease are usually limited to the large toes where increased thickness, yellow color, and atrophic changes have been recorded.

Hyperkeratosis subungualis.—Although this is really a symptom rather than a disease, it should be considered here in order to gain a better knowledge of this important condition, which is so frequently met with in nail pathology. This lesion is strictly limited to the bed of the nail, and only after long continuance does the plate itself become involved, excepting its elevation and increase in convexity. This condition, therefore, illustrates well how little the plate depends for its nutrition upon the bed. The horny mass grows most abundantly at the distal end of the bed and constantly diminishes in height toward the matrix. Consequently the elevation of the plate is greatest near its free border. Unna describes the histological picture as follows: One sees extending into the horny layer papillary-like vascular processes which contain spindle cells and leucocytes. The prickle layer is thickened and passes without definite line of demarcation into the horny layer. A perfectly developed granular layer does not exist. The horny cells retain their nuclei and increase in size even up to the surface, and we note the same medullary processes which have been described in cutaneous horns. Swarms of cocci exist in the upper layers of the stratum corneum and exert a softening effect upon the adjacent cells.

Eczema.—The changes observed in this disease may occur in the nail walls, matrix, bed, and plate, and are produced by the same causes that bring about an eczema of the skin. The involvement of the nails before the age of twenty is distinctly uncommon—only six cases in the writer's one hundred and seven occurring before that age. The disease prevails all through adult life up to the age of seventy, when it diminishes in frequency. In the acute form the nail walls are red and swollen, the plate loses its normal convexity, pain is felt in the bed, the plate becomes rough, the lustre vanishes, discoloration is present, and soft spots appear in the plate which later form minute punctate depressions. If the cutaneous disease continues, the nail exhibits one or more of the following conditions: Transverse depressions or ridges, vertical ridges, hyperkeratosis of the bed with increase in the convexity of the plate, and subsequent disappearance of this granular detritus and thinning of the plate with increased brittleness, exfoliation of surface cells of plate, leuconychia, or finally total loss of the nail. If the matrix is affected, a deep transverse furrow may result.

The pathological changes consist in the formation of eleidin and horny matter with œdema and cellular infiltration about the vessels of the corium. The prognosis is decidedly good, and the treatment for the nail disturbances is the same as for the underlying skin disease.

Paronychia.—This is a very frequent cause of nail deformities, and consists in a severe dermatitis of the nail walls. It is an acute or subacute process, and usually occurs in women who wash dishes or scrub floors; but any individual who subjects his fingers to a constant irritation may develop this localized condition. The most common nail changes are discoloration, transverse depressions, and hyperkeratosis subungualis with its usual sequelæ. These consist of a lifting of the plate and subsequent discharge of the keratosic granules from the bed, leaving a flat, horny floor covered by a thin, dome-shaped roof. All the other alterations of the plate noted under the heading of eczema may appear in cases of paronychia, but the ones above mentioned are by far the most frequent.

Dermatitis venenata.—Under this title will be considered the acute cases of dermatitis which can be directly attributed to some noxious occupation or to some chance poisoning of the skin. Here the commonest symptom is koilonychia, which appeared in twenty-five of the fifty-eight cases recorded by the writer. Other frequent changes in the nail are round punctate depressions, discoloration, transverse depressions, vertical ridges, and hyperkeratosis subungualis with its usual sequelæ of separation from bed, thinning and brittleness of the plate.

The prognosis is good in paronychia and in dermatitis venenata of the nails, and the treatment consists in the application of soothing antiseptic washes and ointments.

Trauma and Felon.—These two accidents frequently affect the nail, and when they are of slight importance or do not involve the matrix, the results upon the nail are unimportant. When, however, the matrix is affected, then we have a permanent change which will reproduce itself as long as the individual lives. The commonest of these constant deformities are transverse depressions, vertical ridges, hyperkeratosis subungualis with its usual sequelæ, and discoloration. The more unusual changes are round, punctate depressions, thinning, exfoliation of surface of plate, increased convexity, brittleness, opacity, koilonychia, gryphosis, leuconychia, transverse ridges, vertical depressions, invasion of air into the plate with subsequent crumbling or total loss of the nail. Under this heading should be considered the results of persistent biting of the nails, which leads to shortening,

Digitized by Microsoft®

thinning, brittleness, and koilonychia, or to the production of transverse ridges or depressions.

Psoriasis.—The involvement of the nails in cases of cutaneous psoriasis is relatively much commoner than is the rule in eczema. The disease can also exist alone in the nails, but such a diagnosis is in truth a hazardous one. The condition is most frequently observed in men, and between the ages of twenty and forty. The simplest cases consist of round, punctate depressions in the plate, and Unna and Heller regard this symptom as pathognomonic of psoriasis; but the writer cannot agree with this position, as these lesions appeared in more than one-fourth of his cases of eczema of the nails. The commonest lesion in the writer's experience is a more advanced condition, and consists in the changes subsequent to hyperkeratosis of the bed, namely, a horny floor, partly covered by a short, thinned, broken, discolored, arched plate. This change was noted in fifty-seven per cent. of the cases. Two other common lesions are discoloration, which varies from yellow to dark brown, and transverse depressions, both of which occur in about thirty-eight per cent. of the cases. After these four deformities come, in the order of their frequency, simple hyperkeratosis subunguealis, brittleness of the plate, thinning, opacity, vertical ridges, exfoliation, increased convexity, total loss of the nail, broken nail, koilonychia, disappearance of lustre, transverse ridges, and vertical depressions.

Pathologically, the psoriasic papules form on the bed, raising up the plate and allowing the air to be imbibed by the plate cells. This leads to opacity and discoloration. In the subungual corium there is great dilatation of vessels instead of the inflammatory œdema observed in eczema. The prognosis is almost always good, but there are severe cases of many years' standing in which the nails have completely fallen, never to return. The treatment, as in all nail disease, is the same as for the skin, only one must remember that Roentgen rays have an atrophic influence on nails and hair, while they exert a tonic action on undifferentiated epithelium, and for this reason one cannot expect the marvellous and rapid results which one often experiences after subjecting chronic patches of cutaneous psoriasis to *x*-rays.

With the completion of the descriptions of the last five diseases, the most important part of nail pathology is finished, for in my experience eczema, paronychia, dermatitis venenata, felon or trauma and psoriasis constitute nearly eighty per cent. of all nail affections, and instead of finding any lesions pathognomonic of any given disease, we note how constantly the same lesions appear in the different processes. This is certainly disappointing; but as we continue the study of diseased nails, we shall be more and more struck by the frequency with which the same lesions occur over and over again in entirely different processes.

Pityriasis rubra pilaris.—Here we may find transverse depressions, subungual hyperkeratosis with increased convexity of plate and onychauxis, yellow discoloration, vertical ridges, and depressions and hyperæsthesia.

Lichen ruber.—The nails become atrophied, light yellow brown, fissured and brittle at the free end, and uneven upon the surface.

Psorospermosis.—In this rare affection the nails are almost always involved, and show one or more of the following abnormalities: thickening, opacity, vertical ridges and depressions, fragility at border, hyperkeratosis subunguealis with elevation of the plate, gryphosis, crumbling away, and final loss.

Alopecia.—During the last three years I have observed five cases of partial or total alopecia with bad teeth and diseased nails. The nails exhibited round punctate and transverse depressions, vertical ridges, or subungual hyperkeratosis with subsequent separation of the plate from the bed, discoloration, and brittleness. In mild alopecia areata, one occasionally finds vertical ridges and an increased brittleness of the plate, while in the severe cases of nervous origin the nails have been completely shed.

Pemphigus.—As a rule the disease is not accompanied by nail disorders, but when the exception is present we find atrophy and brittleness of the plate. When, however, a vesicle or bulla forms under the nail, deformities inevitably result, the commonest of which are hyperkeratosis of the bed, vertical or horizontal ridges, discoloration, thickening, crumbling, and loss. If a bulla occurs in the matrix the plate is always shed.

Epidermolysis bullosa hereditaria.—This condition usually leads to atrophy and exfoliation of the plate, but examples of gryphosis have also been observed.

Hydroa æstivale.—When a vesicle or a bulla forms under or near the nail, we must have a resulting deformity, and in one case I noted vertical ridges and loss of the plate.

Dermatitis herpetiformis.—Usually the nail takes no part in this disease, but when the vesicles form near the nail or the process affects the whole economy, then we find round, punctate, or transverse depressions, vertical ridges, exfoliation on surface of the plate, or invasion of air.

Scarlatina.—Nail lesions are not common, but transverse depressions and loss of the nails are symptoms which have been recorded.

Dermatitis exfoliativa.—In light cases the nails remain perfect, but when the general condition becomes severe, then the most marked disturbances occur in the nail, including round, punctate, or transverse depressions, hyperkeratosis subunguealis, discoloration, opacity, gryphosis, or breaking of the nail.

Pityriasis rubra.—Heller mentions as concomitants of this disease thickness, opacity, fissuring, crumbling, separations from the bed, and gryphosis.

Dermatitis calorica.—In mild cases of dermatitis following exposure to heat or cold transverse depressions, discoloration, separation from bed, and onychauxis have been recorded, but in severe cases the nails fall.

Dermatitis from Roentgen rays.—As in the case of the skin the involvement of the nails usually occurs in the operator rather than in the patient. After repeated exposure to the rays, the nails show transverse depressions, often very deep, increased convexity, vertical ridges, discoloration, separation from the bed, crumbling of plate, and finally total loss of all nails which has persisted in one of the writer's cases for three years.

Scleroderma.—Heller records many accidents upon the nails as sequelæ of this disease. As will be seen by the subjoined list, the variations in degree and variety are unusually large: gryphosis, local asphyxia of bed, thickening of the skin of the bed, vertical ridges of the plate, transverse furrows and ridges, increased convexity, brittleness, atrophy, erosions of plate, and loss.

Atrophoderma.—In this rare dermatosis the nails often become influenced and exhibit vertical ridges, brittleness, atrophy, and vertical depressions, while in severe cases the lunulæ disappear altogether.

Vitiligo may exhibit at times lesions on the nails, and in my experience I have observed transverse depressions and leuconychia.

Pruritus.—With any of the pruriginous diseases the nails may become altered and show transverse depressions, vertical ridges, or even koilonychia.

Syphilis.—Syphilis of the nails is not common, and forms only about five per cent. of all nail disturbances in my observations. Like the general constitutional disease syphilitic manifestations on the nail may be divided into those resulting from the primary lesion, from the secondary eruption, and from the late changes of the disease.

A chancre on the nail wall is followed in a short while by a series of parallel transverse depressions with or without discoloration, or the change may be more intense and the plate will ulcerate and drop off in part or *in toto*.

The secondary stage of the disease shows itself usually in one of two ways: first, by the formation of a papule on the bed, and second, by a general moist ulceration of the nail. The formation of a papule on the bed is indicated by a red spot in the plate, which becomes yellow with the subsidence of the lesion. The plate over the papule becomes thinner and may even be broken, while the horny layer of the bed thickens, and as a result leu

Digitized by Microsoft®

conychia may ensue. The secondary ulcerations of the nail are the most frequent syphilitic manifestations, and the disease is characterized by the large number of the nails involved. The first signs are redness and swelling of the last phalanx accompanied by pain. The nail walls become affected and the epidermis is raised by fluid and finally ulcerates. Pus appears from the eponychium and from under the plate on the sides, and causes the plate to look yellow. Blood is imbibed by the plate cells and the nails become red and later black. Ulcerations appear along the bed, and as a result the nails fall. If the matrix is affected, nails may not be reproduced, or may grow again gryphotically deformed. The restitution of such nails is always a long and tedious task, and must be brought about by mild local antisepsis and prolonged general antisyphilitic treatment.

The nail lesion associated with late syphilis usually assumes a dry form, and has been termed scabrities unguium syphilitica or onyxis craquelé. At the root of the nail white, punctate depressions form in vertical series brought about by parakeratosis and acanthosis of the bed. These pathological processes prevent the formation of onychin, and as a result we find hyperkeratosis subunguinalis with its usual sequelæ, or a thickened, yellow, crumbling plate.

In hereditary syphilis Neumann states that the nails may assume atrophic forms and appear thin and brittle, or poorly developed.

Lepra.—In pure cases of lepra tuberosa nail changes are rarely met with, but in mixed types or in pure anæsthetic forms all degrees of deformities are encountered, extending from simple brown spots to gryphosis and permanent loss.

Variola.—Virchow states that if a pustule of smallpox appears upon the bed, the plate will show a yellow, sunken spot, and may eventually be cast off; and if such an accident occurs, the loss will be a permanent one.

Addison's Disease.—In this affection the nail lesions are practically pigmentary ones. The nails appear white on account of the general anæmia and deposit of pigment in the nail bed or brown streaks or universal darkening of the nails may appear.

Cutaneous Tuberculosis.—The nails show involvement only when the tuberculous process exists in the neighborhood of the nail walls. Transverse depressions and ridges, vertical ridges, discoloration, hyperkeratosis subungualis with its resulting deformities, *i.e.*, raising of plate from bed, increase in convexity of plate, casting off of granular débris, thinning and breaking of nail, and final loss, which in this disease may be permanent, are the lesions usually experienced.

Morbid Processes in the Nail in Connection with Non-Cutaneous Diseases.

Phthisis Pulmonum.—Hippocrates was the first to describe the increased convexity of the nails in consumptive patients, and thus the term Hippocratic is used to denote the high arching which often exists, both longitudinally and vertically, in this disease. Women are affected in this manner oftener than men, and as a rule the thumb nail is the first to show the change. After the thumb the frequency of involvement extends seriatim to the little finger. A plausible explanation of this phenomenon is given by Pigeaux, who says that the regions farthest from the heart are subject to œdema, which lifts up the matrix of the nail and causes elevation of the plate, while imbibition of this same fluid produces a thickening of the plate itself. The dilatation of the vessel causes the disappearance of the lunula.

Empyema.—Hippocratic nails have been observed in this disease also, but have disappeared with the subsidence of the purulent fluid.

Rachitis.—Esbach has noted a shortening of the last phalanx.

Carcinomatosis.—In all cachexias nails become softer, probably on account of the anæmia of the matrix, bed, and walls. Observers have recorded also leuconychia and onychorrhexis.

Heart Disease.—Here, as in consumption, circulatory disturbances are at work, and consequently blueness and Hippocratic nails with "drumstick fingers" appear.

Embolism and Thrombosis.—Observations upon these accidents to the fingers are decidedly rare, but Heller speaks of blackness, gryphosis, and loss as possibilities.

Diabetes mellitus.—The presence of sugar in the blood or the subsequent changes in the vessel walls and tissues, induced by the circulating sugar, may produce transverse furrows, brittleness, exfoliation, or complete loss of the nail.

Malaria.—Writers have noted the phenomenon that before the advent of the chill the nail turns to a pale blue or slate color.

Scorbutus.—In this disease hemorrhage is apt to occur under the nail, producing the variations in color due to oxidation and loss of the nail involved.

Chlorosis and Anæmia.—The lack of nourishment brings about paleness, thinning, and tendency toward koilonychia, while in pernicious anæmia a different class of disturbances have been noted, namely, thickening of the nail with subsequent tissuring and crumbling.

Gout.—Here again apparently opposite results may be reached. On the one hand, the nails may become thin and brittle or, on the other hand, vertical ridges and depressions may form together with elevation of nail from bed, with brownish discoloration and subsequent gryphotic changes.

Rheumatism.—This affection may attack the nails, causing transverse depressions, elevations of the plate with yellow discoloration, brittleness, or gryphosis.

Changes in the Nails in Connection with Diseases of the Nervous System.

Peripheral System.—Paralysis or wounds of cutaneous vessels produce trophic alterations in the nails. Hypertrophic changes cause thickening, vertical ridges or gryphosis, while atrophic modifications are thinning, cracking, loss, slowness in growth, discoloration, vertical or horizontal ridges, and opacity.

Neuritis of Internal Origin.—Here changes are less frequent than after wounds of nerves, but nevertheless writers have described loss of gloss, discoloration, transverse and vertical depressions, brittleness, and bending of the nail.

Morvan's Disease is frequently characterized by disturbances of the nails, such as thickening, blackness, hardening, and gryphosis.

Raynaud's Disease.—Mild cases of this condition may exist without changes in the nails, but in the severer examples we find vertical ridges and furrows, increase in convexity and thickening, hyperæsthesia, and possible loss. When the disease is accompanied by panaritium, then we find the usual results of shortening, bending, vertical ridges, and gryphosis.

Erythromelalgia is often accompanied by nail changes, among which have been recorded transverse furrows, yellow discoloration, thickening of the bed at distal end, bending and thickening of the plate, and loss.

Spinal Diseases.—*Tabes Dorsalis.*—A very frequent concomitant of this disease is loss of the big toe nail, which may fall repeatedly. This phenomenon is caused by trophoneurotic changes and by the invasion of blood between the bed and the plate. Other nail changes are possible, and examples have been recorded of brittleness, thickening, hardening, and transverse and vertical depressions.

Syringomyelia.—The almost constant presence of paronychia and of panaritium in this rare affection accounts for the frequent and severe involvement of the nails. Here we find brittleness, lack of lustre, cracks, thinness, exfoliation, and after panaritium gryphosis, atrophy, loss and stumps of nails growing at various angles.

Anterior Poliomyelitis.—In this disease instances of softening and loss of the nails have been recorded.

Digitized by Microsoft®

Injured Spine.—After such an accident I have noted transverse depressions and ridges and hyperkeratosis subungualis.

Multiple Sclerosis.—The nail changes in this affection are very similar to those observed in locomotor ataxia; namely, brittleness, pain, and invasion of blood between bed and plate, causing the loss of the nail.

www.1lbtool.com.cn

BRAIN DISEASES.—*Apoplexy.*—The possible deformities of the nail resulting from strokes of paralysis are vertical ridges, transverse furrows, increased arching, thinness and greater transparency, smallness, brittleness, koilonychia, ecchymosis of bed with subsequent loss, and gryphosis.

PSYCHOSES.—*Dementia Paralytica.*—The changes occurring in this disease are quite similar to those following apoplexy, and may consist of increased transparency, vertical and transverse furrows, subungual hemorrhage, transverse ridges, yellow or brownish discoloration, and gryphosis.

Melancholia.—In the course of this disorder different observers have noted transverse furrows, increased thickness, and slowness of growth.

FUNCTIONAL NEUROSES.—*Hysteria.*—Nail changes are seldom met with in this condition, but instances of lack of lustre, vertical and transverse furrows, exfoliation, thickening and roughness of surface, and final loss have been recorded.

Epilepsy.—Another disease in which nail disorders are rare, but when present they may include thinness, brittleness, deep transverse furrows, roughness of the plate, and subungual hemorrhage.

Neurasthenia.—In this disease I have observed discoloration and transverse ridges.

Nervous Shock.—As a result of such accidents patients have come to my notice with transverse depressions and ridges, thinning, discoloration, and subungual hyperkeratosis with its usual results.

TROPHIC NEUROSES.—*Myxœdema.*—In my experience the only changes in the nails in connection with this disease have been those of vertical ridges and subungual hyperkeratosis and its resulting deformities.

DISEASES OF THE BONES.—Fractures are often followed by discoloration, which varies from yellow to black, by transverse furrows and by slowness of growth of the nails.

Acromegaly.—This interesting process is almost always accompanied by onychauxis where the nail is enlarged transversely and vertically and appears flat, brittle, and lustreless with vertical ridges upon its surface. In addition to these symptoms I have observed discoloration and subungual hyperkeratosis, but have not observed the usual sequelæ of this condition.

Arthritis Deformans.—In this disease I have recorded vertical ridges and depressions, transverse ridges and depressions, discoloration, thinning, and brittleness and koilonychia.

Acro-arthritis.—In this somewhat allied condition nails have been shown me bearing round punctate depressions, vertical and transverse ridges, discoloration and hyperkeratosis of the bed with subsequent elevation of the plate.

NAILS IN CONNECTION WITH YOUTH AND OLD AGE.

The sucking of nails renders them soft and small, while advancing years produce vertical ridges and a tendency toward increase in size.

Keratosis senilis.—In conjunction with this disease I have seen round, punctate, and transverse depressions, leuconychia, and subungual hyperkeratosis with increased convexity of the bed.

INTOXICATIONS.

Heller records the following changes in connection with the use of poisons:

Arsenic may cause pain, yellow or brown discoloration, raising of plate from bed with eventual loss. Brooke and Roberts observed in the recent English epidemic of arsenical poisoning from beer abnormally rapid growth of the nails with transverse ridges and subungual hyperkeratosis.

Mercury rarely produces changes, but transverse furrows, blackness, thickening, and loss of the nail have resulted from the abuse of the drug.

Nitrate of silver may be deposited in the tissues and discolor the nail bed blue or gray. I have recently observed a very marked example of this condition.

Lead has been known to destroy the nails.

When one has read the facts enumerated and described in the preceding paragraphs, I think one must be greatly impressed by the similarity of symptoms resulting from the many diseases which may induce changes in the nails. This is the effect produced upon the writer, who at the end of three years' special study of these affections feels more than ever that the physician who states that he can make a positive diagnosis from the nails alone is making a rash statement. In closing this article the writer wishes to acknowledge his great indebtedness to Heller, whose unique book, "Die Krankheiten der Nägel," has been the model upon which he has based this article.

Charles J. White.

NANTUCKET, MARTHA'S VINEYARD, AND CAPE COD.—The islands of Nantucket and Martha's Vineyard and the southern district of Cape Cod are climatologically

FIG. 3481.—Nantucket, Martha's Vineyard, and Cape Cod, Mass.

and structurally so similar, and are grouped in such close proximity to each other that it has seemed best in the present description to consider them under one head. Nantucket, as being situated farthest away from the mainland, is to be taken as the climatological type, its climate resembling most nearly the climate of the ocean as experienced on shipboard, of any island on the Atlantic seaboard from Old Point Comfort to the Grand Manan. The climatic attributes may be briefly summed up as follows: (*a*) as being at the ocean level the air contains the maximum amount of oxygen, aqueous vapor, and ozone; (*b*) it contains saline particles, *i.e.*, iodine and bromine; (*c*) it presents the most regular variations of barometric pressure; and (*d*) it presents the minimum diurnal variation of temperature. Other stations included in this article resemble it more or less nearly, according to their proximity to the sea and to modifying local conditions subsequently to be considered.

Digitized by Microsoft®

The Island of Nantucket (41° 15' North Lat., 70° W. Long.) lies in the Atlantic Ocean twenty-five miles due south of the metacarpal joint of the beckoning finger of Cape Cod. It is of a long-horned crescentic shape, and, roughly speaking, is fifteen miles long and four miles wide. It comprises in its entire extent about twenty-nine thousand acres. It is the most easterly of the group of islands known as the Elizabeth Islands, in which are also included Martha's Vineyard, Tuckanuck, Muskeget, and Naushon. It is almost exactly one hundred miles from Boston.

www.libtool.com.cn

Structurally considered, it is a vast mound of sand lightly covered with vegetable mold, gently undulating in surface, and presenting a series of high bluffs to the sea. At different points its surface is dotted by fresh-water ponds of varying size. The soil is of a light, porous, sandy nature. Rocks are so rare that it would be easily possible to count those worthy of the name upon the fingers of the hand. There are, practically speaking, no trees. The flora is large and varied. Five hundred varieties of species are described as growing without cultivation. The botanic range is wide; heather grows upon the moors; cactus is to be found freely flowering in the month of July, while in August a visit to a vast field of hollyhock-like blossoms of the pink hibiscus is a favorite excursion. A large variety of birds pause at the island upon their semi-annual pilgrimages; black duck and quail live there the entire year, and the neighboring island of Muskeget is a breeding place upon which thousands of families of sea-gulls are annually reared.

Nantucket, the chief town, is situated upon the northern side of the island, on Nantucket Sound. The resident population in 1894 was 3,300, though the summer population is, of course, largely in excess of these figures. In that year 16,306 passengers, not including children, were brought to the island. At the height of its prosperity, when the whaling industry flourished, the population of the island was 10,000. The town is very old (the oldest house bearing the date 1686). Many of the dwellings and warehouses are built of brick, and the number of buildings in general is surprisingly large in proportion to the present population. A general impression of size and antiquity is given to the town. The streets for the most part are paved with stone and asphalt; outside the town clay roads extend in many directions, and the State road, a fine piece of macadamized road, eight miles long, connects the town with Siasconset. At a greater distance from the town the roads consist chiefly of "ruts," and one may ride or drive in almost any direction at will over the moors.

Siasconset, formerly a small fishing village, eight miles from the town and connected with it by a narrow-gauge railroad, is now an exceedingly popular summer resort. It is situated on the ocean and is possessed of several hotels and boarding houses, a casino, and a fine golf course. The surf bathing is excellent.

NANTUCKET, MASS., FIVE YEARS, 1897–1901.

Climatic Data.	June.	July.	August.	Sept.
Average maximum	67.1° F	73.9° F	73.9° F	69° F
Average minimum	55.7°	63.1°	63.2°	58°
Average daily range	11.3°	10.9°	10.7°	10.4°
Absolute maximum	78	85	87°	85°
Absolute minimum	44°	54	56°	46°
Average number of clear days	7.6	7.8	10.2	11
Largest number of clear days	11	10	12.	13
Smallest number of clear days	4	1	5	9
Average number cloudy and partly cloudy	22	23	20.8	19
Largest number cloudy and partly cloudy	26	30	26	21
Smallest number cloudy and partly cloudy	19	21	19	17
Average number rainy	8.6	10	9.6	8
Largest number of rainy days	10	13	11	11
Smallest number of rainy days	8	8	7	4
Average total rainfall	1.45	2.45	2.22	1.75
Average relative humidity for four years	86.5	89.2	88.3	81
Average hourly wind velocity for for years	10	9.5	8.2	10.2

The preceding table, compiled from statistics prepared for me by Mr. A. W. Crosby of the weather bureau in Boston, shows climatic data for the five years 1897–1901.

From the foregoing table it is seen that the average number of rainy days for the four summer months, for five years, was nine per month. This number represents the days during which it rained at some portion of the day. The number of days in which an invalid could not exercise out of doors was of course much smaller. In 1894, for the months of July, August, and September, there were ninety-two consecutive pleasant days.

The prevailing direction of the wind is westerly, blowing, as will be seen by the map, over miles of ocean. One of the most remarkable meteorological phenomena of the island is the rarity of electric storms. Thunder storms are exceedingly rare, passing north or south of the island. In the twenty-one summers I have passed at Nantucket I have known the lightning to strike but on three occasions. Fogs are a more variable feature, their prevalence differing in different years. As a rule it is not more foggy than at other seashore resorts.

The average temperature of the water for the summer of 1894 was 72° F. At the bathing beach it is somewhat higher. The cause of this high temperature of the water is a much-discussed question. It is believed by some to be due to the proximity of the gulf stream, but this theory is not borne out by fact. Any one interested in the matter is referred to Dr. Peterman's charts.

The water supply of the town is derived from a large fresh-water pond. It is between two and three miles from the town, and is in an isolated position so far as dwelling-houses are concerned, the house of the engineer being the only human habitation within the water-shed. It would be difficult to conceive of its ever sustaining dangerous pollution.

The sewerage of the town has been greatly improved in recent years by the construction of a sewer to the deep waters of the outer harbor.

The average velocity of the wind for the three months of the summer of 1894 was nine miles.

From its isolated position Nantucket is particularly free from contagious diseases. In the ten years 1890–1900, there have been forty-four deaths from tuberculosis, or eleven per ten thousand; and fourteen deaths from diphtheria, or about four per ten thousand. In 1901 one case of typhoid fever was reported. It was, however, an exceedingly doubtful case, and did not give the Widal reaction. Contagious diseases, when present, are for the most part imported, and are generally so managed as to reduce to a minimum their further dissemination. This is the more readily accomplished because of the intelligent and energetic co-operation of the Board of Health.

The amusements afforded the summer visitors are unusually varied. Boating is excellent. Large cat-rig boats, under the charge of experienced skippers, are provided in abundance. Those preferring still water may sail in the landlocked waters of the inner harbor, eight miles in extent. More accomplished sailors can pursue their excursions upon the rough waters of the Sound. A daily trip by sailboat and by launch is made to Wauwinet, about seven miles up the inner harbor. Still water for rowing is always found in the inner harbor, and excellent light boats may be hired by the hour. It is particularly safe for women and children because of the shallowness of the water. The fishing is excellent; bluefish abound in the season; scup and plaice fish (the latter a large species of flat fish) are found in great abundance, as is also the English turbot. Lobsters, clams, quohogs, and oysters are also abundant. Pickerel and fresh-water perch are found in the ponds. There is some shooting. Marsh birds are present throughout the summer, plover and snipe are frequently killed during their respective flights, and black duck and rabbits are numerous. Driving is very agreeable; the moors are for the most part unfenced and level, and it is the custom to ride and drive across them in any and every direction. Bicycling is also excellent. The State road is a perfect piece of macadam; the clay roads are fair, and there are several agree-

Digitized by Microsoft®

able bicycle paths. Golf is the principal amusement. The course is particularly fine, and in many respects an exact counterpart of the Scotch links. It consists of eighteen holes, is about six thousand yards in extent, and extends over gently undulating ground, in which neither a tree nor a stone interferes with the pastime. The turf is excellent, and fine views of the sea are to be had from many of the trees and greens. Afternoon teas and tournaments are held every week during the season.

From twenty years of summer practice on the island the writer feels able to recommend the climate as especially suited for the extremes of life, the very old and the very young; the smallness of the diurnal range being a most important factor. The absence of contagious diseases also renders it a highly desirable locality for children. It is well suited to those suffering from functional nervous affections, neurasthenia, insomnia, and neuralgia; for valvular diseases of the heart, for convalescence from diseases of the respiratory organs, for chronic dysentery and diarrhœa, and especially is it specific for the entero-colitis of children. Cases of tuberculosis and of the scrofulous diseases of children also do exceedingly well at Nantucket.

Nantucket possesses an excellent public library; a museum, containing many objects of interest; the valuable and interesting collection of the Historical Society; an old mill; several light-houses and life-saving stations; churches of nearly every denomination; gas and electric plants. There is an excellent hot salt-water bathing establishment.

There are several hotels, among which may be mentioned, The Sea Cliff Inn, owned by a syndicate, and the largest hotel on the island, The Ocean House, Point Breeze, and Springfield House.* Prices vary from $10 to $35 per week. There are also a large number of excellent boarding-houses. A. T. Mowry, real estate agent, solicits correspondence upon all matters pertaining to Nantucket, and has a list of available cottages. Rents of the latter vary from $150 to $1,000, average about $400. An eminent Boston surgeon and an equally well-known oculist from Philadelphia are among the summer residents, and can be called on for special service.

Martha's Vineyard.—Twenty miles west of Nantucket and ten miles south from Wood's Hole lies the island of Martha's Vineyard, an island considerably larger than Nantucket and similar to it in climate, its chief differences consisting in its nearer approximation to the mainland and in the fact that it is comparatively thickly wooded.

At the easterly end of the island Edgartown is situated, a small and very picturesque town with a resident population of about eight hundred persons, and a summer population much in excess of these figures. Bathing, fishing, sailing, and driving are excellent, and there are well-arranged golf links.

Nearer the centre of the island and on the northerly shore is the town of Cottage City, probably the most populous summer resort of the cape district. The resident population is about the same as that of Edgartown, but the summer population is estimated as being about twenty thousand.

Vineyard Haven, situated on the north side of the island, lies about a mile to the west of Cottage City, and is an exceedingly popular summer resort. The resident population is about one thousand; the summer population is largely in excess of these figures.

West Chop is a small summer colony northwest of Vineyard Haven. The hotel, casino, and the major portion of the land are owned by a syndicate of Boston gentlemen. The bathing and boating are excellent and the views are particularly attractive.

Similar in climate and in the configuration of land are the summer resorts situated upon the southern border of Cape Cod. Among these resorts may be mentioned Wood's Hole, Falmouth, Cotuitport, Osterville, Hyannis, Yarmouth, Harwichport, and Chatham.

Harold Williams.

* Not intended to be a complete list.

NAPA SODA SPRINGS.—Napa County, California Post-Office.—Napa Soda Springs. Hotel and cottages.

Access.—Take Oakland Ferry (from San Francisco) at 8 A.M. for Napa City, forty-six miles distant, arriving at 10:10 A.M. Then take stage to springs, five miles distant. Spring, summer, and autumn are suitable seasons for visiting the springs.

The resort is charmingly located on the southwestern slope of the Coast Range, at an elevation of about 1,000 feet above the level of the sea. From the Rotunda Hotel many beautiful views are spread before the eye in all directions. Looking southward over the beautiful valley of Napa County one sees a landscape seldom surpassed for loveliness, and which always remains fresh in the memory. The climate is warm, dry, and salubrious, uniting the advantages of mountain air with breezes direct from the sea. The mineral springs here are among the most noted in the State. They number twenty-seven in all, with an average daily flow of about four thousand gallons. The temperature of the water ranges from 65° to 68° F. The main spring, the Pagoda, from which most of the commercial Napa soda is obtained, is an alkaline-chalybeate water, strongly charged with carbonic anhydride. It is delightfully clear and sparkling, and has an agreeably pungent taste. Following is Dr. Anderson's analysis:

Pagoda Spring (Napa Soda Spring).

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	7.14
Sodium bicarbonate	12.95
Sodium carbonate	1.10
Sodium sulphate	1.62
Potassium bicarbonate	Trace.
Magnesium bicarbonate	3.04
Magnesium carbonate	21.76
Calcium bicarbonate	.78
Calcium carbonate	9.55
Ferrous carbonate	7.90
Silica	.74
Alumina	.57
Organic matter	Trace.
Total solids	67.15

Free carbonic acid gas, 143.62 cubic inches. Temperature of water, 67.7° F.

Over this spring is a beautiful pagoda, supported by solid stone pillars, and, resting upon a tessellated marble floor, a natural stone basin has been artistically arranged, through which sparkling soda bubbles in all its freshness. There are many other important springs at Napa, including the well-known Iron Spring and the Lemon Spring. The former was analyzed by Professor Lanzwurt in 1870, with the following result:

Iron Spring (Napa Soda Spring).

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	5.20
Sodium bicarbonate	13.12
Sodium sulphate	1.84
Magnesium carbonate	26.12
Calcium carbonate	10.83
Ferrous carbonate	7.84
Silica	.62
Alumina	.60
Total solids	66.17

Free carbonic acid gas, undetermined. Temperature, 68° F.

The waters of all the springs have the same general characters—alkaline-chalybeate, clear, and sparkling. Napa soda water is highly esteemed as a beverage. It is sold in every city and town of the coast, and is one of the pleasantest summer drinks to be found. The water is an efficient aid to digestion, being antacid and tonic. When taken early in the morning before breakfast its action is gently aperient. The ferruginous salts, held in solution by the carbonic-acid gas, are valuable in anæmia and chlorotic conditions, malarial toxæmia, and many disorders requiring iron for the constructive metamor

Digitized by Microsoft®

phosis of red corpuscles. The grounds at Napa Soda Springs cover over a thousand acres of hill and valley. The place is thoroughly improved, and the visitor will find every arrangement provided for his comfort and recreation while sojourning there. Among the attractive features should be mentioned the excellent bathing facilities, both tub and plunge. There is also a swimming bath measuring one hundred and fifty feet in length by fifty feet in width, and with a depth of water varying from four to ten feet. *James K. Crook.*

www.libtool.com.cn

NAPHTALIN. Under the title *Naphtalinum*, Naphtalin, the United States Pharmacopœia makes official the hydrocarbon *naphthalene* ($C_{10}H_8$), known also by the common name of "tar camphor." Naphtalin (to use the pharmacopœial spelling), like benzene, is the fundamental member of a series of aromatic compounds. Naphtalin is a common constituent of tars, and is obtained from coal tar by fractional distillation. Naphtalin, when purified, presents itself in large, colorless, crystalline, rhombic plates of a pearly lustre and an unctuous feel. It has a burning taste and a faint peculiar odor. It is insoluble in water, but dissolves in alcohol, ether, benzene, oil of turpentine, glacial acetic acid, and warm oils, both fixed and volatile. It melts at 80° C. (176° F.) and boils at 218° C. (424.4° F.), but yet sublimes at a much lower temperature than that of its boiling-point, and, mixed with boiling water, rises in vapor with the steam. Even at ordinary temperatures a gradual sublimation occurs. It should be kept in well-stoppered bottles.

Naphtalin is, locally, but slightly irritant, and constitutionally is not ordinarily poisonous—probably because of incomplete absorption due to its insolubility in aqueous fluids. Yet naphtalin is decidedly "antiseptic" in the common medical sense of the word. Taken internally, some absorption certainly occurs, since naphtalin, swallowed, reappears in the urine. Naphtalin has been used in medicine to prevent decomposition of the urine in cystitis, by administration, by the mouth, of an aggregate of five grains daily; but its main use internally has been for local antiseptic purposes in the intestinal canal, as in diarrhœa and dysentery, and as a vermifuge. It has been vaunted also as an expectorant in bronchitis and as a constitutional remedy in typhoid fever. The ordinary dose ranges from 0.13 to 1 gm. (gr. ij. to xv.), and, because of the disagreeable taste, the medicine is best given in capsule. A case of poisoning—an exceptional circumstance—has been reported from the taking of a dose of eight grains; and it is certainly risky to give much of the drug if there be any kidney disease or weakness. As an anthelmintic for the "seat-worm," naphtalin may be given by enema, in sweet oil (1 gm. in two or three tablespoonfuls of the oil). For ordinary internal uses naphtalin has been largely supplanted by naphtol.

Externally, naphtalin has been used for the making of antiseptic dressings in surgery. In this application naphtalin combines the features of a fair degree of efficiency on the one hand, and freedom from irritant or poisonous effects, and from offensive smell, on the other. The only untoward effects charged against naphtalin so far have been that the sharp points of the crystals may wound tender granulations, and that the powder may cake with fluid exudates, and so tend to obstruct the free drainage of discharges. Most reporters upon the use of naphtalin in surgery, however, have failed to observe either of these effects. Naphtalin may be applied in bulk, in fine powder, to wound surfaces, or by means of gauze or wool charged with the substance, by the device of steeping the dressing in a strong solution of naphtalin, and then permitting the solvent to evaporate. By this means a porous material becomes thoroughly impregnated with a fine powder of the hydrocarbon. A common solution for the making of such dressings is a twelve-and-a-half-per-cent. solution of naphtalin in a mixture of alcohol and ether in equal proportion. [See also Naphtalin in the article on *Antiseptics in Surgery*.] *Edward Curtis.*

NAPHTO-CRESOL is an alcohol-soluble substitute for creolin. *W. A. Bastedo.*

NAPHTOFORMIN is a condensation product of alpha- and beta-naphtol with formaldehyde and ammonia. It is an insoluble powder, and, being readily split into its components, is a powerful antiseptic for use in surgery. *W. A. Bastedo.*

NAPHTOL.—By the substitution, in the molecule of the hydrocarbon *naphthalene*, of a molecule of hydroxyl (—OH) for one of the atoms of hydrogen, a derivate, $C_{10}H_7.OH$, is obtained, bearing precisely the same relation to naphtalin that common phenol ("carbolic acid") does to benzene. Such derivate is styled *naphthol*, and according to the position in the naphtol molecule of the hydroxyl substitution, two distinct naphtols are obtainable, known respectively as *α-naphthol* and *β-naphthol*. Of these two bodies *β-naphthol* is the more easily made, and is the article used in medicine. It is official in the United States Pharmacopœia under the title and spelling *Naphtol*, Naphtol.

The common naphtol of the markets is an impure article, occurring in reddish or deep violet-brown crystalline masses of a disagreeable, pungent smell. Such a naphtol, because of the poisonous nature of some of the impurities, needs purification for medicinal use. Properly purified, naphtol presents itself in beautiful silver crystalline scales, nearly or entirely odorless, but of a sharp, burning taste. The crystals are very slightly soluble in water (in about one thousand parts of cold, and in seventy-five parts of boiling water), but dissolve freely in alcohol, ether, chloroform, benzol, and oils. Gently heated, naphtol sublimes, and may be distilled with steam. It should be kept in dark amber-colored bottles, well stoppered. Naphtol is locally distinctly irritant, exciting upon tender surfaces redness, smarting, and even inflammation, and, upon the healthy skin also, if in *alcoholic* solution, acting occasionally with sufficient energy to develop an eruption resembling nettle rash. Solutions in oils or fats, however, are said to be without effect upon the sound skin, although acting energetically upon an eczematous surface (Kaposi). *Constitutionally*, naphtol, in therapeutic doses, produces but little derangement. Some experimental dosings of animals have been followed by hæmoglobinuria, with convulsions and death, and, in one instance in the human subject, an external application of naphtol produced hæmaturia, ischuria, unconsciousness, and eclampsia (Kaposi). But since these effects are exceptional, it is likely that the samples used in the cases cited were not pure. Ordinarily doses of from 0.20 to 0.32 gm. (gr. iij. to v.), given a number of times daily, are innocent of harm beyond some possible disturbance of the stomach. The medicine therefore ranks among the non-poisonous, and its value lies in the fact that while it is thus non-poisonous to the human system it is yet quite potent to arrest the development of many micro-organisms. It is said to be five times as powerful in this regard as carbolic acid. Naphtol is accordingly used as an internal medicine to disinfect the alimentary canal, as in cases of diarrhœa, dysentery, intestinal dyspepsia, and especially in typhoid fever, in which disease its efficacy was first proclaimed by Bouchard. The doses are those already mentioned. The article is also used as a local application in many skin diseases, notably *scabies*, *psoriasis*, and *eczema*. It is commonly applied in ointment ranging in strength of naphtol from one half to ten per cent., or even fifteen per cent. The remedy should not be used upon denuded parts, and weak applications only should be made to irritated parts such as so commonly present themselves in eczema.

For *iodonaphtol*, see under the caption *Di-iodo-beta-naphtol*, in Vol. III. *Edward Curtis.*

NAPHTOL ARISTOL. See *Di-iodo-naphtalin.*

NAPHTOL BENZOATE is benzonaphtol (*q.v.*).

Digitized by Microsoft®

www.libtool.com.cn

NAPHTOL BISMUTH, orphol, basic beta-naphtol bismuth $[(C_{10}H_7O)_3Bi]_2 + Bi_2O_3$ or $(C_{10}H_7O)_3Bi + 3H_2O$, is a neutral, non-irritating, light-brown powder of very slight odor and slightly aromatic taste. In the intestines and to some extent in the stomach orphol is split up into its components, bismuth oxide and beta-naphtol, and so acts as an intestinal sedative and antiseptic in diarrhœa, dysentery, and intestinal putrefaction. The dose is 0.5 to 1 gm. (gr. viij. to xv.), usually given in capsule. Chaumier gave 5 gm. (gr. lxxv.) a day to young children without ill effects. In such large doses probably most of the drug passes through unchanged. Orphol is also applied externally as an antiseptic dusting and drying powder for impetigo, herpes, etc., and has been used locally in gonorrhœa and other mucous-membrane inflammations. *W. A. Bastedo.*

NAPHTOL CARBONATE, $(C_{10}H_7O)_2CO$, is a di-naphthyl ester of carbonic acid prepared by acting on beta-naphtol sodium with phosgene gas. It occurs as shining colorless scales which are insoluble in water. Recommended as a non-irritating intestinal antiseptic in dose of 0.12 to 1 gm. (gr. ij. to xv.). *W. A. Bastedo.*

NARCEINE. See *Opium*.

NARCOTINE $(C_{22}H_{23}NO_7)$.—Narcotine is, next to morphine, the most abundant alkaloid of opium, varying widely in percentage, both in different varieties and in different lots of the same variety. The amount has been reported as low as one per cent. and as high as ten per cent. It occurs in colorless, shining, acicular or prismatic crystals, melting at 176° C. (349° F.), almost insoluble in water, soluble in 100 parts of alcohol, 35 parts of ether, 2.7 parts of chloroform, 22 parts of benzene, and rather freely in hot acetic acid, by which it is usually extracted. It is only faintly basic and its salts are not crystalline. It is not bitter, but its salts are so, and are at the same time acid. Sulphuric acid turns it, after a time, to a yellow, changing to orange and red; the same, mixed with nitric acid, turns it blood-red. It is decomposable into meconin and *cotarnine* $(C_{12}H_{13}NO_3)$, the latter far more strongly basic than narcotine itself. Various other substances are obtained from it by different methods of treatment, but they are not of importance except from a chemical standpoint.

Crawford and Dohme (Proc. Amer. Phar. Assn., 1902) report experiments on warm-blooded animals, showing that it produces a fall in blood pressure and slowing of the heart, accelerated but weakened respiration, diminished saliva by small doses, increased by large doses, an anodyne effect upon the intestine, prompt and marked diminution of the urine, and a diminished size of the kidney. Partial elimination through the kidneys and stomach was observed, but none from the bowels, at least not as narcotine. Similar symptoms have been observed in man, together with profuse diaphoresis. The alkaloid, if pure, is in no sense a narcotic, for which reason the name "anarcotine" has been proposed for it, though it does not seem wise to introduce this element of confusion.

Therapeutically, narcotine is an antiperiodic, recognized as of considerable value in five-grain doses. Fortunately, since it is used in such large doses, its weakly basic character renders it easily freed from the associated active alkaloids, a character to which careful attention should of course be given. It is a valuable stomachic and digestive tonic in one- or two-grain doses three times daily.

Narcotine has been considerably employed as a secret remedy for the cure of the alcohol and other narcotic habits. Ebert reports many such cases cured or benefited through its use, and his results are confirmed by Schulte. The form of administration in these cases was a grain hourly. No harm resulted from the use of a gram or more per day, beyond the temporary loss of the appetite for food, followed later by an increase of appetite, and by weakening, amounting in some cases to semi-prostration, from the profuse perspiration.

Henry H. Rusby.

NASAL CAVITIES: ANATOMICAL RELATIONS AND RHINOSCOPY.—I. ANATOMY.—The nose forms the commencement of the air tract, and is composed of two large air channels in the centre of the face. The lower portion of this tract is used to convey air; the upper portion has distributed throughout its mucous membrane the terminal filaments of the olfactory nerve; while the whole cavity is employed in voice production.

The nose is divided into the external nose and the nasal cavities. The nasal cavities are separated from one another by a thin partition of bone and cartilage, called the septum. Each nasal cavity is surrounded by a set of accessory cavities, all of which communicate with the nasal cavity. In considering the anatomy of the nose, we find that three divisions may readily be made: (1) The external nose; (2) the nasal cavities; (3) the accessory cavities of the nose.

1. *The External Nose.*—The external nose forms the pyramidal projection in the centre of the face, extending from the brow to the upper lip. It is directed downward and forward. It is composed of bone, cartilage, and muscles which are covered externally with the facial epidermis and internally with the nasal mucous membrane.

The apex of the pyramid—the root of the nose, the radix nasi—joins the forehead; the lateral walls form by their junction the dorsum nasi, or back of the nose, which extends from the tip, the apex nasi, to the root of the nose; the lateral borders slope outward to form two wing-like leaflets, which are known as the alæ nasi or wings of the nose; the free edges of the alæ nasi form the outer borders of the two nasal orifices, known as the anterior nares, which are separated by a median pillar, or columna, the ponticulus nasi. The two anterior nasal orifices open downward and communicate with the vestibule of the nose, which is composed of that portion of the nose which is contained within the cartilaginous framework and extends from the anterior nasal orifice to the commencement of the osseous framework.

The walls of the nose proper are composed of the nasal bones and nasal spine of the frontal bone, the nasal processes of the superior maxilla, the premaxillary portion of the upper maxilla, the pars incisiva, and the lateral cartilages of the nose. The nasal bone articulates above with the frontal bone; its outer border articulates with the nasal process of the maxilla; while along their inner border, by their union, the nasal bones form a crest for articulation with the nasal spine of the frontal bone, the perpendicular plate of the ethmoid and the triangular cartilage of the nose. The outer surface of this bone is smooth; its inner surface presents a longitudinal groove for the nasal nerve. Lying external to the nasal bone is the nasal process of the maxilla, which articulates along its anterior border with the nasal bone, above with the frontal, and posteriorly with the lachrymal bone. Its external surface is smooth, while its inner surface presents two crests for the attachment of the middle and inferior turbinate bones. The pars præmaxillaris of the superior maxilla unites with its fellow below to form the lower rounded portion of the apertura pyriformis, the pear-shaped opening of the osseous nasal cavity. To the apertura pyriformis is attached the lateral cartilage of the nose, thus completing the outer portion of the external nose. The cartilages of the nose are the septal cartilage; the triangular, or superior lateral cartilages; the alar, or inferior lateral, cartilages; the accessory, or sesamoid, cartilages; and the accessory quadrate cartilages.

The cartilage of the septum is the most anterior structure of the septum, and is irregularly quadrilateral in form. Its anterior inferior border is unattached, and lies above and behind the inner plates of the two inferior lateral cartilages, extending to the anterior nasal spine, which it embraces. Its anterior superior border is attached to the crest on the under surface of the nasal bone, and below the nasal bones the sides of its border are continuous with the superior lateral cartilages. Its posterior superior border is in contact with the perpendicular plate

Digitized by Microsoft®

of the ethmoid, and the posterior inferior border is received within a groove formed in the anterior nasal spine of the superior maxilla and the vomer for its reception.

www.libtool.com.cn

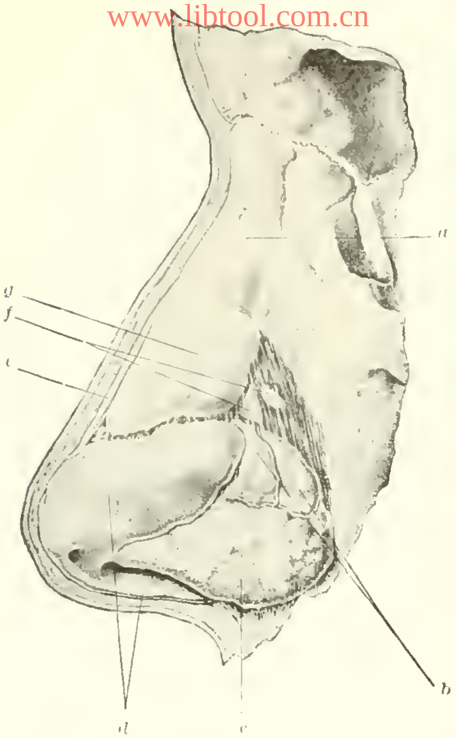

FIG. 3482.—Dissection of the External Nose, Demonstrating the Cartilages and Bones of this Part of the Nose and their Relations to One Another. *a*, Nasal bone; *b*, sesamoid cartilages; *c*, fibrous tissue of ala of nose; *d*, inferior lateral cartilage; *e*, cartilage of nasal septum; *f*, accessory quadrate cartilages; *g*, superior lateral cartilage.

The cartilaginous septum is thinnest in the vestibule of the nose, and increases gradually in thickness as it approaches its attachment to vomer and ethmoid.

The superior lateral cartilage is flat and triangular in shape, partially continuous with the anterior border of the septal cartilage, of which it forms flange-like extensions. It is closely attached along its superior and posterior border to the nasal bone and the nasal process of the superior maxillary bone. Its inferior border is attached to, and partially covered by, the inferior lateral cartilage. The inferior lateral cartilage is bent sharply around in front of the anterior nares so as to form an inner and outer plate. The outer plate lies in the plane of the superior cartilage of the nose, and makes up a part of the outer surface of the nose, while the inner plate lies in contact with the corresponding fellow of the opposite side and forms a portion of the inner border of the anterior nares. The lower lateral cartilages unite over the dorsum, but extend only about half-way back to the maxillæ, so that the intervening space in the alæ nasi not filled with cartilage is made of dense fibrous tissue.

The accessory cartilages are four in number in each lateral wall of the nose. Two of these cartilages are situated in the fibrous tissue which fills in the space between the posterior border of the lower lateral cartilage and the nasal process of the maxilla. Situated immediately above these are two others which are known as the accessory quadrate cartilages. The nose is supplied with certain external muscles which are concerned with the movements of the alæ nasi and with facial expression. These muscles are the pyramidalis nasi, compressor naris, levator labii superioris alæque nasi and depressor alæ nasi. The vessels which supply the external nose are branches of the facial and ophthalmic arteries. The veins empty into the angular vein. The lymphatics empty into the submaxillary lymphatic glands. The muscles of the nose are supplied by branches of the facial, and the general sensation by branches of the first and second divisions of the fifth nerve.

The Nasal Cavities.—The nasal osseous cavities are two large quadrangular-shaped cavities in the centre of the face, and are separated from one another by the septum narium, which extends from the vestibule anteriorly to the choanæ or posterior nasal orifices.

Each nasal cavity has a floor which is almost horizontal; a roof which is horizontal in its middle portion, but inclined downward and forward in its anterior portion, and downward and backward in its posterior portion; an inner wall which is vertically directed; and an outward wall which is directed downward and slightly outward. The inner wall, or septum, is partly cartilaginous and partly osseous. The osseous septum is formed by the crest at the juncture of the nasal bones, the nasal spine of the frontal bone, the perpendicular plate of the ethmoid, the vomer, the crest of the sphenoid bone, and the crest situated at the juncture of the two palatal processes of the superior maxillæ and the two horizontal plates of the palate bones.

The vomer is irregularly quadrilateral in form, its lower border articulating with the nasal crest of the superior maxillæ and the palate bones. Its superior border is attached to the rostrum of the sphenoid bone by two winglike expansions, or alæ. The posterior border is concave and lies free between the posterior nasal orifices. Its anterior border is the longest, the upper portion of which articulates with the vertical plate of the ethmoid, while to the lower portion is attached the cartilage of the septum. Running downward and forward nearly at its middle is a shallow groove for the naso-palatine nerve. The vertical plate of the ethmoid is pentagonal, and its short anterior border articulates with the nasal spine of the frontal bone and the crest of the nasal bones. Its superior border is continuous with the cribriform plate of the ethmoid, and its posterior border with

FIG. 3484. Vertical Transverse Section through the Nasal Fossæ, somewhat Behind their Centre. (Zuckerkandl.) A, Roof of nasal cavity; B, floor of nasal cavity; C, C, alveolar processes; D, external wall of nasal cavity; a, a, a, three meatuses; b, b, middle turbinated bodies; c, olfactory slit; d, respiratory region.

The septum is covered with mucous membrane, which is continuous with that which lines the whole of the nasal chambers.

The roof of the nasal cavity is divided into naso-frontal, ethmoidal, and sphenoidal parts. The naso-frontal portion is directed downward and backward, and is composed of that portion of the roof which is formed by the nasal bone. The ethmoidal portion is horizontally directed, and is formed by the cribriform plate of the ethmoid. It is lined with two rows of foramina for the passages of the median and lateral branches of the olfactory nerve. The most anterior foramina give passage to the nasal nerve. The sphenoidal portion looks downward and forward, and is formed by the body of the sphenoid bone.

The opening of the sphenoidal sinus is to be seen on the anterior vertical surface of the body of the sphenoid. The floor of the nose is flattened from before backward, concave from side to side, and wider in the middle than at either extremity. It has a slight inclination downward and backward. It is formed in front by the pars incisiva of the superior maxilla and its palatine process, and behind by the palatine process (horizontal plate) of the palate bone. It presents, just behind the nasal spine, the upper orifice of the anterior palatine canal. In the region of the anterior palatine canal, the mucous membrane presents a small diverticulum, which is the rudimentary Jacobson's organ. This organ is more highly developed in some of the lower animals, and is an organ of the sense of smell.

The outer wall is the most complicated and interesting portion of the nasal cavity. It is formed, in front, by the nasal process of the superior maxilla and the lachrymal bone; in the middle, through the lateral mass of the ethmoid, by the body of the superior maxilla and the inferior turbinated bone; and posteriorly by the perpendicular plate of the palate bone and the pterygoid process of the sphenoid. The lateral mass of the ethmoid bone, which forms a portion of the outer wall of the nasal cavity, and contains the ethmoid cells, reaches from the roof of the nasal chamber, where it articulates with the frontal bone, to the level of the floor of the orbit, where it articulates with the orbital portion of the superior maxilla and the palate bone. Anteriorly, it articulates with the lachrymal bone and the nasal process of the superior maxilla; posteriorly, with the rough surface on the side of the body of the sphenoid bone. These various articulating surfaces serve to complete the ethmoid cells, and the participating bones frequently contain accessory cells. From the anterior end of the medial plate of the lateral mass proceeds a curved process known as the processus uncinatus, which serves to complete the orifice of the maxillary sinus and forms the lower boundary of the hiatus semilunaris. This process is a narrow bony plate, which curves downward and backward almost parallel with the lower border of the middle turbinate bone. It articulates with the superior maxillary and inferior turbinate bone, and, through this union, aids in closing the orifice of the maxillary sinus.

Encroaching upon the lumen of the nasal cavity are three scroll like shells of bone which are known as the turbinate bones. These bones are scroll-like in form, each larger than the other from above downward; their convex surfaces look upward and inward, with a more or less irregular free border. The superior and middle turbinate bones are projections from the lateral mass of the ethmoid; the inferior is an independent bone.

The superior turbinate bone forms a distinct ridge posteriorly, but merges into the middle turbinate anteriorly. The middle turbinate is a broad, thin, bony plate, scroll-like in outline, curling down upon itself, and has at its anterior inferior surface a slight projection which is known as the agger nasi. The inferior turbinate articulates anteriorly with the inferior turbinate crest of the superior maxilla, behind this by the lachrymal process with the lachrymal bone, and posteriorly it articulates with the ethmoid and the lower crest of the palate bone. Through its maxillary process it aids in closing the lower part of the opening to the antrum. The body of the inferior turbinate curls downward and outward. These three bones, through their situation and outline, necessarily divide the nasal chambers into three anterior-posterior incomplete canals, which are designated as the three meatuses of the nasal cavity. The inferior meatus lies between the under surface of the inferior turbinate and the floor of the nose. Slightly in front of

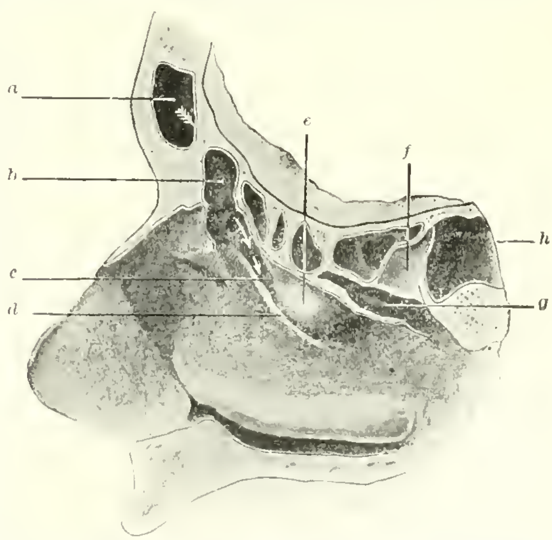

FIG. 3485.—Outer Wall of the Right Nasal Cavity. The superior and middle turbinates have been removed, thus demonstrating the hiatus semilunaris, the bulla ethmoidalis (c), the frontal (a), the ethmoidal (b) and the sphenoidal (h) sinuses, the infundibulum (e), and the openings of the frontal and anterior ethmoidal cells into the nasal cavity (indicated by white arrow heads). The processus uncinatus is shown at d, and the spheno-ethmoidal recess at f.

the centre of that portion which is covered by the inferior turbinate bone is the inferior or nasal orifice of the lachrymal canal.

The middle meatus presents many points of great interest to the rhinologist. This meatus lies between the concave under surface of the middle turbinate bone and

Digitized by Microsoft®

the convex upper surface of the inferior turbinate bone; and it extends anteriorly from the vestibule of the nose, into which it opens widely, through the communication which is known as the atrium of the middle meatus, to the anterior fold of the Eustachian tube posteriorly. It is truncated in form with its widest portion directed anteriorly. The outer wall of the middle meatus presents a deep groove, or semilunar sulcus, known as the hiatus semilunaris. This groove extends from the lower border of the infundibulum, at the anterior extremity of the middle turbinate, to just below its centre. The average length of the hiatus is from 15 to 20 mm. The upper boundary of the hiatus semilunaris is created by a bulbous expansion of ethmoid cells, which is designated as the bulla ethmoidalis. This groove is crescentic in shape, and varies from a shallow furrow to almost a complete canal; its direction is from above downward and backward, with its concavity directed upward and backward. At its upper extremity we have the orifice of the frontal sinus, while at its posterior shallow portion is the orifice of the maxillary antrum; slightly irregular in their locations, but usually quite near the orifice of the frontal sinus, we find the openings of the anterior ethmoidal cells. Behind the opening to the antrum we occasionally find a second orifice communicating with the same cavity, known as the ostium maxillare accessorium. The superior meatus is closed in front and opens downward and backward. This meatus presents the orifices of the posterior ethmoidal cells and the sphenoidal sinus. In reality, the orifice of the sphenoidal sinus is near the roof of the nasal fossa, on a level with the superior turbinate bone in the recessus spheno-ethmoidalis, which is the recess formed by the junction of the ethmoid with the body of the sphenoid.

3. *The Accessory Cavities of the Nose.*—Surrounding the nasal chamber are a set of pneumatic cavities which through their location, as well as by their direct communication with the nasal cavity, have an important anatomical as well as pathological relationship to this organ. The sinuses are called the frontal, ethmoidal, sphenoidal, and antral. The frontal sinus is a small triangular cavity situated between the plates of the frontal bone above the inner angle of the orbit. There are two cavities which are separated, the one from the other, by a thin septum of bone. The dividing septum is usually placed in the mesial plane, although it occasionally shows deflections to one or the other side. This cavity extends from the mesial plate outward a short distance beyond the supra-orbital foramina. The frontal sinuses are very irregular as to their size, shape, and uniformity of relationship one with the other. The average vertical measurement is 31.60 mm., the average horizontal measurement 18 mm., and the average transverse measurement 25.8 mm. The shape is usually triangular, but rarely it may be very irregularly pyramidal through its projecting upward inordinately between the two plates of the frontal, or outward toward the outer angle of the orbit. The cavities are usually of uniform size and outline, although marked variation in this respect is found to exist. There may be only one cavity filling in the space occupied by two, or one larger cavity projecting over toward a second small cavity; in fact, perfectly symmetrical cavities are rare. This cavity is rarely irregularly placed, and more rarely accessory cavities are found. Inspection of the interior of the cavity shows rarely imperfect partitions which form recesses, giving the interior an irregular outline. It has an anterior wall formed by the outer plate of the frontal bone, a posterior wall formed by the inner table of this bone, an inner wall formed by the mesially placed septum, and the floor which is formed by the orbital plate of the frontal bone. The fronto-nasal opening, the ostium frontale, lies in relation to the septum of the sinus, and is situated in the lowest part of the floor. This opening terminates in the middle meatus through the naso-frontal canal at the commencement of the hiatus semilunaris. The ethmoidal cells fill in the space between the orbital and lateral walls of the nasal fossa. They vary greatly in shape and size, and are divided into an anterior and a posterior group. These sinuses are composed of a number of small cavities separated from one another by thin partitions of bone. These small cellular cavities vary in number from one to eight in each mass and usually open by a common duct. Those cells which communicate with the middle meatus of the nose, below the line of origin of the middle turbinate bone, are the anterior ethmoidal cells. Those cells which communicate with the superior meatus above the origin of the middle turbinate are the posterior ethmoidal cells. The space occupied by each collection of cells in the lateral mass is not uniformly constant, nor is there any regularity in the number of cells in each collection. The anterior cells may extend far backward, almost to the sphenoid, while the posterior group may extend as far forward in another specimen. The plate of bone separating the two groups of cells is placed diagonally between the outer and inner walls of the lateral mass, and does not normally present any communication of the one group with the other. The ethmoid cells are bounded externally by the os planum, the lamina papyracea, and internally by the two ethmo-turbinates. The superior wall of the cells is completed by the depressions or foveæ on the ethmoidal edge of the orbital plate of the frontal bone. Inferiorly they are completed by the ethmoidal edge of the orbital plate of the superior maxilla. Anteriorly they are closed in by the nasal process of the superior maxilla and the lachrymal bone. Posteriorly they articulate with the sphenoidal spongy bone.

The maxillary sinus, or antrum of Highmore, is a pyramidal-shaped cavity situated wholly within the body of the superior maxilla. Its roof is a thin plate of bone which also forms the floor of the orbital cavity. The infra-orbital canal, which serves to convey the superior maxillary nerve and infra-orbital vessels in their passage to the face, lies in the roof of the cavity. The floor of the sinus is formed by the alveolar border of the superior maxilla. This wall bears an important relation to the teeth. The converging of the facial and nasal walls at their angle of junction is frequently so acute as to leave a mere groove to form the floor, which is then called the sulcus alveolaris. The floor of the antrum is usually on a level with the floor of the nasal cavity. The layer of spongy bone between the floor of the antrum and the root of the teeth varies greatly. Occasionally this layer is so thin that a mere shell of bone separates the teeth from the antral cavity. Ofttimes slight elevations are seen in the floor corresponding to the fangs of the teeth. When of average dimensions, the floor has in relation to it the second bicuspid and the three molar teeth. The posterior wall is the thin plate of bone which forms the anterior boundary of the zygomatic fossa. The inner or nasal wall of the antrum, as it forms the outer wall of the nasal chamber, is the most interesting aspect of this sinus. That portion of the inner wall which is situated below the inferior turbinate bone is continuously osseous, thinnest immediately below the attachment of the turbinate bone, and forms the outer boundary of the inferior meatus of the nose. In the thin portion of this wall, immediately below the attachment of the inferior turbinate, is the point of selection for exploratory puncture. That portion of this wall which is situated above the inferior turbinate is partly osseous and partly membranous. The aperture, the ostium maxillare, by which this cavity communicates with the middle meatus, is situated here. As the ostium maxillare lies just beneath the level of the roof of the antral cavity, it permits of only imperfect drainage. Sometimes an additional opening exists in the membranous portion of the nasal wall, designated as the ostium maxillare accessorium. This accessory opening is said to exist in about ten per cent. of cases. The accessory opening communicates with the middle meatus at a plane lower than and posterior to that of the ostium maxillare, and this accounts for the occasional draining away of fluids from the antrum posteriorly into the pharynx. The anterior or facial wall is thin; at its upper

www.libtool.com.cn

Nasal Cavities.

margin is the infra orbital foramen. In front this surface is marked by the canine ridge, which corresponds to the socket of the canine tooth. The facial wall is limited externally by the malar ridge. Between these two prominent ridges, the canine and malar, is a depression, the canine fossa. The canine fossa varies greatly in depth. It is at this point that the external or facial opening is made into the antral cavity. The antral cavity varies also in shape and size, and occasionally septa divide the cavity more or less completely by vertical or horizontally placed lamellæ of bone. The average dimensions are as follows: Vertical height, 3.5 cm.; the transverse breadth, 2.5 cm.; and the antero-posterior depth, 3.2 cm.

www.libtool.com.cn

The sphenoidal sinus, on account of its intimate relationship with the cranial, orbital, and nasal cavities, forms one of the most interesting of the accessory sinuses. They are two in number and occupy the anterior portion of the body of the sphenoid bone; a vertical mesial plate of bone forms the division wall between the two cavities. Each cavity presents six walls: a roof, floor, an anterior, a posterior, an external, and an internal wall. The roof is formed by the root of the lesser wings of the sphenoid, the olivary process, and the sella turcica. This wall is in intimate contiguity with important cranial structures. The plate of bone which forms the roof of the sinus is extremely thin. At the junction of the external wall with the roof of the sinus, the optic nerve and the ophthalmic artery pass forward to the orbital cavity. The floor of the sphenoidal sinus forms the posterior part of the roof of the nasal chamber. The anterior wall is in the vertical plane, although at its lower border it inclines slightly downward and backward to join the floor. This wall is extremely thin, and contains the orifice of communication with the nasal cavity. This wall may be divided into an internal portion, which presents the orifice of the ostium sphenoidale (which opens into the spheno-ethmoidal recess), and the outer portion which articulates with the posterior extremity of the lateral mass of the ethmoid, and thus completes the posterior ethmoidal cells. The posterior wall is formed of the posterior portion of the sphenoidal body. The external lateral wall of the sinus varies in thickness, and is in important relationship to neighboring structures. On its cranial aspect, it is in relation to the groove for the internal carotid artery and cavernous sinus. At its anterior aspect it forms the internal boundary of the sphenoidal fissure and the inner wall of the orbit. The internal wall, or septum, is a thin vertical plate of bone which is usually situated in the mesial plane, separates completely one cavity from the other, and rarely is defective. The septum may be irregularly placed, or wanting, thus giving rise to great irregularity in the shape and size of the sphenoidal cavities. These vary in size, shape, and relation to each other. Occasionally accessory cavities are found in the wings of the sphenoid. The average dimensions are as follows: Vertical height, 20 mm.; antero-posterior depth, 21 mm.; transverse breadth, 18 mm. All of these sinuses are lined with a muco-periosteal covering, which is continuous with the mucous membrane of the nasal cavity. The surface of the mucosa is lined with columnar ciliated epithelium.

The Mucous Membrane of the Nose.—The mucous membrane lining the nasal cavities is continuous with that of the pharynx, and extends into the pharyngeal orifice of the Eustachian tube and the accessory sinus.

Anteriorly the integument of the face supplied with hair and sebaceous glands enters the nostrils and extends to the inner extremity of the alar cartilage. At the junction of the superior lateral cartilage and the alar cartilage, the limen nasi, there is a narrow zone where the integument presents the characteristics of mucous membrane, and is lined with pavement epithelium and supplied with muciparous glands. From this point the transition is rapid into the characteristic mucosa of the nasal chamber. The anterior portion of the inferior turbinate, as well as the opposite portion of the septal cartilage, may have a mucosa lined with pavement epithelium, or with the columnar ciliated variety. The portion of the nasal tract, known as the olfactory region, is lined with columnar non-ciliated epithelium. This area extends from the roof as low down as the middle turbinate and the upper third of the septum. The remaining portion of the nasal cavities, the respiratory tract, is supplied with a columnar ciliated epithelium. These cells are long and spindle-shaped, and interspersed numerously among these cells are the so-called goblet or chalice cells. The thickness of the epithelial layer is from 30 to 70 μ. The cilia wave toward the post-nasal orifices. The cilia are stated to move in a thin layer of fluid. The nasal mucous membrane is inseparable from the perichondrium, or periosteum. The mucous membrane is very thin in the accessory sinuses, very thick over the turbinals, somewhat thinner over the septum, and very thin again over the floor and the under surface of the turbinated bodies.

The muciparous glands are of the tubular and racemose variety, and are present in great numbers. These glands do not differ in any essential particulars from similar glands located elsewhere in the mucous membrane, being most abundant at the middle and posterior portions of the nasal cavities, and of greatest size at the lower and posterior part of the septum. Beneath the columnar cells of the mucous membrane, we find a homogeneous basement membrane, and below this there is a connective-tissue layer, which is continuous with the periosteum.

The submucous connective tissue and the epithelial elements contain evidences of lymphoid tissue in the presence of leucocytes, lymphoid collections, and occasional lymph follicles.

In the olfactory region, the mucous membrane has quite a different histological structure from that in the respiratory tract. Here the mucous membrane is very thin, and not so vascular. The epithelium is of the columnar type, but is devoid of cilia, having a branching base and a large nucleus. Lying among them are the olfactory cells of Schultze, which are connected directly with the non-medullated filaments of the olfactory nerve. Beneath the epithelial covering, and opening upon its surface, are numerous branched tubular glands, which secrete a serous fluid. These glands are known as Bowman's.

The gross appearance of the colorization of the mucous membrane in the living subject varies in the different portions of the nasal chambers. In the upper, or olfactory, region the membrane is of a yellowish-pink in color; in the respiratory tract it is a light pink; at the posterior ends of the turbinates it is almost white; while in the accessory cavities it is of a pale pink.

A most interesting feature of the soft structures of the nasal chambers is the arrangement of the submucous tissue over the middle and inferior turbinates and the lower part of the septum. This important feature is the aggregation of venous sinuses and their large size, forming plexuses of blood-vessels over the turbinate bones. These are designated as the turbinate bodies. This term, the turbinate body, is applied to the bone and the investing soft tissue. The mucous membrane over the turbinates is divided into two layers, the adenoid layer with its epithelial covering, and a deep layer forming the periosteum of the turbinate bones. Between these two layers we have a stroma which contains lymph structure. Within this lymph structure we have an abundance of venous channels forming plexuses, which, on account of their rapid dilatation and contraction, under various stimuli, have been designated as erectile tissue, the Schwellkörper of the Germans.

This peculiar action of the venous plexus in the so-called turbinal tissue is not so much due to the arrangement of the veins and their relation with arterial twigs as to the characteristic walls possessed by these vessels and the arrangement of the muscular fibres and elastic tissue in the surrounding stroma. The muscular layer of these walls is very thick, greater than the walls of the corresponding arteries, and the walls are known to be thrown into irregular folds. The arrangement of the

Digitized by Microsoft®

muscular fibres is irregular, although the circular fibres predominate. This arrangement of the vessel walls, as well as the character of surrounding stroma, adapts these walls for the rapid emptying and filling of the venous plexuses. The venous plexuses are more pronounced over the inferior www.libtool.com.cn to its anterior and posterior extremities, over the middle turbinate, especially along the lower border and posterior extremity; and on the septum, in a line with the middle turbinate, corresponding with the anterior extremity of this turbinate—the tuberculum septi.

The vascular supply to the nasal chambers is obtained from the anterior and posterior ethmoidal arteries, branches of the ophthalmic; from the spheno-maxillary and the alveolar arteries, branches of the internal maxillary artery; and from the artery of the septum, which is derived from the facial artery. The spheno-palatine artery enters the nasal chambers through the spheno-palatine foramen with the naso-palatine nerve. Its internal branch, the naso-palatine, accompanies the nerves of the same name, passing downward and forward upon the septum (which it supplies) toward the anterior palatine foramen.

The external branches supply the outer wall of the nose, the nasal fossæ, the ethmoid cells, the frontal sinus, and the antrum of Highmore. The antral and posterior ethmoid supply the roof, upper portion of the septum, outer wall of the nasal fossa, the ethmoidal cells, and the frontal sinuses. The alveolar branch of the internal maxillary supplies the lining membrane of the antrum. The artery of the septum is a branch of the superior coronary, a branch of the facial. The septal artery supplies the columnar and the lower part of the septum.

The veins of the nasal cavity form plexuses beneath the mucous membrane, and these in turn are drained by various veins. The veins which perform this function are the veins which accompany the spheno-palatine artery and empty into the pterygoid plexus, those which accompany the ethmoidal artery and empty into the ophthalmic vein, and those which empty into the facial vein; and still other veins convey the return blood through the foramen cæcum and the cribriform plate to the superior longitudinal sinus and the intracranial veins.

The lymphatic vessels of the nasal cavity empty into the post-pharyngeal, the internal maxillary, the parotid, and the upper deep cervical lymphatic glands. Through the cribriform plate of the ethmoid, the nasal lymphatic vessels communicate with the intracranial lymphatics and the subdural space.

The nerve distributions for the nasal cavity consist partly of nerves of olfaction and partly of nerves of general sensation. The olfactory nerve, the nerve of the special sense of smell, arises by three roots: an external root, commencing in the deep substance of the middle lobe of the cerebrum; a middle root, from the caruncula annularis; and an internal root, from the inner and back part of the anterior lobe of the cerebrum. The three roots unite and run forward as a flat band on the under surface of the brain until it reaches the cribriform plate of the ethmoid, where it expands into what is known as the olfactory bulb. From the under surface of the olfactory bulb are given off from fifteen to eighteen filaments, which, piercing the foramina of the cribriform plate, are further subdivided and distributed to the nasal mucous membrane. They can be divided into three groups: an inner group which spreads out over the upper third of the septum, an outer group supplying the superior turbinate and the upper surface of the middle turbinate, and a middle group which is distributed to the roof of the nasal cavity.

General sensation is supplied to the nasal mucosa through the nasal branches of the ophthalmic division of the trigeminus. This nerve enters the nasal cavity through a slit beside the crista galli, and then divides into two branches. The internal of these two branches supplies the mucous membrane of the anterior part of the septum; while the other, the external, descends in a groove on the inner surface of the nasal bone where, at the junction of the nasal bone with the lower lateral cartilage, it passes out of the nasal cavity. This branch, in its passage through the nasal cavity, supplies the mucous membrane of the outer wall as low down as the inferior turbinate body. Branches of the anterior dental nerve are distributed to the mucous membrane of the inferior meatus and the inferior turbinate body. Branches from Meckel's ganglion gain access to the nasal cavity through the spheno-palatine foramen, and, after further subdivision, supply the mucous membrane covering the superior and middle turbinate bodies, the ethmoidal cells, and the upper and posterior part of the septum. The naso-palatine, in its passage forward across the roof, distributes filaments in its course, and descends downward and forward along a groove in the septum to the anterior palatine foramen, where it joins the anterior palatine nerve. The Vidian nerve supplies the upper and posterior part of the septum and the superior turbinate. Branches of the sympathetic are also distributed to the nasal mucous membrane, being derived principally from the spheno-palatine ganglion of the sympathetic.

II. Physiology.—The physiological function of the nose is of a threefold character: (1) In relation to respiration; (2) in connection with olfaction; and (3) in phonation. The respiratory function of the nose is by far the most important physiological duty that this organ performs. It is during the passage of inspired air through the nasal chambers that it is warmed, saturated with moisture, and freed from coarse material therein floating. According to the experiments of Aschenbrandt, which have been confirmed by others, a column of air, in its passage through the nasal chambers, on reaching the pharynx, has had its temperature raised to 86° F., and its degree of humidity raised to the point of almost complete saturation.

This function takes place whatever may be the degree of temperature or humidity of the external atmosphere, and is so complete in its action as to functionate perfectly during sudden and very marked changes in both of the enumerated conditions. This function is performed through the exquisite working of the so-called turbinal tissue. When we consider the constant and excessive changes in its functional activities that are persistently taking place, one cannot but marvel at the wonderful nature of this mechanism.

The second important physiological function of the nose is that of olfaction. The sense of smell is dependent upon the impinging of the odorous particles upon the terminal filaments of the nerve ends in the olfactory apparatus. In order for various substances contained in the atmosphere to be appreciated as having an odor, it is necessary that the air should reach the olfactory region and that the peripheral apparatus should be normal. According to Paulsen, the inspired air passes first directly upward under the dorsum of the nose, and then follows the roof, the greater portion of the column passing through the superior and middle meatus and then descending downward to the post-nasal orifice. Odorous particles reach the nose in various forms. Various theories have been offered to explain the mechanism of olfaction, the most important of which are the mechanical, the vibratory, and the chemical. (For further information in regard to the sense of smell, consult the article on *Olfactory Nerve*.)

The third physiological function of the nose is the part which it plays in connection with phonation. The nasal cavities, in connection with the pharynx and the buccal cavity, constitute that portion of the vocal apparatus by which quality and character are given to the voice. The importance of the nasal organ in that office is well demonstrated by the alteration of the character of the voice when from any cause one or both nasal cavities are obstructed.

III. Rhinoscopy.—In order to obtain a successful inspection of the nasal cavities and neighboring parts, it is necessary to have the best illumination that it is possible to obtain, means for projecting this light, and aids

Digitized by Microsoft®

through which this light can gain ingress into the remote parts to be examined.

Previous to the inspection of the interior of the nasal cavity, it is always well to make a thorough examination of the external nose. The external configuration of the nose, the aspect which it presents at the root, the evidences of deviation, the presence or absence of marked movement of the alæ nasi, the pres-

www.libtool.com.cn

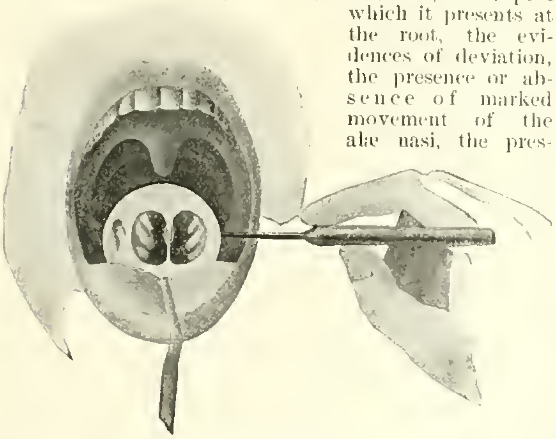

FIG. 3486.—Posterior Rhinoscopy Mirror in Position Showing Image Reflected Therein.

ence or absence of sound in nasal breathing, the relation of the alæ to the septum, and the outlines of the anterior nares should all be thoroughly considered before the interior of the nose is inspected. The appearance of the cutaneous covering of the external nose, the presence of excoriation on the upper lip, the odor of the breath, and the character of the voice should all be thought of in this preliminary examination.

In order that the examination may be successful, it is necessary to have, first, a good source of light; second, a concave reflecting mirror for projecting this light; third, variously devised instruments called speculums by which the vestibule of the nose is expanded and a greater volume of light admitted to the interior; and small plane mirrors for diverting the reflected light and receiving the image which is thus created.

The Light. On account of the exigencies of circumstances, the use of the best light obtainable, sunlight, is not possible. The light which is sought is one as nearly white as possible. The three sources of light which are most frequently used are gaslight, electric light, and lamplight. Any source of light of sufficient intensity and penetrating power can be used when circumstances demand it, and one should adapt himself to these varying conditions. In office work the source of light can be controlled, and one should select that which gives the best illumination with the least inconvenience. For average general utility, gas fed through an Argand burner serves the best purpose. To increase its efficiency use may be made of the Welsbach mantle, which gives a whiter light. With a moderate degree of care the mantles last for many months. The light thus obtained may be fixed or movable. It is better to have the burner attached to a movable bracket which can be placed at various angles and raised or lowered at pleasure. The apparatus is completed by surrounding the light with a cylindrical japanned tin or asbestos chimney, which has a circular opening of two and a half inches in diameter through its lateral wall at the middle. This contrivance shuts off all the rays of the light excepting those coming through the lateral aperture. A further part of the equipment is the device known as the Mackenzie condenser. This latter device is not essential, but renders the examination easier for the examiner.

The electric light may be used in two methods, directly and indirectly. The direct method is the use of the electric headlight; the indirect method is the use of the electric light by reflection, as we use gaslight. The objection to the electric headlight is its weight and its want of penetration. With the use of the ground-glass globes we have a very good source of indirect illumination in electricity. The student's, or Rochester lamp, forms the best form of oil light. This light can be made whiter by the addition of a small piece of camphor to the oil, as suggested by Sajous.

The instrument by which the light is reflected into the various cavities to be examined is known as the head mirror. This mirror is a round, concave mirror, from three to four and a half inches in diameter, with a focal distance of from eight to fifteen inches. It should be supplied with a central orifice. The central orifice is for the purpose of more exact observation, as, through its use, the angles of incidence and reflection are made to coincide, and, therefore, the picture is rendered more perfect. This mirror is more serviceable if it is worn suspended through a ball-and-socket joint from a head-band which encircles the forehead. It may also be suspended from a rod which is attached to the lamp which furnishes the source of light. Steadiness and immobility, when it is fixed at the proper angle, are the most desirable features in the reflecting mirror. One having a diameter of three and a half inches has, in my hands, proved the most serviceable. For the purpose of permitting as much light to enter the nasal cavity as possible, it is necessary gently to dilate the vestibule through the means of a speculum which is introduced into the anterior nares. Those speculums which are constructed on the bivalve system are the most serviceable. Their numbers are legion. I prefer the Schnitzler's. Hartmann's, Ingals', Roth's, and others are of this style. A number of fine, wire-like speculums, such as the Jarvis, the Bosworth, the Goodwillie, and the Ives, are made on the bivalve principle. Others are made to be self-retaining. The Schnitzler instrument, as offered for sale in the shops, is too cumbersome. I have it in a light frame, which not only makes a neater but a more useful instrument. The individual preference in speculums is also a question of adaptability and use. In making examination of the post-nasal space and the nasal cavities from behind, what is called posterior rhinoscopy, it is necessary to have, in addition to a good light and the head reflector, small plane mirrors constructed like those used in examining the larynx, and a tongue depressor. These small plane mirrors are fixed at an angle of 105° to the shaft, and vary in size from three-eighths to three-quarters of an inch in diameter. The largest mirror which it is possible to use in the individual case should always be employed. This mirror is used to reflect the light behind the curtain of the palate.

Usually it is necessary to control the tongue, as only a few patients are able to hold it relaxed in the floor of the mouth during an examination; therefore it becomes necessary to depress it through the aid of a tongue depressor.

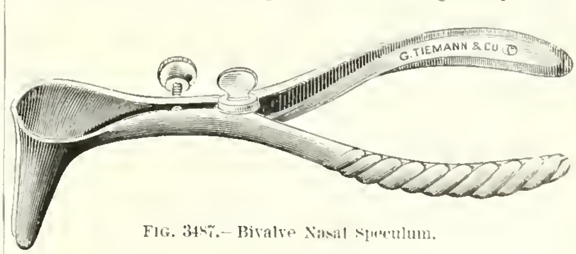

FIG. 3487.—Bivalve Nasal Speculum.

Numerous forms of depressors are on the market, but one that especially recommends itself, on account of its simplicity and of the ease with which it may be kept aseptic, is the one invented by Dr. D. Braden Kyle (Fig. 3488).

The nasal probe is indispensable to a thorough examination and understanding of diseased conditions in the nasal cavities.

Examination of the nasal chambers through the anterior nares is called anterior rhinoscopy, while examina-

Digitized by Microsoft®

Nasal Cavities.

tion of the upper pharynx and nasal chambers from behind is known as posterior rhinoscopy.

In these examinations of the nasal cavities the relationship of the patient and physician with regard to the source of light is absolutely the same as it is in laryngoscopic examinations. The patient sits in a simple straight-back chair, without head support. The physician sits directly in front of the patient, or, what is preferable, directly beside and on the left hand side of the patient. The source of light should be to the right of the patient, just to the side of and on a level with the upper border of the right ear. The patient should sit in an easy, erect, comfortable position, when the examiner reflects the light in a circle just upon the area to be examined. Either may then move, within a certain latitude, from this fixed position; nevertheless, it will be noted that when they return to the examining position the light will fall directly on the point upon which it originally fell. The method of examination, as well as the character of furniture used for patient and doctor, is a question of individual preference and perfected method on the part of the operator.

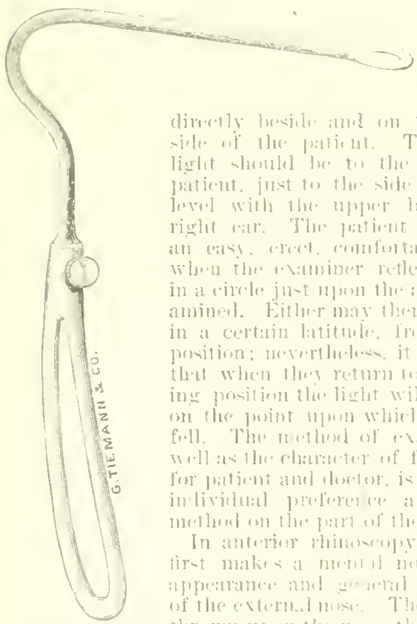

FIG. 488. — Kyle's Tongue Depressor.

In anterior rhinoscopy the operator first makes a mental notation of the appearance and general configuration of the external nose. The light is then thrown upon the nose, the head of the patient is slightly tilted backward, and the general appearance, the patency, and the outline of the anterior nares are noted, after which the tip of the nose is slightly tilted upward and the vestibule is thoroughly inspected. Little children fear instruments, and, as their hairs are undeveloped, we can often make a thorough inspection without the use of specula. Special care should be made to note fissures, abrasions, or pimples on the inner surface of the nares, which would make the introduction of the speculum painful.

We are now prepared to introduce the speculum. This instrument should be gently insinuated into the anterior nares in a closed state. After the speculum is placed slightly within the vestibule, it is moderately dilated until slight resistance is felt. No pain should ever be given. With the instrument in position, the two crura being controlled by the pressure of the thumb and index finger of the left hand and with the little finger of the same hand hooked under the lower jaw, the patient is practically under control of the examiner. Slight pressure is usually all that is sufficient to make the patient move in a required direction. With the patient's head slightly tilted forward, the first object that attracts attention is the prominent rounded red mass on the outer wall projecting nearly to the floor of the nose and which we recognize as the anterior end of the inferior turbinate body. Opposite this we recognize the cartilaginous wall of the septum, and below, the floor of the nose and the inferior meatus. According to the amount of space between the inferior turbinate and the septum we can see to a greater or less depth within the nasal cavity toward the pharynx. In many cases, with a fair amount of space between these parts, or when the turbinal tissue is contracted under the use of cocaine, we can well see the posterior pharyngeal wall. A tilting of the patient's head slightly backward brings into view the middle turbinate, which is paler and more translucent than the inferior, and just opposite its anterior extremity on the septal wall is seen often an aggregation of erectile tissues, which is designated the tuberculum septi. The whole extent of the visible upper surface of the inferior turbinate is seen in this position, as well as the middle meatus. It is only when the middle turbinate is removed or has undergone great atrophy that the interesting features contained within the middle meatus are brought under observation. Tilting of the patient's head still farther backward brings into view the upper portion of the middle turbinate and the roof of the nasal cavity. It is rather unusual to be able to demonstrate the superior turbinate body. Occasionally the orifice of the sphenoidal sinus can be made out. The use of the probe is indispensable in making this examination, and so also is the instillation, after the preliminary examination, of a very mild solution of cocaine, —a procedure which should be followed by a re-examination of the parts after the effects of the drug have become manifest. Great care should be exercised in examining the septum; it should be viewed from both sides, and the head should be held carefully in the middle line.

Posterior rhinoscopy is the most difficult procedure in the examination of the upper air tract, and therefore requires more tact and skill in its prosecution. The position of the patient and of the source of light, and the methods of reflection are the same as in anterior rhinoscopy. The only instrumental addition is the rhinoscopic mirror and the tongue depressor. I have never found it necessary to make use of the so-called palate retractors, but see no objection to the use of such an instrument, for holding forward the soft palate, if the examiner so desire. The most desirable instrument for retracting the palate is that invented by Dr. J. A. White. Occasionally the examination can be made without the use of a tongue depressor, but this is exceedingly rare. After depressing the tongue, and noting the space between the soft palate and the pharyngeal wall, as well as that between the pendent uvula and the base of the tongue, the largest size mirror which it is possible to use is gauged. The mirror is first heated to a proper temperature and the tongue carefully depressed. In introducing the tongue depressor care should be exercised in so introducing it that the tip of the tongue depressor first comes in contact with the tongue just posterior to its arch, which is somewhat anterior to the circumvallate papillæ. The tongue is then drawn downward and forward into the floor of the mouth. Backward pressure of the tongue is always to be avoided, as it is certain to give rise to retching and gagging.

If the depressor is so placed as to excite distress on the patient's part it should be immediately removed and replaced. The depressor should be held between the thumb and index finger of the left hand, while the other fingers pass under the patient's chin. The mirror, which has been properly warmed, being lightly held between the thumb and index finger of the right hand, is now quickly introduced into the widely open mouth along its left wall until we come to the dependent palatine arch. The important feature in the introduction of the mirror is so to insert it as not to come in contact with any of the tissues. As the palatine arch is reached, the mirror is gently insinuated by slight depression and rotation so as to glide through the space between the left pillar and the base of the tongue without coming in contact with either.

After the mirror has passed behind the palate and has reached the pharyngeal space, the operator, by slightly rotating the handle, may bring the reflecting surface around so as to face him, and then he should slightly depress the handle so as to carry the mirror upward until its upper border is slightly hidden behind the soft palate. The mirror now being in position, its handle is so held toward the left angle of the patient's mouth that there is no interference with the thorough illumination of the buccal cavity. Finally, the mirror is to be rotated from right to left, depressed and elevated, and given different degrees of angles while in position so as to bring into view in rapid succession the various surfaces and parts of the upper pharynx and back of the nose.

Digitized by Microsoft®

Nasal Cavities.

The success of the procedure depends upon the depression of the tongue, the careful introduction of the mirror, and the ability of the patient, not only thoroughly to relax the soft palate, but also to hold it immobile in this relaxed state long enough for the operator to make a thorough inspection of the parts. The patient is an uncertain quantity. Many can submit to a rhinoscopic examination without any difficulty; others require careful manipulation and several efforts have to be made before a successful view is obtained; and, finally, there are a few who are so constituted as to present almost insurmountable difficulties to the exploration. The greatest difficulty is the retraction of the soft palate, which in some individuals takes place immediately upon the introduction of the mirror into the mouth. Careful training in nasal breathing with the open mouth and with the sounding of the nasal consonants en and em, will often overcome this obstacle. Among the other methods which have been suggested for overcoming these obstacles may be mentioned the application of a five-per-cent. solution of cocaine to the palate and post-pharyngeal wall, and the employment of the palate hook. The image reflected in the mirror at any given moment represents only a small section of the whole region. Consequently, in order to gain a fairly complete view, it is necessary to construct it in one's mind from the separate smaller pictures obtained by changing from time to time the angle at which the mirror is placed. Usually one observes first the upper surface of the soft palate and the lower portion of the posterior border of the septum which forms the inner boundary of the post-nasal orifice, the choanæ. Then, by giving the mirror a slight upward inclination, it will bring into view the whole length of the septum, broad above and tapering to a narrow edge below, and the posterior view of the nasal cavities as displayed through the choanæ. On either outer wall, from above downward, will be noted the ridge of the superior turbinate body; immediately below it and separated from it by a dark line—the superior meatus—will be observed the middle turbinate body which stands out as a somewhat elongated fusiform body of a very faint pinkish-white appearance. Below the middle turbinal body will be seen the middle meatus, and immediately below this the upper half of the inferior turbinate body, which oft times seems to merge into the floor of the choanæ.

www.libtool.com.cn

The color of the inferior turbinal body is of a grayish-white, resembling much the color that an ordinary mucous membrane assumes when œdematous. By slightly inclining the mirror to right or left, the corresponding mouth of the Eustachian tube will be observed, as well as the depression which separates it from the post-pharyngeal wall—the fossa of Rosenmüller. By changing the angle of the mirror to a more obtuse angle, the dome-like vault of the pharynx will be brought into view, as well as the upper portion of the post-pharyngeal wall. The vault of the pharynx is usually dome-like and smooth in its contour. In some individuals it may show elevations and depressions, or be so filled out as to appear flat, these alterations depending upon the amount and degree of enlargement of the pharyngeal tonsil.

Besides the rhinoscopic methods of exploration of the nasal chambers and post-nasal cavity we have, as additional aids to diagnosis, the digital exploration and the use of electric transillumination. Digital exploration is especially of value in exploration of the post-nasal cavity in very youthful patients and in adults in whom it is impossible to make use of posterior rhinoscopy, or in whom, for various other reasons, it is desirable to make use of this method. This procedure can usually be made in little ones, without causing alarm, by the use of judicious tact. No instruments are necessary. The hands should be well washed and the index finger scrubbed with a nail brush before the examination is made. The child is seated in the examining chair while the parent sits in front of the child and holds the little one's hands. The operator stands to the left side of and facing the patient, with the right hand firmly grasping the vertex of the head. I usually find it wise to tell the patient what I propose doing and of its unpleasant nature but at the same time I assure him that the procedure does not cause pain. The patient is then told to open widely the mouth, the hands and head are firmly grasped, and the index finger of the right hand is quickly but dextrously introduced into the mouth and behind the soft palate into the post-nasal place. In this manner the character and condition of this region may be quickly determined through the tactile sense.

Another method of making the examination is by placing the child in the position described by Dr. A. A. Bliss. By this method the child is placed in the lap of a nurse or parent, facing forward. The little one's legs are held firmly between the legs of the assistant, while the arms of the assistant are slipped under the armpit of the patient and the hands extended upward and held firmly on either side of the head. The child is thus held immobile. Transillumination of the accessory cavities is resorted to as an aid to the diagnosis of the condition of these pneumatic cavities. The value of this method of exploration lies in the fact that most of the pneumatic spaces in the normal state allow the transmission of rays of light through their thin walls. The light used for this purpose is electric, furnished through the medium of a small lamp of about six candle-power. The method of its application will be described in the article devoted to the diseases of the accessory sinuses.

Charles W. Richardson.

NASAL CAVITIES, DISEASES OF: ABSCESSES OF THE NASAL SEPTUM.—Abscess of the septum may be either acute or chronic. The former is generally the result of hæmatoma, erysipelas, typhoid fever, or small-pox, and is located upon one or both sides of the cartilaginous septum. The chronic abscess is generally due to syphilitic infection, but it may be the result of poisoning by arsenic, copper, or mercury, or it may possibly be traumatic.

While the acute abscess is commonly found over the cartilaginous septum, the chronic abscess generally extends to the bony part, and it is often caused by disintegration of gummatous infiltration of the mucous surfaces. The swellings are usually rounded, and they appear red and inflamed and sensitive to the touch. When a syphilitic abscess is opened it emits foul-smelling pus, and if a probe be introduced into the abscess cavity necrosed cartilage or bone may be detected. In most chronic cases the treatment, after the abscess has been opened, is the same as that recommended for nasal syphilis. *E. Fletcher Ingals.*

NASAL CAVITIES, DISEASES OF: ACTINOMYCOSIS.—I have been unable to discover any report of well-marked cases of actinomycosis of the nose, though it is probable that the disease sometimes affects this organ. *E. F. I.*

NASAL CAVITIES, DISEASES OF: ACUTE INFLAMMATIONS.—The many varieties of acute inflammation of the nasal mucous membrane that are mentioned in medical literature may be comprised under the following headings: (1) Acute Catarrhal Rhinitis, (2) Acute Purulent Rhinitis, (3) Acute Membranous Rhinitis, (4) Acute Phlegmonous Rhinitis, and (5) Acute Rhinitis due to Occupation or to Trauma.

(1) ACUTE CATARRHAL RHINITIS.—Synonyms: Acute Coryza, Cold in the Head, Acute Nasal Catarrh, etc.

This disease is an illustration of the simplest form of exudative inflammation occurring in a mucous membrane and affords us the most accessible illustration of such a process inasmuch as the changes occur under direct observation. Any special peculiarities which it presents are amply explained by the vascular mechanism of the nose, which calls for a somewhat extended consideration.

Vascular Mechanism of the Nose.—The vascular mechanism of the nose (and the glandular as well) is somewhat unique, and a full understanding of it is called

Digitized by Microsoft®

for in order to explain the sequence of various pathological changes. To the blood supply of the turbinates does this observation apply with special force. The larger arterioles are well supplied with muscular coats and lie in the deepest layers of the mucosa close to the bone. They give off branches which supply, by a network of capillaries, the periosteum, glands, and the epithelial layer. These capillaries are collected into veins which dilate into venous sinuses, the larger lacunæ of which are the deeper, while with them the superficial lacunæ (cortical network) communicate. These lacunæ again empty into the veins accompanying the primary arterioles into the periosteal layer. As a rule the capillaries do not enter directly into the sinuses but are at first collected into veins. It is a matter of doubt whether the arterioles empty directly into the sinuses, as is the case in the erectile tissues of the genital tract. There is in the nose nothing comparable to the tunica albuginea of the genitals to exert direct compression on the sinus contents.

These views as to anatomical structure are those of Zuckerkandl (as quoted by J. Wright), who also reminds us that the arteries enter the nose through various bony foramina along with the veins. If the artery dilate from any cause, such dilatation must compress the vein against the bony wall. While therefore the inflow of blood to the part supplied is increased, the outflow is diminished and engorgement results. Arterial contraction produces of course the reverse effect.

Another point deserves mention. Sections of the mucosa taken from infants show veins compressed between the parallel fibres of the periosteal layer and the elastic fibres and glands external thereto. It is here also evident that engorgement of the superficial tissues supplied by dilated arterial twigs will bring an increased pressure to bear against the vein and obstruct the outflow of blood. As a result of this general arrangement here and in the radical vessels there may be serous transudation, especially in the region of olfaction, without any necessary glandular intervention. It is estimated that under normal conditions this transudation amounts to one pint in twenty-four hours. Zuckerkandl has also described a special network of veins surrounding the glandular mouths in such a way that the engorgement of the former would necessarily close the latter. Wright believes that the foregoing facts clearly explain the phenomena of ordinary acute inflammations of the nasal mucosa. The first visible stage of a coryza is a nasal occlusion following upon vascular engorgement of the erectile bodies. A preceding vascular constriction is assumed, but this is problematical. Now with the blood-vessels all full and with the stimulation of the glands, we should expect the secretion of mucus to be discharged almost coincidently with the congestion; but this is not so, for secretion is scanty for the first few hours, and even for days it may be almost watery. Later, when vascular tension relaxes, it begins to assume a mucous character. Evidently this absence of secretion is due to the occlusion of the glandular conduits by the surrounding plexus of veins. The primary watery exudate comes by transudation directly from the blood-vessels through the areolar tissue and surface epithelium.

The contraction of the smooth muscle-fibres and of the elastic fibres of the stroma contributes to the collapse of the venous sinuses, the floodgates of the radical veins being opened by the contraction of the encroaching arterioles. Expression of glandular contents follows, the glandular mouths having been opened by the subsidence of the superficial venous engorgement.

Causes of Acute Catarrhal Rhinitis.—These are predisposing and exciting. The former include the various diatheses, especially the syphilitic, rheumatic, and gouty. The existence of the uric acid or lithæmic state strongly predisposes to coryza. A patient who eats heartily of animal food and who does not take sufficient exercise is far more liable to "take cold" than is one leading an opposite life. Furthermore, the prevalent habits of living in overheated houses and of swaddling the body with too heavy clothing, especially the wearing of tippets, mufflers, etc., powerfully invite the very dangers they are popularly supposed to avert. The combined effect of the foregoing modes of life is easy to appreciate. The system is overloaded with nitrogenous food and elimination is deficient. As a result there is set up a sort of autotoxæmia ready to be fanned into open outbreak by any one of a large class of excitants. Excesses in alcohol, tobacco, and venery also predispose to coryza.

The exciting cause is generally exposure of some kind, wet feet, draughts, standing or sitting in a cool place when the skin is covered with perspiration. Often a localized exposure, such as a draught through a partially open door or window, seems to act more powerfully than a general exposure. The amount of moisture in the air, as well as its temperature, requires consideration. A combination of cold and moist air offers the most favorable conditions for exciting an attack.

Coryza may be a symptomatic lesion in many general diseases, *e.g.*, measles, scarlatina, smallpox, scurvy, whooping-cough, typhoid fever, influenza, diphtheria, diabetes, erysipelas, and rheumatism. The affection under these circumstances offers no pathological or clinical peculiarities.

Pathology.—At first the nose is dry, but after a few hours a serous discharge comes on, and in the course of a day or so becomes very abundant. As the disease progresses it becomes mucous and finally muco-purulent. It may consist of almost pure yellowish pus. Later, it lessens and at last ceases, and the patient is well again. No special bacteriology attaches to the affection The discharge contains the usual micro-organisms which have their habitat in the nose. They are relatively, as well as absolutely, increased in quantity. Lennox Browne refers the yellow color of the later secretion to the staphylococcus pyogenes aureus, which he says exists under these conditions in nearly pure culture.

Symptoms.—An attack commences with a sense of nasal occlusion, burning, tickling, and occasional sneezing. Later come headache, mild general malaise, fever, pains in the eyes and over the regions corresponding to the various accessory sinuses. These pains may be due to direct extension of the inflammatory process into the sinus linings or to their occlusion and consequent impaired ventilation. This extension of the inflammation to the sinuses explains the large amount of discharge regularly present, for it is difficult to believe that the quantity of muco-pus voided in a severe coryza can come from the lining of the nasal fossæ alone. In an ordinary case the foregoing sequence of changes will extend over a period of from four to seven days, often longer.

Prognosis.—While the lesion is a comparatively trivial one, it must not be forgotten that frequent coryzas lay the foundation for subsequent hypertrophic changes and may possibly introduce some serious disease; they should therefore be promptly cared for.

Treatment.—This may be prophylactic, abortive, or palliative. Most of the patients who consult the physician for a cold in the head, commonly regarded as a trivial affair, do so because they are sufferers from an intermittent or continual series of such attacks. No sooner is one ended than another begins. For such patients a plain talk on the necessity of changing their mode of living is the first thing required. It will afford more satisfaction to both physician and patient than will drug administration. In season and out of season three things must be insisted on. (1st) Avoidance of too much animal food. Meat should be eaten only once a day. To the gouty the time-honored advice may be given of "no red meat and no vegetables taken from the ground"; (2d) proper daily exercise; (3d) proper care of the skin and the eliminative functions; this includes regulation of the bowels and daily bathing. Not every patient may be led to jump into a tub of cold water on rising, but every patient should go over the surface of the body daily with water. At first this may be tepid, but as tolerance is established the temperature should be lowered until the water is distinctly cool. Actual thermo-

www.libtool.com.cn
Digitized by Microsoft®

metric figures are not so good a guide as the patient's sensations, for a personal equation is concerned in the sensation of coolness. In winter the bath should be taken in a room properly warmed, and in case a tub-bath be taken the patient should dry himself not standing in the water but on a bath-mat or rug. In this way much of the immediate chilliness after the bath and sluggishness of reaction can be avoided. Delicate patients may be advised to sponge one-half of the body on rising and the other half on retiring, the unbathed portion being clothed. Some fortitude may be required to inaugurate the process on the part of those who have never been properly trained in this respect, but they should be encouraged to persevere until a daily bath is taken on rising. *This is the time of the day in which to bathe, not at night.* If for any reason one wishes to take an old-fashioned hot-water and soap bath at bedtime, it should be followed by a cool affusion. One soap bath weekly is ordinarily sufficient for those who take daily ablutions. In all cases, after the bath and the application of the drying towel, there should be a vigorous application of the flesh-brush, or Turkish towel, "Luffa" sponge, etc., to promote reaction. Brisk, light gymnastic exercises may be employed by those whose reactive powers are deficient.

Finally comes the matter of proper body covering. Good stout shoes should be worn with felt or cork insoles if necessary. Rubbers should be regarded as a device of the enemy of good health. Of course in a heavy rainstorm they are permissible, but the habit some people have of wearing rubbers whenever the walks are the least damp is dangerous to health. Being practically air-tight, they prevent evaporation from the feet and elimination of waste material. With equal vigor a protest is uttered against all chest protectors and pads, also against the wearing of heavy furs, etc., unless they be immediately removed on coming in from the cold. Our prevalent habit of wearing our heavy wraps when inside the house is most reprehensible. The old saying that "sealskin sacks kill more people than does smallpox" is not far from the truth. The clothing next to the skin should be woollen, or at least contain a certain proportion of that substance. Some of the meshed garments of silk and linen are also commendable. There is no sense, however, in swathing the body in heavy woollen so as to bathe it almost constantly in perspiration. "Sanitary" woollens are sanitary only in so far as they conform to physiological laws, it matters not in what country they are made or whose name they bear. The so-called "union-suit," with vest and drawers made in one piece, is the ideal garment for both winter and summer, the weight being changed according to the season. Theoretically the same weight should be worn next to the skin the year round, the outer clothing varying to fit the season, but there are not many who will take the pains to live in this physiological manner. Some textiles are composed of a woollen layer covered on both sides with a cotton mesh. In this way the porous qualities of the woollen are retained without its irritating effect on the skin. So-called "medicated" underwear belongs to the category of "medicated" flannel and "medicated" toilet-paper. Excesses in alcohol, tobacco, etc., must be sternly interdicted.

If undue space seems to have been devoted to the foregoing directions, it must find its excuse in the writer's increasing experience that full directions in these respects will often render any drugs unnecessary.

In some instances it is possible to abort an ordinary coryza, but the efficiency of the countless measures devised for this end is conditioned upon their early employment. The combination of a hot drink with five grains of quinine and ten of Dover's powder is undoubtedly one of the most common. This aims at elimination by relaxation of the skin, in other words, at diaphoresis. The plan has the following objections: digestive activity is retarded and the biliary flow diminished, and with opium in full dosage there is also an increased reflex excitability. Full dosage of quinine checks oxidation, depresses the circulation, lowers body temperature, and lessens perspiration. Under the conditions we are discussing, abstraction of water by heat is not sufficient to restore the bodily equilibrium. It is preferable to give a full dose of calomel, followed by small and frequent doses of quinine.

Many physicians use the familiar rhinitis or coryza tablet triturates. Familiar combinations are the Lincoln formula: Camphor gr. $\frac{1}{4}$, belladonna extract fl. ♏ $\frac{1}{8}$, and quinine sulphate gr. $\frac{1}{4}$; and the Edwards formula: Atropine sulphate gr. $\frac{1}{500}$, aconitine gr. $\frac{1}{500}$, morphine sulphate gr. $\frac{1}{100}$, and calomel gr. $\frac{1}{10}$. Either or both of these may be taken hourly until physiological effects are manifest, when they must be continued at longer intervals.

Recently stress has been laid upon the autotoxæmia presented by many coryza patients, especially by those who are its frequent victims. These patients are sufferers from uric-acid excess. Hence the advice is given to put the patient through some vigorous exercise such as gymnasium work or a ride on horseback, etc., scour out the bowel (not merely give a light laxative) and then give full doses of the simple alkalies such as the bicarbonates of soda or potash until the urine is freely alkaline, the patient meanwhile going to bed for a day or so or at least remaining quiet. In the case of plethoric individuals this plan of treatment is far more efficacious than are the older methods. These latter aim at establishing relaxation and favoring elimination but they take no account of the special underlying diathesis. In so far, they are but partially ideal remedies. Undoubtedly they are of service, but it must be remembered that coryza is not a long disease and will generally get well of itself. Moreover, they do not always abort an atack.

The Turkish bath has always enjoyed a high reputation for aborting coryza. If it be tried, the patient must keep in-doors for some time, and if practicable should remain at the bathing establishment over night.

In some instances the malady will yield to frequent applications, in the form of a spray, of the active principles of the suprarenal bodies (adrenalin), in say 1 to 2,000 solution. This contracts the vessels by its action on their unstriped muscular fibres. It must be added that some patients show a decided idiosyncrasy toward this remedy, and that while its immediate effect is in the line of relief there quickly comes a secondary relaxation, sometimes so severe that the patient's last state is worse than his first.

Palliative treatment consists in the thorough flushing out of the nares with some warm alkaline solution. It is doubtful whether the addition of distinctly antiseptic preparations is of much advantage. Normal salt solution or a mixture of salt, borax, and bicarbonate of soda, one teaspoonful of the mixture to the pint of lukewarm water, is as good as any. By such remedies the excess of secretion is removed from the nasal passages, and conditions are set up favoring a restoration to the normal. The smarting in the nares can be relieved by some such remedy as Ferrier's snuff (Morphine muriate gr. ij., powdered acaciæ ʒ ij., and bismuth subcarbonate ʒ vi.). A little of this may be insufflated every few hours. If the patient comes for office treatment, the nares may be cleansed with some alkaline solution, then sprayed with a little *weak* cocaine (not over two per cent.) and adrenalin, and this followed up with some oily preparation such as menthol in albolene, resorcin with benzoinol, weak camphor menthol, etc. Frequent sufferers with coryza should *never* be given cocaine solutions to be used at their own discretion.

Spiess insists that most of the sneezing in an ordinary coryza comes from a post-nasal irritation. He therefore advises the insufflation into this region of an anæsthetizing powder, such as orthoform 2 parts to sozoiodolate of soda 10 parts.

In the case of very young children a laxative should be given with a hot bath, and then they should be put to bed. Cocaine, if used at all, must be employed with the greatest caution. In infants the disease seems to be conveyed from one patient to another in the same family.

Digitized by Microsoft®

and consequently temporary isolation is advisable. Dentition and carious teeth seem to be predisposing causes. Difficulty in nursing is one of the most important features. For local treatment a weak menthol solution in albolene may be used, the application being made through a medicine dropper.

www.libtool.com.cn

(2) ACUTE PURULENT RHINITIS.—Synonyms: Blennorrhagic, Gonorrheal Rhinitis.

The condition designated purulent rhinitis commonly occurs in children and runs a chronic course. There are, however, in both adults and children, cases of acute inflammation with the free discharge of almost pure pus. These are not to be confounded with sinus affections in which the nose serves merely as the conduit for the escape of discharges.

Causes.—The disease is essentially the expression of some form of infection. In very young children and babies a leucorrheal discharge in the mother seems to be the infecting agent; in fact, most of the cases occurring in early life are due to this cause.

Pathology. A high degree of inflammation of the mucosa exists with excoriations, and gonococci may be found in the discharge.

Symptoms.—If the child is only a few days old it begins to sneeze, while pus flows from the nares and excoriates the surrounding skin. This character of the discharge is in strong contrast to the earlier appearances of the discharge in a simple coryza. There is often a complicating purulent conjunctivitis and the inflammation may spread to the middle ear.

Treatment. This consists in the thorough cleansing of the nasal passages with antiseptic washes. With young children the patient must be held in the upright position with the head slightly bent forward; otherwise some of the fluid may run down into the larynx and set up spasm. Boric-acid solutions are serviceable in the earlier stages and may be followed by slightly astringent combinations. The oleostearate of zinc serves as an efficient vehicle for medicinal agents. With adults, and even with children in whom the malady runs a longer course, it may be advisable to apply cocaine and then make a single application of silver nitrate, sixty grains to the ounce. This may be followed by a temporary increase in the discharge, but its ultimate effects are advantageous. Some of the newer silver salts find here a suitable field. We may mention protargol in ten-per-cent. solution and argonin in the same strength. The latter is said to lead to the early disappearance of the gonococcus, subsidence of discharge, and prompt restoration of tissue integrity. Of less value are argentamin and largin. With any of these, insufflations of some antiseptic powder, such as aristol, dermatol, nosophen, etc., may advantageously be combined.

(3) ACUTE MEMBRANOUS RHINITIS.—By this designation we refer to that form of acute rhinitis in which we find a deposit of fibrin on the septum, on the turbinated bones, or on both.

Causes.—A consideration of the causes at once sharply divides the cases into (1st) those due to the Klebs-Loeffler bacillus (nasal diphtheria) and (2d) those due to various other micro-organisms, pus- and fibrin-producing cocci, especially the staphylococcus, streptococcus, bacillus coli, and pneumococcus. A French observer reports several cases due to the bacillus of hog septicæmia. Solutions of continuity of the intranasal tissues naturally predispose to and invite infection. The latter is not so common in the nares as might be at first supposed, for it must be remembered that there is a constant serous outpouring which cleanses the tissues, that the passages are continually flushed with air, and that the cilia of the epithelial cells tend to ward off all deleterious physical agents.

Pathology.—In membranous rhinitis the whole thickness of the mucosa becomes congested and swollen. There are an emigration of leucocytes and exudation of plasma from the vessels. Hence there is formed fibrin which infiltrates the interstices of the connective tissue elements of the mucosa, and also arranges itself as a membrane on its surface. At times there is a superficial coagulation necrosis of the superficial layers of the epithelium. Under these circumstances the membrane is formed, not of true fibrin and pus, but of necrotic epithelium alone. In most cases the combined effect of vascular congestion and pressure of the exudate is sufficient to starve out a portion of the mucosa involved, and thus sloughs are formed, the separation of which gives the familiar ulcer.

It is thus seen that the process is identical with membrane formation anywhere, and that the appearance is the same no matter what the exact exciting cause. Frequently there is partial organization of the membrane, in the sense that it becomes laminated, permeated with leucocytes and epithelial cells, and presents partial vascularization. The areas most frequently affected are the faces of the inferior and middle turbinates and the anterior portion of the septum.

Symptoms.—In many cases the onset of symptoms is not unlike that of an ordinary coryza. There is dryness of the nose followed by irritation and sneezing, with headache, fever, and general malaise. Next follow the group of symptoms referable to obstructed nasal breathing, anosmia, aprosexia, sore mouth from direct impact of air, paresis of the soft palate, leading to a muffled voice, etc. In other cases, and especially in young children, there is the typical appearance of a drooping child without any special features suggesting nasal trouble, unless perchance the stoppage of the nares or the appearance of a purulent discharge at the outset calls attention to that area.

Examination shows the mucosa covered with a false membrane of a whitish gray color. Removal generally causes bleeding, but gentle manipulation may clear the membrane without this sequel. The membrane frequently exfoliates and re-forms, so that the process is extended over days and even weeks. The general health does not seem to be depleted so much as might be expected considering the nature of the lesion.

Diagnosis.—The question to be decided in the presence of a given case is, Is it diphtheritic or not? While typical cases of the two conditions may present sharply defined boundaries, there are many in which the diagnosis can be made only by the culture test. There has been much discussion as to whether there are really two distinct affections or whether all are not true diphtheria with a bacillus of diminished virulency in the milder cases. Wishart has divided the partisans on this matter into three groups: (1st) Those who consider diphtheria and membranous rhinitis to be distinct affections; (2d) those who consider that there is but one disease, but that the degree of contagiousness so varies that we may safely neglect to isolate such cases as offer no clinical or bacteriological evidence of diphtheria; and (3d) those who would isolate every case. (It may be added that Wishart does not believe in the duality of the disease and advises isolation under all circumstances.)

Out of ninety-eight cases collected by this observer from various sources and reported as membranous rhinitis, sixty-nine showed the Klebs-Loeffler bacillus. E. Mayer notes that the earlier in the disease the test is made the more likely are the bacilli to be found. In the light of our present knowledge, then, the differential diagnosis in a doubtful case is to be made by the culture test. Some cases are found in which no Klebs-Loeffler bacilli are met, yet there is incontrovertible evidence that such cases have spread contagion to others and that the membrane in the secondary cases *has* shown the bacilli. A possible explanation would be that the bacilli were overlooked in the primary cases; but this experience has happened to some of our most careful bacteriologists. If culture media are not at hand, we must rely upon the general clinical features of the disease. Factors suggesting the presence of true diphtheria would be a history of exposure, coexisting deposits in the throat, swelling of the cervical glands, distinctly fetid odor from the nose, a marked constitutional involvement, and an offensive discharge excoriating the surrounding skin. Not

Digitized by Microsoft®

Nasal Cavities.

much reliance, however, can be placed on the degree of severity of constitutional symptoms. The occurrence of albuminuria and the development of paralysis would also bear in the direction of diphtheria. The opposites of the factors just enumerated would suggest mere coccus rhinitis.

www.libtool.com.cn

Nasal diphtheria has always been regarded as a most malignant form of the disease, and this view still holds in those cases in which the deposit begins in the throat and spreads to the nose. But we see at the present time cases of true diphtheria with the deposit confined to the nasal mucosa and in which the constitutional symptoms are very mild. In this connection reference may be made to some recent studies by R. O. Neumann concerning the forms under which nasal diphtheria may occur. He has several times seen cases in which apparently simple coryza was due to the diphtheria bacillus. In many instances the general symptoms produced were more marked than those of a simple coryza, but very much less marked than in an ordinary case of diphtheria. The discharge from the nose was sometimes sero-purulent, sometimes markedly purulent. Neumann comes to the following conclusions from his study: Simple rhinitis, associated with virulent diphtheria bacilli, is much more frequent than is commonly supposed. The symptoms of this disease are not always the same. It comes on very often in a very mild form and may even be unobserved by the patient. It is quite in contrast with the so-called rhinitis fibrinosa, as there is no formation of membrane. Both forms exist upon a similar basis, so that one should not speak of them as two different diseases; they should be divided into nasal diphtheria with membrane formation, and nasal diphtheria without membrane formation. If the fact be considered that not only rhinitis fibrinosa, but also nasal diphtheria, especially the last, may serve as a focus of contagion for the surrounding neighborhood, it would be wise to investigate bacteriologically all doubtful cases of coryza.

Prognosis.—This is always good, although after either form there may be an anæmia, especially in those living in bad surroundings. Either type of the disease may attack all classes in society.

Treatment.—As a matter of precaution every case of membranous rhinitis should be isolated until a culture test can be made. In other words, it is better to consider all cases diphtheritic until the contrary is definitely shown to be true. If the Klebs-Loeffler bacilli are found, full antitoxin dosage should be administered and the usual hygienic and quarantine measures instituted. If the test is negative, we may give calomel in half-grain doses every four hours until five grains are taken. This is given with a view of aborting the membranous formation which in young children is apt to accumulate rapidly and be very thick. For the purpose of counteracting hyperinosis we may give to a child of five years, eight to ten minims of the muriated iron tincture in glycerin, every three hours. For local applications nearly every antiseptic in use has been at some time suggested. The systematic use of any one is preferable to the desultory and changing use of several. The nares should be cleansed with a warm alkaline spray, and if there is much tenacious secretion it may be loosened up with equal parts of hydrogen peroxide and lime water. If the membrane shows the least tendency to exfoliate, this should be assisted by gentle manipulation and the passages should be carefully dried with antiseptic cotton. Then it is well to apply pure iron tincture by means of a swab and to follow it by the insufflation of some powder, as iodol, aristol, nosophen, etc. Iodoform emulsion has also been suggested.

(4) Acute Phlegmonous Rhinitis.—This is a process attended with the localized formation of pus, generally in the deeper layers of the mucosa and submucosa covering the septum, and it generally presents itself under the form of the familiar septal abscess. One or two instances of abscess in the mucosa covering the turbinated bones are recorded, but in such cases the abscess has been caused by the burrowing of pus from the maxillary sinus; so also dentists have found a purulent collection on the nasal floor from some tooth abnormality, but these cases are so rare that they need not be considered here.

Causes.—Septal abscess is practically always referable to some trauma, as from a blow or a fall. Other possible causes are some intranasal operation and infection in measles, scarlatina, diptheria, erysipelas, and typhoid.

Pathology.—Following the trauma there is an effusion of blood into the tissues (hæmatoma), and this effusion may separate the two lamellæ of the cartilage. The initial injury may have been so slight as to escape notice and yet lead eventually to abscess. If the effusion is small it becomes absorbed; if it is large, absorption is but partial and is followed by the breaking down of the remains of the clot and formation of pus in the usual manner.

Symptoms.—These naturally follow from the history of the case. There is the initial pain of the injury followed by swelling of the external parts and nasal occlusion, unilateral or bilateral. The outer swelling subsides, while nasal occlusion persists, and, in case of abscess, the formation of pus is accompanied by burning and irritation with perhaps a slight general febrile movement and malaise. Examination reveals on one or both sides a tense, bulging swelling, soft on palpation, and with evidences of severe local inflammation.

Diagnosis.—The use of the probe will differentiate the swelling from the turbinated bones and from all forms of tumors projecting down from points of attachment higher up in the nares. The swelling does not subside under cocaine. Spontaneous rupture never occurs. Any unilateral purulent discharge from the nose suggests sinus disease or a foreign body. The history of the case will generally clear up all doubt as to the nature of the lesion.

Treatment.—Cases of recent trauma in which abscess seems threatened may be treated with ice compresses over the nose, while iodine tincture or five-per-cent. carbolic solution may be applied directly to the septal mucosa. As soon as the presence of pus is determined, the latter should be evacuated by free incision on both sides of the septum, as the abscess contents are apt to form a pocket. The cavity is syringed with hydrogen peroxide and a warm alkaline solution. A delicate strip of antiseptic gauze is then carried to the bottom of the cavity to provide for drainage. This should be changed in twenty-four hours. This dressing provides for healing from the bottom; otherwise the cavity may refill. With a view of maintaining the patency of the incision, it has been recommended that the latter should be made with the galvano-cautery knife. If the case is one of any duration, the pus will have a very foul odor. Subsequent cleanliness is all that is required.

It must be borne in mind that the initial escape of blood may be between the perichondrium and the cartilage or between the two cartilaginous plates which are united by a diploëtic structure. The cartilage may fracture, allowing a communication between the two nares. In case the contents of the cavity are at all grumous it is well gently to curette through the incision and remove all necrotic particles. If the perichondrium remains, the cartilage will be reproduced. Perforation may occur. It is well to be cautious in promising a perfectly normal contour of the nose after healing is complete, for some cases show a slight depression just behind the tip.

Another condition quite rare but requiring mention in this connection is that known as acute serous perichondritis of the nasal septum. While perichondrial inflammations are, as we have seen, common enough after trauma, there is a form of inflammation which develops in this locality without known cause. It must be due to some form of infection, though the time and mode of entrance of the infecting agent cannot be determined. The clinical history is somewhat as follows.

The first symptom is nasal stoppage, gradually increasing and attended with the phenomena of local inflammation. At times there are mild general symptoms. Examination reveals the septum swollen on one or both

Digitized by Microsoft®

sides and generally fluctuating. Incision may evacuate pus, while probing may show a carious condition of the cartilage, which may be partially gone. Sometimes cartilaginous sequestra of considerable size come away under this manœuvre. The especial danger of the condition is that it may lead to a marked depression of the contour of the nose just at the junction of the bones and cartilages.

www.libtool.com.cn

Thus far, the condition has been practically that of a septal abscess with a maximum destruction of tissue, but there are cases in which incision evacuates only clear serum, which is odorless, and hence a separate classification is given by some authors to the lesion, which is often called serous cyst of the septum. Treatment is the same as for abscess.

(5) Acute Rhinitis due to Occupation or Trauma.—Certain occupations lead to acute rhinitis; this is especially true of those which are attended with the giving off of dust—*e.g.*, milling, weaving, stone-cutting, cement grinding, etc., or of those which are associated with the giving off of noxious fumes—occupations, for example, which require the handling of ammonia, chlorine, arsenic, mercury, bichromate of potash, etc. Workers in phosphorus often have a coryza from the constitutional effects of the remedy, as do patients who take the iodides. Laboratory workers may be thus affected by the fumes of osmic acid. Burns, scalds, smoke, steam, foreign bodies, and operations on the nose must also be included in the list of causes. The arsenic eaters of Styria frequently show septal perforations which have originated in a similar way.

Pathology.—There are no special features in the earlier stages of an attack. In fact the affection often runs a subacute rather than an acute course. The changes are generally accentuated on the anterior part of the septum, which soon becomes irritated and, in dusty surroundings, covered with a scab of dirt and secretion. The patient rubs this off and takes some of the epithelium along with it. The deposit reforms, is again removed, and a vicious circle is thereby inaugurated. As a result there are hemorrhage, ulceration, and often perforation. After perforation has taken place the edges generally heal, and curiously enough these patients afterward seem quite immune to the ordinary causes of acute catarrh.

Symptoms.—These are the same as in acute coryza from any cause. Deformity never arises from the perforation.

Treatment.—Obviously the first thing to do is to remove the patient from the source of irritation. Workers in bad atmospheres should wear respirators. Thorough local and general cleanliness should be maintained, with application of stimulating remedies, such as camphor-menthol, to ulcerated surfaces. Healing may be assisted by astringents, such as alumnol and weak zinc chloride. Tincture of benzoin and boroglyceride may be used as local sedatives. *James E. Newcomb.*

NASAL CAVITIES, DISEASES OF: CHRONIC RHINITIS.—(Synonyms: Rhinitis chronica, Chronic catarrh, Chronic coryza, and Hydrorrhœa.) This affection consists of a chronic inflammation of the nasal mucous membrane, characterized by excessive secretion (rhinorrhœa) with discharge from the anterior or posterior nares, or by dryness of the nose with the formation of crusts. It occurs in all climates and among all classes of people, but is more frequent where the atmosphere is often damp and chilly, as beside large bodies of water; however, it is also found in the arid regions of the West, particularly at high altitudes where there is much dust, and it also occurs inland, in localities far removed from bodies of water and free from any unusual amount of dust. The symptoms are most common in the winter, spring, and fall months, and are usually aggravated by damp chilly weather. Persons who are much out of doors are less likely to be affected by it than those whose occupations confine them to the house. Although all are subject to the disease, it is more common in children and young adults, but it is not infrequent even among infants and those past middle life. According to the various manifestations of the disease it may be convenient to divide it for the sake of description into four varieties: (1) Simple chronic rhinitis, (2) intumescent rhinitis, (3) hypertrophic rhinitis, and (4) atrophic rhinitis. The first is characterized by inflammation with considerable secretion, but with little or no swelling and obstruction of the nares. The second is marked by intermittent swelling, occurring usually when a person is lying down and especially in the latter part of the night, by much aggravation of the symptoms on slight exposure to cold, by frequent clearing of the throat, often by hoarseness, and sometimes by excessive discharge. The third variety is characterized by more or less constant obstruction of the nares with hypertrophy of the soft tissues over the turbinated bones, and sometimes of the bones themselves, and also by hypertrophy of the soft tissues over the septum. The fourth variety is characterized by wasting of all of the tissues within the nares and a corresponding enlargement of the cavity, with the collection of mucous crusts, which decompose and cause a foul odor from the nose. In the majority of cases all of these varieties originate in much the same way, though there are individual instances in which neither variety can be traced to any previous affection.

Simple Chronic Rhinitis.

Simple chronic rhinitis is characterized by catarrhal congestion and inflammation of the mucous membrane with but little swelling. It is usually attended by a good deal of irritability of the Schneiderian membrane and excessive discharge of a thin watery fluid which, under the influence of the frequent exacerbations caused by cold, becomes muco-purulent in character.

Etiology.—Chronic rhinitis in many cases appears to result from debility, due to digestive disorders or improper food, or to confinement within doors and lack of exercise. In some cases it is clearly of nervous origin and is occasionally one of the manifestations of neurasthenia, but most commonly it appears to be caused by frequent colds, improper clothing, and exposure to dust-laden or damp and chilly atmosphere. In numerous cases an inherited predisposition may be detected.

Anatomical and Pathological Characteristics.—The mucous membrane is usually evenly congested and moderately swollen, but at times the swelling is limited to the turbinated bodies or upper part of the septum. Erosions particularly of the cartilaginous septum may be present, but ulceration is not a feature of the disease unless it has been caused by frequent removal of crusts by the finger nail. The epithelium and the subepithelial tissues are found infiltrated with round cells, especially about the glands and vessels. The layers of the epithelial cells become increased and the upper cells are flattened, with here and there patches of normal ciliated epithelium remaining. The conditions, it will be seen, are not very different from those of inflammation of the mucous membranes in other parts of the body, the pathology of which is described elsewhere, and therefore need not be considered in this article.

Symptomatology.—The patient usually gives a history of often recurring colds in the head, which have become more frequent and persistent until the symptoms are present the greater part of the time. Itching, burning, and tickling sensations are experienced in the nose, and sneezing may occur upon the slightest provocation, as upon exposure to a slight draught or slightly irritating vapor. Weakness of the eyes with pain and headaches is frequent, and often there are partial anæmia and defective hearing. Occasionally the sense of taste is also obtunded. Lachrymation is easily excited, and commonly there is an excessive watery discharge from the nose which, with the progress of each recurring inflammatory attack, becomes muco-purulent and acquires a more or less offensive odor. The nose is commonly obstructed

Digitized by Microsoft®

Nasal Cavities.

for a few days during the recurring colds, but at other times nasal respiration is free excepting when it is impeded by the profuse secretion. The general health is usually good, but slight derangement of the digestive organs is common. In some cases cobweb-like shreds of mucus are seen stretching from one side to the other of the nasal cavity with but little secretion. In others the surfaces may be dry, and in still others watery or muco-purulent secretions may be found in abundance, especially in the lower part of the nasal cavity. In most cases the naso-pharyngeal mucous membrane is also congested and more or less covered with secretion similar to that in the nose, but generally less watery in character. This causes frequent hawking and attempts to clear the throat. The nares are usually somewhat obstructed by swelling of the mucous membrane, especially during the acute exacerbations, but in some cases it is difficult to draw a distinct line of demarcation between this condition and true hypertrophy of the mucous membrane.

Diagnosis.—The diagnosis is usually easily made by inspection, and there are no diseases excepting hyperesthetic rhinitis or autumnal catarrh and diseases of the accessory sinuses that are apt to be mistaken for simple chronic rhinitis, provided intumescent rhinitis be excluded by a careful study of the history. In simple chronic rhinitis the prolonged duration with gradually increasing susceptibility to cold, the nearly normal size of the nares, the absence of exquisite tenderness, and the occurrence of exacerbations independently of the conditions producing hay fever will generally enable us to exclude the latter and intumescent rhinitis. The occurrence of profuse secretions upon both sides instead of one, with the history, will nearly always enable us at once to distinguish this from disease of the accessory sinuses. Sometimes, particularly in children when there is excessive purulent discharge, cleansing of the nares will be necessary before a diagnosis can be made.

Prognosis.—The affection is tedious and apt to extend over several years, and may terminate in one of the other forms of rhinitis, particularly the hypertrophic or atrophic. In some instances, especially in children, owing to secondary infection with pyogenic germs, a simple watery discharge that might otherwise have continued unchanged for months or years becomes purulent and offensive in character.

Treatment.—The treatment of this form of rhinitis must be tentative and symptomatic, and is therefore not very satisfactory. Attempts to cure it by local measures alone will nearly always be disappointing. It must be remembered that in many instances it is kept up by a loss of tone of the general system or by various disturbances of the digestive organs, and until these are relieved by proper hygienic and tonic measures little can be accomplished in the treatment of the nose. Whenever practicable, the patient should be removed from the sources of irritation and his mode of life should be so ordered as to prevent unnecessary exposures; and by improvement in the general health, to steel him against those which are unavoidable. Two principal objects are to be kept constantly in view in the treatment of these cases: First, to relieve irritability of the nasal mucous membrane by sedatives and protective applications; and second, to check the secretions or to prevent their collection in the nares. When the secretions are watery and profuse, nothing is needed for cleansing the nasal cavity; but when they become muco-purulent detergent washes or sprays may be necessary to clear the nose before local remedies can have any effect. Wherever practicable, watery applications should be avoided, as these tend to increase the swelling of the parts and appear to have little influence in checking secretion; furthermore, the watery applications not infrequently find their way through the Eustachian tubes to the middle ear and cause deafness. Commonly, excepting in cases in which the secretions dry and form crusts, oily applications are sufficient, aided by the patient's efforts at blowing the nose to cleanse the cavity. It is only in the most exceptional cases that these cause inconvenience by passing into the Eustachian tubes, and the protection which they afford the mucous membrane from irritating substances or from the cold or damp atmosphere is a distinct advantage. Non-irritating disinfectant and slightly astringent powders are usually beneficial. For detergent purposes a weak solution of potassium permanganate, an alkaline solution containing about four grains of the bicarbonate and the chloride of sodium to the ounce; Dobell's solution, or a solution prepared from Rhodes' or Seiler's tablets may be employed in warm water, care being taken that it be not forced into the Eustachian tubes. These solutions cannot safely be used with the nasal douche, but ordinarily they may be snuffed from the hand or from a glass without danger. Freer's irrigating tube, which consists of a straightened Eustachian catheter perforated with three or four fine openings just back of the closed end, throws very fine streams which may be employed to wash out the nose and naso-pharynx without danger to the ear. The removal of the drying crusts is aided by treating them with oily substances applied either by the atomizer or by a medicine dropper. The sensitiveness of the mucous membrane varies greatly in different patients, and therefore it is necessary to begin the treatment with the mildest remedies, and it should be the invariable rule that the applications be not strong enough to cause discomfort for more than five minutes; this applies to those made by the patient three or four times a day; those which are made by the physician once or twice a week ought not to cause discomfort for more than half an hour. Commonly it is better that little or no irritation be caused by any application that is made. Oily sprays tend to coat the surface and protect it from irritating particles, and therefore are most advantageous in hypersensitive conditions of the mucous membrane. Those most commonly employed consist of various volatile oils in melted vaselin, or, better, in oleum petrolatum album. These should be applied by the patient four or five times daily by means of an atomizer which throws a large spray, or they may be applied by a medicine dropper or even a small oil can. Various substances may be combined with these bases for the purpose of diminishing the secretion. One of the most efficient of these is terebene in the proportion of ten or twenty minims to the ounce. Thymol half a grain to the ounce, menthol from two to five grains to the ounce, oleum pini sylvestris one-half drachm to the ounce with oleum caryophylli from three to five minims, or oleum cinnamomi from one to two minims to the ounce, have proved most satisfactory in my hands; but other similar applications may be employed with advantage if care be taken that they be not too stimulating or irritant. A watery solution of adrenalin chloride, 1 part to 5,000, containing about eight grains of boric acid to the ounce, will be found beneficial in some cases, and weak solutions of silver nitrate, copper sulphate, and zinc sulphate or chloride, from one to two grains to the ounce of distilled water, are sometimes efficient. Sedative powders are frequently more advantageous than sprays, and are commonly employed in addition to the oily applications already recommended. Boric acid, bismuth, iodol, benzoin, and various other substances may be employed for this purpose, mingled with starch and sugar of milk. A sedative powder containing ten per cent. of boric acid, twenty-five per cent. of iodol, two per cent. of starch, and enough sugar of milk to make one hundred parts, with occasionally one per cent. of cocaine, will sometimes give much relief. When there is an offensive odor, aristol may well be used in place of iodol; and various combinations may be made with other remedies, such as bismuth, oxide of zinc, and pulverized gum benzoin. It is well to use these powders after the oily spray has been applied.

In cases in which there is marked hyperæsthesia of the nasal mucous membrane, the greatest good will be obtained by superficial cauterization of the sensitive spot. The spot should be searched for with a flat probe lightly rubbed over the surface; when found, and after it has been anæsthetized with cocaine, it should be cauterized with a flat guarded electrode with sufficient thorough-

www.libtool.com.cn

Digitized by Microsoft®

ness to whiten the mucous membrane over an area about a centimetre in diameter, but the cauterization should not be carried far enough to destroy this tissue. The effect of this treatment is to destroy the terminal fibres of the hypersensitive nerve and thus the cause of the disagreeable symptoms is removed. The sedative sprays and powders should be used in the intervals between the cauterizations, and the latter should not be repeated oftener than once in five or ten days.

www.libtool.com.cn

Intumescent Rhinitis.

This affection is often spoken of merely as chronic catarrh, and is sometimes classed as hypertrophic rhinitis; but on account of the pathological condition it might well be called coryza vasomotoria chronica. It is characterized by swelling of the Schneiderian mucous membrane, especially of the inferior turbinated bodies, but also of the middle turbinals and sometimes of the tuberculum septi. This swelling causes obstruction to respiration through the occluded naris. It often involves only one side at a time, though it changes frequently from side to side, and both nares may be obstructed at once. One of the characteristic features of the disease is the swelling which occurs upon one side while the patient is lying upon that side, and which may be transferred to the other side within a few moments when the position is changed. These sudden changes in the seat of swelling are also noticeable even when the patient is erect, and sudden disappearance of swelling upon exercise is a common symptom.

Anatomical and Pathological Characteristics.—The pathology of inflammation of mucous membranes is described elsewhere; but we should note that in this condition, although congestion is usual, the membrane is not infrequently paler than normal. The swelling occurs most frequently over the inferior turbinated body, but may involve other parts, as already mentioned; it results from a paretic state of the muscular elements of these structures and of the muscular walls of their cavernous vessels. The inflammatory changes are the same as those in the variety known as chronic rhinitis and hypertrophic rhinitis, though less extensive than in the latter. The naso-pharynx and pharynx are nearly always involved, and not infrequently the inflammation extends to the larynx and trachea. In consequence of extension of the inflammation along the Eustachian tubes, partial deafness is present in many cases, and this is usually aggravated by exposure.

Etiology.—The causes are the same as those of simple chronic rhinitis.

Symptomatology.—Patients suffering with this disease usually give a history of unusual susceptibility to colds which are present during the large part of the changeable weather in the spring and fall, though in some cases they are also present in the winter and even in the warmer summer months. The disease gradually increases until eventually the patient is annoyed much of the time, especially at night, by obstruction of the nasal cavities. This occlusion causes mouth breathing, and sooner or later in most instances sets up inflammation of the naso-pharynx, the pharynx, and even the larynx and trachea. Indeed, the great majority of cases of chronic mild laryngitis are due to intumescent rhinitis, the effect of the intermittent swellings appearing to be even more disastrous to the larynx than is the more persistent obstruction due to hypertrophic rhinitis or nasal mucous polypi. As a result of disturbed sleep, the patient is apt to awaken unrefreshed and with a headache. In most of these cases the nasal mucous membrane is hypersensitive, and the paroxysms of sneezing may be excited by breathing cold air or the inhalation of dust, and in some cases even by stepping into a bright light. Sudden changes of temperature, whether from heat to cold or the reverse, are very apt to bring on attacks of sneezing with occlusion of the nares. Sometimes the obstruction is brought on quickly by exposure to cold, but usually the reverse is true, and it is only in the temperate atmosphere within doors that the patient experiences the greatest annoyance. A patient who may get along comfortably with the temperature at 72° F. will frequently find the nasal passages obstructed when the mercury rises three or four degrees higher. Occasionally such patients are annoyed by attacks of redness and inflammation of the end of the nose; and not infrequently they are troubled with itching or tickling of the nose, or by similar sensations in the mouth associated with dryness. A stuffy sensation in the nares or one of pressure with actual pain is not infrequent, and these patients are often the victims of a temporal or occipital neuralgia or hemicrania due to the pressure. It should be understood, however, that these are not common symptoms. Mental hebetude, loss of memory, and inability to concentrate the thoughts are due to this disease in rare cases. Among other nervous phenomena that sometimes result from intumescent rhinitis may be mentioned paroxysmal cough, spasm of the larynx, and even spasmodic asthma, which may occasionally be removed by curing the catarrhal condition. Excessive lachrymation and photophobia are also sometimes caused by this form of catarrh. In a considerable number of these patients the secretions from the nares are increased, but in the majority the patient does not have to use a handkerchief excessively, and the greatest complaint is of the desire to hawk and clear the throat, especially in the early morning or after eating. The secretions are essentially the same as those of simple chronic rhinitis, though usually they are not so abundant. However, the amount of discharge may vary much from time to time, and exacerbations are frequent from slight colds in the head. Many patients who present the usual symptoms of intumescent rhinitis deny the existence of obstruction of the nares, even though upon examination the cavities may be found more than half closed. The reason for this is that they have become so accustomed to breathing through the narrow orifice and to existing upon a minimum amount of air that they have no realization of the comfort of normal respiration. In intumescent rhinitis the tongue is so commonly coated and the digestive organs are so frequently disturbed that the suspicion arises that, in some cases at least, gastric disturbance is the primary disease. Upon inspection of the nares the mucous membrane may or may not be seen to be congested, or it may be even paler than normal. Usually it is swollen upon one side or the other, although frequently at the first examination one must rely largely upon the history in making the diagnosis, for both nares may be perfectly free. If the membrane upon the turbinals or the tuberculum septi be swollen it may be made to contract speedily by the application of a small quantity of cocaine, or it may be readily compressed by a probe. Sometimes, indeed, the mere dread of an examination will cause rapid retraction of a swollen membrane. The normal width of the nares in an adult is about one-eighth of an inch, and the color of the mucous membrane is a few shades deeper than that of the gum. Probably in four-fifths of all cases of intumescent rhinitis the congestion is considerably greater than this, and the constriction of one or other or both of the cavities may be from thirty to seventy-five per cent. The swollen membrane over the tuberculum septi is generally a few shades darker in color than the normal tissues; but the swollen membrane at the back part of the septum, when brightly illuminated either from the front or by posterior rhinoscopy, is apt to appear of a grayish color. The posterior ends of the turbinated bodies may also, when swollen, appear grayish in color, and may somewhat resemble mucous polypi; but these changes are more apt to be found in hypertrophic rhinitis. The mucous membrane of the naso-pharynx is often congested and bathed in secretion, and commonly more or less follicular inflammation of the pharynx is present.

Diagnosis.—Intumescent rhinitis is to be distinguished from simple chronic rhinitis, hypertrophic rhinitis, hay fever, and nasal mucous polypi. It is distinguished from simple chronic rhinitis by the absence of swelling in the latter. If at the first examination the history in-

Digitized by Microsoft®

dicates that the patient is troubled by frequent obstruction of the nares, although the cavities may appear free, he must be sent away and directed to keep watch of the symptoms and report specifically at another visit. At a second visit it is probable that swelling of one side will be present. Intumescent rhinitis is distinguished from hypertrophic rhinitis by the history, which indicates intermittent swelling, and usually by the presence of swelling in the intumescent form only upon one side at the examination, by the yielding of the tissues before slight pressure of the probe and their retraction under the influence of cocaine. In hypertrophic rhinitis, although the tissues retract under cocaine, they do not to so great an extent as in the intumescent variety. Hay fever is distinguished from intumescent rhinitis by the history of repeated attacks at a certain time year after year, by the excessive sneezing, and by the irritation of the eyes and throat which usually attend hay fever. Nasal mucous polypi can hardly be confounded with intumescent rhinitis excepting by the tyro. Their color a light grayish, their position as a rule in the upper part of the nasal fossa, their mobility as indicated by the probe, and the fact that a probe may be passed on both sides of them should be sufficient to establish the diagnosis in any case.

www.libtool.com.cn

Prognosis.—Left to itself, intumescent rhinitis occasionally subsides spontaneously, but it commonly extends over a long period of time; and eventually true tissue hyperplasias occur and hypertrophic rhinitis is the result. In rare cases, however, this form appears to pass directly into atrophic rhinitis. The frequent obstruction of the nares, occurring chiefly at night in this affection, leads to chronic pharyngitis and laryngitis, and often the Eustachian tubes and middle ear become involved and throat deafness follows. In singers the voice is likely to be ruined by persistence of this affection. The general health suffers from imperfect oxygenation; and, although to the casual observer the patients may appear robust, they have little endurance. By proper treatment the obstruction may be entirely removed, and as a rule the hypersensitiveness of the mucous membrane will disappear with it. Most of the other symptoms speedily subside soon after the nasal cavities are made free, and a final cure may be predicted in nearly all cases. The effects upon the general health of the cure of the local trouble are most gratifying. Sleep is no longer disturbed, the nasal respiration is restored, and the patient becomes more vigorous mentally and physically. There is some liability to recurrence; nevertheless it is best to relieve only the obstruction that is apparent, rather than to make the nasal cavities abnormally large. The treatment may be resumed at some future time if found necessary, but usually the symptoms do not recur for several years at the worst, and in the majority of cases the patient is completely cured.

Treatment.—All sources of irritation should be shunned, and special care should be taken to avoid cold. Exposure to draughts, cold, or even undue heat, especially in badly ventilated rooms, or the inhalation of irritating dust or vapors is especially liable to cause this variety of inflammation. Much may be done to guard against rhinitis by care as to clothing. The daily cold bath with vigorous friction and regular exercise do much to prevent the nervous exhaustion and the loss of tone of the vascular system, which are often responsible for this affection. The condition of the digestive organs should always be carefully attended to. Local treatment of a sedative character is important during the early stages, and will often be sufficient to prevent further development of the disease. The various oily preparations mentioned in the treatment of chronic rhinitis will be found beneficial at this stage of the disease, and sedatives and mildly astringent powders may do much to lessen the discharge and will sometimes give considerable relief to the obstructed respiration. Adrenalin chloride in solution or in powder, of a strength of about 1 to 4,000 or 5,000, may in some cases be used four or five times a day with great advantage. Cocaine gives the greatest relief, but unfortunately its continued use causes a paretic state of the muscular coats of the veins of the cavernous tissue of the turbinals; and after a few weeks or months the patient's condition is much worse than it was in the beginning. There is reason to believe also that the cocaine favors hypertrophy. Aside from this, its pernicious effects upon the nervous system and the great danger of the formation of the cocaine habit render it absolutely unsafe excepting for very short periods of time. The physician should never give a prescription containing cocaine lest the patient have it repeated and so form a cocaine habit; and even while the patient is under the physician's observation he should not be allowed to use more than from an eighth to a quarter of a grain daily, and this should be discontinued as quickly as possible. When it is necessary to employ it, a one- or two-per-cent. solution in a saturated solution of boric acid in distilled water may be employed, or a similar amount may be rubbed up with one per cent. each of sodium bicarbonate and sodium biborate, two per cent. of the light carbonate of magnesium, and sufficient sugar of milk to make the required quantity. These sprays may be applied with any good atomizer, but the No. 50 Davidson is the best in my opinion for oily applications. The powders are most conventiently applied by a simple insufflator with a glass tube and rubber handball and tube. For personal use the patient may have a short glass tube, about four inches in length, to which is attached a rubber tube, about ten inches in length; one end of the glass tube should be flattened. The powder is placed in the round end, the rubber is slipped over this end, and then the flat end of the tube is placed in the nostril; the other end of the rubber tube is taken in the mouth, and the patient gives a quick puff which throws the powder well through the naris. Oily applications may also be made to the nose with a medicine dropper or a small oil can when the patient finds this more convenient. More stimulating applications may be made to the nares once or twice a week.

The applications made by the physician should never cause discomfort for more than ten or fifteen minutes, and those made by the patient should not cause irritation or smarting for more than a minute, and should not be sufficiently strong to give a feeling of stuffiness in the nares afterward. Of the aqueous solutions recommended for personal use by the patient three or four times daily, some of the best are boric acid, eight grains to one ounce, sodium bicarbonate and sodium biborate, of each two grains to one ounce, listerine forty to sixty minims to one ounce, or distilled extract of hamamelis or of pinus canandensis thirty to fifty minims to the ounce. The saturated solution of boric acid in camphor water is also recommended. For personal use an excellent application consists of one-third grain of thymol with three minims of the oil of cloves to the ounce of oleum petrolatum album, or its strength may be increased by the addition of various substances, combined or singly, which should seldom exceed the following amounts to each ounce: Menthol, gr. ij.; terebene, ♏ xv.; oil of cassia, ♏ ij.; camphor, gr. i.; ol. pini sylvestris, ʒ ss. Some prefer the use of heavier oils, and many employ vaseline, which is melted each time before the application, the theory being that it remains longer in contact with the mucous membrane than would the lighter oil. When the secretions are free, the nose should be cleansed in the same manner as recommended for simple chronic rhinitis. Indeed, most of the remedies applicable to that disease may be used at times with advantage in this affection.

The foregoing measures, however, can relieve only the milder cases, and it is not proper for a physician to keep a patient under treatment more than two or three weeks before he adopts more radical measures, unless what he is doing is found to be accomplishing great good. The radical treatment of intumescent rhinitis consists in destruction of a portion of the tissues by chemical agents or by the galvano-cautery or by removal of the swollen masses by the snare, or cutting them away by knife or scissors.

Cauterization by Acids.—When satisfactory galvano-

Digitized by Microsoft®

cauteries could not be obtained, there was much reason for the employment of the chemical caustics, and these are still preferred by some physicians, although they cause much greater irritation of the parts with corresponding discomfort to the patient, and do not, commonly at least, yield such accurate results. Of the chemical agents used for the purpose chromic acid is perhaps the best. A few crystals of this may be fused on the end of a flat aluminum probe by holding it over a light for a few moments, and then the parts may be accurately touched without much danger of the chromic acid extending beyond the part to be cauterized; however, the operator should be ready to spray the parts immediately with an alkaline solution in order to neutralize any excess of the acid. A very small amount of the acid, not exceeding in bulk a pellet 2 mm. in diameter, should be employed, and the area of membrane touched at any one time should measure not more than an eighth of an inch in width and from a half to three-fourths of an inch in length.

The cauterization should not be repeated within less than from ten to fourteen days. Some prefer touching the surface at several points with the acid, and some use solutions of various strengths instead of the fused acid, and repeat the cauterization in four or five days. The principal objections to the chromic acid are the difficulty of controlling the extent of cauterization and the pain that is likely to follow the cauterization for many hours. Monochloracetic and trichloracetic acids are also used for the same purpose, but in my hands they have not proven satisfactory. Some operators have obtained good results from the employment of electrolysis, commonly using a bipolar electrode, the needles of which are 4 or 5 mm. apart. A current of from 2 to 10 milliampères, lasting for from three to five minutes, is employed. If the effect of this electrolysis could be confined entirely to the submucous tissue, it would prove a very attractive operation, but many times a slough forms, and often the wound thus resulting is larger than that obtained by the usual forms of cauterization.

Galvanocautery.—Cauterization by the galvanocautery should be done with a wire heated to a cherry-red color only. If heated less than this the line will not burn sufficiently deep and the heat will radiate more to other parts; and if a white heat be employed, the instrument will cut almost like a knife, and bleeding will result. I like best for the purpose a knife-like electrode, about 10 cm. in length, the blade of which consists of No. 21 platinum wire and is about 15 mm. in length. A finer wire heats much quicker and cools more rapidly so that we either get a sharp cut with bleeding or fail to burn the tissues deeply enough. The parts should be first anæsthetized with cocaine, the solution of which should not ordinarily exceed a strength of four per cent.; this is best applied by a thin swab of cotton wound upon a flat aluminum probe, with which all of the part to be touched is gently rubbed about every minute and a half until from two to four applications have been made, by which time the anæsthesia will be completed. This is much better than to employ a spray or a tampon of cotton, which spreads the cocaine over a large area and causes absorption of an unnecessary amount, to the detriment of the patient. A solution which has been found by long experience to be satisfactory on account of its good effects upon the parts, and the absence of constitutional symptoms excepting in the rarest cases, consists of atropine gr. $\frac{1}{10}$, strophanthin, gr. $\frac{1}{5}$, oil of cloves ♏iij, carbolic acid gr. x., cocaine muriate gr. xx., and enough water to make an ounce. When the anæsthesia is complete, the soft tissues will be thoroughly affected, and then the electrode should be carried to the posterior end of the turbinated body where the platinum wire is pressed against the tissues, the current is turned on, and with a slight to-and fro movement the electrode is drawn to the front part of the nasal cavity, burning the soft tissues down to the bone throughout the whole line. Usually two lines extending from the back to the front part of the inferior turbinated body will be necessary, one at the junction of the upper and the other at the junction of the lower with the middle third. In sensitive persons not more than half the line can be made at one sitting, and in no case should more than a single line across the whole length of the turbinated be made. The electrode should always be lifted from the tissues before the current is cut off, otherwise it is apt to tear out the eschar and cause bleeding. After the cauterization the nose should be sprayed with a solution of about five minims of oil of cloves in an ounce of liquid albolene, and this followed by insufflation of three or four grains of iodol. The nostrils should then be closed with a pledget of cotton, and the patient should be told to wear cotton whenever out of doors, or in any position where he is liable to take cold, for four or five days; then he should be allowed to change it and put in fresh cotton as often as desired. A ten-per-cent. solution of methylene blue may be employed to touch the line of cauterization in place of iodol, or the compound tincture of benzoin may be used for this purpose. The latter in some cases has seemed peculiarly efficacious in the prevention of subsequent reaction. A similar cauterization may be made in the opposite naris in from ten to twelve days, and these may be repeated at similar intervals until the swollen tissues have been sufficiently reduced. Usually two cauterizations upon each inferior turbinated body are sufficient; sometimes one is necessary upon each middle turbinated, and occasionally two short lines will have to be drawn through the tuberculum septi. It is well to have the patient return to the office four or five days after the cauterization, and to pass the probe between the opposing sides of the nares in order to prevent adhesions. The patient is given a small quantity of powder containing three per cent. of cocaine and twenty-five per cent. of iodol with one and one-half per cent. each of biborate and bicarbonate of sodium, and three per cent. of the light carbonate of magnesium, with sufficient sugar of milk to make the whole quantity about one hundred grains. This the patient is directed to insufflate into the nasal cavity two or three times a day for the purpose of keeping down the swelling. He is also given an oily spray containing one-third of a grain of thymol and from three to five minims of the oil of cloves to the ounce of liquid albolene, which he is directed to use freely in both nares four or five times daily. The powder is continued for four or five days and subsequently is used only once a day, but the oil is continued regularly until other treatment is instituted, or for two or three weeks. The frequent superficial cauterizations which are recommended by some appear to destroy more tissue, to give the patient more discomfort, and to be much less efficient. I have seen one death from ulcerative endocarditis evidently caused by the suppuration set up by this latter method. Usually such cauterizations cause little or no pain either at the time or subsequently, and may give the patient no more discomfort than would be experienced from a severe cold in the head. However, the patient should be warned, in order to prevent unnecessary anxiety, that there is likely to be some bloody discharge from the nose for two or three weeks. The principal discomfort following cauterizations is from the effects of the cocaine upon the nervous system; therefore care should be taken to use as little of this as is practicable. There are occasionally patients who cannot tolerate a sufficient quantity of cocaine to produce anæsthesia, in whom eucaine may be advantageously substituted; ten or fifteen grains of the bromide of potassium or a cup of strong coffee will commonly relieve the immediate poisonous symptoms caused by the cocaine; but it will not always succeed, and in patients peculiarly sensitive to the drug, none of it should be employed in the subsequent treatment except to prevent the pain of actual cauterization. When the turbinated bone itself is enlarged, or when there is a prominent deflection or spur from the septum, adhesions are very likely to occur if cauterization upon the turbinated body is made upon that side. In these cases, therefore, an operation upon the bony tissue should usually first be done. In spite of all precautions, adhesions sometimes result.

Digitized by Microsoft®

When this accident occurs it is best to wait until complete healing takes place, and then the adhesions should be cut with scissors. A pledget of wool or bit of rubber tissue may be placed between the opposing surfaces to prevent renewed adhesion, and after four or five days the healing will usually occur without difficulty. Sometimes adhesions may be prevented by touching the raw surface with monochloracetic acid, as this forms an eschar that tends to remain until the healing has taken place under it. Follicular tonsillitis occasionally follows the cauterization of the nares. I have seen it in about one-half of one per cent. of the patients operated upon, though not more than one-fourth as frequently as this if the individual cauterizations are considered. In rare cases otitis media is said to have followed the operation, and I have known of one case in which an inexperienced operator made an extensive cauterization that was followed by fatal meningitis. More or less blood is mixed with the discharges in the majority of cases for two or three weeks, and occasionally a secondary hemorrhage may occur at the end of a week or ten days. I have never had this experience myself, but have known of two cases in the practice of experienced operators in which an alarming hemorrhage recurred time after time until the patient was in the gravest danger; however, in both the bleeding was eventually checked and the patients made a good recovery. I recall two or three cases in my own experience in which erysipelatous inflammation of the skin covering the nose, lips, and cheek invariably followed cauterization. It is needless to say the operations were not repeated when this tendency was discovered. Occasionally in cases of extreme intumescence the swollen tissues may be grasped with a snare, providing this is done before cocaine has been applied; but excepting in the rarest instances this operation is reserved for hypertrophic rhinitis. D. Braden Kyle removes a prism-shaped piece with a knife instead of cauterizing, and believes that he gets better results in this way. The pharyngeal and laryngeal symptoms usually improve speedily after the nares have been made free, though it is well to carry on appropriate treatment for these parts during the treatment of the rhinitis. In professional singers whose living depends upon the voice, the cure of intumescent rhinitis is of the very greatest importance for the prevention of chronic laryngitis, and in nearly all cases, fortunately, we may confidently predict the happiest results from judicious radical treatment.

Hypertrophic Rhinitis.

Hypertrophic rhinitis is a common affection, but it is not met with so frequently as the intumescent variety. It is characterized by obstruction of the nares with discharge from the naso-pharynx and the nostrils, and frequent hawking to clear the throat. It is often associated with chronic laryngitis. The obstruction in the nares is permanent, yet it varies considerably from time to time on account of the varying degrees of swelling.

Anatomical and Pathological Characteristics.—Permanent thickening of the mucous membrane and sometimes also of the turbinated bones is found in this disease, and the nasal cavities are usually from one-third to three-fourths closed by the swelling. The mucous surface may be congested or paler than normal. It is sometimes smooth as in intumescent rhinitis, but is often more or less nodulated, and at times presents one or more tumor-like masses which are sometimes mistaken for fibrous or fibro-mucous polypi. The condition affects both the middle and the inferior turbinated bodies, and is not infrequently observed on the tuberculum septi. In many cases the inferior turbinated body is nearly as smooth in appearance as in the intumescent form of the disease, but usually its anterior extremity is more or less furrowed or nodular. The anterior end of the middle turbinated not infrequently presents numerous nodules, more or less translucent, and having something of the appearance of nasal mucous or fibro-mucous polypi. The hypertrophy at the upper part of the septum is generally smooth, and at first appears to the observer like thickening of the bony septum. Hypertrophy of the posterior ends of the turbinated bodies usually presents a raspberry-like appearance, and may vary in color from a whitish-gray to a dark livid hue; the posterior end of the middle turbinated, however, is generally lighter in color and less granular upon the surface, and it often appears much like a mucous polypus. The condition is due to overgrowth of the connective tissue and bony elements in varying degrees, but the pathology of the disease will be considered elsewhere.

Symptomatology.—The symptoms are not unlike those of intumescent rhinitis excepting that the nasal obstruction is more persistent and usually more complete. The patient generally complains much of accumulation of the secretions in the naso-pharynx and often of complicating laryngitis. Pressure symptoms, such as loss of the sense of smell, headache, nasal or supra-orbital neuralgia, and sometimes ocular symptoms, are more often present in this than in the intumescent form of the disease, and when present they are more persistent. Middle-ear disease with throat deafness is also common, and unfortunately after the hypertrophic rhinitis has persisted for some time, its effects are very likely to remain even though the disease in the nose may be cured.

Diagnosis.—Although the disease is frequently mistaken by general practitioners for nasal mucous polypi, careful inspection of the nares should exclude all affections excepting intumescent and syphilitic rhinitis. Intumescent rhinitis is distinguished from the hypertrophic form by greater variation in the degree of nasal obstruction, by yielding of the tissues readily before the probe pressed upon them, and usually by contraction of the swollen mass to its normal proportions or even less, upon the application of a weak solution of cocaine. Commonly, also, the mucous membrane is more congested in intumescent rhinitis than in the hypertrophic form. Syphilitic rhinitis causing uniform swelling of the turbinated bodies cannot always be distinguished from simple hypertrophy, but the history of the case and the effects of treatment, or the occurrence of ulceration of the Schneiderian membrane with evidences of former syphilitic involvement of the fauces or other parts of the body, will usually enable one to make an accurate diagnosis. Nasal polypi are commonly recognizable upon inspection; but if this is not sufficient, the passage of a probe upon both sides of the polypus and its movability will generally distinguish it at once from the hypertrophied turbinated body.

Prognosis.—Left to itself, there is little tendency for hypertrophic rhinitis to terminate in recovery. On the contrary, it is liable to increase gradually until the nares are three-fourths or four-fifths obstructed and then to remain permanent for a long time; in other instances the hypertrophy gives way to atrophy, and ultimately well-marked atrophic rhinitis results. There are also undoubtedly some cases in which the hypertrophy gradually subsides and the nares are left practically in a normal condition, but these are extremely rare. Subjected to proper treatment practically all cases of hypertrophic rhinitis may be cured in a comparatively short time, though the gentle or puttering treatment that is often adopted is likely to extend over years without much relief.

Treatment.—The more vigorous treatment recommended for intumescent rhinitis is equally applicable in the hypertrophic form of the disease, but the tentative soothing treatment recommended in the former is almost useless. The hypertrophied tissue must be removed in some way so as to bring the nasal cavities to a normal calibre. In doing this, however, the physician should be careful not to render the nares abnormally large, because if they are left too small they may be made larger; but once too much tissue is removed, nothing can restore it. Care should also be taken not to destroy mucous membrane when it is possible to avoid this, or rather to leave as large a surface of mucous membrane as should normally be present. The author is not at all in sym-

Digitized by Microsoft®

pathy with the little dabs or cuts that keep a patient dancing constant attendance for months, but believes in radical operative measures that will usually not average more than one treatment per week for from six to twelve weeks, by which time the patient should be cured. Among the operative procedures to be employed are those recommended for intumescent rhinitis, namely, cauterization with acid or preferably the galvanocautery. These are to be done in the way described for that affection. When it is possible to engage a considerable portion of the hypertrophied soft tissues in the loop of a cold wire snare or of the galvanocautery écraseur, it may be removed provided that too much mucous membrane be not sacrificed. Of these methods the cold wire snare is preferable in most cases, as it leaves less scar tissue. In some cases cutting away of a V-shaped piece, as recommended by Kyle, is an excellent operation. In some the spoke shave may be used for removing redundant tissue; in others, particularly when there is a mass of soft tissues pendent from the lower edge of the inferior turbinated, the hypertrophied tissue can easily be cut away with nasal scissors, but in the milder cases the galvanocautery is preferable. In many cases it is important not to sacrifice the mucous membrane; in such, hypertrophies of the tuberculum septi or of the turbinated bodies may often be speedily reduced by the nasal trephine passed beneath the mucous membrane. When the bony tissue is also increased, removal by the nasal burr is perhaps the best operation. It is passed through the mucous membrane and the bony tissue is cut away beneath without the danger of bleeding that sometimes attends cutting with other instruments. When the hypertrophy involves the tissues just in front of the posterior edge of the vomer, linear cauterizations have proven to the author most satisfactory. A number of cases have been seen in which all other obstructions of the nares had been removed and the nasal cavities appeared free, but yet the patient continued to complain of hawking to clear the naso-pharynx, and this was not relieved until the submucous infiltration at the sides of the vomer had been cured by cauterization. In any of these operations local anaesthesia and subsequent treatment are carried out, as recommended in intumescent rhinitis. Whenever cutting operations are performed, it is safest to pack the naris with a strip of surgeon's lint, which has been saturated with boric acid and iodoform, to prevent the danger of bleeding which is apt to occur two or three hours after the operation. The packing should be allowed to remain for two or three days, after which it should be gradually removed, or removed all at once if it can be done without giving the patient pain or exciting hemorrhage.

Atrophic Rhinitis

Atrophic rhinitis is a chronic inflammation of the nares in which not only the membrane but the bony framework undergo atrophy whereby the nasal cavities become more or less enlarged. It is characterized by collection of the secretions which become dried into scabs and adhere to the wall until decomposition takes place, thus causing an extremely offensive odor which is known as ozæna. It occurs in all countries and among all classes of people, but is most frequent in young adults particularly in girls. It is seldom observed before the tenth or after the thirty-fifth year of age.

Anatomical and Pathological Characteristics.—In consequence of the atrophy of the mucous membranes or of both the mucous membranes and the bony tissues the nasal cavities become enlarged, sometimes to two or three times their normal dimensions. The atrophy may be confined to the mucous membrane, but usually the bones also are involved and they may be shortened in every direction. The turbinated bodies are most affected, and not infrequently the turbinal bones are entirely absorbed. Shortening of the nasal bones causes sinking in of the bridge and may produce a flat pug, or saddle-shaped nose. The disease is often a sequel of hypertrophic rhinitis. Moritz Schmidt has observed cases in which part of a turbinal was hypertrophied and other parts were atrophied.

Etiology.—In many cases the causation of the disease cannot be ascertained, but there is certainly a considerable number in which repeated colds lead to hypertrophy which terminates in atrophy. Many have sought to find a specific micro-organism, and Abel and Löwenberg have isolated the bacillus ozænæ which has been supposed to act as an etiological factor. D. Braden Kyle by repeated inoculations from advanced cases of atrophic rhinitis was unable to discover any specific micro-organism, though various pathogenic bacteria were commonly found, such as the pneumococcus of Fraenkel, Klebs-Loeffler bacillus, Koch bacillus, the bacillus fœtidus, and various streptococci and staphylococci. The origin of the disease not infrequently dates from one of the exanthematous fevers.

Symptomatology.—Commonly the patient's general health is not impaired by the disease, and headache and other nervous symptoms that commonly attend rhinitis are not often present; but as the affection progresses the general health may suffer and eventually pallor, loss of strength, and emaciation, strongly suggestive of tuberculosis, may occur. Often the patient presents the appearance of what is commonly known as the strumous diathesis. The nose is apt to be broad, the nostrils and the lips are prominent, and the whole physiognomy is lacking considerably in expression. There is usually but little discharge from the nose, excepting once or twice a week when the crusts come away; decomposition of the secretions causes a persistent offensive odor, which, although the patient does not recognize it himself, makes him an object of disgust to others. Occasionally this condition is unaccompanied by stench, and in almost any case thorough cleansing may prevent this symptom. Usually there is but little if any difficulty in breathing through the nose, excepting when it becomes blocked by crusts of mucus. The eyes are often weak, the sense of smell is usually lost, and partial deafness commonly exists as the result of extension of the disease to the middle ear. When the process invades the accessory sinuses, the patient may suffer from distressing headaches and neuralgia.

Although there is a tendency to formation of dry scabs and crusts in the nose, occasionally the secretions consist only of a semi-fluid adherent pus or soft purulent coagula. This condition is especially apt to be present during intercurrent attacks of acute rhinitis.

The mucous surfaces are not usually entirely covered by the crusts, and where they are exposed the membrane is commonly pale. Immediately after the scabs have been cleared away and the nares have been washed, however, the mucous membrane is apt to appear congested, though not ulcerated. Secretions are found in the nose in varying quantity and of varying consistence. Those which have remained the longest have a brownish or blackish color; others may be of a yellowish or greenish hue. There may be various patches of pasty or sticky pus, or hard yellowish, grayish, brownish, or black scabs of various size. The odor clings to the crusts after their removal, but after the nose has been kept thoroughly cleansed for a few days it will entirely disappear excepting in very rare cases in which there is persistence of a fetid odor in spite of thorough cleansing. Cases of this sort sometimes result from involvement of the accessory sinuses. In rare instances the disease is confined to one side, but it is usually bilateral.

When the nasal cavities have been cleaned the turbinals may appear as mere shrunken ridges, or they may have been entirely absorbed. Not infrequently the naso-pharynx can easily be seen through the nostrils, and sometimes the orifices of the Eustachian tubes are in sight and the motions of the soft palate are plainly visible. In some cases the atrophy of the bones proceeds more rapidly than that of the mucous membrane, and then folds of more or less congested mucous membrane will be found hanging, particularly from the upper part

Digitized by Microsoft®

of the nares. The process is rarely confined entirely to the nasal cavities, but also involves the naso-pharynx and middle ear, and in many cases the mucous membrane of the larynx and trachea will be found congested and swollen or partially covered by adherent pus. The drying secretions not infrequently lodge in the naso-pharynx or even lower upon the pharyngeal wall.

www.dlibool.com.cn

DIAGNOSIS.—The affection is to be distinguished from lupus, syphilis, suppuration of the frontal, ethmoidal, or maxillary sinuses, and from rhinoliths or foreign bodies in the nares. The essential factors in the diagnosis are the offensive odor, the disgusting scabs, the enlargement of the nares with a history of preceding catarrhal symptoms, and the absence of a syphilitic history, and of eruptions or scars indicative of this disease.

Lupus nearly always involves the external surface first, and the ulceration and cicatrization are quite different from the appearances found in atrophic rhinitis; there is very little danger therefore of confounding the two.

Syphilitic disease of the nares is attended by an extremely offensive odor, though different from that of atrophy, the quality being sufficient to establish the diagnosis with those who have seen much of the two diseases. Syphilis usually attacks the septum and causes destruction of bone, whereas atrophic rhinitis causes atrophy of the turbinated bodies. In syphilis there is commonly extensive and marked ulceration, which is not present in atrophic rhinitis. The history of the two is commonly quite different. In doubtful cases the diagnosis may be aided by specific treatment.

Suppuration of the accessory sinuses gives rise to an offensive odor, though somewhat different from that of ozæna. An inspection of the parts should make it easy to differentiate sinus disease from simple atrophic rhinitis. In suppuration of the accessory cavities there is usually more or less thickening of the mucous membrane instead of atrophy. The affection is commonly confined to one side, whereas atrophic rhinitis is generally bilateral. In suppuration of the sinuses the nasal cavity may be more or less filled with liquid pus, though usually it does not contain a great quantity, and there is seldom the tendency to the drying of secretions and the formation of thick scabs and crusts which is so prominent in atrophic rhinitis.

Rhinoliths and foreign bodies in the nares give rise to an offensive discharge, but this is unilateral. When the secretions have been cleared away, inspection and palpation with a probe enable one readily to differentiate between these and atrophy.

PROGNOSIS.—The disease usually continues for many years, but there is a tendency to recovery about the thirty-fifth year of age. With appropriate treatment the disagreeable symptoms may be promptly removed and the disease may often be cured in from one to three years, though sometimes the patient will have to continue cleansing the nose two or three times a day until middle life. There seems to be some relation between atrophic rhinitis and pulmonary tuberculosis, but this may be only casual; however, the gradual deterioration of health due to the persistent disease in the nose may place the system in a condition for the development of a general or localized tuberculosis. It cannot be expected that the atrophied tissues will be renewed even under the most favorable circumstances, but occasionally this result will be obtained. I have even seen hypertrophic rhinitis following atrophy.

TREATMENT.—Of greatest importance is the frequent and careful cleansing of the nares not only for the purpose of relieving the offensive odor, but also in order that the remedial agents may be brought in contact with the mucous membrane. Commonly some alkaline wash is necessary to remove the dry secretion, and for this purpose a solution of equal parts of the bicarbonate and of the chloride of sodium, from a half drachm to a drachm each to the pint of warm water, answers about as well as anything that can be employed; but various combinations of salines and antiseptics are recommended by different authors. The patient should be directed to cleanse the nares from two to four times daily, using from one to three pints of water, as occasion may require, so that the secretions shall all be removed. When this is done regularly, he will not be annoyed by the offensive odor. The wash may be snuffed from the hand or from a nasal cup, or it may be used with a syringe or nasal douche; but the last two methods are dangerous because water may pass into the middle ear and set up inflammation, resulting in deafness. As a rule it is best for the patient to snuff the fluid from the hand or from a nasal cup made for the purpose. A good instrument for cleansing the nasal passages is the Freer nasal irrigating tube mentioned in the section on simple chronic rhinitis. A powder containing six drachms each of sodium bicarbonate and sodium chloride makes an excellent wash when used in the proportion of one drachm to the pint of tepid water. Rhodes' or Seiler's tablets, from two to four each to the pint, may be used similarly. The patient should attend to the washing himself, but he should be seen by the physician at least once a week during the beginning of the treatment in order that thoroughness may be secured. After the washing the patient may apply to the nares various powders or sprays, and occasionally the physician should make stronger applications. Powders are especially useful when the secretion is thin and free, and the sprays when a tendency to desiccation is marked. The powders may be applied by any simple insufflator. I commonly recommend a glass tube about four inches long with one-eighth to three-sixteenth inch calibre; one end of this is flattened, the other end round. From a quarter to half an inch of powder is inserted into the round end—amounting to from half a grain to a grain and a half; the end of a rubber tube, about ten inches in length, is slipped over the same end, the flattened end of the glass tube is placed in the nose, the opposite end of the rubber tube is taken between the lips, and a quick puff is given whereby the powder is blown thoroughly into the nares. The powders that I have found most beneficial, and which may be variously combined, are made by rubbing up the active ingredients with sugar of milk. For this purpose we may employ yellow oxide of mercury from one-half to three-fourths of one per cent.; iodol 25 per cent., boric acid 10 per cent., aristol from 5 to 8 per cent., gum benzoin or myrrh 25 per cent., berberine muriate 10 per cent., and cocaine from 1 to 2 per cent. The latter must be used guardedly, but when carefully watched it is sometimes an excellent remedy, which by causing paresis of the vaso-motor nerves appears sometimes to induce regeneration of the tissues. Kyle also recommends the nitrate of silver, from 1 to 4 per cent. with stearate of zinc. The sprays are commonly prepared by dissolving various substances in oleum petrolatum album. The drugs most frequently used are carbolic acid from one-half to one per cent., iodine from one-tenth to one-fifth per cent., oil of cloves from one-half to one per cent., oil of cinnamon one-half per cent., thymol one-fifteenth of one per cent., menthol from one to two per cent.; five per cent. of ichthyol has also been highly recommended. It is often desirable after a thorough cleansing of the nares to apply one of these oily sprays and to follow it by the powder. Gottstein's wool tampons sometimes produce excellent results. Moritz Schmidt, Gautier, and Jouslain have highly recommended copper electrolysis by the bipolar method; or the positive pole with a copper needle may be used in the nose alone and the other pole applied indifferently to other parts of the body. In the bipolar method a steel needle is inserted into the lower turbinal while a copper needle is introduced into the middle turbinal, or the copper needle may be inserted into the lower turbinal and the steel needle into the septum, the copper needle being connected with the positive pole. If preferred a platinum needle may be used in place of the steel. The nares having been anæsthetized, the needles are introduced and currents of from 3 to 15 milliampères are passed for from five to ten minutes. The treatment may be repeated after a week or two. It is best to reverse the current for about half a minute just before removing the needle in order to

Digitized by Microsoft®

loosen the coagulum that fastens about the positive pole. The current should, however, be reduced to zero before the switch is changed to reverse it, otherwise it will cause the patient a good deal of pain. Meningitis has followed this operation and the cribriform plate has been carelessly performed. www.libtool.com.cn and orbital neuralgia sometimes follow. Excellent results have been obtained by this treatment in some cases, but in others it has proven useless. Injections of diphtheria antitoxin have been tried but without avail. Vibration massage has also been employed with, it is claimed, good results. *E. Fletcher Ingals.*

NASAL CAVITIES, DISEASES OF: CONGENITAL AND ACQUIRED DEFORMITIES.—I. DERMATOID CYSTS AND FISTULE.—These conditions are congenital or are noticed shortly after birth. They appear at the junction of the nasal bones with each other and of both with the frontal, as rounded tumors (in case of cysts) of variable size, not freely movable but rather adherent to the deeper tissues. They are covered with normal skin, and the centre line is generally on a level with the canthi of the eyes. A trauma of the mass may lead to a fistula or the latter may be congenital. The mode of origin of these conditions is thus explained by Bland Sutton: The rudiment of the nose in the embryo is represented by that process of the primitive skull, known as the fronto-nasal plate, which is separated from the lateral portions of the face by the orbito-nasal fissures. The rounded angles of these plates are known as the globular processes, each one of which forms a portion of the ala of a nostril and the corresponding præmaxilla. These processes fuse in the median line, giving rise to a central piece (philtrum) of the upper lip. Dermatoids are invariably situated in the line of the internasal fissure and are in all probability due to incomplete fusion of the globular processes.

According to Witzel dermatoids in this situation are not to be regarded as "sequestration" growths—*i.e.*, formed by a squeezing off of tissue when the lateral halves of the body coalesce,—but result from the imperfect apposition of the two tuberosities which, projecting from the centre of the face, arising on both sides of the median nasal furrow and approaching each other to complete coalescence, ought to form the cartilaginous nose and septum.

Strictly speaking, a dermatoid tumor is composed only of tissues found in the skin and mucosa. The cysts variously contain sebaceous material, cellular débris, fat crystals, and hairs. Unstriped muscular fibres may appear in the cyst wall. The fistulæ are lined with a fibrous material covered with sebaceous matter. The walls are covered with typical pavement epithelium, while the subepidermoidal tissue shows scattered aggregations of round cells. The deeper layers show connective tissue of low grade, scattered mucous glands, and giant cells.

Symptoms may be wanting, the swelling being noticed only as something objectionable from a cosmetic point of view. Fistulæ generally give off a constant or intermittent discharge of sebaceous or muco-purulent matter, which causes an excoriated area on the surrounding skin.

Treatment calls for the laying open of the cyst or fistula, with excision of the entire fistulous tract by means of a raspatory or sharp spoon. If the fistula branches off the top and burrows beneath the nasal bones, this tract may be cauterized with the galvanocautery. The whole is then allowed to heal from the bottom. The fistula may reopen after it has once healed. Sometimes a plastic operation may facilitate recovery.

Cysts are rare. Birkett, writing in 1900, reported two instances and collected six others from various sources. Since then Krieg has reported two more. Fistulæ, however, are by no means uncommon. The *x*-ray may help to clear up a doubtful diagnosis.

II. CONGENITAL OCCLUSION OF THE NARES.—Complete congenital occlusion of the anterior nares is an extremely rare condition. Jarvis reports two cases, and claims that they are the first on record. One of his patients was a boy of eighteen, who presented, instead of the dark outlines of the nares, cup-shaped depressions about 4 mm. in depth, the barrier being of membranous consistency; one side admitted a very fine probe while the other was absolutely impervious. The other case was that of a girl of sixteen, in whom the inferior meatus on both sides was blocked by bony growths of ivory hardness. At times she had been able to expel a little air through the nose. Krieg has reported a case—probably of syphilitic origin—in a boy of three years.

Congenital occlusion of the posterior nares is by no means uncommon. The barrier may be either membranous or bony (the former being far more common), complete or partial. According to C. H. Knight, the condition may result from (1) exostosis or simple hypertrophy of the osseous structure of the middle or inferior turbinate; (2) a ridge or exostosis from the vomer; and (3) an adventitious bony plate springing from the floor of the nose or from its outer cavity. However, in most instances which belong strictly to this category, the bony plate spreads like a web over one or both choanæ, being directly continuous with the palate bone, of which it forms an integral part. Sometimes the obstruction is a deflected vomer which enlarges one choana at the expense of the other. Luschka believes that the bony plate is a continuation of the free border of the horizontal plate of the palate bone; Kundrat, that it is an extension of the vertical portion; both conditions are possible. In some cases the central portion of the barrier appears membranous, surrounded by an irregular fringe of bony spicules projecting inward from the periphery; such cases are naturally attributable to hypernutritive changes. Ingals believes that membranous closure in this region is not congenital, but always the result of syphilitic, diphtheritic, or other disease processes.

Symptoms.—These naturally vary according to the degree of obstruction. If the latter is complete at birth, the chances of survival are very few. Difficulty in nursing may be the first thing to call attention to the possibility of the existence of the lesion. If the obstruction is partial, the patients grow up, laboring under all the disadvantages of nasal occlusion, both in its local manifestations and the distal disturbances to which it may give rise. In unilateral occlusion there is often a partial lack of development of the corresponding side of the face and of the vertebral column. By animal experimentation Ziem has shown that these effects are directly due to nasal occlusion of the corresponding side. In infants there is "not only the inability to suckle and the consequent difficulty in obtaining sufficient food, but also the exposure of the bronchial tubes and delicate air cells of the lungs to the constant irritation of air insufficiently moistened, filtered, and warmed." The nose generally secretes moisture, but the secretion is apt to accumulate in an annoying manner. From mouth-breathing the oro-pharynx is generally dry. The voice lacks its normal resonance. The sense of smell is in abeyance while that of taste may persist though impaired for its finer qualities. The effect on hearing is variable. This function is often perfect. Toynbee contended that under these conditions the act of swallowing would cause a constant suction on the Eustachian tube and thus lead to a depression of the membrana tympani, but such a sequel is by no means constant. In many instances the ease with which the patient will sustain impairment of these three special senses is quite remarkable, and, as Knight observes, in notable contrast with the disturbance following a similar acquired post-nasal obstruction.

Treatment.—The barrier must be pierced, the opening enlarged, and the patency thus acquired maintained. In patients of fortitude this may be done under cocaine. For membranous occlusions the galvanocautery will suffice; bony barriers require the trephine or chisel and subsequent enlargement with revolving burrs. The openings should be made as large as possible. Much difficulty may be experienced in keeping them pervious. For some time after the operation pledgets of oiled gauze should be inserted, and after healing has taken place bougies and dilators should from time to time be passed.

www.libtool.com.cn

III. MALFORMATIONS.—Several cases of congenital median fissure of the nose have been reported; also cases of nasal hemiatrophy. In one instance of the latter the right half of the organ was normal. The median portion was covered with skin, but instead of the left half there was a body 1.5 cm. long by 0.5 cm. wide, and in shape like an elephant's trunk. This process was extirpated, leaving a permanent fistula. The patient was a child of five years. Such cases are among the curiosities of medicine, and each one can be considered only in the light of the problems which it presents.

Malformations of the alæ may be congenital or they may result from disease. Various plastic operations have been suggested. One devised by Koenig merits special mention. He takes a flap made up of the entire substance of the auricle and sutures this in place of the defect in the ala. As this flap contains cartilage it heals well.

Outside of the various alar deformities resulting from tissue destruction, especially from syphilis, there may be a simple collapse of the alar cartilages, so that insufficient air reaches the interior of the nose, and the impact of the inspired air tends still more to close the nasal entrance. The condition appears at times to be merely an accentuation of a congenital condition, or it may result from lack of development, or from inactivity of the nasal wings. The whole ala may be affected, or merely the plica vestibuli—*i.e.*, the outer border of the inner nasal opening. There may be a laxity of the entire nasal wall with defective action of the dilator and levator muscles. In the congenital cases it will be found that the part principally at fault is the band of tissue at the junction of the lower lateral cartilage and the bony margin of the anterior nares, its position being noted externally by the depression usually seen immediately above the lower expanded part of the nose. If the middle turbinate becomes enlarged, the entrance to the naris is apt to become smaller.

The main symptom of the condition is nasal obstruction leading to mouth-breathing.

The condition in old persons may often be relieved by the wearing of a delicate tubular spring within the nares to hold the alæ in position, or a flat metallic band may be inserted. A similar procedure is often of great benefit in the temporary collapse seen in typhoid fever, pneumonia, etc.; also in tuberculosis involving the larynx. The increased air supply is very grateful to the patient. In young persons an effort should be made to restore the tone of the dilator alæ muscles. Practice in stretching these will increase their activity. The lubrication of the interior of the nares with some unguent carried on the finger will stretch the parts and assist in the recovery of their normal tension. In other words, we should apply the principle of massage.

IV. FRACTURE AND DISLOCATIONS OF THE NASAL BONES.—Fractures of the nasal bones constitute about one per cent. of all fractures. They may be simple, compound, or comminuted. Both bones are generally involved. The injury may also affect the perpendicular plate of the ethmoid, but the vomer generally escapes. The fracture may also extend to the nasal processes of the superior maxillæ; the cribriform plate of the ethmoid is, fortunately, rarely involved. It may also involve the zygomatic arch or extend to the frontal sinuses, thus possibly opening a portal for septic infection of the meninges. Occasionally the lachrymal bone is involved, with obstruction of the tear duct. Very often the nasal bones are not really fractured but simply separated from their attachment to the superior maxillæ, or the bones may become separated from each other; this separation may allow the bones to remain in perfect apposition, or they may be depressed.

The causes of this class of injuries are blows and falls. It has been said that displacement in the infant may come from the pressure of burying the nose against the breast or in the pillow.

The exact lesion produced varies according to the direction of the trauma. If it is from below, the brunt of impact falls upon the septum, while the nasal bones may escape. The triangular cartilage is detached from its bony surroundings, including the nasal spine of the superior maxilla. Here there is merely swelling of the septum, which may run on to abscess with not much external deformity. If the trauma is from the side, both bones may be dislocated laterally, while their internal borders remain in contact. If it is from in front, the nose is flattened, the inner borders of the bones are driven outward and tilted so as to form a sharp ridge on either side of the nose. Perhaps the most common form of injury is a transverse fracture about the middle of the bones, driving back the lower fragment or possibly both bones backward between the nasal processes of the superior maxillæ, thus leaving a depression instead of the normal nasal convexity. Unless the upper half of the bone is distinctly driven in, the perpendicular plate of the ethmoid generally escapes.

The symptoms are epistaxis, deformity, and marked swelling. The latter may extend to the cheeks and eyelids. From the direct results of the trauma or from forcible blowing of the nose immediately after, there may be a subcutaneous emphysema with crackling on pressure. The latter condition on the forehead (when the nose has not been blown) is an evidence that the frontal bone has also been fractured. More or less ecchymosis quickly forms. The swelling may mask the exact nature of the injury. The nose may retain its normal shape or be but part of a diffused swelling. In the latter state, bony crepitus is elicited with difficulty; it may possibly be obtained in minor cases.

Diagnosis is made from the foregoing conditions and from careful digital examination. It is to be remembered that many of the so-called "broken noses" have never been actually fractured. Rhinoscopy should never be omitted. In doubtful cases the *x*-ray may accurately determine the relative positions of the various bony structures.

Treatment calls for the restoration of the bony parts to their normal contour and for the adoption of such means as will keep them in their proper positions. The actual relations must first be determined, and for this purpose a general anæsthetic (a little chloroform) is often necessary. The under surface of the nasal arch should be carefully probed for irregularities. In many cases the bony parts are easily replaced and only a cold compress is required. In more difficult cases an instrument, such as a metal catheter (female) or the closed blades of a dressing forceps should be introduced into the nares and the bones elevated to their proper level, while their position is regulated by the fingers on the outside. The object is to restore the nasal arch. If this can be done and the patient is a self-controlled person who will let his nose alone, the above measures are all that is required. Instruments should be covered with light rubber tubing. It is better, as a rule, to dispense with external splints and plugs in the nares. The emphysema requires no treatment. Epistaxis is treated in the usual manner. Firm union results in from two to three weeks.

If the bones should show a tendency to fall in again, they may be raised by the insertion, within the nose, of an india-rubber dilator, introduced empty and then filled with water, or a piece of rubber tubing may be used. Plugs and splints are generally useless because they rest on the floor of the nose, while the trouble is higher up, and thus is not reached by them. If the nasal bones show a tendency to separate, we may make a plaster splint by having the patient lie flat while several layers of a plaster bandage are moulded over the nose, the ends being carried out on to the cheeks. The ends carry tapes which fasten behind the head. Thus the apparatus is well worn at night. Another serviceable material is gutta-percha, which may be cut to the general shape of the part, covered with antiseptic gauze and then rendered malleable by insertion in hot water. It is then accurately fitted to the nose and secured by tapes. Block tin, thin copper, and aluminum may be used in the same way. These splints may be padded with cotton to exert

Digitized by Microsoft®

pressure in any direction required for maintaining the proper shape of the nose. Another device is the employment, within the nose, of the Bernays sponge material, cut to fit the naris. Various head bands with forehead plates, to which nasal apparatus may be fastened, have been employed. www.libtool.com.cn It is often justifiable, if marked deformity has resulted, to cut down on the fragments, replace them, and close the wound. The resulting scar will be trivial in comparison with the deformity unrelieved by operative intervention.

V. Saddle Nose.—This term is applied to that particular deformity in which the usual convexity of the nasal bones is replaced by a depression which is the more marked from the fact that the mechanical conditions causing it also tip the point of the nose upward. The deformity is generally the result of some ulcerative process, syphilis being responsible for the majority of cases. The nasal bones are supported in their anterior third by the quadrangular cartilage, and in their posterior two-thirds by the perpendicular plate of the ethmoid. Consequently the entire cartilage may disappear without any change in the external contour of the nose; but when the destructive process encroaches upon the ethmoid or subjacent vomer, the support of the arch begins to crumble and deformity results. The latter is still further aggravated when the destructive process invades the nasal processes of the superior maxilla.

Various operations have been devised for the relief of this condition. In minor conditions a support may be introduced through a subcutaneous incision. Marked deformities require external incision. With such operations the names of Israel and Koenig are intimately associated. A deep incision is made along the dorsum of the nose, and a flap from the forehead containing skin, periosteum, and a small fragment of bone is diverted to fill the sunken area, the flap being stitched to the lower portion of the nose. The denuded space on the forehead is then closed, while secondary operations are required to close the lateral gap.

Another type of operation is that of raising the depressed area and maintaining it in position by a bridge of some light metal, such as platinum or aluminum; celluloid has also been used for the same purpose. With such procedures the names of Lerievant and Martin are associated. A very convenient form of bridge is that devised by F. E. Hopkins, in which the rounded convexity of the bridge is supported on each side by an arm which runs out on to the upper surface of the superior maxilla and is there secured. For the insertion of such apparatus it may be advisable first to perform Rouge's operation, consisting of incision through the gingivolabial fold, dissection of the lip and face from the subjacent bone as far as the border of the nares, and the division of the septum, so as to allow the entire nose to be turned up over the face, thus more or less completely exposing the bony openings of the nasal passages. The great objection to all such apparatus is that we cannot foresee that it will be comfortably worn, and moreover there is always danger that the pressure of the bridge will lead to ulceration and destruction of tissue. In several instances the pain attending the wearing of the bridge and the threatened integrity of the tissue have compelled the removal of the support.

A very recent plan of treatment, and one that promises much, is that of paraffin injections under the skin so as to raise the latter to a normal position and thus restore the normal contour of the nose. It was devised by Gersuny, of Vienna, in 1900, and while it is still *sub judice*, sufficient time has elapsed in several instances to predicate its success and wide applicability. The skin is carefully disinfected and cocainized with a four per cent. solution, which is also carried into the area to be occupied by the paraffin. The melting-point of the latter should be about 105° F. The ordinary white paraffin is too hard, while the soft variety, known as white vaseline, is too soft. A mixture of the two may be made of just the right melting-point. A syringe, made entirely of metal, is preferable, with a needle of moderate calibre. The paraffin mixture is first sterilized and then drawn into the syringe, which is kept in sterilized hot water. When all is ready for the injection the syringe is allowed to cool until its contents issue, not as a liquid but as a coherent string. The needle should be inserted at a little distance from the depressed area, but carried beyond the point of greatest defect, and the material slowly expelled, the syringe being meanwhile slowly withdrawn. The paraffin remains plastic for about half a minute, during which time the nasal convexity thus produced can be properly moulded. A temporary lymphatic œdema may follow, but it has been found that the paraffin will retain its shape, and that it produces no deleterious consequences when once lodged under the skin. It gradually becomes encapsulated by connective tissue, a fact which is still further advantageous in helping to retain the new shape of the nose.

Objections have been made to the effect that this new mode of treatment may cause some danger of lung embolism; also that any rise of body temperature might cause a melting of the paraffin. On this account some have preferred a paraffin with a higher melting-point, say one of 110° F. As far as is known, no cases of embolism have resulted from supranasal injections.

VI. Synechiæ.—Adhesions may occur in any part of the nasal chambers, but the great majority of them are visible by anterior rhinoscopy. They assume various appearances and are of various shapes.

Causes.—In many of these cases the synechiæ are the result of some operation in the nose, especially the over-zealous or careless use of the galvanocautery; less frequently, they follow the use of cutting instruments. Some cases are attributable to traumatism, such as a fall or a blow. Even when operative intervention has been fully justified and skilfully performed, neglect of after-treatment may lead to unfortunate results. Adhesions may also result from the use of chemical caustics, or of powerful hæmostatics, as the Liquor ferri chloridi. A few congenital cases are recorded. The condition also follows diphtheria, measles, scarlet fever, and occasionally acute and chronic rhinitis. Basing his statements upon autopsy records, Zuckerkandl found inflammatory cases far more common than traumatic, his figures being in the proportion of seventeen to three respectively; statistics based on clinical experience show traumatic cases to be more common. They are more apt to occur between the upper turbinates and the septum than between the latter and the inferior turbinate.

In all acquired cases the mode of production is essentially the same. Either from trauma or from some trophic disturbance leading to loss of tissue two opposing surfaces become bared, and later approaching each other become fused in the process of healing.

Symptoms.—Symptoms depend on the degree of nasal obstruction. Diagnosis is made by inspection, and the extent of the adhesion is determined by the probe.

Treatment.—This consists of the removal of tissue excess and the prevention of readhesion until both sides have healed. The question turns upon the proper method to be adopted in each individual case. In operating on either the septum or the turbinates the utmost care should be exercised not to wound the opposite surface; if inadvertently the least injury has been inflicted on the healthy tissue, some form of tampon should be worn for a few days. A pledget of oiled gauze or cotton, a thin plate of celluloid, or some form of tubular splint may be used. These should be removed daily, cleansed, and reinserted. So also in treating severe acute injuries of the septum or alæ nasi, we should bear in mind the necessity of maintaining the patency of the nostrils during healing. In cases in which the adhesion is firm and hard, it may be cut through with the galvanocautery or scissors, and the cut edges kept apart as above indicated. In narrow nostrils it is extremely difficult to prevent re-adhesion. Watson has advised persistent friction with a cotton-wrapped probe, stating that he has often seen absorption of the adhesion follow this manœuvre. Others have suggested the encircling of the adhesion with a loop

EXPLANATION OF PLATE XLV.

Figs. 1, 2, and 3.—Papillary Growths Removed from the Nasal Mucous Membrane by Means of the Wire Snare Heated to a Red Heat. They represent simple hypertrophies of the mucous membrane.

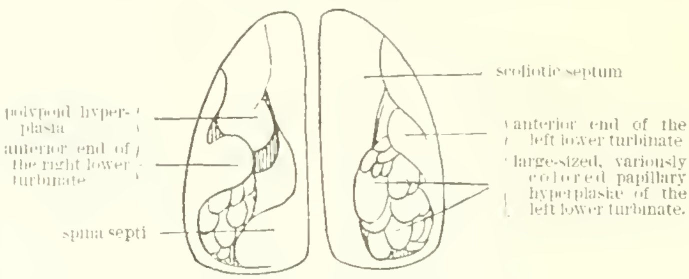
www.libtool.com.cn

Fig. 4.—Ulcer on the Left Side of the Septum Narium, the Nasal Mucous Membrane Everywhere Else Being Quite Healthy. Syphilis many years previously. Specific treatment was tried in vain. Healing finally took place under the combined use of a long series of cauterizations and a paste containing resorcin.

Fig. 5.—Smooth Hypertrophy of Both Lower Turbinates, in a Man Fifty-three Years of Age. The most marked pathological changes existed in the pharynx and larynx. The picture gives a faithful representation of a genuine connective-tissue hyperplasia. Neither pressure with a probe nor the application of cocaine caused the mucous membrane to yield to a noticeable degree. Both sides were about equally affected.

Fig. 6.—Polypoid Degeneration of the Middle Turbinates, in the Case of a Woman, Sixty-five Years of Age, who had Suffered for Some Time from Dacryocystoblennorrhœa. Smooth hypertrophies of the middle turbinates are often scarcely distinguishable from true polypoid growths. It is only after the mass has been extracted that one is able to establish the fact that it represents an altered state of the mucous membrane covering the concha. After the operation the latter will sometimes be found denuded of all covering throughout quite an extensive area. (Note the vascularization of the tumor.)

Fig. 7.—Papillary Hypertrophy of Both Lower Turbinates in a Woman Forty-two Years of Age. Excrescences of considerable size are visible in the picture. Those situated in front and above are very vascular and red, whereas those which lie farther back and below are quite pale. The right middle turbinate shows a condition of smooth hypertrophy.



Key to Fig. 7 of Plate XLIII.

Figs. 8 and 10.—Epistaxis due to a Varicose Condition of the Blood-vessels of the Cartilaginous Septum. In both of these pictures the artist, in making the drawing of the right half of the nose, has turned the patient's head as far round toward the left as he could, in order to secure as broad a view of the septum as possible. In the case of the left half of the nose he has simply reversed the process.

Fig. 9.—Hypertrophy of the Lower Turbinates: of the Smooth Variety on the Right Side, of a Papillary Nature on the Left and at the Posterior End of the Turbinate.

Fig. 11.—Papillary Hypertrophy of the Posterior Ends of the Lower Turbinates, of such Dimensions, on the Right Side, as Entirely to Cover up the Mouth of the Eustachian Tube and Close the Posterior Entrance of the Right Narial Passage. On the left side the hypertrophy is less pronounced.

Fig. 12.—Polypoid Hypertrophy of the Posterior Ends of the Lower Turbinates. (Also remains of pharyngeal tonsil.) The patient was a young man, eighteen years of age. Although these polypoid masses are somewhat hummocked or knobbed, as they generally are, they should, in the present instance, still be classed as smooth hypertrophies.

Fig. 13.—Abscess of the Septum Narium, Probably of Traumatic Origin, in the Case of a Child Fifteen Months Old. On the left side there is a spot where softening has already taken place and where a spontaneous rupture is about to occur.

Fig. 14.—Perforation of the Septum Narium in the Cartilaginous Portion, Quite Far Forward. The margins of the opening still show irregularities of the surface and are eroded. The nasal mucous membrane as a whole is pale and atrophic. On looking through the opening, either from the right side or from the left, one can see the surface of the opposite turbinate as far back as to its posterior end. The patient was a woman thirty four years of age, and the cause of the defect was probably lupus.

Fig. 15.—Another Instance of Perforation of the Septum Narium in a Patient who Manifested No Other Evidences of Disease. The etiology in this case is unknown.

Fig. 16.—Abscess of the Septum, with Protrusion of the Overlying Mucous Membrane only on the Left Side. (Perforation occurred spontaneously.) The anterior end of the left lower turbinate is in an inflamed and swollen condition.

of steel wire, which is worn in the nose and gradually tightened from day to day; the adhesion is thus gradually cut through, and the parts heal as the section advances. Still others pass a silk thread loop through the centre of the adhesion, wait until the central opening has healed, and then cut from it—that is, the familiar method employed in separating the adhesions between webbed fingers from burns. Reunion is always prevented by the presence of the narrow strip of cicatricial tissue at the base of the cut. In the use of the knife to make the separation, care should be taken not to injure the tissue at its back. After healing is complete, the narrow band back of the original central perforation may be severed. In all these cases the systematic after-use of some form of dilator is for a while advisable.

www.libtool.com.cn

VII. Perforations of the Septum.—These may result from syphilis, typhus, typhoid, scarlet, and other fevers in which trophic disturbances lead to a local disorganization of tissue. Other causes are acute primary chondritis (rare), trauma (either accidental or surgical), pressure of tubes and splints, etc. A frequent variety of perforation is that following the lesion known as "simple perforating ulcer," which occurs in perfectly healthy persons without any dyscrasia. It is distinguished from tubercle and syphilis by the condition of its edges which are regularly smooth and healed, by the absence of accompanying lesions on the outer walls of the nose, and especially from syphilis by the fact that the latter shows a selective affinity for the bony structures, while the simple perforating ulcer is strictly confined to the cartilage. In the latter, four stages present themselves: (1) injury or long-continued irritation, as from picking the nose to remove the crusts that frequently form at this site; (2) hemorrhage into the mucosa (the xanthosis of Zuckerkandl); (3) erosion of the capillaries with consequent impairment of nutrition; and (4) partial atrophy leading to perforation or not, according to the presence or absence of infection. The exposed site of the ulcer regularly leads, however, to infection. After the perforation has taken place we find, as noted, a rounded or oval fenestra in the septum with smooth edges. It occupies the area known as the "locus Kiesselbachii." There is no specific bacteriology of the affection, the ordinary staphylococci and streptococci being found. While forming, the ulcer appears as a truncated cone with the base superficial. The area becomes macerated by the nasal secretions, and there is really a necrobiosis of the mucosa. The tissue loss is also favored by the fact that at this site the mucosa is unusually thin, and contains a small congeries of rather large vessels. Symptoms are wanting after the edges have healed. Many cases come under observation only on systematic examination, having given no symptoms whatever. (See Plate XLV., Figs. 14 and 15.)

Treatment calls for measures to combat any existing dyscrasia. If the edges are raw, a fifty-per-cent. solution of silver nitrate may be applied; later, we may use iodine gr. v., iodide of potassium gr. x., in half an ounce of glycerin.

VIII. Outgrowths from the Septum.—These may appear as crests, spurs, ridges, or rounded masses on any portion of the septum. A favorite area is along the lines of junction of its various bony and cartilaginous components. Some of these excrescences are little more than thickenings of the mucosa, and if their removal be deemed necessary, it can be effected with the galvanocautery. Reaction following the application of this agent to cartilage is often severe and it must be used with caution. If the outgrowths contain cartilage we may employ knives, scissors, gouges, draw-shaves, and electrolysis; if they contain bone salts or true bone, we may use trephines, saws, or chisels.

Previous to all such manipulations the nose should be carefully cleansed with some disinfecting agent and then cocaine and adrenalin applied. Most of these operations can be done under local anaesthesia. After-packing is best omitted. If the wound is smooth and respiration can be carried on through the affected side, bleeding will quickly cease. Packing causes retention of secretion with liability to infection. So also antiseptic powders should not be so freely employed as to form a crust in the nose. The patient must keep quiet for a time and wear just inside the vestibule a *loose* plug of cotton to strain out the dust from the inspired air. He must *keep his fingers out of his nose* and be taught the proper method of blowing the organ when using cleansing washes.

IX. Deviations of the Septum.—The causes of this condition may be trauma, the long continuance of turbinal abnormalities, or a faster growth of the cartilaginous septum than of its bony frame. It is not always easy to establish the history of trauma, for it may refer back to any one of the numerous falls of childhood. Many of these, regarded at the time as trivial, may be the starting-point of hypernutrition with consequent deviation. It is impossible to make any classification of deviations that is entirely satisfactory. They may involve the bone or cartilage, and may be vertical, horizontal, or both. They are generally associated with some local outgrowth.

The symptoms are those of nasal obstruction with its effects upon both neighboring and distant organs. Many minor degrees of deviation give no symptoms and require no treatment.

The number of operations devised for the correction of deviated septa is legion. Only a few of the more useful ones can here be mentioned.

The Asch Operation.—This is done under general anaesthesia. Nitrous oxide is an ideal agent. Previous to the administration of the anaesthetic, adrenalin solution should be applied to both sides of the septum. If any adhesions exist between the septum and turbinates, they are broken up by means of the gouges belonging to the special set of instruments devised for this operation. The blunt blade of the scissors is inserted into the obstructed nostril and the cutting blade into the other. A crucial incision is then made, the scissors being withdrawn for the change of position in the second cut; this latter crossing the first as nearly as possible at right angles at the point of greatest convexity. The forefinger is then inserted into the obstructed nostril; the segments made by the incisions are pushed into the opposite nostril and the pressure is continued until they are thoroughly broken at their base and the resiliency of the septum is destroyed. *On this point depends the success of the operation; for unless the fracture of these segments is assured, the resiliency of the cartilage will not be overcome and the operation will fail.* The septum is then to be straightened with the flat-bladed forceps. The little blood there may be in the nostrils is wiped out with a cotton pledget and a flattened hard-rubber or block-tin splint is inserted in each nostril. These act as supports for the septum and tend to prevent secondary hemorrhage. The patient should be kept in bed for two or three days, ice cloths being applied over the nose if there is swelling or pain. The nares should be sprayed through the tubes with some antiseptic. Twenty-four hours after the operation the tube on the previously patent side is removed and not replaced. The nostril is cleansed and an antiseptic powder insufflated. It is well to protect the naris with a loose pledget of cotton when in the open air. The tube on the previously occluded side may remain *in situ* for another twenty-four hours, when it is to be withdrawn, the nostril cleansed, and the *tube replaced.* It is a splint for the septum and may be withdrawn daily for a week, then on alternate days, and gradually at lengthening intervals until healing is complete. If the case can be seen daily, the tube can probably be removed at the end of from two to three weeks. It must be of such a size that it can be easily reinserted without pressure, else it will be crowded out by the tissues behind and the operation will be at best but partially successful. It is completely hidden by the alæ, and if well fitting causes no discomfort to the patient. Subsequently to its permanent removal small bits of granulation tissue may require cauterization or removal with forceps in order that an entirely smooth surface may be

Digitized by Microsoft®

www.libtool.com.cn

left. Care should also be taken so to make the incisions that the tube will rest on the floor of the nose.

The Watson Operation.—This is especially applicable to those cases in which the deviation is marked and low down, so that it is impossible to bring the lower fragment into line. Instead of cutting out an elliptical piece along the horizontal line, as is recommended by some authors, Watson makes a bevelled incision, the edge of the knife being directed upward and toward the opposite side, and carried *through the cartilage but not the mucosa* of the opposite side. The incision is made on the crest of the deviation. If a vertical deviation exists at the same time, a triangular-shaped portion with the apex uppermost may be removed. The upper portion in the horizontal incision is pressed over toward the other side, where it hooks on to the lower and is thus held in place. The projecting base can afterward be removed.

The Gleason Operation.—The field of operation is cocainized and exposed by a self-retaining nasal speculum. A thin saw is introduced along the floor of the septum beneath the deviation. The sawing is continued in a horizontal direction until the blade has penetrated somewhat deeply into the tissues, when the direction is rapidly changed to one nearly vertical. It is of the utmost importance that the blade be now held exactly parallel to the septum in order that the cut shall be around and not through any part of the deviation. The length of the vertical crura is then quickly increased by means of a small bistoury curved on its flat, and the flap is thrust through the hole in the septum by means of the forefinger.

While the finger is still in the nares, it is carried up along the anterior and posterior crura in order to make certain that the edge of the flap has completely cleared them, and the neck of the flap is then sharply bent. It is not necessary to denude the edges that are in contact. The pressure results in necrosis (at least of the superficial epithelial layer) of the mucosa, after which the parts unite. The special claim made for this operation is that it destroys the resiliency of the flap (a condition of success in any operation) at its neck. It is at this point, and practically at this alone, that resiliency is active—*i.e.*, at the neck of a comparatively long, narrow flap—and hence has a powerful leverage to overcome before it can thrust the inferior edge of the flap back through the septum. The neck should be bent to nearly a right angle.

The Pin Operation.—This operation, devised by Roberts, is performed by making an incision through the most prominent portion of the convexity, breaking up the resiliency with a stellate punch, and introducing a steel pin through the more open nostril, thrusting its point through the anterior part of the septum, forcing the curved portion of the latter into proper position, and then burying the point of the pin in the posterior part of the septum on the previously occluded side. The head of the pin should be covered with some smooth material to prevent irritation of the columella.

Ingals' Operation.—In cases in which the cartilage is bent almost at right angles across the nostrils, Ingals dissects up the mucosa, removes a triangular piece of cartilage of sufficient size, incises the latter farther back at its upper or lower part to destroy its resiliency, and maintains the septum in place by a plug in the occluded naris.

Roe's Operation.—Roe has devised an operation applicable to either bony or cartilaginous deviations. He insists upon the necessity, even if the deviation be confined to the cartilage alone, of fracturing the bone at or adjacent to the attachment of the cartilage. The change in direction of the latter attachment tends to hold the cartilage in its new position. Roe's operation requires a special fenestrated forceps, one blade of which is an ovate ring while the other—long, narrow, and rounded—fits loosely into it, so as not to injure the septum. The length of the handle prevents compression of the anterior portions of the septum. The male blade is introduced on the convex, and the female blade on the concave side of the deviation. The closure of the blades crowds the deflected portion of the septum into and partly through the opening, indenting and fracturing it without affecting the surrounding area. The septum is held in its new position by a plug of metal wrapped with sterilized cotton or gauze. It is placed on the originally convex side and fills the naris.

Moure's Operation.—Moure, of Bordeaux, has devised an operation which he regards as an improvement on that of Asch. Spurs and thickenings are first removed with a special instrument consisting of an elongated ring with cutting edges on its elliptical extremity. These blades are concave externally and convex on the opposite side. Bleeding is checked by the cautery. Luxations of the antero-inferior part of the septum are resected with a knife, the mucosa being sutured. After full healing has occurred, the septum is attacked. Under cocaine an incision, 2 or 3 cm. long, is made close to and parallel with the nasal floor, special scissors resembling those of Asch being employed for the purpose. A second incision is then made at an acute angle to the first and near the front of the nose. There results a movable fragment held in front by the anterior part of the base of the septum, which has been left untouched toward the tip of the nose, and behind by the perpendicular plate of the ethmoid and the vomer. The next step consists in the introduction, on the side of the deviation, of a tubular dilator formed out of the parallel blades, the outer one being rigid and the inner one malleable. The inner one is modelled to the septum by forceps introduced with a dilator. The dilator is left *in situ* for eight days, the parts being kept meanwhile scrupulously clean.

All these operations have been variously modified by surgeons according to the requirements of individual cases. The main points to bear in mind are: (1) To remove all excess of tissue before attempting to straighten the septum; (2) to weaken the support of the latter by incision, fracture, etc., making sure to destroy the resiliency of the parts so that the septum will remain in its new position; and (3) to hold it there by some form of splint until healing has occurred in the new position. Scrupulous post-operative care, frequent changing of the plugs or splints, etc., so as to avoid retention of nasal secretions, are very important factors in the attainment of a successful result. *James E. Newcomb.*

NASAL CAVITIES, DISEASES OF: FOREIGN BODIES.

See *Air Passages, etc.*

NASAL CAVITIES, DISEASES OF: GLANDERS.—

(Synonyms: Malleus, Farcy, Equinia.) Glanders is a contagious disease contracted from the horse and characterized by the formation of nodules, which soon become pustular and ulcerated, with symptoms of septicæmia and thick muco-purulent or sanious offensive discharge from the nose. It would not deserve space in this place were it not that from its rarity we are especially in need of an accurate account of its symptoms and signs, because personal experience is generally wanting. Although the disease is generally contracted from the horse, it must be understood that it also affects mules, donkeys, goats, cats, dogs, sheep, and pigs.

ANATOMICAL AND PATHOLOGICAL CHARACTERISTICS.—In men the disease is characterized by irregular and sometimes very extensive ulcers in the nose, especially if it has been of long duration. As the ulcers expose the cartilage and bone, these tissues become necrosed, and thus the entire septum and hard palate may be destroyed. Ulceration sometimes extends to the frontal sinus, pharynx, larynx, trachea, and bronchi. Œdema of the larynx may result from the inflammatory changes. Microscopically, the tubercle or nodule of glanders differs from that of tuberculosis, in that it is vascular, has no giant cells, and breaks down by suppuration instead of undergoing cheesy degeneration. At the autopsy conditions are generally found which closely resemble those of pyæmia.

ETIOLOGY.—The affection is contracted from the horse or other animals and is caused by the bacillus mallei.

SYMPTOMATOLOGY.—The disease may be either acute or

Digitized by Microsoft®

chronic. The chronic affection runs from four to eight months, but the acute generally terminates within three weeks. The stage of incubation is from three to five days. After this period an inflammatory reaction takes place at the site of inoculation, which may be progressive and lead to abscess formation or may retrograde. Later, there are symptoms of general infection, malaise, headache, pains in the joints and muscles, and high fever, often attended by an erysipelatous rash of the nose and throat, which is soon followed by vesicles that burst and discharge a thin serous fluid. The disease may affect various parts of the body, but its most marked manifestations are in the nose and throat. The discharge from these parts is always extremely offensive and usually thin and profuse at first, but later thick and glutinous and sometimes streaked with blood. The voice commonly becomes husky or it may be lost, and cough and dyspnœa may develop. The chronic form is ushered in by a chronic nasal discharge, which may be so scanty that it merely forms crusts, or it may be quite profuse and purulent; or as the result of ulceration the discharges may be yellowish, brownish, or bloody. Upon inspection small ulcers are often found situated beneath the crusts, and sometimes characteristic nodules of a whitish color are seen seated upon an inflamed mucosa. These nodules soon break down in the centre, making small ulcers which may extend and coalesce with others. In man the nodules are much less common than in the horse, and indeed they may be entirely wanting. As ulceration progresses, necrosis of bone and cartilage occurs, and the septum may be perforated. As the disease extends backward, ulcers and inflammatory infiltration appear on the posterior pharyngeal wall, in the mouth, and on the tongue. When the larynx is reached the voice becomes hoarse and breathing may be difficult. In the lungs glanders produces symptoms of bronchitis. The intestinal canal may also be invaded, as indicated by gastric disturbances with diarrhœa, and the disease also attacks the skin, causing multiple abscesses or ulcers.

Diagnosis.—Glanders is to be distinguished from nasal syphilis and tuberculosis. Nasal tuberculosis is usually associated with tuberculosis at the apex of one lung; it is commonly much slower in its progress than glanders, and it cannot be traced to contact with the horse. Finding of the pathogenic bacilli in either case will make the diagnosis certain.

Syphilis frequently resembles glanders, but the constitutional symptoms are much less pronounced. The history is very different and the bacillus mallei cannot be detected in this disease. Notwithstanding this, however, most cases of glanders are ineffectually treated for syphilis for some time before the real nature of the ailment is discovered. The chronic disease may last for weeks or months, and whenever an obstinate nasal catarrh exists in people who are much occupied with horses, a careful examination for glanders must be made. If nodules and ulcers appear, together with abscesses and ulcerations of the skin, in stablemen and others having much to do with horses, the existence of glanders should be suspected and the pus carefully searched for the bacilli. In order to confirm the diagnosis it may be even necessary to inoculate a male guinea-pig, in which case the characteristic nodes appear in the testicles after three or four days. The inoculations are made into the peritoneal cavity.

Prognosis.—The chronic disease runs its course in from four to eight months and terminates fatally in at least ninety-five per cent. of the cases. The acute affection often is superadded to the chronic disease, and when this occurs death invariably results in from six to eight days, but primary acute disease usually lasts for about three weeks. As the disease progresses, the patient passes into a typhoid condition which, in the acute form, soon terminates in coma and death.

Treatment.—Prophylaxis is of the greatest importance, and those working about horses should be able to recognize the disease promptly, but the insidious course of chronic glanders in the horse may make the diagnosis very difficult for a long time. In all such instances the services of a veterinarian should be employed. Little can be hoped for from the treatment of the disease, but locally strong solutions of creosote, tincture of iodine, nitrate of silver, and carbolic acid have been recommended, and it is claimed that recovery has in some cases followed the use of mercurial ointment. General supporting remedies are of course indicated. The secretions and discharge coming from the nose of a patient suffering from glanders should be carefully disinfected.

E. Fletcher Ingals.

NASAL CAVITIES, DISEASES OF: HEMORRHAGE.

—The term epistaxis is applied to bleeding from the nasal cavities and adjacent sinuses. Owing to the unusual vascularity of the nasal region, the delicacy of its construction, and its liability to accident, nosebleed is of very common occurrence.

Etiology.—It may be due to traumatisms; to local affections of the nasal cavities, such as hyperæmia, dilatation of superficial blood-vessels, superficial erosions of the mucous membrane, ulceration; to the presence of foreign bodies or of pharyngeal adenoids; to various systemic affections such as anæmia, purpura, and scurvy; to diseased conditions of the brain, heart, liver, or kidneys; to typhoid and typhus fever, measles, scarlatina, diphtheria, pneumonia, etc.; it may be vicarious, occurring in women at the menstrual period; or, finally, it may arise from a variety of other causes dependent upon severe excitation of the circulation or irritation of the surface of the nasal mucous membrane.

It may occur as a result of toxic doses of certain drugs which are eliminated through the mucous surface of the upper air passages. It is present in fractures of the skull, especially at the base, and is also found with necrosis or caries of the bony skeleton of the nose. It has been caused in gunners by the severe concussion of heavy firing. It occasionally follows coitus. Sudden transition from a normal into a rarefied atmosphere may cause it. It is not infrequently the precursor of cerebral apoplexy. It is commonly met with in boys at the age of puberty, and in girls it may precede the establishment of the catamenia. It may occur in women during pregnancy and at the menopause. It is common in childhood, less so in middle life, and again more apt to occur with advancing age.

The bleeding may come from one or both nostrils. Originating from the deeper part of one nasal cavity the blood may be deflected into the nasal cavity of the opposite side, and escape outwardly through that nostril or into the pharynx. Dangerous nasal hemorrhage may occur during sleep, the blood being swallowed without attracting the attention of the patient. Serious loss of blood may thus result. The presence of bleeding in such a case would probably be demonstrated by changing the position of the patient and causing him to clear his throat.

Bleeding most frequently originates from the anterior and inferior part of the nasal septum, and when it comes from this locality it is seldom dangerous, although in some rare cases it may be severe and through frequent recurrence it may cause serious anæmia.

The bleeding point may be located in any part of the nasal cavity, or there may be a general oozing, widely diffused over the surface of the membrane, as in hæmophilia, purpura, and the anæmia of children. When coming from the anterior portion of the nares the blood escapes from the nostrils, but when from the deeper parts of the nasal cavities it may pass backward and be swallowed and later vomited, or it may pass into the trachea and be coughed up. The latter accident is not common. When the bleeding is from the upper and anterior part of the nasal cavity the hemorrhage may be serious. This is explained by the close connection between the anterior ethmoidal vessels and the intracranial circulation.

Plethora, especially when accompanied by deficient menstruation, portal congestion, and some forms of Bright's disease, may be relieved by epistaxis.

www.libtool.com.cn

Digitized by Microsoft®

Nasal Cavities.

Hæmatomata of the nasal cavities are more commonly met with on the septum. They are occasionally seen as the result of traumatism. Examination will often determine the location of the bleeding point, which is apt to be found upon s[illegible]ginous septum. The anterior region of the nose is the most frequent seat of this trouble.

www.libtool.com.cn

Diagnosis.—In hemorrhage from the anterior nares the nasal cavity, having been carefully cleansed, should be examined by anterior rhinoscopy, and an attempt made to locate the precise spot from which the bleeding takes place. This will generally be found in the region of the septum. Epistaxis must be differentiated from hæmoptysis, from hæmatemesis, and from bleeding from the lower and median pharynx. This may be done by careful examination of the nasal cavities.

Prognosis.—The prognosis is generally good. When, however, the bleeding is dependent upon a general diathesis or some systemic disease it may be very dangerous.

Treatment.—The treatment of epistaxis must depend upon its origin and upon its cause. It is necessary, therefore, to determine as far as possible what these may be. Vicarious bleedings and those which occur at the crises of certain fevers, may, if they are not excessive, be allowed to continue. In conditions of plethora and in vicarious menstruation it should not be unnecessarily checked. Under ordinary circumstances simple means will usually be effective in stopping the flow. These consist in absolute rest and in keeping the head erect and avoiding the common mistake of inclining it forward and downward. If the bleeding is from the anterior part of the nose, pressure of the ala against the septum may check it. The application of cold to the nose or the insufflation of cold water is often effective. When the bleeding point can be found, applications should, if possible, be made directly to it. This should be done by first drying the place with absorbent cotton and then applying to it nitrate of silver, chromic acid, or even the galvanocautery. Astringents, such as alum or tannin, may also be applied. The iron preparations are as a rule worse than useless, and should never be employed. Of late the use of two remedies has been suggested, both of which experience has proved to be of great value. One of these is antipyrin, the other is the extract of suprarenal glands. The antipyrin should be dissolved in water about ten grains to the ounce. The suprarenal extract should also be used in strong solution. The bleeding cavity having been freed from clots by means of cold water, about half an ounce of one of the above solutions should be insufflated and retained in the nose as long as possible. This should be repeated once or twice unless the bleeding is immediately checked.

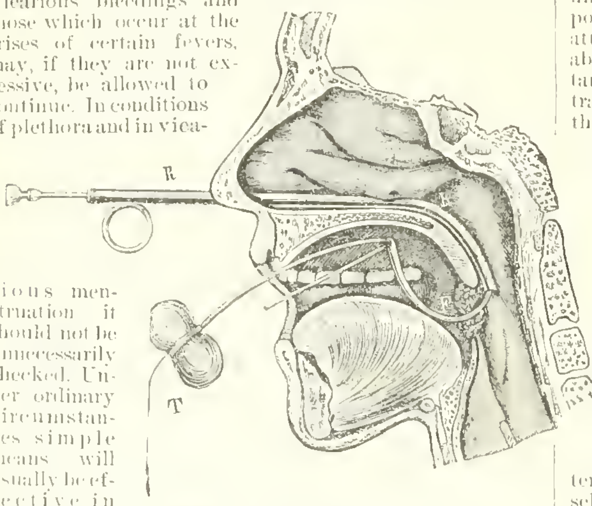

Fig. 3489. Plugging the Posterior Nares by Means of Bellocq's Sound.

The careful employment of this method is very effective. When simpler means fail, the hemorrhage may be controlled by packing that part of the nasal cavity from which the bleeding comes. For this purpose a sponge should never be used. Far better is it to introduce into the nasal cavity a narrow strip of surgical gauze and then to pack it in carefully against the required spot. If the bleeding point is in the upper part of the cavity, the lower part may be left free to permit of normal respiration. The proximal end of the gauze strip should be left free, so that in the withdrawal of the tampon only so much need be removed at one time as can be readily detached. Forcible removal is certain to cause a recurrence of the bleeding. Great care should therefore be exercised and the plug should be saturated with some solvent solution before any manipulation is applied to it. As a rule the plug should not be retained for more than one day. If it occurs posteriorly the bleeding may be checked by inserting a tampon into the naso-pharynx, and, if necessary, at the same time packing the anterior part of the nasal canal. For packing the naso-pharyngeal region a flexible catheter or a Bellocq's cannula (*R*, in Fig. 3489), to the distal end of which a loop of silk has been fastened, should be passed through the nose and its distal end brought into the pharynx. To the loop a strong ligature should be fastened and drawn upward and then forward until the attached end is outside of the nostril. A tampon of lint or cotton (*T*), saturated with vaseline and attached to the middle of the ligature which should be about eighteen inches long, should be in readiness. The tampon should then be drawn carefully into place by traction upon the string, aided by manipulation with the finger in the pharynx. The tampon having been placed, it is well to make a firm block of absorbent cotton around which the anterior end of the string may be wound and held in the vestibule of the nose. The pharyngeal end of the string should be brought out of the mouth and loosely attached to the patient's ear. To remove the tampon, the best plan, as a rule, is first to cleanse the parts as thoroughly as practicable and then apply to them a solution of suprarenal extract in order to secure the greatest possible contraction of the blood-vessels. Lastly, the parts should be covered with liquid vaseline, and time enough allowed for it to saturate the surface of the tampon as deeply as it can penetrate. Only the gentlest traction should be applied to the string while the tampon is being removed.

Severe bleeding may require the use of revulsives intended to cause reflex contraction of the nasal blood-vessels, the administration of remedies intended to quiet the action of the heart, the application of pressure, externally and internally, and in extreme cases transfusion or some kindred measure. In the most severe and intractable cases of epistaxis the nasal cavity may easily become septic, and thus another serious feature be added to the case.

D. Bryson Delavan.

NASAL CAVITIES, DISEASES OF: LEPROSY.—

Leprosy of the nose attends some cases of general leprosy or elephantiasis, and is characterized by a formation of nodular masses and diffuse thickening of the skin of the bridge of the nose, which by being thrown into vertical folds causes the condition known as facies leonina. The nose, especially below the bridge, becomes deformed by the growth around it of nodular masses that enter into the substance of the nasal tip and alæ, changing them into three tumor-like masses that lie side by side, separated by deep fissures. It is also attended by congestion of the mucous membrane with uniform or nodular swelling and considerable deformity and ulceration.

Etiology and Pathology.—This part of the subject has been fully discussed in the article entitled *Leprosy*, and the reader is therefore referred to it for information on the subject.

Symptomatology.—Among the early symptoms are diffuse thickening of the skin over the bridge of the nose. This is at first bright red, but later of a brownish red and shiny appearance; in a still later stage it becomes paler and of a light grayish-brown, or finally it darkens to a chocolate color. Deep, painful, and bleeding fissures occur between the tumor-like projections at the end of

Digitized by Microsoft®

the nose, ulcerations develop, and cicatrices are formed leading to a great variety of deformities. In time the nose flattens, broadens, and sinks in, the nostrils often being narrowed to mere slits by thickening of the alæ nasi. The appearance of a nose in this condition is likened to that of a hound. This change is due mainly to destruction of the cartilages of the external nose and the cartilaginous septum, and to cicatricial retraction of the external nose. Sticker believes that the initial lesion of leprosy is usually an ulcer above the cartilaginous part of the nasal septum, and it has often been found that the disease attacks some portion of the nasal cavity before there are any external manifestations in other parts of the body. The primary focus may thus be hidden for a long time and the disease may easily be mistaken for other affections of the nose. At first there are obstruction to nasal respiration and a free watery discharge which later becomes purulent and extremely offensive on account of ulceration and necrosis. Severe epistaxis also frequently occurs. After a period of months or years, the discharge gradually ceases and the nares become dry. About this time leprous nodules may appear on the face and external nose. The nasal mucosa, which is at first red, gradually fades and becomes yellowish, grayish, or pure white, due to the hard leprous infiltration. This infiltration may be diffuse at first, or it may form tubercles and tumors, from 5 to 15 mm. in diameter, which spring from the anterior part of the septum and the anterior end of the inferior turbinals. Unless preceded by pharyngeal leprosy the disease first invades the anterior portion of the nares, but as it progresses the cartilaginous or bony septum may be destroyed by ulceration. In this stage the secretions often dry and fill the nares with large hard crusts that can be removed only with considerable force, a procedure which is likely to cause free hemorrhage that may be sufficient to require packing of the cavity. The destructive process may also affect the turbinated bodies. Finally ulceration ceases, cicatrization follows, and the dense scars may obliterate the nasal cavities. As a rule the ulcers and other leprous lesions display characteristic anæsthesia when touched with a probe, and the sense of smell is lost.

Diagnosis.—The diagnosis must depend upon the presence of the peculiar thickened nodular formation, ulceration, cicatricial contraction, and the odor of the secretions, and the finding in them of the bacilli lepræ, which are apt to be abundant. It is often difficult to make an examination of the nares because of the contraction of the nostrils or of the sensitiveness of the formations at the end of the nose. The thick dry crusts may also prevent a satisfactory inspection. The disease can generally be distinguished from tuberculosis by the presence, in the latter, of tuberculous deposits in other parts of the body and by the occurrence of thickening and cicatricial contraction in leprosy. In a few cases syphilitic infiltration may simulate leprous nodules, but the history and the effects of antisyphilitic treatment usually clear up the diagnosis in a short time. Again, the progress of syphilis in the nose is much more rapid than that of leprosy.

Prognosis.—There appears to be no tendency to spontaneous recovery, and unfortunately treatment offers little hope of cure.

Treatment.—Internally the gurjun and the chaulmoogra oils have been highly recommended, the former in doses of five to ten minims, the latter in doses of two drachms, but there is much doubt as to whether either does any good. By way of palliative treatment the dry secretions should be softened by ointments and alkaline or oily sprays. The obstruction of the nares may be relieved partly by severing adhesions or by other surgical measures, and bougies may sometimes be employed to keep the nares free from obstruction. However, care should be used not to cause much bleeding or to give the patient much pain.

E. Fletcher Ingals.

NASAL CAVITIES, DISEASES OF: MUCOUS POLYPI.—Nasal mucous polypi are hyperplastic, œdematous outgrowths originating commonly from the mucous membrane of the parts of the nasal cavity above the lower turbinated bodies. They cause obstruction of the nares and usually free discharge of watery mucus. Mucous polypi occur oftener in men than in women. They are seldom found before the twelfth year.

Anatomical and Pathological Characteristics.—Mucous polypi are generally smooth, glistening, and translucent, and of a grayish-white color, but they may also have a pink or yellowish tinge. Occasionally they are opaque and bright red. Portions of the growth that are exposed to the air in the nasal vestibule are sometimes covered with thick pavement epithelium that has the appearance of white paint. These growths may be sessile or pedunculated, and rarely they are found hanging by a mere thread. According to their surroundings they may be globular, pyriform, or flattened. Many may cluster together, large, small, and minute specimens arising from the same attachment. The number of the growths varies greatly, but they are generally multiple and often fill both nasal fossæ from the nostrils to the posterior nares. Polypi originate most commonly from the lower border and outer surface of the middle turbinated body and from the region of the hiatus semilunaris, though they may also grow from the superior meatus and turbinal. They are very rarely attached to the septum, and so seldom do they arise from the lower turbinal and nasal floor that their origin from these parts is a pathological curiosity. The pathology of these growths is considered elsewhere.

Etiology.—The most frequent cause of the disease is chronic rhinitis with polypoid hypertrophy of the middle turbinated body, a condition which precedes the formation of true polypi. Polypi are occasionally caused by foreign bodies, and often appear to result from chronic suppuration; they are therefore a frequent accompaniment of empyema of the accessory sinuses. They occasionally precede malignant growths originating in the deeper parts of the nasal cavity or in the sinuses. Successive crops of polypi may thus be removed until the carcinoma or sarcoma has made enough progress to become visible.

Symptoms.—Polypi often exist for years before the patient is made aware of their presence by obstruction in the nose. A watery or occasionally purulent discharge from the nostrils is one of the first manifestations of the disease. This symptom is accompanied or soon followed by gradually increasing obstruction in one or both nares. Many patients do not seek relief until the nasal passages become nearly or completely closed. The sensation of a body moving to and fro in the air current is sometimes felt. As the growths increase in size, sensations of fulness and pressure occur in the upper part of the nares, or there may be actual pain that may radiate to the forehead.

Polypi growing from the septum are often vascular and cause severe nosebleed, and rarely the growths in other locations are angiomatous and give rise to the same symptom. In most cases the sense of smell is lost. The catarrhal inflammation is liable to extend to the lachrymal duct and to cause its stoppage with resulting lachrymation, and deafness frequently results from deflation of the middle ear and catarrhal otitis media. The symptoms of polypi are aggravated during damp weather by swelling, while a dry atmosphere improves the patient's condition. The usual results of mouth-breathing, such as injury to the incisor teeth from drying of the enamel, pharyngitis, and laryngitis, follow the disease, which frequently also gives rise to reflex disorders. Prominent among the latter are fits of sneezing, lachrymation, and conjunctival irritation. Asthma is frequently caused by polypi, though not so commonly as reported by some authors. Other reflex phenomena such as nightmare, migraine, headache, giddiness, hay fever, epilepsy, and gastric disorders are occasionally observed, but they often remain unchanged after operation. Inspection usually discloses only the foremost of the growths, but the polypi at the posterior part of the group may often be seen by posterior rhinoscopy. A large polypus may appear as

www.libtool.com.cn
Digitized by Microsoft®

a translucent spherical tumor resting upon the soft palate, while the pedicle by which it hangs is usually hidden. Smaller growths fill the space between the turbinals and posterior end of the septum, or that between the lower and middle turbinals or between the middle turbinal and the upper border of the choana. In this location the growths are sometimes of almost glassy transparency and difficult to see. In other cases they appear like muco-pus.

www.libtool.com.cn

Diagnosis.—Polypi have so characteristic an appearance that they are not easily mistaken when seen by anterior or posterior rhinoscopy, and palpated with a probe. In a case of nasal obstruction the nasopharynx should always be examined, as there may be no polypi in the anterior part of the nose while the posterior nares may be occluded by them. The inexperienced might possibly confound septal deflection with a polypus, especially when the convexity of the deformity presents the appearance of a pink or red tumor in the nasal vestibule. The concavity of the deflection in the opposite naris, and the fact that a probe can be passed on only one side of the prominence of the bent septum, while it may pass on both sides of a polpyus, should prevent error.

Polypi are distinguished from thickening of the turbinated bodies by their translucence, lighter color, lack of resistance when touched, and their great mobility. When the turbinals are firmly pressed upon with the end of a probe, a characteristic sense of bony resistance and immobility is felt. The swelling of the septum, due to chronic abscess, is of a deeper color than that of a polypus; it is usually much the same in both nares, and it is not possible to pass a probe between it and the septum. Foreign bodies generally cause unilateral offensive purulent discharge, while polypi are commonly attended by bilateral, watery, and odorless secretion. The sensation given to the probe is also quite different. Malignant tumors of the nasal cavity or of one of the sinuses may be hidden from view by polypi created by the irritating effect of their growth, and they then cannot be recognized. Visible malignant growths have a grayish, pinkish, or deep red color and often a sloughing and ulcerated surface. They commonly spring from the septum, a site rarely occupied by polypi, and they usually bleed easily. Pain and rapid growth are characteristics of the malignant neoplasms, and carcinoma generally ulcerates early and gives rise to stench. The hardness and immobility of enchondroma and osteoma make it impossible to mistake these affections for polypi.

Prognosis.—This affection is not dangerous to life, and in the great majority of cases the patient need expect no worse troubles than nasal obstruction and annoying discharge. Deformity of the bones of the face, formerly attributed to mucous polypi, is seldom if ever caused by them, but is a result of the distending effect of fibroid tumors upon the skeleton of the nasal cavity or is due to the destructive and distending advance of malignant disease. In prerhinoscopic days these growths were often confounded with polypi, and hence frog face and other deformities were attributed to the latter. In rare cases vascular polypi produce dangerous epistaxis. Although single polypi are sometimes expelled, spontaneous recovery does not occur; and even after careful removal of the growths there is a notorious tendency to recurrence, so that many patients suffer from the dread of repeated operations. Assurance may be given that polypi do not change into malignant tumors, and patients should not be worried by the statement that they may possibly precede the latter.

Treatment.—Procedures undertaken without the aid of rhinoscopy, such as evulsion with polypus forceps or curettage after laying open the nose externally, inflict needless injury on the patient and are not to be recommended. The most satisfactory method of treatment is removal of the growths with the steel wire snare or écraseur. The one preferred by the author is a modification of one devised by Clarence Blake. The snare is armed with No. 5 steel piano wire, which in practice has been found to answer better than the other sizes. The loop is passed in vertically, its under edge turned beneath the polypus, and then with a backward and forward movement it is worked up as near the pedicle as possible. The loop is now tightened, and, if thought best, the polypus is cut off at once, but usually better results are obtained if it is torn from its base by traction. There is little danger in this way of removing any of the normal tissues, for it is almost impossible to include within the snare anything but the polypus. When polypi grow from broad bases, and are attached over the whole surface of a turbinated body, the bone may be torn off with the snare if much traction be made. Under such circumstances the experienced operator, noticing the increased resistance of the normal tissue, instead of continuing the traction, will tighten the wire loop and cut the growth as near its base as possible. When polypi repeatedly grow from a large surface of the middle turbinal, it is sometimes better to remove the body entirely to prevent recurrence. The operator should have at hand forty or fifty applicators wound with absorbent cotton for swabbing out the blood while the operation proceeds, as it is useless to try to catch the tumors when the nose is filled with blood. Spraying the nasal cavities before operation with a solution of adrenal extract will materially lessen the bleeding. Whatever operation is performed, the parts should first be thoroughly anæsthetized with a four- to ten-per-cent. solution of cocaine, which is best applied by means of a hypodermic syringe fitted with a long, blunt, silver nozzle bent at the end, so that the solution may be thrown up about the base of the tumors. Sometimes both cavities may be cleared at once, but it is usually preferable to remove the growths that can be easily reached, and to complete the operation at one or two subsequent sittings, as this generally gives the patient much less discomfort than one long sitting. After the polypi have been removed, the patient should cleanse the nose once or twice daily with a wash of sodium bicarbonate, a teaspoonful to the pint of lukewarm water. Antisepsis and healing will be promoted by insufflation two or three times daily of a powder containing ten per cent. of boric acid and twenty-five per cent. of iodol, with sugar of milk sufficient to complete the mixture; together with the use of a spray containing about one minim of oil of wintergreen, two minims of carbolic acid, and three minims of oil of cloves to an ounce of Oleum petrolatum album. If the secretion be profuse, ten minims of terebene may be added with advantage. The patient should return in about a week, when it will often be found that polypi which were invisible at the time of operation have descended and may be removed. He should return again in from four to six weeks, so that if the polypi are growing they may be thoroughly destroyed with the galvanocautery.

In some cases mucous polypi do not return after one thorough removal, but usually recurrence takes place and operative procedures must be repeated from time to time until complete destruction of the growths is effected. When empyema of one or more accessory sinuses exists, this must be relieved before the patient can be freed from relapses, and in those instances in which the tumors originate from the region of the hiatus semilunaris or superior meatus it is occasionally necessary to remove the middle turbinated body in order to reach the site from which they grow. In order to get at polypi located behind a deflection or large spur of the septum, it may be necessary first to correct this deformity. In the majority of cases operations upon the nasal skeleton are unnecessary, and careful treatment will eradicate the disease. Polypi in the posterior nares can in most instances be reached by passing the snare through the nostril, but the assistance of a finger in the nasopharynx to adjust the wire may be needed; and in cases in which the polypus is very large, the wire loop may have to be drawn in through the mouth and passed up behind the soft palate by an instrument devised for that purpose, as recommended by the author in the removal of retronasal fibrous tumors.

NASAL CAVITIES, DISEASES OF: NEUROSES.—I. Neuroses of Olfaction.—The olfactory nerve consists of about twenty fibres given off from the under surface of the olfactory bulb. These fibres pass down through the cribriform plate, dividing into two groups as they enter the nose—an inner group distributed over the upper third of the septum, and an outer group distributed over the superior turbinate bone and the upper half of the middle turbinate bone. In structure it differs from other nerves in being composed of non-medullated fibres. The olfactory centre in the cortex is not definitely known, but is generally associated with the temporal lobe (Gray).

www.libtool.com.cn

The nerve is liable to disorders in connection with both its point of origin and its distribution.

Parosmia is a perversion of the sense of smell. While the sense of smell may or may not be perfect for ordinary odors, there are in addition certain imaginary odors. This is comparatively common among the insane, and is found in epilepsy, hysteria, and syphilis. It has occurred in connection with the epidemic disease—the grippe, cases having been reported in which the patient was annoyed for days by unpleasant odors and tastes. The writer has observed this condition in connection with atrophic rhinitis when the ordinary sense of smell was destroyed. Here the condition is one of considerable annoyance to the individual. The affection is comparatively rare.

Hyperosmia is an exaggeration or hyperæsthesia of olfaction. In this affection odors which are not ordinarily noticeable to the healthy nose are present as exaggerations, causing great annoyance. The odor of an offending substance is often retained for several hours after the removal of the offending material. Like parosmia, it is comparatively rare. There seems to be some connection between it and certain disorders of the sympathetic nerve. Both parosmia and hyperosmia seem to be dependent more on some general nervous disorder or some neurotic predisposition than upon any disorder of the olfactory nerve within the nose itself.

The *treatment* of both the foregoing affections should be directed to the cause so far as it is possible to ascertain it, as direct treatment of the nerve is not likely to do much good.

Anosmia, or Loss of Smell.—This is by far the most common of the affections of the olfactory nerve, and may have its point of origin within the cranial cavity or within the nose.

Anosmia Intracranialis.—This may be caused by injuries, tumors, degeneration, as in locomotor ataxia, general paralysis, senile decay, intracranial syphilis, congenital absence of the olfactory nerve, hemorrhage, meningitis, and abscess. Cases illustrating these various forms of origin have been reported by several observers. Compared with the total number of cases of anosmia, those of central origin must be considered to be rather rare.

Anosmia Nasalis.—This form of anosmia, in which the pathological condition is of nasal origin, is by far the most common. It may be the result of either acute or chronic processes. For the function of the sense of smell to be properly performed, air, with odoriferous particles, must freely reach the terminal filaments of the nerve, and these are stimulated to activity only when in a moist medium; hence anything that interferes with the free access of air or with the moisture of the part will cause partial or complete loss of the sense of smell. Acute anosmia is usually due to acute processes, like colds in the head, the grippe, acute ethmoiditis, hay fever, or to any condition that temporarily blocks the nose. With the subsidence of the acute condition the sense of smell usually returns.

Owing to the close relationship between the sense of smell and the sense of taste, anosmia is usually accompanied by very pronounced loss of taste, especially of flavors. If the sense of taste is unchanged, the loss of the function of olfaction is only partial.

The chronic forms of anosmia occur in connection with anatomical changes in the nose, such as spurs, pronounced deviation of the septum, or any changes which close the nostril, especially hypertrophic conditions of the middle turbinate. They also accompany the degenerative conditions of the mucous membrane, such as atrophic rhinitis, in which the nasal cavity is abnormally widened, its walls are covered with crusts, and the mucous membrane is dry to such an extent that the sensitiveness of the terminal nerve filaments is lost.

The *symptomatology* and *diagnosis* offer no particular difficulty. In testing the question of loss of smell, acrid, sharp, or pungent substances must not be used, as they produce irritation of the sensitive nerve filaments rather than stimulation of the olfactory nerve.

In the acute affections the *prognosis* is usually good. In the chronic forms, when the disease has lasted for any length of time, degeneration has probably taken place, and the prognosis is not so good. White[1] reports two cases which were entirely cured by treatment of the nasal disease, one after twenty years and another after ten years of complete anosmia. The author has had several cases in which the sense of smell returned after the removal of nasal polypi. In one instance the sense of smell had been lacking for a period of several years. But cases like the one just referred to must be regarded as comparatively rare, as it is the rule that when the sense of smell has been deficient for a long period of time, the possibility of its recovery must generally be considered doubtful; and the correction of the apparent cause in the nose is not always followed by as gratifying results as could be desired.

The *treatment* consists in the adoption of measures which improve the general nervous system and bring the nose and throat into the best possible condition, so that all parts of the olfactory nerve distribution will be accessible to the air. The area of the distribution of the nerve should be stimulated by such agents as friction, the use of iodoglycerin, solutions of the various stimulating oils, as camphor, menthol, eucalyptol; and an attempt should be made to increase the blood supply and the secretion of the part. While the improvement secured will frequently be satisfactory, the writer has many times been disappointed as to results of treatment, and more often than otherwise in those cases of anosmia in which examination of the nose does not show any apparent physical cause for the condition. Several of these have followed attacks of the grippe, and have been only partially relieved, and occasionally not at all, by treatment; nor have all the cases resulted satisfactorily even when intranasal conditions such as polypi, etc., have been found which were apparently sufficient to account for the condition.

II. Reflex Nasal Neuroses.—The connection between some irritation of the nose and sneezing has been known and considered from the time of Hippocrates; while the writings of the early physicians, as Aurelianus, Avicenna, Pechlinus, Salmuth, and Van Helmont, show that they were familiar with various reflexes of probable nasal origin, such as rose cold, cough, headache, and difficult breathing. The influence of powerful and disagreeable odors on the organism was noted by many authors.

In the eighteenth century Gumprecht advanced the theory that irritation of the trigeminus in the nose was transferred to the pneumogastric, producing reflex phenomena in the throat, stomach, heart, and lungs. Rega carried this theory still further, and demonstrated or suggested the relationship between the genital tract and the upper air tract; while Wepfer described a large number of cases in which headache, cough, vomiting, vertigo, disturbances of vision, and other nervous symptoms were dependent upon nasal disorders.

One of the first attempts to define this connection between distant organs as a distinct reflex was made by Müller, in his physiology of 1843, when he wrote that irritation of any mucous membrane in the body could give rise to a respiratory reflex. The credit of first calling attention to the nose as a definite point of origin of various reflexes, with practical observations as to the

Digitized by Microsoft®

www.libtool.com.cn

treatment and cure of the same, probably belongs to Voltolini,[2] who advanced the proposition that nasal polyps cause asthma reflexly, or else by hindering respiration they change the chemistry of breathing and alter the structure of the lungs. His publication in 1871 was soon followed by a host of observations, confirmatory and otherwise, by different authors. Among these was Haenisch,[3] who observed that asthmatic paroxysms disappeared after removal of polypi, and reappeared only upon the return of these growths, and B. Fraenkel,[4] who regarded the asthma from polypi as a reflex cramp of the bronchi produced by irritation of the sensitive nerve fibres, and, in agreement with Schaeffer,[5] also stated that this irritation could depend upon or be brought about by catarrhal changes in the nasal mucous membrane.

Asthma was the first disease to be regarded as a reflex neurosis, but various other affections were soon placed in the same category, especially various colds in the head—the so-called nervous head colds.

Next came the observations of Hack, who in various publications in 1882, 1883, and 1884,[6] widened very much the range of reflex nasal neuroses, until there were included migraine, supraorbital and ciliary neuralgias, nightmare, various coughs, vaso-motor disturbances of the vessels of the skin, epilepsy, and secretory neuroses. These were later followed by reports still farther extending the field of reflex nasal trouble. Among these were cases of exophthalmic goitre, diabetes, affections of the larynx, heart and stomach, chorea, dysmenorrhœa, enuresis, and so forth, until a large part of the pathology was said to be dependent upon disorders of the nose.

These publications of Hack's, with their accompanying brilliant results, called the attention of the whole world of medicine to this subject. Considerable opposition to his views was aroused; and he admitted before his death that his theories had been carried too far by many of his followers. In the main, however, they have received general confirmation; the subject of nasal neuroses already has a considerable literature; and these neuroses are frequently seen to play an important part in pathology.

In order to produce a reflex, a sensitive or sensory nerve in connection with a ganglion, and a motor or vaso-motor nerve fibre are necessary. The chain, of which the ganglion is the centre, being present, the point of origin of the reflex can be at either extremity. All the conditions necessary for the production of reflexes are found in their highest development in the nose; since the nerves supplying the nasal mucous membrane are sensitive nerves, originating near the floor of the fourth ventricle and having connections with many ganglia, as the otic, spheno-palatine, Gasserian, ophthalmic, and others, which in turn connect with motor and vaso-motor fibres and with many sensitive areas in the respiratory tract by means of the pneumogastric and spinal accessory nerves. Connected with these is the sensory nerve of the nose, the olfactory, which supplies the upper portion of the nasal cavity over both the septal and turbinal areas.

Pathology.—The nose through its normal physiology is particularly liable to reflex influences; as its whole function of warming, moistening, and filtering the inspired air is controlled by a highly complex nervous mechanism, which anatomically adjusts itself under normal conditions to the varying atmospheric changes. Its power as a protective organ, through the information which it gives of the presence of various odors and poisonous gases, and by alarms such as sneezing, cough and glottis spasm, is also dependent upon a reflex action.

In proportion to the number of cases of nasal trouble, the number of pathological nasal reflexes is probably comparatively small. Their presence in the individual case depends largely upon the nervous make-up of the individual; and they are more apt to be present to a pathological extent whenever there is increased sensitiveness of the general nervous and reflex mechanism of the entire body.

An attempt has been made to find certain so-called reflex points or specially sensitive areas in the nasal mucous membrane, and such have been described by various authors. J. N. Mackenzie[7] thinks that the posterior portion of the inferior turbinate is the most sensitive area, though he does not claim that this is the only one. That this area is sensitive, and that its irritation will frequently bring about a severe paroxysmal cough is easily determinable in some individuals by passing a Eustachian catheter without previous cocainization; in many persons quite a paroxysm of coughing will be set up. The author has met with several instances in which it was impossible even under cocaine so to abolish this reflex that the catheter could be used satisfactorily. In one case vomiting was invariably brought about whenever the catheter was used. Other authors have regarded the middle turbinate area as the sensitive one, but Spiess[8] thinks that the principal point of irritation is the tuberculum septi. A survey of the literature, however, will soon convince one that there is no certain reflex point, but that the entire nasal mucous membrane can be the subject of reflexes in every point of its entire extent, the septum as well as the turbinate area.

Hack theorized that the condition was due to swelling of the erectile tissue through the nervi erigentes, a theory not accepted by others, as the presence of nervi erigentes in the nasal mucous membrane has not been proven.

Anatomically, the nasal mucous membrane is supplied by the first and second branches of the trigeminus as to ordinary sensation, and as to special sense by the olfactory; and impressions are taken not only directly to the brain, but also indirectly, by means of the branches of communication with the various ganglia and the brain, to the entire nervous system—sensitive, motor, sympathetic, and special sense. The nasal or ethmoidal nerve comes from the first branch of the trigeminus, and covers in its distribution the anterior portion of the nose, the septum, the anterior ethmoidal cells, and the frontal sinus. The second branch, the superior maxillary or dental nerve, supplies the floor of the nose and the maxillary antrum; while the posterior part of the nose, the septum, the posterior ethmoidal cells and the sphenoid sinus are supplied from branches of the spheno-palatine ganglion.

Irritation can be carried to the brain through the motor, the vaso-motor, the secretory, or the sensory tracts. Through the brain the olfactory is brought into contact with the entire system, while the trigeminus is in connection with the spheno-palatine, otic, and ciliary ganglia, and the point of origin of the latter in the medulla is in communication with all of the motor fibres coming therefrom. It is therefore clear that, under favorable conditions, sensory or sensitive irritation of the nasal nervous elements can be referred to far-removed parts of the body, and the most various symptoms produced.

Etiology and Pathology.—The method of origin of all of the nasal reflexes is the same. The first act is an irritation of the afferent nerve fibres, sensory or sensitive. This is followed by the transmission of this irritation to the ganglion and its appearance as an action, motor or otherwise. The exact way in which all this is brought about is still imperfectly understood. The nerves of the nose have a close relationship to the respiratory centre, aside from the fact that inflammation beginning in the nose frequently passes by direct continuity to the lower respiratory region. Irritation begun in the nose has experimentally brought about closure of the glottis, expiratory tetanus, and stoppage of respiration. The same phenomena are caused by irritation of the vagus. The origin of a number of reflex neuroses of the respiratory organs can be explained on the theory that nasal irritations are carried by way of the ganglia to the respiratory centre, and then pass along fibres of the spinal accessory and vagus or along the spinal nerves. This is seen in the case of glottis cramp, paroxysmal cough, and bronchial asthma.

Many eye affections, such as blepharospasm, strabismus, anomalies of accommodation, asthenopia, and pupil changes, seem sometimes to be dependent upon nose affections. The reflex tract is by way of the motor root of the facial and oculomotor nerves, and irritation along this

Digitized by Microsoft®

Nasal Cavities.

tract can cause clonic or tonic action of the muscles. The tear function is affected directly through the lachrymal nerves, branches of which supply the mucous membrane of the nose. On the other hand, Ziem[9] thinks that the relationship of eye diseases to nose affections is brought about chiefly through the blood and lymph tracts, and only seldom through the nerves.

www.libtool.com.cn

According to Jurasz, these reflexes can be advantageously divided as to their causative significance into three groups:

First, those reflex neuroses in which the sensible irritation originates in the nose and the resultant reflex appears in an organ outside of the nose; in this class are asthma, cough, bronchitis, epilepsy, eye and general nervous and neuralgic disorders.

Second, reflex neuroses in which the sensible irritation is in the nose, and asserts itself as a reflex within the nose itself; under this head are embraced the various forms of nervous catarrh, vaso-motor rhinitis, hay fever, hydrorrhœa, rose colds, and others.

Third, reflex neuroses that have their sensible irritation in some other organ and are carried reflexly to the nose, producing nervous colds, hyperæmia, swelling of the mucous membrane, nosebleed, erythema, œdema, and other anomalies of the outer nose; contained in this last group are those dependent upon digestive disturbances and the class of affections caused by disorders of the sexual apparatus, to which latter the researches of J. N. Mackenzie, Grayson and others have called attention.

Pathologically, the theory of origin of the first group is one of irritation of the afferent nerves of the nose, which pass over through the ganglion to the efferent vaso-motor nerves; and the final effect is produced by changes in the volume of the blood-vessels.

In the second group we have only to do with vaso-motor and secretory disturbances in the nose itself, the pathway of communication probably passing through one of the near-by ganglia. The primary irritation comes from the trigeminus or olfactory nerve endings, to be transferred to those nerves which effect changes in the volume of the vessels and in the quantity of the secretions. In these cases the brain and spinal centres are not necessarily concerned, but the circle is made complete with the help of the peripheral ganglia, and the reflex curve is often short.

In the third group the theory of origin is not yet satisfactory. The phenomena appear as the result of the sensible irritation of organs far removed, as the skin in case of colds, the alimentary canal, and the genital apparatus, and consist in changes in circulation and secretion in the nose. The sympathetic system is probably the principal medium of communication between the parts involved.

In such a highly complex mechanism as the nervous apparatus, the localization of the irritation is frequently difficult, especially so as the irritation can be at either end of the chain. In the main, those reflexes which have their point of origin in the nose itself, and which are the most common, are due to direct irritation of the parts, which may be produced in a variety of ways—by simple changes in volume, by touching, rubbing, or pressing them, by active hyperæmia, by the direct effect of cold, or by the odor of flowers. When there is complete closure of the nostril, the reflex is less manifest than when there is variation of volume, irritation being caused at one time and not at another.

The severity of the reflex explosion does not necessarily bear much relation to the degree of apparent irritation, as slight irritants frequently cause considerable reflex irritation; in fact, the most marked reflexes seem to be associated with the least manifest pathological changes. Slight ulceration in the nose has been known to cause considerable cough, scraping of the throat, and inability to sing, and has been entirely relieved by cauterizing the spot with nitrate of silver. Such a case has been reported by M. Schmidt, and somewhat similar ones by others. These cases are more likely to occur in those of highly nervous make-up. The excessive irritability of any single portion of the reflex tract may be due to a local disturbance or may be a partial manifestation of some general neurosis, such as neurasthenia or hysteria.

Heredity does not seem to play any particular part. These cases are more common among the better classes than among the poor, and occur in those of highly nervous organization.

The arthritic diathesis has been regarded by French writers as an important factor, and there are many who regard hay fever as dependent upon this diathesis. While, as regards nasal neuroses in general, the arthritic diathesis may be a predisposing factor, it is certainly not the only one.

These neuroses are rare in children, and are most common between the ages of fifteen and forty. Race has but little influence.

Climate and the season of the year are important factors, and one class of nasal neuroses—hay fever, the term being used here generically—is especially frequent in the summer and autumn seasons. The climatic vagaries of asthma are well known; nearly every asthmatic has his private climate, one asthmatic doing well in a climate in which another does badly, and *vice versa*. The writer has known asthmatic members of the same family, one of whom was relieved by removal to a certain place while another was invariably made worse.

As regards the etiology of asthma, it is probable that many cases are dependent upon a nasal reflex condition, but not all. The pathology and etiology of asthma have not yet been satisfactorily worked out. Want of space will prevent its discussion in any detail here. It seems evident that both local and general factors are concerned in its causation. Asthma is a vaso-motor bronchitis, with —in many cases—a cause or an exciting factor in the nose. Certain it is that the correction of nasal pathological conditions relieves and not infrequently cures the disease.

The nervous area of the interior of the nose is extremely sensitive; and any abnormal nasal condition can set up reflexes. The most common of these pathological causative conditions are chronic hypertrophic catarrh, new growths, deviations and spurs of the septum, synechiæ, cicatrices, foreign bodies—that is, any condition which causes increased volume and pressure in some part of the nasal mucous membrane; while in atrophic conditions the nervous sensibility is so far diminished that the reflexes themselves are also greatly diminished and reflex neuroses are rare.

Operative procedures frequently bring about reflex disturbances, such as sneezing and cough, and may even be followed by vertigo, laryngeal spasm, or more serious conditions. The use of the galvanocautery snare has been succeeded by exophthalmos and rapid pulse; such a case has been reported by Semon. F. R. Packard[10] has reported a case of transient monocular blindness of the left side following removal of the anterior end of the left middle turbinate with the cold wire snare. The writer has seen acute insanity follow operation on the nasal septum in a boy of ten. It was evidently due to the pressure of the retaining plugs, and on their removal recovery was prompt.

There seems to be some sympathetic relationship between the erectile portions of the generative tract and the other erectile structures of the body. Ungratified sexual excitement, as well as excesses in coitus or unnatural sexual habits have brought about coryza of reflex origin. In type this closely resembles that of hay fever, and in the absence of a history might be mistaken for it.

Grayson[11] has reported a case in which turbinal engorgement in an engaged young woman was due to excessive demonstration on the part of the young man to whom she was engaged. This brought about ungratified sexual excitation, which was the cause of the nasal engorgement. He cites another case, the patient being a male, in which excessive sexual indulgence had caused nasal obstruction accompanied by marked hypersecretion, sneezing, and headache. All kinds of treatment, local and general, had been tried, the cause not having been suspected. When this was ascertained and the

Digitized by Microsoft®

habits corrected, the nasal condition promptly got well without further treatment.

Mackenzie[12] gives an account of a somewhat similar case, the patient being a woman, and the cause excessive sexual indulgence on the part of herself and husband. Here there was difficult asthmatic breathing, with stoppage of the nostrils. Moderation in their marital relations soon brought about a cure.

www.libtool.com.cn

That there is a physiological connection between the sexual apparatus and the nose is shown by various reciprocal relations between engorgement of the turbinate tissues and menstruation, such engorgement occurring in some women regularly during menstruation. Occasionally in those whose menstruation is irregular there is an engorgement of the nasal erectile tissue corresponding to the regular time of the menstrual epoch. Fliess[13] made investigations, the results of which seemed to show that painful, profuse, or irregular menstruation may in some instances depend upon an intranasal cause. He cites a number of cases to show that the pain of certain forms of dysmenorrhœa may be temporarily dissipated by the application of cocaine to the nasal mucous membrane, or permanently controlled by cauterization. Such a case is reported in the table of cases appended. Fliess regarded the inferior turbinate and the tuberculum septi as those portions of the nose which have a special relation to dysmenorrhœic pains. Vicarious menstruation sometimes occurs in the nose. In boys around the age of puberty nosebleed of apparently sexual origin has not infrequently occurred.

A case of sneezing following tooth extraction in a fifteen-year-old girl has been recorded.

Hypertrophic rhinitis in connection with digestive disturbances is one of the most common of observations; and many catarrhal cases of this class, even with considerable hypertrophy, frequently get well on the correction of the digestive disturbance. It sometimes happens that complete nasal stenosis will follow a full meal. Whether these cases dependent upon digestive disturbances are true reflex neuroses or only parts of a general congestion which is circulatory in origin, may perhaps be a question; since all of the hypertrophic conditions of sudden onset that are dependent upon digestive disturbances might be brought about through a passive congestion or through a loss of the normal vaso-motor tone.

Symptomatology.—Patients usually complain of the particular condition that troubles them and not of the disease of the nose which is the cause. Asthma, neuralgia, migraine, nervous disturbances of the eye, voice, and heart, epilepsy, muscle cramp, goitre, spasmodic cough, and the like, can appear without any manifest signs of affection in the nose and yet be of nasal origin. Again, complaints of the nose, as narrowing, anomalies of secretion, itching, pressure or pain, may be so mild as hardly to be noticed, or the patient may not complain of the nose at all. Frequently cases of this sort are not correctly diagnosed until they have lasted a long time, and the diagnosis may then be reached only by the method of exclusion.

In the first group the rhinoscopic findings are swelling, hypertrophy, ulceration, new growths, foreign bodies, septal deviations, abnormal adhesions. These are also the principal objective causative factors in the second group, as these two classes are dependent upon the same general reflex mechanism, and differentiate themselves only through symptoms varying in causation and quality.

The neuroses of the second group have been given an enormous number of names. They can all be described under one head, to which Jurasz has given the simple designation of "nervous head colds." The general term "hay fever" includes them all.

Hay Fever.—The symptoms of hay fever come on in paroxysms, and in persons apparently well they last minutes or hours and then disappear. When the patient has been under the influence of a pathological condition for a long time, the attack can last weeks or months with occasional short breaks. While most frequent in summer or autumn it may also occur at other seasons of the year. Here there is a direct irritation affecting the sensory or sensitive nerves of the nose. This irritation may be due to an emanation from plants, as in pollen hay cold, hay fever and hay asthma; to the odor of flowers, such as roses, violets, and others; to the cooking of certain foods; to the odor of various aromatic substances; or to the emanations from various living animals. It is well known that now and then attacks of asthma are brought about by riding behind a horse. These are usually personal idiosyncrasies. In 1893 Bishop advanced the theory that the real cause of hay fever was an excess of uric acid in the blood, favored by profuse sweating, and common at the hay-fever period of the year. For the development of the disease specially sensitive nerve centres, hyperæsthesia of the sensitive nerves of the nasal mucous membrane, and the presence of irritating agents are necessary. His theories have been accepted by many.

The condition begins by irritation or itching in the nose, followed by sneezing and the discharge of a copious, clear, serous fluid. These symptoms are of all degrees from mild to severe, and the sneezing may be terrific. Bobone has reported a case of unconsciousness and cyanosis as a result of cramp-like sneezing. Fink[14] thinks the large amount of secretion comes from the accessory cavities, the antrum principally, and that the secretory fibres of the trigeminus are the ones affected. The secretion is usually thin, but may be thick; frequently large numbers of handkerchiefs are required. On the other hand, sneezing may be present and the condition be one of hydrorrhœa only; or with occasional attacks of sneezing the patient may complain of hindered respiration, stopped-up nose, reddened eyes, swollen conjunctivæ, abundant tears, intolerance to light, itching in neck, cough of an irritating character, pain in head, migraine, trigeminal neuralgia.

In addition to the above there are frequently a laryngitis and a pharyngitis, with cough and sense of oppression in the chest, difficult respiration, and more or less distinctive asthmatic symptoms. Fever is rare.

On inspection the nose conditions are frequently found to be not in accord with the severity of the symptoms. While marked pathological conditions are sometimes present, there may be only redness and swelling; on the other hand, the mucous membrane often appears pale or even anæmic.

This group of cases appears most frequently in the summer and autumn seasons; and the principal exciting cause seems to be the presence of the pollen of certain plants, as roses, hay, golden rod, ragweed, and others. There has to be an individual susceptibility, but the pollen is apparently the exciting cause. From June to September is, in the United States, the most susceptible period, and from the 10th to the 31st of August the worst time, as the ragweed, the pollen of which is then in bloom, is the most irritating of all the pollens.

In the third group, originating outside of the nose, the symptoms are those of a nervous head cold—swelling of the mucous membrane, stopped-up nose, sneezing, irritation, increased mucous secretion. Vicarious menstruation, abnormal dryness of the mucous membrane of the nose, anosmia, hallucinations of odor, changes of the skin of the nose, redness—all these may be of genital origin. Indigestion may also cause many of the same symptoms.

Diagnosis is not usually difficult in the group in which the whole process is in the nose, but is difficult when the origin is in the nose and the apparent seat of the symptoms is in other organs. Jurasz thinks that inasmuch as nasal neuroses sometimes follow brilliant results of nasal therapy, we have assumed that *post hoc, ergo propter hoc.* The teaching of Hack's went so far in its results that, given any pathological nose condition, it was stated as the cause of any affection present, and the diagnosis was made entirely as a result of the nasal examination. This belief gained such a foothold that it was said at one time that the whole pathology was seen through the nasal speculum, and everything abnormal that could not be defined was considered a nasal reflex.

Whenever we have a reflex neurosis which is not clear

Digitized by Microsoft®

Nasal Cavities.

in its origin, or there is the remotest suspicion of one, the nose should be carefully examined, since doubtless many pathological conditions do come from changes in this organ; but, on finding some trouble in the nose, one cannot be exactly certain that the cause of the neurosis is found, as the nasal condition may be only an accompaniment and not a cause. Many people have extreme pathological changes in the nose without any accompanying reflex phenomena. The mere presence of a nose affection in the course of a disorder known to be a reflex neurosis will neither prove nor disprove that the nose is the cause of the reflex neurosis. An attempt should be made experimentally to bring about a reflex irritation of the supposed zone of origin. While this is probably accurate as a diagnostic measure, it is not absolutely certain.

Cocaine is one of the most valuable diagnostic remedies, since if under its influence the reflex disappears it is probable that it is of nasal origin. Weak solutions of adrenalin chloride will act in the same manner.

In doubtful cases treat the nasal condition and await results. If a cure is effected, the probability of the diagnosis being correct is very great.

In neurasthenic patients the moral effect of doing something in the nose may bring about relief and cure, even when the real cause is not in the nose at all; hence it will not do to label every neurosis that improves under intranasal treatment as a reflex nasal neurosis, though of course this is probable.

In the third group it is difficult to make the diagnosis, since it is not easy to demonstrate with exactness that a nose affection is the result of a remote pathological process. Here therapy has only slight diagnostic value.

The *prognosis* is good after the removal of the cause, but there are apt to be many relapses. If the affection has lasted a long time, as in asthma, secondary trouble, as emphysema, may be the result.

Therapeutics.—The treatment of the nose must be directed to the condition present. In the first group of cases, correct whatever is abnormal in the nose so far as possible, but do not promise too much. While the results are often brilliant, as in cases cited in the table, they may not be. In cases in which pressure is the cause of the reflex, leave the nose as roomy as it is possible to make it. The details of treatment will depend entirely upon the condition present. The moral effect of intranasal surgery is often considerable.

The treatment of *hay fever* must depend somewhat on the conditions found. Whether the uric-acid theory be correct or not, it is certain that remedies which favor general elimination are of great value, although the writer has not had any specially brilliant results from treatment based upon this theory. He is in the habit of getting the nasal mucous membrane into as good condition as possible before the attack; and during the attack he cauterizes with chromic acid, allows the patient a spray of adrenalin chloride (1 to 16,000) to be used as needed at home, and gives internally a tablet of: Quin. sulph. gr. ss., ammon. chlorid. gr. ss., camphor. gr. ss., opii pulv. gr. $\frac{1}{10}$, ext. acon. gr. $\frac{1}{10}$, ext. bellad. gr. $\frac{1}{10}$; one of these tablets to be taken every two to four hours, with such remedies for the general elimination as seem demanded. While this does not cure, it greatly relieves.

Fink (*l.c.*) thinks the cautery is of no permanent influence, and says he relieves his patients by insufflating raistol into the antrum. As the natural opening of the antrum is very difficult to find even by the experienced rhinologist, and especially difficult when the tissues are swollen, this method of treatment can have but limited application.

Adrenalin chloride, the active principle of suprarenal gland, is at present a much-vaunted specific for hay fever. That it causes the mucous membrane to shrink and produces immediate relief at the time it is used, and that it is the most powerful devascularizing agent for the mucous membrane yet discovered, are undoubted facts. Its effects are more positive and last longer than those of cocaine, which was formerly used for temporary relief in hay fever.

In the writer's experience with powdered suprarenal extract he did not find that its effects were lasting. It produced immediate relief, but there was a stage of reaction in which the condition was about as uncomfortable as before; indeed, any agent of so powerful a constringing nature would seem of necessity to be followed by a reactionary stage in which dilatation takes place; this has been the experience of several who have used the adrenalin chloride. On the other hand, it must be admitted that many practitioners are apparently having good success in the treatment of hay fever at the time of the attack, with a 1 to 5,000 solution of adrenalin chloride used as a spray two or three times daily. Whether it has any permanent value it is too soon to state. Inasmuch as it produces temporary relief at the time of the attack, it is a valuable adjunct to the therapeutics of the disease. Used in connection with the previous correction of any nasal difficulty, the sufferer from hay fever may be enabled to go through the attack with only slight discomfort.

In regard to the strength of the solution to be given, it seems to the writer as though the weakest solution that will produce the desired effect should be used, even though it is stated that there is no danger of acquiring the habit. As stated above, he has found a solution so weak as 1 to 16,000, to answer very well. The diluting solution may be either decinormal salt solution or some weak alkaline nasal spray solution. The 1 to 1,000 solution of adrenalin chloride is used as the base for dilution. Adrenalin solutions are probably not very stable, and if used for some time should be frequently renewed. Whenever the remedy is ordered for the patient's use, weak solutions should be given, never stronger than 1 to 10,000, the stronger solutions being administered by the physician himself in the form of spray, or applied on cotton pledgets directly to the swollen mucous membrane.

In addition to the local use of adrenalin in hay fever, the extract of the suprarenal gland is administered internally, in doses of from five to ten grains at frequent intervals, until the nasal mucous membrane shows that the vasomotor paralysis is under control, when the dose is diminished or the intervals between the doses increased so that from fifteen to twenty grains are given per day. Should giddiness or palpitation appear, the dose is to be diminished. Five to ten grains three or four times a day may also be given for one or two weeks before the expected time of attack. The internal administration is to be kept up during the hay-fever season. The adrenalin chloride, 1 to 1,000 solution, in doses of five to thirty drops, may be used instead of the extract of the gland.

Adrenalin has also been administered by instillation into the eyes, reaching the nose through the tear passage. It may also be given hypodermatically.

Curtis[15] has proposed to obtain immunization by administering the fluid extract of the plant, the pollen of which acts as the exciting cause, and he has had some success with ragweed.

In all conditions of nasal neurosis, in addition to the local measures, treatment should be directed to the general system so as to lessen the nervous irritability.

The bibliography of this subject is so extensive that space cannot be given to it here. The reader desiring to study the subject in detail is referred to the extensive bibliography given in the article by J. N. Mackenzie on the same subject in the previous edition of this Handbook; to the article by Dr. Mackenzie on the relations between the nose and sexual apparatus, already referred to; to the article on nasal neuroses in Burnett's "System of the Diseases of the Nose and Throat," by Joseph A. White; and to the very extensive and comprehensive bibliography in the article on nasal neuroses in Heymann's "Handbuch der Laryngologie," by Jurasz, to which article the author desires to express his special obligations in the preparation of the foregoing.

The following table gives a number of examples of the various reflexes considered, with the detailed treatment and the results. These cases are mostly unpublished,

CASES ILLUSTRATING VARIE

Sex.	Age.	Symptoms complained of.	Duration.	Nasal conditions.	Relationship between nose and symptoms complained of, and how determined.
M.	42	Asthma	Three or four years; began as hay fever twenty years ago.	Deviation of septum to right apex pressing hard on lower turbinate; hypertrophy of left middle turbinate pressing on septum and of left lower turbinate pressing on floor of nose.	Wheezing, cyanosis, and dyspnœa almost instantly and completely relieved when the congestion of the interior of the nose was relieved by cocaine and contact prevented.
M.	..	Asthma	Nightly for ten years.	Bilateral ethmoiditis with polypi	By exclusion and result of operation.
M.	44	Severe asthma	Three years	Polypi	Cocaine gave relief as did partial removal of polypi.
M.	49	Asthma, severe whenever nose obstructed; neurotic temperament.	Several months....	Exostosis of left septum; hypertrophy of right inferior turbinate; mucous membrane very sensitive; watery discharge; obstructed nostrils, worse at night.	Severe asthma only when nose occluded; under nervous excitement mucous membrane would swell and asthma come on at once.
F.	40	Asthma and cough	Asthma several years during wet months; cough six months.	Right middle turbinate much hypertrophied; septal crest on right side.	Asthma always relieved by cocaine spray.
F.	30	Asthma..........	Twelve months....	Abscess of antrum..........	Evacuation of pus from antrum followed by immediate relief; recurrence of empyema caused return of asthma.
F.	46	Asthma, nasal obstruction, headache.	Years	Large rhinolith with hypertrophy of turbinate tissue.	By treatment..........
F.	40	Asthma	Five years	Hypertrophy of posterior ends of inferior turbinates with complete nasal stenosis.	No exciting cause except general nervousness outside of nose; touching diseased parts with probe brought on attacks of dyspnœa.
F.	30	Cough; larynx irritation; occasional hoarseness.	Several years......	No complaint of nose, but spurs in contact with inferior turbinate of each side were found.	Treatment for cough and larynx did little good; cautery of each inferior turbinate so as to remove contact with septum, afforded relief.
F.	30	Severe coughing	Several months....	Hypertrophied inferior turbinates, and later, stenosis at night.	Diagnosis in doubt for some time; involvement of lung and unfavorable prognosis given by competent physician; taken to a specialist who examined nose and suggested treatment for nasal conditions.
M.	57	Dyspnœa, severe, continuous........	Three months	Septal spur on right side with deflection of septum to the left and enlarged inferior turbinates.	By result of operation: no organic cardiac disease; some emphysema.
F.	68	Spasmodic breathing at night........	Fifteen years	Two small polyps at lower edge of right middle turbinate, none elsewhere; no nasal obstruction.	Irritation of polypi with probe caused spasmodic, almost convulsive breathing.
F.	23	Spasmodic cough..........	Twelve years......	Hypertrophied inferior turbinates ...	Had been treated for uterine trouble, vesical trouble, rectal trouble, and nervous trouble with no result; cocaine to nose caused cessation of cough.
M.	16	Epilepsy	Two years...	Deflection of septum with complete stenosis.	History of trauma followed by attacks of epilepsy.
M.	22	Epileptiform attacks every two to three weeks.	Six years..........	Complete closure of left nostril due to deflected septum and left nasal bone.	Followed a broken nose ....
M.	11	Epilepsy	Nine years	Marked lymphoid hypertrophy	Removal under ether was followed by cessation of attacks for eighteen months.
F.	40	Sneezing and watery discharge from nose with erythema of the skin of the external nose.	One year	Both middle turbinates hypertrophied and pressing against septum; edges of turbinates puffy and red.	Determined and verified by treatment.
F.	22	Paroxysmal sneezing	Three years	General swelling of nasal mucosa; sensitive to probe; sneezing induced by contact with flowers and intensified when nervous.	When away from flowers sneezing stopped.
F.	45	Vaso-motor periodical neurosis (hay fever) followed by severe attacks of asthma.	Twenty years without relief.	Hypertrophied inferior turbinate, left long bony spur on septum of the same side pressing on turbinate.	Other treatment ineffective; operation on nose suggested as offering some hope.
F.	75	Hay fever. Attacks began June 1st every year.	Fifty years	Hypertrophy of both middle turbinates; complete stenosis at time of attacks which have occurred in the winter also.	Relief from cocaine and from local treatment of the nose.
M.	49	Vertigo with tendency to falling ...	Three months	Hypersensitiveness of mucous membrane; general hypertrophic rhinitis; swollen middle turbinate; deviated septum.	Treated for liver, kidneys, and nervous system without avail; spasmodic cough elicited on touching sensitive area together with sense of giddiness.
M.	65	Tic douloureux..........	....	Pressure deviation of septum on anterior end of right middle turbinate which was hypertrophied.	By area of pain and result of treatment.
M.	45	Tic douloureux	....	Hypertrophy of septum and opposing middle turbinate of right side.	No treatment except to the nose gives any relief; cocaine and adrenalin give temporary relief.
M.	42	Conjunctival congestion; photophobia	Three to four years.	Deflected septum causing intranasal pressure.	....

Nasal Cavities.

TIES OF NASAL NEUROSES.

Treatment.	Result.	If improvement, has it continued?	Reporter.	Where reported.	Remarks.
Refracture of the septum and replacement in median line; reduction of swellings and abolition of contact. This treatment continued off and on for two years as occasional colds caused renewed thickening, rendering cauterization necessary.	Attacks gradually diminished in severity and complete relief was finally attained.	So far as known; relief since 1893, last report 1899.	G. A. Leland...	Personal communication.	
Removal under general anæsthesia of all necrosed bone and polypoid tissue.	Almost complete relief.	Yes.............	G. B. Rice.....	Personal communication.	
Complete removal of polypi with cauterization at point of origin.	Cure............	....	Wm. Porter...	Personal communication.	
Exostosis removed; turbinal hypertrophies reduced; sensitive area cauterized; temporary change of climate; general tonic; treatment with regulation of habits of life; stimulants and tobacco stopped.	Apparently complete cure.	Yes.............	C. F. Theisen..	Personal communication.	Reporter thinks this case one of pure rhinitis nervosa.
Right middle turbinate removed February, 1894, followed by relief from asthma and cough for one year; recurrence was followed by further operative work, since which no further trouble.	Cure after second operation.	So far as known; last heard from in 1901.	W. A. Martin..	Personal communication.	Reporter regards impacted or hypertrophied middle turbinate responsible for more nasal neuroses than any other condition.
The usual treatment for cure of antral empyema.	Cure	Yes	Chas. W. Richardson.	Personal communication, also *Laryngoscope*.	
Removed rhinolith which weighed fifteen grains and had a cherry stone as nucleus.	Cure	Yes	M. D. Lederman.	Personal communication.	
Removal of hypertrophies..................	Cure	Yes	J. E. Schadle..	*Northwestern Lancet*, 1890.	
Occasional cautery; relieved and declined any further operative treatment.	Improvement....	Two years to present.	Author.		
Cautery to turbinates......................	Cure	Yes, for ten years.	Within knowledge of author	....	This case was a patient of the author's many years ago; the correct diagnosis was made by Dr. F. I. Knight, to whom credit for suggesting treatment is due.
Removed spurs and corrected deviation of septum.	Worse for ten days then great improvement.	Yes, but still has sensations of pressure about the chest.	M. D. Lederman.	Personal communication.	
Removal of polyps with cold snare	Complete and immediate relief.	Yes.............	L. B. Graddy..	Personal communication.	
Cautery to turbinates......................	Complete and lasting relief.	Yes.............	J. A. Stucky...	Personal communication.	Reported by author in article on "Reflex Cough," *Medical Record*, August 5th, 1899.
Operation on septum.......................	Relief for six months then returned, but after second operation there has been no attack for two years.		T. J. Harris ...	Personal communication.	
Operation of straightening septum..........	No seizures since four days previous to operation.	Yes, since January, 1902.	Name unknown.	Personal communication.	
Operation as stated and then reoperation after attacks began again.	Apparent cure after last operation until a blow on the head brought on petit mal again.		Urban G. Hitchcock.	*N. Y. Medical Journal* and personal communication.	Petit mal has continued; operated on for hypertrophy of the inferior turbinate in last two years without result.
Removal of tips of each middle turbinate...	Cure	Yes	C. N. Cox	Personal communication.	
Tonics, adrenalin 1 to 10,000..............	Two or three slight attacks in past three years.	....	C. F. Theisen..	Personal communication.	
Removal of septal spur; galvano-cautery applied to turbinate.	Four weeks after treatment annoying symptoms disappeared.	Yes, as far as known.	M. D. Lederman.	Personal communication.	
Removed anterior end of each middle turbinate.	Great improvement; no June attack; August attack less severe.	Yes.............	Author's case..	....	No attack in year 1902. Patient apparently permanently cured.
Removal of right middle turbinate; cautery of inferior turbinate.	Cure	....	O. J. Stein.....	*Laryngoscope*, December, 1898.	
Septum placed in proper position; worse immediately after, then gradual diminution of attacks in frequency and severity.	Final cure.......	No return of attack since 1896.	G. A. Leland ..	Personal communication.	
Galvanocautery	Good...........	....	W. Cheatham..	Personal communication.	Many cases nasal reflex relieved by cautery but many not; is not so hopeful as to results as formerly.
Removal of piece of septum with saw relieved pressure.	Permanent relief.	....	G. D. Murray..	Personal communication.

Cases Illustrating Varie

Sex.	Age.	Symptoms complained of.	Duration.	Nasal conditions.	Relationship between nose and symptoms complained of, and how determined.
F.	24	Intense supra- and infraorbital neuralgia, right side of face.	Four years.	Exostosis of right lower turbinate pressing on septum.	Shrinking under cocaine relieved pain at once.
M	36	Severe pain in head	Two years	Intranasal pressure from spur of left nostril.	Constant pain more noticeable during cold in head.
F.	23	Headache	Two to three years.	Chronic hypertrophied rhinitis.......	Headache worst when hypertrophy is greatest.
F.	40	Sick headache (migraine) with complete prostration.	Each attack several days.	Sharp exostosis buried in posterior end of inferior turbinate.	Increased tension in nose from any cause brings on attack.
M	..	Headaches, chorea, pain in eyes; inability to fix vision.	Several years	Polypus in left nostril; closed ethmoid cells.	Complete relief from treatment of nose; none from other measures.
F.	23	Following nervous excitement had increased conjunctival congestion, lachrymation and profuse watery nasal discharge.	Three to four years.	Septum thick; spur on one side; turbinates boggy; polypoid degeneration of left middle turbinate which was pressing against septum.	By result of treatment ....
F.	37	Headache; inability to fix vision; chorea in arms and legs; skin sensations neurotic type. For years in sanitoriums. Diagnosis of petit mal (neurotic family history).	Several years......	Both middle turbinates solid; no cells.	By result of treatment ....
M	13	Unable to swallow solid food since early childhood; if attempted always vomited.	Many years	Adenoids..........................	Suggested as possible cause ....
F.	37	Indigestion with cough	Several years	Reported nose perfect but examination showed spur in each nostril and hypertrophied tubercles of each septum.	By results of examination and treatment.
F.	20	Dysmenorrhœa	Several years......	Hypertrophy of middle turbinate	Results of treatment.................
F.	41	Diffuse œdema joints, hand and ankle	....	Polypoid degeneration of mucous membrane near hiatus semilunaris.	....
M	9½	Tachycardia	....	Pedunculated myxofibroma of the posterior end of middle turbinate.	....
M.	10	Temporary insanity..................	One week	Followed removal of adenoid and operation for deflection of septum, done under ether.	Seemed to be due to effect of plugs placed in nose to hold septum in position.

NASAL CAVITIES, DISEASES OF: NEW GROWTHS.—Perhaps contrary to what is quite generally believed, new growths in the nose are exceedingly rare. Mucous polypi, spurs, and thickenings of the bony and cartilaginous septum are seen more commonly than any or than all forms of new growths combined, but, being of purely inflammatory origin and not tumors in the true sense, are not described under this heading.

Moritz Schmidt, among 32,997 nose and throat patients seen in ten years, found that but 24, or 1 in every 1,370, presented some form of true neoplasm in the nose. Of these, 757, or 1 in every 43, had mucous polypi; *i.e.*, mucous polypi occurred more than forty times as often as all forms of true new growths combined. Of benign and malignant neoplasms, there would seem to be about an equal proportion, if anything, malignant growths appeared more often than benign tumors.

1. Benign Neoplasms.

Angioma.—This new growth is usually found on the septum and is composed almost entirely of blood-vessels, generally large cavernous veins, surrounded by a slight network of connective tissue, its epithelial covering being the same as that of the part from which it sprang. Bosworth says that it may be located in any part of the nasal cavity; however, if seen anywhere but on the septum, it is probably but a localized hypertrophy of the mucous membrane in which the vascular changes are most marked. It occurs at all ages, most frequently in early life, when it may be congenital, and very rarely in old age. It is a soft, rounded, mulberry-like growth, varying in color from a bright red to a purple, movable, pedunculated or sessile, bleeding easily on touching with a probe, and, as before stated, is almost invariably found on the anterior part of the septum. The tumor may be reduced or emptied by pressure, and, if connected with an artery, pulsation may be detected. Frequent attacks of nosebleed, always beginning on the same side, constitute the earliest symptom. The epistaxis may be alarming and difficult to control. Nasal stenosis on the affected side develops with the growth of the tumor, which may be rapid or slow. More or less discharge is likely to be present. There is no pain.

Treatment consists in the removal of the growth by the cold wire snare under cocaine anæsthesia and adrenalin to lessen the hemorrhage. If the growth be pedunculated, the application of the snare is simple; if it be sessile, a needle transfixes the growth at its base, the loop of the snare being thrown over this; and in either case one or two hours should be taken in removing the tumor. Recurrence does not take place if the removal has been complete.

Bony Cysts.—Osseous cysts in the nose are not rare. When present, they are found invariably at the anterior end of the middle turbinated bone in persons above twenty, and much oftener in women than in men. The etiology is interesting—several theories having been advanced as to the mode of their production. McDonald thinks the lesion was originally an "osteophytic periosti-

tis," secondary to an hypertrophy of the mucous membrane of the middle turbinate, causing the inferior border of this to curl outward and upward until it met the body of the bone above where at length adhesion took place, finally causing a closed bony cavity lined within and without with mucous membrane. Another explanation is that the cyst results from a rarefying osteitis, the inflammation beginning in the mucosa, involving later the periosteum and bone, and finally resulting in the porous formation observed in other hyperplastic processes. A simpler and more probable explanation than either of these is to be found in the fact that there frequently exists in the anterior end of the middle turbinated bone an ethmoid cell, which communicates with the middle meatus or with the other cells of the ethmoid labyrinth. Inflammation causes complete or partial stenosis of the orifice, the secretion is retained, and the cell gradually becomes larger as the walls distend, until finally there is produced a bony cyst. This is covered externally with mucous membrane that may either be normal or have undergone polypoid degeneration with polypi resulting, or, again, may have atrophied. The mucous membrane lining the cavity has columnar ciliated epithelium, and, through pressure of the retained secretion, often becomes attenuated, the glandular elements undergoing absorption, the membrane becoming polypoidal or granulating. The cyst contains air or may be filled with a yellow viscid fluid, muco-pus, or clear pus. On several occasions the writer, on opening the cyst, found a mucous polyp present in the cavity.

The tumor presents itself as a smooth, rounded, anterior end of the middle turbinated body, and varies greatly in size, being often so small as to pass unobserved, while at other times it may be so large as to reach down to the inferior turbinate or even to the floor of the nose, and frequently pushes the septum over sufficiently to cause stenosis of the opposite naris, the tumor occupying the concavity of the septum which it has produced. The symptoms are those due to pressure of retained secretion and to obstruction. Hemicrania with exacerbations of acute pain during colds in the head is the most characteristic and distressing symptom. The pain is referred to the inner side of the eye, radiating to the forehead or across the face, causing often intense trigeminal neuralgia. There is a feeling of pressure and throbbing. Actual exophthalmos may occur from the outward pressure. Attacks of megrim with vertigo and partial unconsciousness and vomiting are often complained of. Nasal obstruction, depending upon the size of the tumor, is present on the affected side and may be quite marked in the opposite naris.

Prognosis is good and recurrence is not to be expected following proper treatment.

Treatment is surgical and consists in the removal of the cyst (under local anæsthesia) by the cold wire snare, Grunwald's or other nasal cutting forceps.

FIBROMA.—Fibroma is a connective-tissue growth, somewhat resembling histologically the mucous polyp, but differing from it in the large amount of connective-tissue fibres crowded together with but few intervening interstitial spaces. The epithelial covering is the same as that of the polyp. It springs from the submucosa or outer layer of the periosteum, and arises from the posterior third of the middle or superior turbinated bodies or from the roof of the nose, and is said never to spring from the septum. It may arise in the sinuses, and often extends from the nasopharynx into the nasal fossæ. It has a rather thick, firm pedicle or may have a very broad base. If pedunculated, the growth is downward and backward into the nasopharynx, where it appears as a round or pear-shaped grayish-pink tumor, firm and hard to the finger, bleeding easily on probing, having a rather smooth surface, and tending to fill the postnasal space. In the nose it is of the same character, but is longer and more slender, conforming to the shape of the nasal cavity. Its growth is steady and persistent, pushing aside adjacent bones, causing ulceration and adhesions, invading the neighboring sinuses and orbital cavities, and producing finally much deformity, such as the characteristic frog face and exophthalmos. The tumor is very vascular and the walls of the blood-vessels are very much thinned. This form of growth occurs in early life, between the ages of fifteen and thirty or forty, and in males more often than in females. Of six cases of

Digitized by Microsoft®

fibroma in the nose and nasopharynx seen by the writer, four were in men, two in women,—the youngest in a boy of sixteen, the oldest in a man about forty.

The *etiology* is not known, trauma possibly having to do with the development. Early in the disease the patient has repeated attacks of epistaxis, often severe, the blood coming not only from the tumor, but also from the ulcerated mucous membrane, and nasal obstruction develops first on one side, then on the other, as the nasopharynx becomes filled with the tumor. A copious watery or mucopurulent discharge constantly flows from the nose. The voice becomes thick and nasal, the mouth dry and open, the senses of smell and taste become impaired or lost, and tinnitus and impaired hearing develop. Pain is absent at first, but, as pressure on adjacent parts develops, it becomes steady. Deformity arises if the tumor is not soon removed.

Prognosis is good if the tumor be removed. If it be not removed, death will ensue from copious hemorrhages or from extension of the disease to the brain.

Removal can usually be accomplished by the cold wire snare, but it may be difficult to surround the growth. The large loop is passed through the nose into the nasopharynx, the index finger of the left hand then pushing the wire about the tumor, when the loop is drawn. The pedicle may be so hard or the base so broad that the wire may be repeatedly broken and the galvanocautery snare be required before the tumor can be severed. The pedicle or base may be cut with scissors, and in unusually large tumors it may be necessary to expose the nose by an external operation before the tumor can be removed. Profuse hemorrhage is to be expected in the removal of fibroma by whatever operation, and death has occurred during operation from this cause. Electrolysis has been employed to lessen the size and reduce the vascularity of the growth before operating.

Osteoma and Chondroma.—These true bony and cartilaginous tumors are not to be confounded with the exostoses and ecchondroses so frequently met with on the septum.

Osteoma originates from the ethmoid, vomer, accessory sinuses, and other parts of the bony framework. Both the cancellous and the eburnated varieties are met with. The tumor grows steadily, though slowly, pushing everything before it, invading the orbital cavity, displacing the eyeball, and causing intense pain. The tumor has a bony connection with its point of origin or a pedicle of mucous membrane and connective tissue. It is covered with mucous membrane, and is so hard that it cannot be penetrated by an exploring needle. It is usually single, smooth or irregular, and may be of any size, depending upon the time it has been growing. The symptoms are pain, early and continuous until the pressure destroys the nerve filaments, nasal obstruction with all its results, impaired sense of smell, muco-purulent discharge, and frequent attacks of epistaxis. Exophthalmos, with or without blindness and epiphora, is produced sooner or later, as well as other evidences of external deformity. The diagnosis is made by the history of a slow growth, by the use of the probe or the needle, and in doubtful cases by the microscope.

Prognosis depends upon the extent of the tumor at the time of examination, but it is usually good. The treatment is entirely surgical and nearly always intranasal. The tumor may have to be divided into fragments by the motor trephine, bone forceps, or saw, and removed in pieces when it is too large to be extracted through the nostril. When the tumor is quite large and inaccessible, an external operation will have to be made, but much can be done by modern intranasal surgery without resorting to the more radical external operation.

Chondroma occurs less often than osteoma. It springs generally from the anterior part of the septum, but may come from the ethmoid or other accessory sinuses. It is a smooth, rounded, sessile tumor with a broad base covered with normal-appearing mucous membrane. It is found in early life. The symptoms are those of osteoma, excepting that there is no tendency to bleed. It is differentiated from osteoma by its permeability to the needle and by its sessile base; from malignant tumors by its slower growth, absence of hemorrhage, and harder sensation conveyed through the probe.

Prognosis is good if the tumor is entirely extirpated. Removal is accomplished by the knife, saw, cold or galvanocautery snare.

Papilloma.—Both hard and soft varieties of papilloma are met with in the nose. The hard variety resembles in all respects the cutaneous wart, and is confined to the vestibule and anterior part of the septum, usually of one side, and is commonly single, but may be multiple. Many cases of the soft variety have been reported, but the majority of them are not true papillomata, being nothing more than papillary hypertrophies. These latter, sometimes known as "Hopman's papilloma," are of common occurrence in hypertrophic rhinitis, occurring along the inferior border and posterior ends of the inferior turbinated bodies—sites where true papillomata do not occur. Jonathan Wright, who has investigated this neoplasm with perhaps greater thoroughness than any other rhinologist, says that only about a dozen cases of unquestioned papillomata of the nose have been recorded in literature. True papilloma appears to be restricted to the anterior part of the septum, the floor of the nose, and the anterior part of the external wall. It occurs at any age and in either sex, and is usually single, unilateral, and of small size, but may grow to be as large as a hazelnut, obstructing the nasal orifice. It may be sessile, but almost always is pedunculated, grayish-pink in color, with irregular surface and well-marked papillæ, somewhat resembling a raspberry. It is very vascular, bleeds easily, causing frequent attacks of epistaxis, and has some tendency to ulceration. Pain is seldom present. There is more or less profuse nasal discharge. Unless the growth is completely removed, it is likely to recur.

Treatment.—Removal is best accomplished by the cold wire snare, and any part remaining should be destroyed with the galvanocautery. Vaseline or other emollient should be kept applied until healing has occurred, and irritation by picking the nose is to be avoided. Ingals recommends the application of the tincture of thuja occidentalis to prevent recurrence. The possibility of papilloma degenerating into or later becoming a malignant tumor, especially in persons in middle life or later, should always be borne in mind.

2. Malignant Neoplasms.

Adenoma, sometimes classified as a benign tumor, shows sooner or later malignant changes, undergoing either carcinomatous or sarcomatous degeneration. This has been so in nearly, if not quite all, cases which have been observed and reported. Pure, unmixed adenoma in the anterior nares is necessarily extremely rare, because of the absence of gland structure in the nose. Hopkins and Leland each reported a case of adenoma in the nose at the meeting of the American Laryngological Association in 1897, both cases ultimately taking on carcinomatous change, and Leland's showing also a transition in one part to papilloma. Mayer has recently reported (*Am. Medicine*, August 2d, 1902) a case of adenoma, showing sarcomatous degeneration in parts. The tumor is to be regarded as malignant. It presents itself as a grayish-white granular polypoid mass, firm in consistency, the surface soft and pultaceous, bleeding easily. It develops much more slowly than either sarcoma or carcinoma.

Sarcoma is the commonest form of tumor met with in the nose, if we exclude mucous polypi and other tumors of purely inflammatory origin. All varieties found in other parts of the body occur in the nose, but the round- and spindle-celled sarcomata are most frequently seen, and after these in points of frequency are myxosarcoma, melanosarcoma, and fibrosarcoma, the other forms being much more rare. Both sexes are equally attacked. The period most susceptible to sarcoma in the nose is the fifth decade, between the fortieth and fiftieth years, but

Digitized by Microsoft®

no age is exempt, cases being seen in early infancy and in extreme old age. Of eighty-four cases collected and analyzed as to age by Harris (*Phila. Monthly Med. Jour.*, June, 1899), thirty-four, or forty per cent. of the cases, were between thirty and fifty; four were under ten years of age and two between seventy and eighty.

www.libtool.com.cn

As to *etiology*, little is known. Sarcoma is found so frequently associated with mucous polypi that there would seem to be some basis for the belief that under certain unknown conditions mucous polypi do undergo sarcomatous degeneration. Trauma, accidental or surgical, may be an etiological factor in this transformation from a benign to a malignant growth, and crude methods in operating have been suggested as a possible cause; but facts are wanting to substantiate this, too few cases bearing on this being reported to base any conclusions upon.

Symptomatology.—The earliest symptoms are unilateral nasal obstruction, progressing steadily and rapidly, and repeated attacks of nosebleed. Epistaxis is a prominent symptom throughout the course of the disease, and may become a very serious and alarming one. Discharge from the nose is profuse, at first watery, then muco-purulent and bloody, and later on the odor of necrosis makes it offensive. Pain is conspicuously absent in the early part of the disease, but, as the growth encroaches on the accessory sinuses, it becomes constant and steadily increases in severity. With the spreading of the tumor into the accessory sinuses and neighboring cavities more or less deformity of the face occurs, such as exophthalmos and fulness at the side of the nose and of the cheek with discoloration of the skin over the affected area. The growth may protrude forward through the nostril or backward into the pharynx, as in the case of a two-year-old child seen by the writer. Vision may become impaired from pressure on the optic nerve after involvement of the sphenoidal sinus. Nasal obstruction becomes so complete that the patient has great distress in breathing and in eating, speech becomes thick and muffled, the senses of smell and taste are lost or much impaired, nasal discharge becomes most profuse and offensive, pain is constant, insomnia adds to the distress, and the patient loses weight and strength, and finally dies, unless relieved by surgical intervention, from extension of the tumor through the cribriform plate of the ethmoid or roof of the sphenoidal sinus to the brain, or death may result from sepsis and exhaustion.

The objective appearances of sarcoma are not altogether characteristic. It is usually pedunculated, but may be sessile, and arises most often from the cartilaginous and bony septum and the middle turbinated body, but it has been seen originating from any and all parts of the nose. The color varies from that of a simple mucous polyp to a yellowish-pink or dark red, most often the latter. It is ordinarily quite soft to the touch of the probe and bleeds easily on examination, as in the round-celled variety, or it may be quite firm, as in the fibrosarcoma. The surface is smooth, unless ulceration has occurred. The tumor may have originated in any of the neighboring cavities, invading the nose secondarily. The writer, some ten years ago, had under his care a physician in whom a gliosarcoma of the dura mater perforated the base of the skull at the region of the sella turcica, invading the sphenoidal sinus, and causing softening and absorption of the cribriform plate of the ethmoid. The glands of the neck are not involved, unless it be by direct extension of the disease to them. Sarcoma is to be differentiated from simple mucous polyp, angioma, adenoma, carcinoma, and syphilis. The iodides should be administered to exclude syphilis in a doubtful case, and a microscopical examination of a piece of the tumor removed by the cold wire snare should always be made.

Prognosis depends upon the site of the origin of the tumor, the extent of its invasion, and the variety of the neoplasm. Sarcoma, having its origin in the septum, especially the cartilaginous part, offers the most favorable outlook, while one arising from the middle or superior meatus is most unfavorable. The round-celled sarcoma, the commonest variety seen in the nose, is also the most virulent. More than fifty per cent. of all cases are fatal. Of one hundred and three cases in Harris' table, the final termination was stated in but fifty five, and of the latter twenty-five ended in death and thirty in recovery. All but one of the thirty were operated upon. Twenty-two of these latter, however, were reported as cured within a year of operation, and it is probable that recurrence took place in some or many of them later.

Treatment.—Surgical intervention at present offers practically the only chance of recovery. The operation must be thorough and the tumor completely eradicated.

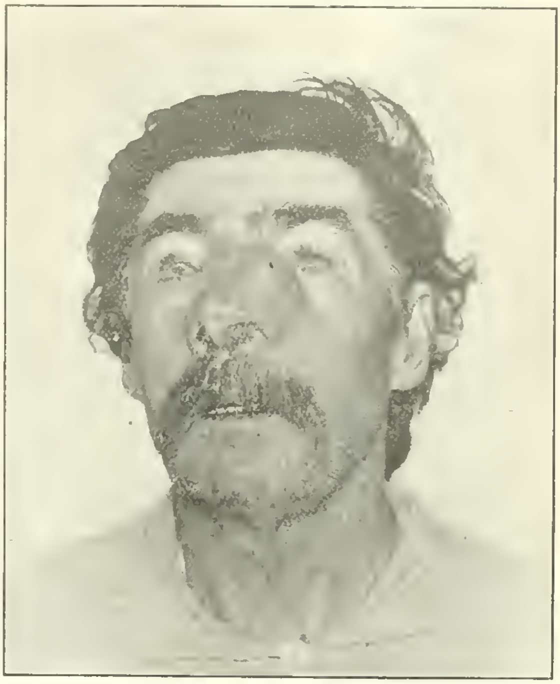

FIG. 3490.—Adenoma of the Nose, with incipient Sarcomatous Degeneration. (Case reported by Dr. Emil Mayer in *American Medicine*, August 2d, 1902.)

If the tumor is pedunculated and arises from the septum, especially at its anterior part, an intranasal operation with the snare may be entirely efficient; but if the growth comes from the middle or superior meatus or invades or involves the accessory sinuses or is inaccessible in any way, an external operation must be done. The nose is released and the parts involved are laid bare, the tumor is removed by cutting or the use of the snare, and the base is thoroughly curetted. Should recurrence take place, this should be removed at once. In inoperable cases—and many are inoperable—Coley's mixed toxins may be given with some hope of diminishing the size and retarding the development of the tumor, even if not curing it; such a course being specially indicated in the spindle-celled variety.

CARCINOMA, much more rarely seen in the nose than sarcoma, is always primary and occurs as epithelioma or cylinder-celled carcinoma. It originates most frequently from the cartilaginous septum and the turbinates, but more often still it is an extension into the nasal fossæ from the neighboring accessory sinuses, especially the maxillary. It is found during or after middle life, differing in this respect from sarcoma, which occurs at all ages. Unlike sarcoma, which has its origin in the deeper structures and forms a distinct tumor, epithelioma begins in the mucous membrane, ulcerating and destroying as it progresses. Nasal obstruction and pain of a neuralgic character are early symptoms. The discharge at first is acrid and of a sero sanguinolent character, but as ulceration occurs the discharge is more profuse and be-

Digitized by Microsoft®

comes putrid and fetid, giving to the patient and his surroundings an odor that is persistent and offensive. Repeated attacks of epistaxis occur. Tinnitus and impaired hearing and earache are often complained of. As the growth extends into the accessory sinuses, the orbital and cranial cavities, a new set of symptoms develops. The cheek becomes full, the eyeball is pushed out, vision may become impaired, pain is greatly increased, and finally signs of meningitis or brain abscess develop.

Objectively, epithelioma presents itself early in the disease as an infiltration of the mucous membrane, suggesting a papillomatous hypertrophy, but ulceration soon takes place, leaving the edges of the ulcer hard and the surface angry and covered with a thick, grayish secretion. Bleeding follows the slightest probing. The tumor shows marked tendency to invade the deeper parts, with little inclination to extend outward to the skin. Sooner or later the submaxillary and cervical glands become involved, though this is not always so, and cachexia develops only after the disease has existed for some time. The differential diagnosis is to be made usually from syphilis, lupus, and tuberculosis. Antisyphilitic treatment will often clear up a suspected epithelioma, and when any doubt exists the iodides should be given, if but for diagnostic purposes. Lupus has a very marked tendency to extend to the skin, which is usually involved. In a case of suspected primary tuberculosis, the bacillus will be found if that disease is present. The microscope may be required to determine the diagnosis of epithelioma; in employing it, however, one must not overlook the possibility that the removal of a piece of the tumor may be followed by renewed activity of the growth.

The *prognosis* is absolutely bad, few if any authentic cases of recovery having been reported. The disease appears to be more rapidly fatal in the nose than in most other parts of the body. Treatment heretofore has been unavailing; operation seemingly not only not eradicating the disease, but not affording even temporary relief. The growth recurs rapidly. While the *x*-ray as a curative or remedial agent in the treatment of cancer is still experimental, yet the very favorable reports of its use in other parts of the body would make it seem that the patient should be given whatever benefit there may be in this treatment. Pain may be relieved somewhat by orthoform or other local anæsthetic, and toward the end narcotics should be given to relieve the sufferer, and antiseptic washes used locally throughout the disease.

Thomas H. Halsted.

NASAL CAVITIES, DISEASES OF: PARASITES.—

The presence of animal parasites within the nasal cavities is of relatively infrequent occurrence. In the majority of cases such an event is purely accidental; true parasitic infection—*i.e.*, the presence of animal forms which reproduce, or pass one or more stages of their existence, within the nose—is very rare. As is the case with the external auditory canal, the nasal orifices, under certain conditions, may form favorable avenues of entrance for such creeping forms of animal life as are fond of escaping the light by crawling into dark places. The residence of such animals within the nose is usually but temporary; during this time they do not draw nourishment from the body tissues. The effects produced are chiefly those of local irritation or obstruction. To this condition the term pseudoparasitism may with propriety be applied.

PSEUDOPARASITISM.—Among such pseudoparasites of the nasal cavities may be mentioned earwigs, centipedes, numerous beetles, insects, spiders, mites, bedbugs, leeches, and worms. Entrance into the nose is usually obtained during sleep, very often in the open air, during the daytime. The local symptoms of irritation and obstruction may be very slight or severe. Bloody or mucopurulent discharges may be produced. In many cases the chief symptoms are of a nervous character, due to fright or worry. The intruder may penetrate into the frontal sinuses. Such cases may be attended by dangerous symptoms or even result fatally. It is said that centipedes are especially likely to reach the frontal sinuses. Cases are reported of these animals remaining in the frontal sinus for years, drawing their nourishment from the secretions of the cavities.

The occasional entrance of round worms (*Ascaris lumbricoides*) into the upper air passages and into the nasal cavities is of clinical importance. As is well known, these worms may, during the sleep of the affected individual, wander from the intestine, through the stomach and œsophagus, into the mouth and upper air passages. Ordinarily no especial symptoms are produced, but the passage of the worm into the larynx may cause serious symptoms of suffocation or even result fatally. Important obstructive symptoms may also arise from the penetration of the worm into the Eustachian tube or tear duct.

The *Oxyuris vermicularis* may be transferred from the anus to the nose through uncleanly habits, but does not remain in the new location.

TRUE PARASITES.—*Protozoa.*—Various forms of protozoa (*Amœba*, *Cercomonas*, and *Trichomonas*) have been reported as occurring in the nose, in such conditions as ozæna, purulent catarrh, whooping-cough, noma, etc. It is very doubtful if any of the appearances, described in the majority of such cases, were really protozoa; it is much more likely that they represented degenerating cells, leucocytes, etc. More careful observations are needed to settle this point.

Worms.—The accidental presence in the nose of *Ascaris* and *Oxyuris* has already been mentioned. I have been unable to find in the literature any well-authenticated case of *Cysticercus* of the nasal cavities. Only two or three cases of nasal *Echinococcus* have been reported. In one of these, observed by Rogers, the patient, a woman aged thirty-four years, had had a severe nasal obstruction for two and a half years. During a violent effort to clear the nose there was an escape of a large quantity of clear, straw-colored fluid. Two months later a cyst-like body was removed by snare from the middle turbinate; this was ruptured during removal. The microscopical examination showed the presence of numerous echinococcus booklets in the walls of the cyst.

Arachnida.—*Pentastoma denticulatum*, the larval form of *Pentastoma tænioides*, is found in the nasal, frontal, and maxillary sinuses of various animals, particularly in the dog. Rarely, the parasite may be found in the human nose; the infection usually takes place from dogs, or through the accidental inhalation of the young larvæ, or by the eating of contaminated food. In the latter case the parasite later wanders from the alimentary tract into the nasal cavity. Its presence there causes inflammation, nosebleed, etc. The diagnosis rests upon the occurrence of severe irritation, and the demonstration of the parasite.

Insects.—The most common and important nasal parasite belonging to this class is the maggot or larva of certain flies, both of the biting and the stinging varieties. The fly lays its eggs upon either the normal or diseased mucous membrane of the nose; in the latter case probably attracted by the odor of secretions. Certain varieties may force their way into the healthy nose and there deposit their eggs. Such an infection occurs, in the great majority of cases, when the affected individual falls asleep in the open air during the daytime. The *Sarcophaga carnaria*, *Sarcophaga Wohlfahrtii*, *Musca anthropophaga*, *Musca cadaverina*, *Musca domestica*, *Musca stabulans*, *Piophila casei*, *Lucilia macellaria*, *Œstrus bovis*, etc., have been reported as producing maggots within the human nose. In certain tropical countries, Mexico, Central America, the tropical portions of South America, West Indies, Hindustan, etc., such infections are not uncommon. The condition is known as *Myiasis narium*. In the great majority of cases the affected individuals have a history of ozæna or purulent nasal catarrh. The *Lucilia macellaria*, however, frequently attacks the healthy nose.

The symptoms of myiasis are usually very severe; it is said that the sufferings may be so intense as to lead to suicide. The number of eggs laid upon the nasal mucosa

Digitized by Microsoft®

may be very great, as many as five hundred eggs of *Lucilia macellaria* (Texas screw-worm) having been removed at one time. In other cases several hundred larvæ may be removed or discharged. The eggs hatch rapidly, and nasal obstruction soon results, with intense pain in forehead, cheeks, etc. A watery or bloody discharge, œdema of the neck and face, vertigo, sleeplessness, delirium, coma, reflex vomiting, and convulsions mark the affection. Fever may or may not be present. The nasal mucosa may be completely destroyed and the bones denuded through the efforts of the growing larvæ to obtain nourishment. Within a short time, one to two weeks, the larvæ leave the nose to form their cocoons outside. The character of the nasal discharges usually changes after the maggots have left the nose, becoming more purulent. The inflammation may persist for a long time, or in other cases the symptoms may abate immediately upon the removal of the parasites.

www.libtool.com.cn

The history of the case, the symptoms of rapid obstruction with watery or bloody discharge, and the demonstration of the presence of the maggot make the diagnosis clear. The prognosis is on the whole favorable, but fatal cases may occur.

The treatment of nasal parasites in general consists, first, in the removal of the parasite; secondly, in the treatment of the local condition caused by its presence. In the case of maggots or other parasites which are more or less firmly attached to the mucosa, various antiseptics may be used for the purpose of stupefying or killing the parasite. Inhalation of chloroform, ether, turpentine, bichloride solutions, calomel powder, decoctions of tobacco, balsam of Peru, are among the remedies suggested. The filling of the nasal cavities with warm glymol is advised, especially in the case of maggots; the oil filling up the spiracles of the larvæ kills them, and they are then easily washed out. In very rare cases it may be found necessary to explore the frontal sinus.

Aldred Scott Warthin.

NASAL CAVITIES, DISEASES OF: RHINOSCLEROMA.—On account of the wide diffusion of the lesions it has been suggested to substitute the name scleroma, without a local qualification, for this affection. It is a rare disease which is seldom found excepting in Austria, Hungary, and Italy. It is characterized by a peculiar connective-tissue growth in the mucous and submucous tissues of the respiratory tract which forms nodes, tuberosities, or slightly raised, smooth, flat, and extremely hard patches. In course of time these are seen about the nostrils or upper lip, and finally they invade any and every portion of the respiratory tract. These new growths are of a cartilaginous hardness, and owing to the atrophy of the new tissue, they form dense cicatrices without the intervention of ulceration.

Anatomical Characteristics and Course of the Disease.—Hard prominences, varying usually in size from a millet seed to a pea, and diffuse infiltrations characterize the disease. The affection usually begins in the salpingo-palatal fold or in the choanæ, and gradually progresses forward until the vestibule of the nose is reached, where it may terminate, or it may involve the external integument, occasionally invading the upper lip and changing it into a hard, snout-like protuberance. It also extends downward involving the pharynx, larynx, trachea, and bronchial tubes which become constricted by the contracting cicatrices. The diffuse infiltrations are firm and very rigid, and in proportion to their size mechanically obstruct the nares. Later, they undergo cicatricial transformation, and further obstruct or completely obliterate the nasal passages by the contraction of the resulting scars. When the cartilaginous external nose is involved in the disease, it becomes deformed by nodular protuberances of intense hardness. The integument of the nose is at first dense and white; later it reddens or acquires a livid hue. Occasionally slight ulceration occurs and fissures sometimes form, especially between the alæ and the cheek. In the nasal vestibule the disease often forms voluminous folds, which may protrude from the nostril. These are of a bluish-red color and are sometimes a centimetre in thickness.

Etiology.—Among those who have given this affection the most study it is generally believed to result from the presence of the Frisch bacterium, which is always found in considerable numbers in the cells in the lymphatic spaces of the affected part. There is no proof that it is contagious.

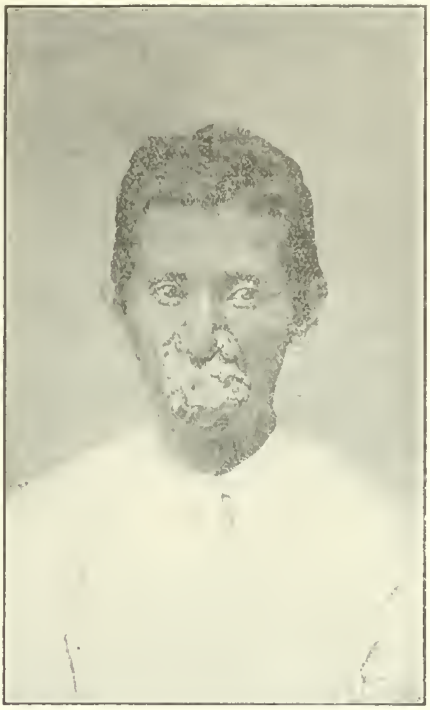

Fig. 3491.—Rhinoscleroma. (From Le Dentu et Delbet's "Traité de Chirurgie.")

Symptomatology.—In the beginning the disease is marked by symptoms of simple chronic rhinitis, which may extend over a period of several years. The secretion, at first watery, gradually becomes purulent. Afterward it dries into scabs or crusts, which as they decompose emit a very offensive odor, different from that of ordinary ozæna and apparently peculiar to rhinoscleroma. The scleromatous tissue is not usually deposited until the catarrhal symptoms have existed for several years. On account of the painlessness of the disease and its gradual accession, patients commonly do not present themselves for treatment until a number of years after its beginning.

Diagnosis.—Rhinoscleroma is to be distinguished from syphilis, epithelioma, and keloid, though as the latter is distinctly a disease of the skin which often appears in old cicatrices, it is not at all likely to be confounded with rhinoscleroma. The essential features in the diagnosis are the chronic course of the disease, the cartilaginous hardness of the infiltration, the formation of cicatrices without previous ulceration, the invasion—during the latter portion of the disease—of the larynx, trachea, or pharynx, and the broadening and deformity of the external nose by the scleromatous deposit.

Syphilis in the tertiary stage also leads to cicatrices which might be mistaken for those of rhinoscleroma, but syphilitic lesions differ from those of the disease under consideration in that their progress is more rapid and the hardness of the gummy deposits less marked. The syphilitic nodule also commonly ulcerates, whereas the scleromatous one does not. Again, the specific treatment of syphilis is usually followed by speedy improvement,

Digitized by Microsoft®

whereas the iodides and mercurials do not affect the progress of scleroma.

Epithelioma causes induration and some nodular infiltration of the skin, but the nodules are softer than those of rhinoscleroma and they ulcerate and bleed. The disease also runs a much more rapid course than the one under consideration.

PROGNOSIS.—This affection commonly extends over many years. There is no tendency to spontaneous recovery, and unfortunately treatment is unavailing except in the way of palliation. In consequence of the tendency to cicatricial contraction, when the affection involves the larynx, the trachea, or bronchial tubes, it may prove fatal by obstruction to respiration, but it does not usually shorten life.

TREATMENT.—The treatment is entirely operative and palliative. Obstructive infiltrations may be removed and thus relief be obtained for several years, though it is impossible to prevent recurrence and extension to other parts. Even extensive radical operations in the beginning have no influence in preventing the progress of the disease. In the operative measures outgrowths in the nose may often be removed by the snare, but the harder tissues must be cut away with a scalpel or trephine, or removed with a sharp spoon, and the operation may be finished with a galvanocautery, or hardened nodules may be reduced by electrolysis. The wounds left by these operations readily heal. It is generally thought best not to interfere with facial deformities, as recurrence is practically certain and excision would only necessitate repeated plastic operations to cover the defects resulting.

E. Fletcher Ingals.

NASAL CAVITIES, DISEASES OF: SINUS AFFECTIONS.—The antrums of Highmore are irregularly shaped cavities situated in the head between the upper teeth and the orbital cavities. They vary in their dimensions, the horizontal and antero-posterior diameters averaging about 25 mm. There is one normal opening in each sinus—the hiatus semilunaris—which is situated in the uppermost part of the inner wall. This opening frequently becomes occluded by inflammatory processes, and an artificial opening is then created by the internal wall rupturing at a point posterior and inferior to the normal aperture. Occasionally the roots of the molar teeth project upward and form small pyramids on the floors of the sinuses. Semicircular membranes, bands, and bony partitions, one-fourth to one-half inch high, are frequently found dividing the lower and lateral portions of the cavities into compartments.

The walls of the canine fossæ and the inner or nasal walls, beginning at a point about one third of an inch above the floor, are very thin, excepting those parts which give attachment to the middle turbinate bones. The inner lip of the hiatus semilunaris forms a small canal which connects with the mouth of the infundibulum or naso-frontal canal; a frequent result of this being that the fluids from the frontal sinus and anterior ethmoid cells flow down into the antrum of Highmore. The principal physiological function of the nasal accessory cavities is to supply fluid secretion and warm air to the nose and to serve as resonance chambers within the head. During inspiration the apertures, including the naso-lachrymal ducts, have a tendency to open, while during expiration they partially close; at the beginning of inspiration the partial vacuum produced takes a part of the latent air from within the cells and the velocity of the inspired current further draws from them. Toward the end of the inspiratory act new air enters the cells to fill the partial vacuum, this entrance being aided by the natural law by which warm air is displaced by cold; on expiration the *vis-a-tergo* pressure partially closes the cells. These to-and-fro currents of air constantly draw the tenacious mucus from the cells, overcoming the adverse conditions of small openings and the law of gravity.

There are four groups of sinuses which communicate with the nasal cavities, viz., the frontal, the maxillary, the ethmoidal, and the sphenoidal. As the diseases of the frontal sinuses have already been fully discussed in Vol. IV., under the heading *Frontal Sinuses, etc.*, the present writer will consider only the affections which involve the other three groups of sinuses.

I. DISEASES OF THE MAXILLARY SINUSES.

ETIOLOGY.—Much has been done of late to solve the problems as to the cause of diseased conditions within the antrum of Highmore. Distinguished writers differ considerably concerning the relative frequency of different morbific agencies as causative factors. Careful observers are proving that acute infectious diseases are responsible in many cases that were formerly attributed to other causes, and this is in accord with my own investigations.

The teeth are responsible for nearly one-half of the seriously diseased cases that have come under my observation. A careful examination of the teeth extracted in a series of cases gave abundant evidence of alveolar periosteitis, caries, and necrosis at the root end. In other cases the maxillary bone was necrotic, carious, and destroyed to a variable extent. Œdema of the nasal mucosa and polypoid changes existed as definite causal factors in a large proportion of the cases of nasal origin. More or less pressure upon the middle turbinal by a deviated and thickened septum, this in turn pressing upon the ostium maxillare, approximately closing the hiatus and causing retention of secretions more or less laden with pathogenic bacteria, was a prominent factor in many cases of chronic muco-purulent discharge from the antrum.

I am convinced that the suppurative rhinitis of childhood often leaves a local suppuration in the antrum which continues generally through adult life, unless proper surgical procedures are employed to relieve it. Syphilis, tuberculosis, tumors, and foreign bodies occasionally cause suppuration of the antrum.

SYMPTOMS.—Empyema with complete occlusion gives rise to extremely painful conditions, and there is a feeling as though the antrum would rupture from the intense pressure. These symptoms disappear immediately after a vent is secured. In those cases in which the acute and subacute catarrhal processes occur in the nasal cavity and extend into the antrum by continuity, there are a slight fulness and a sensation of stuffiness in the region beneath the eye, associated with a thick muco-purulent discharge into the middle meatus beneath the bulla ethmoidalis.

Complete convalescence in these cases takes place within from three to six weeks. Postnasal catarrh is a constant symptom. In the chronic cases mucus and pus are discharged through the anterior nares. Most patients who have very thin fluid in the antrum complain of it running down over the upper lip whenever the head is inclined forward.

Asthma, tubal stenosis, and tinnitus aurium, impairment of hearing, mental lassitude, and inability to concentrate the attention for any length of time are all common symptoms. Pain is a most irregular symptom; it is absent at times even in the most severe cases. It is often localized in the temporal or the occipital region. The most constant symptom is more or less discharge of muco-pus over the lower posterior part of the lip of the hiatus semilunaris.

PATHOLOGY.—A classification which I made several years ago of the pathological conditions practically holds good to-day. In this there were eight subdivisions, as follows: I. Acute, catarrhal, suppurative, and infectious sinusitis without complete stenosis of the normal outlet. II. Acute catarrhal, suppurative, and infectious sinusitis with complete occlusion of the normal outlet. III. Subacute and chronic catarrhal and suppurative sinusitis with moderately obstructed opening, with or without decomposing puro-mucoid débris. IV. Polypoid degeneration. V. Alveolar periostitis and periodontitis attended by suppurative caries, necrosis, or other pathological changes

Digitized by Microsoft®

at the root end. VI. Atrophic rhinitis. VII. Tumors and foreign bodies. VIII. Syphilis.

The cases of the first class are very common. The disease is usually self-limited and frequently leaves the mucous membrane much swollen and hyperplastic. Occasionally associated with an acute infectious disease there is a necrosis of the antral mucosa as well as of other parts of the mucous membrane of the respiratory tract. When there is complete stenosis, and when neither nature nor the surgeon relieves the condition, the consequent tension causes necrosis of the soft tissues, and this occasionally extends to the bone. In the subacute and chronic catarrhal suppurative cases, when the opening is moderately obstructed, the muco-purulent secretion frequently becomes partially inspissated, forms an accretion, and acts as a foreign body, causing the destruction of tissue. These by-products frequently destroy the surface of the mucosa and start small ulcerated areas which, if not cured, extend in time to the periosteum and often to the bone itself. Polypoid and œdematous changes which involve the ethmoid often have their origin in the antral membrane. If they occur on the lateral or upper walls of the cavity and remain more or less flat or mammillated, there is a possibility that the mucous membrane at these points will, under favorable circumstances, return to its normal state. But if these growths once become pedunculated it seems to be impossible for them to return to the condition of a normal mucous membrane. Caries, necrosis, and periosteitis in the molar or bicuspid roots frequently extend through the bony floor of the antrum and give rise to fistulæ, the discharge from which pushes up the periosteal lining of the cavity, and often leaves it floating in a muco-purulent medium. Ruptures may take place through this membrane at different points, causing a discharge of secretion into the antrum. The antral membrane becomes very thick and granular, and the mucosa and bony wall of the cavity degenerate. The atrophic process, which is the consequence of suppurative rhinitis in early childhood, invades the antrum, frequently destroys the epithelium and the glandular structures of the mucous membrane, and leaves a sclerosed membrane which secretes a semipurulent matter; this decomposes in the warm air of the antrum and issues through the normal opening into the nose, where it is formed into crusts by the inspired air.

Tumors, especially the syphilitic gumma and the epithelioma, may form in the antrum.

Diagnosis.—A discharge of pus from one nasal cavity is by far the most suspicious individual symptom of empyema of the maxillary sinus. It is the writer's custom in all cases of nasal and rhinolaryngeal disease to make a complete investigation of the condition of the nasal cavities and the rhinopharynx, and then to account for the condition of the accessory sinuses as far as modern methods will allow. When a disease of one of the sinuses is associated with a discharge, cocaine and adrenalin are carefully applied throughout the middle and inferior meatuses. After the shrinkage of the mucosa has taken place a soft silver probe is used in the region of the ostium maxillare. The patient's head is placed in different positions, the best one being that with the top of the head on the floor, the patient lying across a chair. When this position is assumed, and especially when the patient at the same time forcibly blows his nose, the secretion within the antrum will generally be forced to flow over the lip of the hiatus beneath the bulla ethmoidalis.

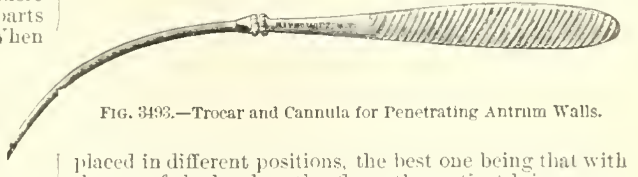

Fig. 3493.—Trocar and Cannula for Penetrating Antrum Walls.

In making the test by transillumination, I usually employ a four-candle power electric lamp of moderate brilliancy, the patient being in a dark room, and the lamp, attached to a suitable holder, being held within the closed cavity of the mouth. I do not rely entirely, however, upon the electric lamp, but use it only as an indicator for further efforts at determining the condition within the maxillary cavity. If there is a unilateral umbra, warranting the suspicion that the antrum of that side is diseased, the investigation must be pushed in other ways until the condition of the antrum is ascertained. Frequently after a curved irrigator has been passed through the normal opening, and more or less forced irrigation employed, definite evidence of a suppurative process is obtained. If this procedure cannot be accomplished, puncture should be made with a curved trocar through the antral wall near the uniciform process, at a point situated posteriorly and inferiorly to the hiatus. In other cases it may be necessary to pass a trocar through the wall of the inferior meatus, when, under forced irrigation, some of the retained secretion or débris will be expelled through the natural opening. In certain cases of cystic tumors I have found it necessary to make an exploratory opening through the canine fossæ before the diagnosis could be definitely settled.

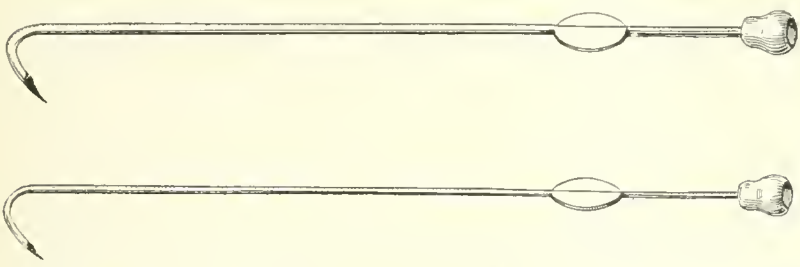

Fig. 3492.—Cannula Needle for Aspirating and Irrigating the Antrum of Highmore through the Wall of the Middle Meatus.

Prognosis.—The prognosis of diseases of the maxillary sinus will depend upon the pathological conditions present in each individual case. The ordinary cases of empyema are extremely annoying and affect the general health in many ways;—constant swallowing of the fetid pus is one of the most objectionable features.

The diseases of these sinuses are not nearly so fatal as those of the other sinuses on account of their distance from the cranial cavity. Even malignant tumors are more curable here. In empyema cases the prognosis depends upon the manner, method, and extent of the surgical procedure. If sufficient drainage can be secured, either into

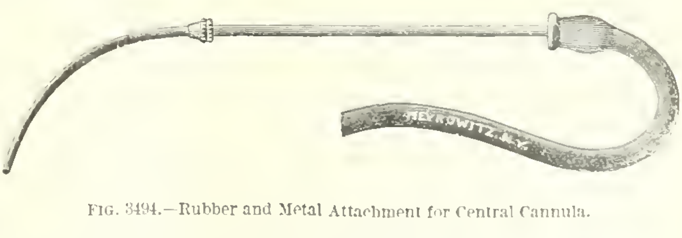

Fig. 3494.—Rubber and Metal Attachment for Central Cannula.

Digitized by Microsoft®

Nasal Cavities.

the mouth or into the nose, and if careful curettage of the antrum be employed, the drainage and ventilation being maintained until nature's process restores approximately the mucosa, the prognosis can be said to be fairly favorable.

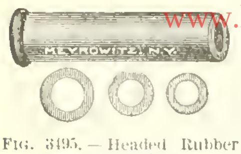

Fig. 3495.—Headed Rubber Antrum Tubes.

In all infectious cases the prognosis is favorable if complete irrigation can be carried out through the normal opening.

Treatment.—In considering the best treatment for the individual cases, one must ascertain, through every known method, the exact pathological conditions. It must be borne in mind, however, that while some of the apparently worst forms of antral empyema have been cured by the extraction of a tooth and a few weeks' irrigation through the socket, there are other cases of apparently a much less serious character, which resist all our therapeutic efforts in the most stubborn manner. Thus, for example, the writer has seen cases of trivial discharge (the only symptoms being a moderate postnasal catarrh), which, after a thoroughly radical operation, have terminated in the most obstinate purulent condition. Since we cannot obliterate the antrum without objectionable results, we must try to restore its functions without destroying too much of the lining membrane.

The author believes that he was the first to insist upon not treating the antrum in full accordance with the prevailing surgical teachings. It is his belief that thorough curettage frequently induces a worse condition than the disease for which it is employed. It is his rule, in cases of long history and severe disease manifestations, to make large openings through the region of the canine fossa and malar ridge and counter-openings through the inferior or middle meatus, and then to carry out a gentle and careful curettage of the mucosa and a firm and decided curettage of whatever bare bone may be found. After these steps have been taken the cavity is to be packed with aristol or iodoform gauze which has been passed through mercuric-bichloride solution. This packing is never allowed to remain longer than a week. At the expiration of this time the mucous membrane is inspected occasionally, the exuberant granulations are removed with the curette, and the cardinal principles of free drainage and free admission of air are utilized as far as the conditions of the individual case will permit. As supplementary measures various forms of tubing may be introduced into the antrum, for drainage purposes, and the membrane may be re-incised as it closes over the aperture. I have occasionally had patients who apparently were cured by treatment through the natural opening, but these evidently were cases in which purulent semi-decayed collections had formed and acted as a leaven to perpetuate the suppurating foci.

When one is called upon to treat a case of antral disease, the difficult problem of selecting the best operative procedure at once presents itself. If it is a case in which the evidence points to a diseased tooth as the causal factor, removal of the tooth is imperative. A certain proportion of these cases may be cured by this procedure alone without any further interference. And even if the dental disease has already involved the antral walls, causing caries and granulation tissue, in some of these cases a cure may still be effected by drilling a hole into the floor of the sinus through the tooth socket, for the purpose of securing proper irrigation and ventilation. When the granulation tissue extends practically throughout the antral walls and more or less bare bone exists, removal of the nasal wall of the antrum is indicated in either the inferior or the middle meatus, preferably in the former. During the first few weeks after the establishment of such an opening it is usually best not to use any tube. A rubber tube is extremely useful in favorable cases, but if the opening is larger than the head of the tube, the latter is apt to disappear into the antrum and cause annoyance.

With the aid of Dr. Dixon, a dentist of New York City, I have had constructed a permanent tube of gold or silver. A small band is placed around the most available tooth, a silver or gold wire is welded to the band, and then the gold tube is welded to the distal end of the wire. The patient can insert and remove these tubes at will, and when properly made and inserted they give little or no annoyance or discomfort.

The small curette with a malleable handle should be introduced from time to time to ascertain the condition of the mucosa, and if exuberant granulations abound they should be gently curetted.

Thorough cleanliness is essential, but it has been found that too frequent irrigations are injurious. A solution of boric acid or of common table salt is the most acceptable to the mucous membrane. Certain foul-smelling cases have been relieved in a few days by the injection of a mixture of three grains of iodoform in two drachms of liquid albolene; this mixture being left in the cavity for two or three days.

In cases in which polypi develop, it will sometimes be necessary to remove these, at frequent intervals, from different parts of the cavity of the antrum. In cases of sarcomatous disease a complete and thorough removal of all parts of the antrum is necessary; and the same procedure would be advisable in epithelioma if the disease could be detected in the early stages; but, unfortunately, in most cases of epithelioma the disease has already invaded the ethmoid and involved the lymphatics by the time when it is discovered.

II. Diseases of the Ethmoidal Cells.

The ethmoid cells consist of a number of cavities, irregular in size, situated beneath the anterior part of the brain, from which they are separated by a very thin lamella of bone. They lie to the inner, upper, lower, and posterior sides of the inner half of the orbital cavity. They are divided into posterior and anterior cells. The anterior cells communicate with the middle meatus of the nose, and the posterior cells empty into the superior meatus. The anterior cells have several openings. Some open into the infundibulum and cause confusion in differential diagnosis between frontal sinus and anterior ethmoidal cell disease.

The cell of the bulla ethmoidalis opens high up near the attachment of the middle turbinated bone. These cells are frequently hidden from view by the middle turbinal.

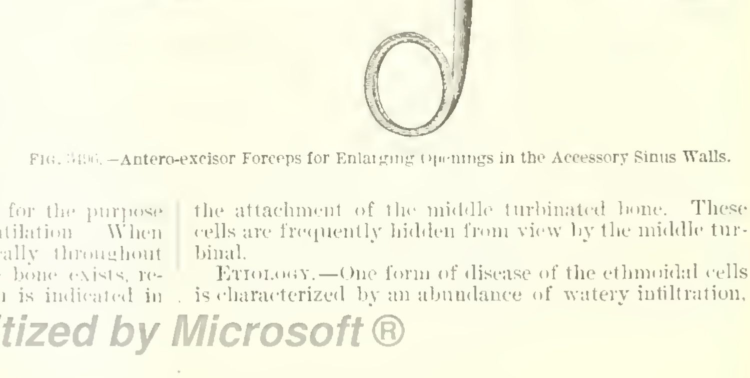

Fig. 3496.—Antero-excisor Forceps for Enlarging Openings in the Accessory Sinus Walls.

Etiology.—One form of disease of the ethmoidal cells is characterized by an abundance of watery infiltration,

www.libtool.com.cn
Digitized by Microsoft®

which, if not relieved, usually terminates in the development of a polypoid state. This infiltration, in the writer's opinion, is caused by intumescent pressure upon the venous vessels. The anatomical construction of these cells favors the retention of bacteria and the continuation of the so-called polypoid state when once it has been established. Occasionally the septum or an exostosis or enchondroma protruding from it presses upon the middle turbinal, so as to close the nasal openings, and then degeneration occurs within the ethmoid cells as a consequence. In a few cases an inflammatory and necrotic process in the antrum extends from this cavity to the ethmoid; in others the disease extends from the frontal sinus. Cysts occasionally form in one of the cells and extend backward and forward through the intercellular walls, finally making their appearance above the inner canthus of the eye where the bone is probably thinnest.

www.libtool.com.cn

Acute catarrhal inflammation of the Schneiderian membrane sometimes obstructs the openings of the cells for a period of several days. This causes putrefaction of retained secretion, and this in turn destroys the mucous lining of the cells. The pus thus formed discharges either through the normal outlet or through an artificial opening. If the pressure has been sufficient to produce necrosis and the drainage has not been free, we have as a result chronic thickening with pus production or watery œdema with polypoid changes.

In cases of syphilis tumors in the ethmoid cells sometimes break down and form the basis for polypoid degeneration. Osteosarcomata in this region are frequently the cause of pain and of a discharge of broken-down tissue products.

Symptoms.—Post-nasal discharge is one of the most common symptoms of ethmoidal cell disease. Dull and deep-seated pain around the orbit, and in the frontal, temporal, and occipital regions is often experienced. In cases in which there is retention of the secretion under tension, the pain varies according to the amount of periosteal disease and the degree of interference with the drainage. The patients show some mental dulness, and especially complain of a disinclination to mental activity. Sneezing, an escape of watery fluid, and more or less nasal stenosis, especially during autumnal weather, are some of the general symptoms of polypoid ethmoidal disease.

Diagnosis.—Diagnosis of ethmoidal cell disease is usually made without any special difficulty. In cases of latent empyema in the individual cells, however, the diagnosis is frequently not made until after the patient has been under observation for some time. The cavity should be thoroughly cocainized and sprayed with adrenalin in 1 to 10,000 solution. The nose should be cleansed of all secretion, careful note being made of the examination with a probe around and within the ostia of the respective cells. Cotton applicators should be used. To cleanse thoroughly the region of the suspected ostium, time should be allowed for the discharge of more pus before a second examination is made with the soft silver probe to ascertain whence the discharge comes. A small posterior rhinoscope is most useful in demonstrating secretion in the superior meatus. The extent to which the pathological process has advanced, and the question whether there is an œdematous, a polypoid, or a sclerosed state, are matters which can be determined partly by the patient's appearance, and especially by the character of the pus and mucus. The probe will convey a good idea of the state of the mucous membrane, but it frequently misleads us in regard to the condition of the bone. The combined periosteum and mucous membrane of these bones is very thin, and often it feels as if the probe were on exposed bone when as a matter of fact the latter is in a fairly normal state. This has led many of our best writers into controversies in regard to diseases of this region.

Treatment.—Whenever there is extensive serious disease in the ethmoid bones it is the wiser policy to remove a part of the middle turbinal at once. This rule would not hold good, however, in all atrophic cases. In the polypoid cases all visible polypoid tissue should be removed with the snare or excisor forceps; when there are intracellular polypi the floors of the sinuses should be removed with trephines provided with specially constructed guards and by means of lateral and antero-posterior cutting forceps. The curette provided with a malleable handle has proved most serviceable in removing intra- and intercellular diseased tissue and cells. The securing of free drainage and the free admission of air are just as important here as they are in the case of the antrum. In removal of the middle turbinal the lateral cutting forceps should be passed beneath the septum and the outer wall, engaging the middle turbinal between its jaws, and then a section of the bone should be removed. This enables the wire écraseur to be easily adjusted around either the anterior or the posterior end. I have found the smallest cannula and the Bosworth snare to be the most feasible instruments.

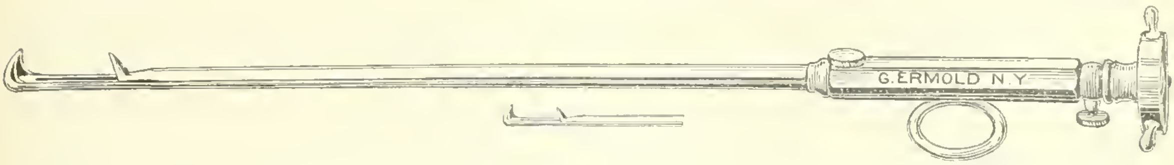

Fig. 3497.—Jackscrew Excisor Forceps for Removing Portions of the Floors and Walls of the Ethmoid Cells and Antrum of Highmore.

The proximity of the ethmoid cells to the orbital cavity and the brain, and the necessity of operating in a field covered with blood, should make the boldest operator cautious. With the aid of cocaine and adrenalin and with the patient's assistance, the difficult operation of penetration and removal of the floor of the sinus is made comparatively easy and safe. When the artificially established openings in the cells are large enough they usually drain so well that it is necessary to irrigate them at stated intervals only. When the process extends far up into the little cells above the orbital cavity or into some of the recesses under the cranium the results of treatment are not so satisfactory. I have found the daily insufflation of a powder composed of aristol two parts, boric acid one part, to be the most satisfactory after-treatment. When there is considerable pus a modified spray of Dobell's solution or of a solution made with Seiler's tablet is effective. Under this treatment the patient usually makes marked improvement. Frequently, however, a small amount of discharge continues from some inaccessible cell, and often also the condition is aggravated temporarily by taking cold.

III. Diseases of the Sphenoidal Cells.

Inflammation of the sphenoidal cells is usually consequent upon acute rhinitis, especially when due to infection. Polypoid changes are frequently the cause of chronic disease. Syphilis commonly affects the cell wall with a gummatous deposit and the ethmoidal mucocele occasionally extends through the dividing cell. Tumors sometimes develop in or extend into the cavities.

Symptoms.—The subjective symptoms of an acute inflammation of the sphenoidal sinuses are headache and a full, heavy feeling over and behind the eyes. In cases of chronic suppuration there are deep seated pains in the orbital, temporal, and occipital regions, feelings of depression and oppression, discharge of pus or muco-pus over the anterior surface of the sphenoidal cell at the posterior extremity of the middle turbinal body, and disturbances of the field of vision. The objective symptoms are hyperplastic œdema of the nasal mucosa cover-

Digitized by Microsoft®

ing the cell, discharge of pus and muco-pus, polypi, and pharyngitis sicca, due to destruction of the epithelium by the pus, which flows constantly over the postpharyngeal wall.

PATHOLOGY.—Changes involving the bone substance and the lowering of its vitality occur in those sphenoidal cases in which the mucosa has undergone polypoid degeneration. The bone becomes brittle under these circumstances and loses much of its cohesive quality. In neglected syphilitic cases necrosis of the bone or soft tissues always follows the gummatous process. The chronic suppurative cases with more or less stenosis of the normal opening are usually protracted by the irritating qualities of the degenerating products.

www.libtool.com.cn

FIG. 3498.—Guarded Trephine for Removing Obstructing Portion of the Septum near Anterior End of Middle Turbinal.

DIAGNOSIS.—Diseases of the sphenoidal cells are usually easily diagnosed. The obstruction in many cases is at the posterior end of the middle turbinal, and its early removal will facilitate matters greatly. Pus under favorable conditions can be seen at the normal opening in the uppermost part of the anterior wall of the sphenoidal cell. An irrigation tube passed through this opening will confirm the provisional diagnosis.

TREATMENT.—The treatment of sphenoidal disease is more satisfactory in its results than that of the other sinuses. Complete removal of the posterior end of the middle turbinal will usually demonstrate the point from which the pus makes its exit. The upper anterior wall should be penetrated with a guarded awl or trephine and afterward curetted. Extensive removal of the anterior wall with a cutting forceps, gentle curettage, irrigation, insufflations, and repeated excisions of the membrane which forms over the opening will often cure the most obstinate and apparently hopelessly diseased conditions of the sphenoidal sinuses.

I do not favor the procedures of opening the sphenoidal cells through either the antrum or the ethmoidal cells, as I do not think such extensive destruction of tissue is warranted. *Robert C. Myles.*

NASAL CAVITIES, DISEASES OF: SYPHILIS.—Syphilis, either congenital or acquired, may appear in the nose in any of its three stages. The disease is characterized by obstruction of the passages from swelling of the mucous membrane, or by more or less extensive ulceration with destruction of cartilages and bone.

ANATOMICAL AND PATHOLOGICAL CHARACTERISTICS.—The mucous membrane may be found thickened in patches or ulcerated, or obstruction may arise from gummatous thickening of the perichondrium or periosteum. In the latter case the cartilage or bone beneath often suffers necrosis and is finally separated by the process of suppuration. Necrosis occasionally results from extension of the ulcerations from the mucous membrane, and rarely the parts undergo molecular destruction and are gradually absorbed, being replaced by granulation tissue. Primary syphilis is occasionally conveyed to the nose by picking with the finger nail, but the hard chancre is very seldom seen. On the external nose the primary sore usually appears as a flat induration of moderate size; within the nose it commonly occurs on the septum as a red flat, hard growth covered with purulent secretions, which bleeds easily, the external nose at the same time being swollen and red. Neuralgic pains and fever may coexist and the submaxillary and sublingual glands and those in front of the ear are often indurated. In secondary nasal syphilis the appearances may be simply those of an acute coryza, or mucous patches may be found upon the Schneiderian membrane similar to those so commonly observed in the throat. In this case copper colored papules or macules with fissures at the junction of the nose and the upper lip or in the sulcus alaris are apt to be present. Gummatous syphilitic infiltrations may involve the mucous membrane, the perichondrium, or the periosteum. These soften after a time and deep, sharp-cut ulcers with undermined borders result, with sooner or later destruction of cartilage or bone. Often this destruction is limited to the septum, especially its bony portion; but in some cases it involves all of the surrounding parts. When the nasal bones are destroyed the bridge falls in, but this does not occur from destruction of the septum alone.

ETIOLOGY.—The affection is caused by the specific virus which may infect the fœtus in utero or during birth or which may be acquired afterward in various ways.

SYMPTOMATOLOGY.—Primary syphilis of the nose causes the symptoms of an acute catarrhal rhinitis of a severe grade. The initial lesion is likely to be comparatively large, and various lymph glands may be infected and greatly swollen. In the secondary stage there are much congestion of the mucous membrane and abundant muco-purulent secretion with obstructed respiration. Mucous patches are likely to be found at the edge of the nostrils and upon the anterior portion of the nasal mucous membrane. At the same time secondary manifestations are apt to occur in the throat and upon the skin. The tertiary symptoms commonly come on between the first and third years after infection, but sometimes not until many years later, and they are not infrequently seen at any time between the fifth and the fifteenth years. When the disease attacks the turbinated bodies it sometimes causes an appearance very like that of simple hypertrophic rhinitis and the parts do not retract readily under cocaine; but this condition is frequently associated with yellowish ulcers having a clean-cut border and hard infiltrated base with more or less induration about the ulcer, and is therefore not apt to be confounded with hypertrophic rhinitis. When the disease attacks the periosteum or the perichondrium, a smooth elastic swelling results which is usually apparent upon only one side. Later, breaking down takes place and ulceration results. The denuded cartilage or bone dies and is subsequently separated by an ulcerative process from the surrounding tissue. Commonly the patients do not present themselves for treatment until ulceration has occurred, and then the necrosed cartilage or bone may be found firmly attached or lying partly loose in the nasal cavity. Atrophy of the turbinals may also occur and destruction of the orbital plate of the ethmoid bone and of the hard palate is not uncommon. The dead bone usually presents a blackish, uneven surface, and is the source of an extremely offensive odor.

DIAGNOSIS.—The primary lesion in the nose may be mistaken for a malignant growth. The most valuable points in the diagnosis are its hardness and the great swelling of the lymphatic glands. Frequently the true nature of the disease is not recognized until the secondary symptoms appear. The secondary stage of the disease in the nose causes the symptoms of chronic catarrhal rhinitis, but it comes on much more speedily than the latter, and by careful inspection mucous patches or condylomata may sometimes be detected. The history of the case should be very carefully scrutinized, and any external manifestations may aid in the diagnosis. Tertiary syphilis of the nose is not likely to be recognized when it involves the turbinals alone, as the appearance is that of hypertrophic rhinitis; but when gummata and ulceration occur, a careful weighing of the history of the antecedent symptoms and signs will generally enable one to make a correct diagnosis, although often the patient will deny any specific infection. There is generally no difficulty in distinguishing tertiary nasal syphilis from atrophic rhinitis if the nasal cavities be first thoroughly cleansed. It should be recollected that simple perforation of the cartilaginous septum is seldom syphilitic, whereas perforation of the bony septum is nearly always so.

Lupus is to be distinguished from syphilis, first by the fact that it usually occurs at an earlier age than syphilis, excepting when the latter is hereditary; second, that the

Digitized by Microsoft®

reddish papules or tubercles of lupus are quite distinct from many syphilitic manifestations, and that they are often associated with distinct signs of lupus externally. Lupus also is much more prone to attack the cartilage than the bone, and it is much slower in its progress than syphilitic ulceration.

www.libtool.com.cn

PROGNOSIS.—The outcome of nasal syphilis is materially affected by early recognition of the disease and efficient antisyphilitic treatment. Although in many cases the destructive process is not extensive, in others not only the septum but the nasal bones, orbital plates, and hard palate are involved in widespread necrosis. In rare cases the disease progresses rapidly in spite of all treatment, and may terminate fatally within three or four months. Death has also resulted from fragments of the necrosed bones falling into the larynx.

TREATMENT.—Secondary symptoms and those of the tertiary disease, when mild, usually yield rapidly to appropriate internal and local treatment. In syphilitic affections of the nose, prompt and thorough antisyphilitic treatment should be immediately instituted, the nares should be kept clean by mild alkaline sprays or washes, condylomata or mucous patches should be touched with nitrate of silver or tincture of iodine, and the latter or solutions of from ten to twenty grains to the ounce of sulphate of copper should be used in case of tertiary ulceration. Dead bone should be removed as soon as it becomes loosened, and sometimes it is best to cut it away earlier in order to prevent the prolonged offensive odor; but it should be recollected that if the bone be cut away too early, the disease is liable to extend to tissues that would otherwise have escaped. Antiseptic sprays and powders, such as are recommended in the article on atrophic rhinitis, may also be employed advantageously.

E. Fletcher Ingals.

NASAL CAVITIES, DISEASES OF: TUBERCULOSIS.—Though tuberculosis seldom involves the nasal cavities, secondary tuberculous lesions are occasionally met with in this locality and a few cases of the primary disease have been noted. Michelson observed nineteen instances of the primary disease in thirty-eight cases of nasal tuberculosis. It should be remembered, however, that the early symptoms and signs of the pulmonary affection are not always recognizable, so that they may have been present in some of the cases believed to be primary nasal tuberculosis.

ANATOMICAL AND PATHOLOGICAL CHARACTERISTICS.—The disease may be observed as a diffuse infiltration, or as a tuberculous tumor with or without ulceration, or in the form of exuberant granulations. Ulcers may follow the infiltration or the tuberculous tumors, but they sometimes appear to be the primary lesion; however, they are nearly always secondary to pulmonary tuberculosis. The disease commonly attacks the anterior part of the cartilaginous septum, but it may involve any portion of the nose or nasopharynx. The tumors are generally small and of a grayish-white color, but may attain the diameter of 2 or 3 cm. before they finally break down. They are sometimes pedunculated, at other times sessile, and they commonly bleed easily. The tuberculous infiltration is prone to attack the septum, but may also invade the turbinals. It causes a firm, resistant swelling of a pale color having a somewhat granular surface. This, like the tumors, is ultimately followed by ulceration. The tuberculous ulcer is generally round or oval and at first shallow, but ultimately it becomes much deeper. The borders are irregular, having a worm-eaten appearance; they may be level or may be prominently raised by tuberculous infiltration. Miliary tubercles may often be seen on the floor of the ulcer and surrounding it. The floor of the ulcer is of a pale, grayish-red color and is sometimes covered with granulations, while the miliary tubercles which surround the ulcer are translucent or of a yellowish or grayish-white color. On breaking down they cause irregularity of the edge of the ulcer, and by the extension of the process the cartilage or even the bone may be destroyed, leading to perforation. Exuberant granulations may spring up and hide the ulcer or perforation or even a tumor. They are analogous to fungous granulations found in other parts of the body.

ETIOLOGY.—The causation is the same as that of other forms of tuberculosis.

SYMPTOMATOLOGY.—The disease comes on insidiously, causing the symptoms of an offensive rhinitis with free purulent discharge, which tends to collect and form scabs and crusts that hide the ulcers. Epistaxis is an occasional occurrence. At first the constitutional symptoms are slight. In the majority of cases this affection is secondary, and in nearly all instances it terminates with laryngeal or pulmonary tuberculosis.

DIAGNOSIS.—The disease is to be distinguished from lupus and syphilis. Lupus resembles the infiltrated form of nasal tuberculosis, but commonly begins in the integument and slowly extends, showing a marked tendency to cicatrization, whereas the tuberculous ulcers spread more rapidly and there is little if any tendency to healing; indeed, it is impossible to cure one of these ulcers unless the general condition improve.

Syphilis, especially in the late hereditary form, is sometimes very difficult to distinguish from tuberculosis, but usually its more rapid course, the headaches and neuralgias that are apt to accompany it, and its proneness to attack the bone instead of the cartilage distinguish it from tuberculous disease. The antecedent history may be of great value in the diagnosis, and a microscopical examination of the secretions or the scrapings from the ulcers or granulations is liable to reveal the tubercle bacilli, though the latter can seldom be discovered in the infiltrative form or in the tuberculous tumor. The results of treatment are also important—a syphilitic ulcer usually improves speedily under specific medication, whereas the same treatment is likely to aggravate tuberculosis.

PROGNOSIS.—The course of the disease is slow unless the lungs be already involved, and it may possibly extend over several years; but when the tuberculosis also affects other organs it runs a more rapid course to a fatal termination.

TREATMENT.—Detergent sprays and washes may be used to keep the nares clean, and tuberculous tumors that interfere with respiration may be removed by the snare or otherwise. The infiltrations are best destroyed by the sharp spoon or by electrolysis; fungous granulations may be scraped away with a curette and the base treated with lactic acid; indolent ulcers may be curetted and then treated with lactic acid. In these cases the parts should be anæsthetized as thoroughly as possible, and lactic acid of a strength from fifty to one hundred per cent. should be carefully applied. It is well to add to it from three to five per cent. of carbolic acid in order to prevent prolonged pain after the effects of the cocaine have disappeared. In some instances excellent results have been obtained by carefully touching the surface of the tuberculous ulcer with the galvanocautery. It is of prime importance to attend to the general health, because until this is improved we cannot hope to obtain much betterment in the nose. Even in primary cases we can scarcely hope to remove all of the tuberculous tissue by curettage or by other surgical measures, and therefore we can seldom, if ever, completely cure the disease.

E. Fletcher Ingals.

NASROL—sodium sulphocaffeate, symphorol sodium—is a bitter crystalline powder slightly soluble in cold water. It is a more powerful diuretic than caffeine, and the caffeine effect on the heart is said to be lessened. Dose 1 gm. (gr. xv.) daily. *W. A. Bastedo.*

NASSAU.—The town of Nassau, capital of the Bahama Islands, lies on the north shore of the island of New Providence, at a distance of about two hundred miles due east from the southern point of the Florida peninsula, and about thirty miles north of the parallel of latitude which passes through Key West. The exact latitude of Nassau is 25° 5′ 36″ N., only two degrees north

Digitized by Microsoft®

of the Tropic of Cancer; its longitude is 77° 21′ 15″ W. It is the largest town in the Bahamas, and has from twelve to sixteen thousand inhabitants. The island of New Providence has an extreme length from east to west of nineteen and three-eighths miles, an extreme width from north to south of [illegible] miles, and an average width of about five miles. The highest ground in the island is only 120 feet above sea level, and nowhere throughout the whole group of the Bahama Islands, many of which are very much larger than New Providence, does the surface attain an elevation above sea level of more than 230 feet. "The formation of all the islands is the same—calcareous rocks of coral and shell hardened into limestone, honeycombed and perforated into innumerable cavities, without a trace of primitive or volcanic rock; the surface is as hard as flint, but underneath it gradually softens and furnishes an admirable stone for building. . . . The soil, although very thin, is very fertile. . . . Except in the island of Andros, no streams of running water are to be found in the whole group."

www.libtool.com.cn

The town of Nassau "extends along the water front for about three miles and back to the crest of a slope, on which stand the Government House and many of the finest private residences, at an elevation of ninety feet above the harbor. The streets are laid out at right angles with each other, and are uniformly macadamized, as are also the numerous excellent drives around the island; and the houses are generally built of stone, with the surrounding grounds ornamented with a tropical profusion of flowers and trees." As for the general character and appearance of the country back of the hill just mentioned, we read, in Mr. Charles Ives' work, entitled "The Isles of Summer," that, "with the exception of a very few square miles occupied by Nassau and its suburbs, there is little upon the island, except water and wilderness; the former is brackish and throbbing, and in some places appearing and disappearing with the long pulsations of the sea's diurnal tides, and the latter, to a large extent, a dense low jungle, with stretches of pine forests rising from a thick undergrowth of scrub palmettoes."

Turk's Island, and Dunmore Town, on Harbor Island, are other health stations or winter resorts of the Bahamas, but I possess no detailed information respecting either, and practically it is true, as stated by Mr. Ives, that "Nassau is New Providence and the Bahamas."

The climate of Nassau is tropical, and far warmer than that of the Bermudas; but for the fact that the Bahama Islands lie in the track of the trade winds, and for the fact that they are islands of small size and of rather sparse population, the climate could hardly fail to be an unhealthy one; as it is, the climate may be regarded as a healthy one, at least during the colder months of the year. The following figures, derived from one year's observations, were sent me by the superintendent of the Canadian Meteorological Service, being kindly procured by Mr. H. Beaumont Small, of Ottawa. They show the mean temperature (degrees Fahr.) of each of the twelve months of the year in question.

January, 69°; February, 73°; March, 76°; April, 78°; May, 79°; June, 83°; July, 87°; August, 88°; September, 87°; October, 80°; November, 74°; December, 70°. Yearly mean, 78.7°.

The data of Table A show the "Mean of Daily Observations on week days, for ten years, from 1855 to 1864." This table is quoted from Mr. Ives' book, where it is "copied from the official report of Governor Rawson for 1864, page 14, compiled from the records kept at Nassau's Military Observatory." Governor Rawson's conclusions, based upon this table and upon others given in his report, are also quoted by Mr. Ives, and from them we extract the following statements: "The greatest maximum heat exceeds the average heat by not more than 12°; the greatest minimum falls short of it 10°. . . . From May to October . . . the rainfall amounted to forty-four inches, and during the remaining six months to nineteen inches. . . . Northeasterly and easterly winds are the most prevalent from September to February, during

which months they blow during one-half or two-thirds of the whole time. Northerly winds seldom blow, except during those months, and then only for three days in a month." As for northwest winds, the bane of the Atlantic coast of North America during the winter season, they occur from November to March, about two days in a month." "The Bahamas," says Mr. Ives, "are slightly but agreeably refreshed by the coldest winds that ever reach them from the north and west." The relative frequency of the winds from the different points of the compass is given by Mr. Ives, in a table quoted from Governor Rawson's report, showing "the percentage proportion of days in a year during which they prevailed at 9 A.M.," as follows:

North	7.2 per cent.	South	11.0 per cent.
Northeast	26.2 "	Southwest	5.0 "
East	24.4 "	West	2.3 "
Southeast	18.6 "	Northwest	5.3 "

In Table B the reader will find data, derived from official reports, and quoted from two tables in Mr. Ives' book, one of which presents data for the year 1878, the other data for 1879.

The maximum and minimum temperatures, and the rainfall for each month of the year in the three years, 1880 to 1882, are published in one of the English "Blue-books" for 1884 ("Statistical Abstract for the Several Colonial and Other Possessions of the United Kingdom in Each Year from 1868 to 1882"), which was kindly sent me by Mr. H. B. Small. Without quoting these in full, suffice it to say that the absolute minimum temperature throughout the whole three years of observation was 64° F., occurring in March, 1881; that the absolute maximum was 90° F., occurring in July and in August of the same year; and that the average monthly rainfall for each of the six months, November to April, was as follows: November, 1.5 inches; December, 1.5 inches; Janu-

Digitized by Microsoft®

ary, 2 inches; February, 1.8 inches; March, 1.5 inches; April, 2.1 inches. Mr. Ives' rainfall statistics for 1879 correspond very closely with those just given, and the higher average figures found in Table B are caused by the exceptionally heavy rainfall of 1878.

Despite the high figures for minimum temperatures which have been given in the accompanying tables, I find a writer in the New York *Times*, Mr. William Drysdale, referring to the occurrence of a temperature of 55° F. at Nassau, and speaking of the desirability of securing at the hotel one of the few rooms in which a fire may be had in cold weather. He also complains of the strong wind which prevails at Nassau. The relative humidity in winter is eighty-three per cent. and in spring seventy-six per cent. (Hinsdale).

Excellent sea-bathing may be enjoyed at Nassau throughout the year, the temperature of the sea water being usually in the vicinity of 70° F. throughout the year (Solly). Yachting and boating are favorite pastimes, and the facilities for both are excellent.

Huntington Richards.

[As will be seen from the above, the climate of Nassau is a moist, warm, marine one, agreeable for a winter residence of several months. After some days of acclimatization it is found to be not uncomfortably warm, though it is more or less debilitating. It is warmer than the Azores, Madeira, Teneriffe, or Bermuda (Solly).

There is very little if any rain during the winter, and there is a continuous succession of fine days. The humidity is high and the nights are damp, so that the invalid had best be in doors after 6 P.M., and not venture out too early in the morning.

The water supply is from rain water kept in cisterns, and its purity obviously depends upon the care exercised in keeping the cisterns clean. So far as known to the writer, there is no general sewerage system at Nassau, but the natural drainage is good, as the town lies at an elevation of one hundred feet above the level of the sea. The soft, porous limestone rock absorbs water rapidly, and wells and cisterns in the vicinity of cesspools and vaults may easily become contaminated. The Bahama Islands in general are said to enjoy a reputation for healthfulness, the mortality being under eighteen in one thousand (Hinsdale).

There are two great hotels at Nassau, the "Royal Victoria" and "The Colonial," the latter affording accommodations for a thousand guests; there are also good boarding-houses, and guests can be accommodated in private families.

Nassau can be reached direct from New York by well-equipped and comfortable steamers; or one can go by rail to Miami on the east coast of Florida, and from there by steamer in about twelve hours.

There are many attractions at Nassau, although after a while life becomes rather monotonous. The vegetation is tropical and very varied in fruit and flower. The roads are very good for driving or cycling, both inland and along the shore. Sailing, fishing, and bathing are also a feature of the place. A visit to the Sea Gardens is a delightful excursion in the bay, where, through the clear blue water, coral growths of varied hues and forms and sea sponges are seen. There are a good public library, schools, and churches, and reliable medical service. There are both still-water and surf bathing, and an excellent sandy beach. "Not a beach from Panama to Para, where anything like the comfort and benefit can be found as on this beautiful sweep of sand at Nassau" (Hutchinson). Golf and other outdoor sports are also to be had here.

By chartering a small schooner pleasant excursions for several days can be made to Eleuthera Island, Governor's Harbor, and other neighboring islands.

This climate is essentially the same as that of the lower coast resorts of Florida, and is suitable for a similar class of cases. It is not favorable for tuberculosis, as no moist, warm marine climate is, as has been elsewhere discussed in this HANDBOOK. Neither is it good for rheumatism or neuralgia, on account of the dampness, especially at night. It is, however, favorable for chronic bronchitis and catarrhal affections of the pharynx and larynx. It is said to be very beneficial for Bright's disease, especially the early cases. Cases of neurasthenia and those suffering from the effects of overwork do well here. Convalescents from various diseases with lowered vitality are favorably influenced by the winter climate here, where "no rain falls at that season, and each day is a repetition of the one just passed, balmy breezes and cloud-flecked skies," and where the usual daily range is from 70° to 73° F. *Edward O. Otis.*]

NAUHEIM. (BAD-NAUHEIM.)—Of the almost innumerable health resorts and watering places that abound in Germany, none is better known than Bad-Nauheim, incorrectly spoken of as Nauheim. I say incorrectly, because not such a great distance away is another town called Nauheim, which is devoid of all interest to sightseers or invalids. The prefix Bad signifies a bath, and hence designates any place to which it is prefixed as a watering place or spa. This explanation is necessary, since mistakes are sure to occur if letters intended for this famous resort are addressed merely to Nauheim without the distinctive prefix Bad, or if the invalid in quest of health inquire of German railway officials for Nauheim, and not Bad-Nauheim.

The chief interest attaching to this resort lies in the nature and properties of its springs and the diseases to which their waters are applicable, and yet there is much of interest in the history of the place. It is situated about twenty miles north of Frankfort, whence it is reached in forty minutes by the Main-Weser Railway. The location of the town is both healthful and picturesque, since it lies on the eastern slope of the Johannisberg, which forms a spur of the range of mountains known as the Taunus. The slope on which the town is built descends gradually to the bank of the Usa River, and thus provides excellent drainage, so that the soil dries quickly and permits visitors to walk out directly after a shower, which, judging from the summer I spent there, is of comparatively frequent occurrence.

Alighting from the train and walking down Bahnhof Allee (Depot Street), which descends rather sharply toward the west, one obtains a beautiful view of the Johannisberg beyond and of the town with its magnificent park and cluster of springs and bath-houses in the foreground. Emerging from this short Depot Street the traveller comes on to the Ludwig Strasse, which, lined with attractive villas along its eastern side, curves in a semicircular direction toward the west, and joining the river helps form the ovoid space in which are situated the bath-houses and springs that are the pride of the inhabitants and the object of the invalid's long journey.

On the further bank of the Usa spreads out the spacious park, which is said to be the finest of its kind in Germany, and with its shaded walks, covered seats, and Kursaal, offers irresistible attraction, and invites to the out-of-door pleasures of which the Germans are so fond.

The southwestern extremity of Ludwig Strasse leads into Park Strasse, which runs to the west, and is bordered by attractive shops, while the quaint town once enclosed by a wall, of which the remains may still be seen at the south, lies mainly to the south and west of the park on the slope of the Johannisberg. From this brief description it is plain that Bad-Nauheim can justly claim both healthfulness of site and beauty of scenery, which must minister to the comfort and pleasure of the summer visitor.

Digitized by Microsoft®
www.libtool.com.cn

The semi-invalid or tourist who can enjoy the pleasures of walks and drives is afforded ample opportunity for the indulgence in such pleasures. The more seriously ill, confined to a chair in the garden or to an apartment, can feast his eyes on the beauties of the Taunus range in the distant background, or on the beautiful park with the throngs of pedestrians, carriages, and wheel chairs moving restlessly in and out among its trees and on the shores of its artificial lake.

www.libtool.com.cn

The hours for recreation are many in Bad-Nauheim, for baths and the morning drinking of its curative waters consume but a small portion of the time; and hence the visitor must have varied pleasures and pastimes if he is not to find his sojourn wearisome and suffer from homesickness. It was the realization of this fact and of the powerful aid to health derived therefrom which led Dr. Friedrich Bode, one of Bad-Nauheim's early physicians and benefactors, to insist on the necessity of suitable provision for agreeable recreation as well as of desirable homes and means of treatment. He was a far-sighted physician who realized that healthfulness of body requires healthfulness of mind, and that to the latter contentment and diversion are essential.

To-day, therefore, Bad-Nauheim is no longer a meagre little village without an apothecary shop, or even tolerable lodgings for invalids as in Bode's time, but is a beautiful spot where twenty thousand invalids besides other visitors are comfortably, even luxuriously, housed and fed every year between May 1st and October. Besides fine hotels with modern comforts where the wealthy may be amply provided with all they can desire, there are innumerable private homes and boarding-houses for persons of humble means.

Bad-Nauheim is a Mecca for invalids from all over the world, and hence one there meets delightful people whose acquaintance is both a pleasure and a profit.

No lover of music who has passed a summer at this charming resort can fail to recall the delightful band concerts which are given three times a week at the Kursaal, and are enjoyed in the open air after the German custom, with the accompaniments of cigars and beer or other liquid and solid refreshments. These concerts are of high order, and the stirring music is rendered with a spirit and precision that never fail to arouse the most unimpressionable. Of a Sunday afternoon the usual weekly programme of instrumental music is varied by grand vocal performances rendered by well trained choral societies of male voices from neighboring cities. These concerts are rare treats and are very largely attended by enthusiastic and appreciative audiences. The air of the midsummer afternoon is usually comfortably cool and freed from annoying insects, so that to sit in the open ministers to health as well as to pleasure.

The history of Bad-Nauheim goes back to the days of the Romans when those stern warriors contended with the fierce Teutons for the possession of this part of Germany. Even in that early day it was a highly prized possession, not, however, for its baths, but for the salt contained in its waters. By the uncivilized Teuton the salt was procured by sprinkling the water on to a fire and then obtaining the saline precipitate from the ashes. The Romans, on the contrary, as shown by modern excavations, evaporated the water in large pans supported above the fire by foundations of brick.

Saline springs were considered so precious by the Romans that they were regarded as holy. It was the custom to cast coins into the springs as votive offerings, and to this day it is stated that pieces of copper money, bearing the impression of Hadrian, Domitian, and Trajan are often found upon cleaning out the basin of the Schwalheimer Brunnen. There are to be seen in the vicinity remains of old Roman villas and of that wonderful wall of defence which extended through Southwest Germany for a distance of five hundred and fifty kilometres, and enclosed that portion of the land which had been conquered from the native inhabitants. One of the best preserved remains, probably of a Roman temple, was disentombed near Homburg, another frequented spa, to which visitors at Bad-Nauheim may drive comfortably in two hours or less. It is thus seen that the subject of this sketch lies in a part of the Fatherland which is full of historic interest.

According to tradition it was Bonifacius who came to the heathenish inhabitants of this Wetterau district and converted them to Christianity. He is said to have built the chapel still standing on the Johannisberg, which mountain had for ages been consecrated to the worship of Baldur, the god of the sun. For two thousand years the Germans had annually assembled on the Johannisberg and celebrated the feast of the midsummer solstice, July 24th, now known as Johannistag or St. John the Baptist day.

It is also interesting to note that for many years the holy chapel dedicated to Christ by Bonifacius and the temple at which worshipped the still unconverted Germans stood not far apart, and on each 24th day of July could be heard the sacred music of the two congregations, the one in praise of our Blessed Redeemer, the other in praise of Baldur the sun god.

The subsequent history of Bad-Nauheim is eventful. It was twice ravaged by war in the Thirty Years' War, at the close of which the Wetterau country was desolated and almost depopulated, and again in the succeeding century during the Seven Years' War.

During all these centuries Bad-Nauheim remained still only a source for salt. Baths were not given as a therapeutic agency, nor were its waters drunk by invalids as were those of not far distant Homburg and Wiesbaden. In the fore part of the last century we read that the officials of the salt works used the saline water for bathing, not however therapeutically but merely for the purpose of cleanliness, since other water was not convenient.

In 1833 Salt Inspector K. Weiss persuaded Internal Revenue Commissioner Meisterlin to try a bath in this salt water, which he found so agreeable and invigorating that he determined to propose to the Kurfürst the erection of a bath-house. This establishment was first opened to the public in July, 1835. Thus was instituted this world-renowned resort which, from receiving ninety-five patients that first year, is said now to accommodate about twenty thousand invalids annually, to whom are given an average of three hundred thousand baths.

Of all the various springs that have been bored from time to time only five are now in use, namely: Kurbrunnen and Karlsbrunnen, which are saline purgative waters; Ludwigquelle, which is alkaline in consequence of its containing sodium bicarbonate; the Great Sprudel or No. 7, in use since 1839, and at that time the largest and strongest of all; and last but not least the Friedrich Wilhelmsquelle or No. 12, now the spring furnishing the greatest flow and extremely rich in CO_2. No. 14 (Ernst-Ludwig) was completed in 1900, having a depth of two hundred and nine metres.

There are six bath-houses of which No. 4 receives water, after having been freed from gas and impurities, from Spring No. 7. In this house only simple brine baths are given. Houses Nos. 1 and 6 receive water direct from the two springs at a temperature of 87° to 92° F., and very rich in acid and salts so that it can be employed in the "Sprudelstrombad" or flowing effervescing bath. The other houses also obtain waters from the two great springs, but only after they have flowed into their respective basins, so that the temperature of the water is somewhat lower (85° to 90.5° F.) and not quite so rich in CO_2.

The baths in use may be simple saline or warm saline, and the flowing saline or flowing effervescing bath, as the case may require. In addition, of course, douches, hip baths, etc., found at all watering places, are given. The analyses of the various springs will be found appended. At first the waters of Bad-Nauheim were recommended for the treatment of gout, rheumatism, anaemia, and disorders of the female pelvic organs, but their scope has been widened and now embraces diseases of the heart and nervous system.

For the first-mentioned affection patients are advised to

drink freely of the water of the Kurbrunnen, which is rich in chlorides of lithium, potassium, and the bicarbonate of lime, and, when a more strongly alkaline water is indicated, of that found in the Ludwigbrunnen. These springs are thought to be of special virtue in the removal of deposits about the joints. For the stiffness and swelling of the articulations occasioned by gout, baths are ordered which, beginning with thermal brine baths of a temperature of 93° to 95° F., are gradually changed to more stimulating ones, the effervescing water of Spring 12 being considered especially suitable. Finally, resort is had to the flowing effervescing bath, which is powerfully stimulating to the circulation, and is a specialty of Bad-Nauheim owing to the unequalled richness of Spring 12 in carbonic acid with its temperature of 92° F.

Patients suffering from anæmia and chlorosis are said to be much benefited by bathing in the waters of these springs on account of their containing iron as well as stimulating salts and CO_2, while at the same time they drink the purgative waters of the Kurbrunnen and Karlsbrunnen.

Disorders of the female pelvic viscera, particularly pelvic exudates, are said to be favorably influenced by the warm brine baths, either with or without the addition of carbonic acid.

Diseases of the spinal cord, as well as neurasthenia and other disorders of the nervous system, also receive treatment at Bad-Nauheim, and Medicinalrath J. Groedel, in his little work, "Bad-Nauheim: Its Springs and Their Uses," cites cases of the kind which have been remarkably helped. Professor Erb, of Heidelberg, sends numerous patients thither and highly praises the virtues of its waters in this class of cases.

As already stated, the waters of Bad-Nauheim are reputed to be of special efficacy in the treatment of both acute and chronic articular rheumatism, being employed in the form of baths, as has been the plan of management at other health resorts for centuries. Cases of comparatively recent development are subjected to the influence of the simple warm saline bath, but in protracted and chronic forms of the affection the stronger and carbonated waters are employed. The design of the bath is to promote healthy circulation in the affected joint, and it is believed that the comparatively cool (92° to 95° F.), strongly saline, effervescing, and hence powerfully stimulating baths of this spa accomplish this result more certainly than do the hot weaker baths given at other resorts.

The treatment of cardiac diseases, for which Bad-Nauheim has justly attained so great a renown, is an outgrowth of the treatment of articular rheumatism. It was Dr. Beneke, one of the earlier physicians at this resort, to whom credit is mainly due for the development of this use of Bad-Nauheim waters, although the Schott brothers, Groedel, Heineman, and others have brought the treatment to its state of perfection. Beneke contributed reports wherein he showed that this means of therapy is beneficial in four ways: (1) by preventing collapses of acute rheumatism, which would increase an existing valvular defect; (2) by promoting absorption of endocarditic products in the same way that these waters favor the absorption of inflammatory deposits in the joints; (3) by exerting a soothing effect on the heart's action; (4) by improving compensation in old-standing valvular disease. It was this last-mentioned effect which led Groedel to affirm in a paper contributed to the *Berliner klinische medicinische Wochenschrift* in 1878 that these baths improve cardiac energy and are a powerful heart tonic in other diseases besides valvular.

Carbonated thermal brine baths tend to quiet and regulate the action of the heart, improve its innervation, and increase its muscular tone. It is this effect which, in the experience of all physicians who have employed the treatment, makes it applicable to all forms of circulatory disorder, whether depending upon endocardial or myocardial disease, or merely upon nervous derangements. It is generally taught that severe degrees of arteriosclerosis and aortic aneurism are injuriously affected by such baths, but Groedel has shown that if they are given in such a way as not to augment blood pressure, even these two diseases may be materially benefited.

The methods of employing balneology in the management of cardiac diseases is simple and yet requires an intelligent conception of the principles concerned, and of

Digitized by Microsoft®

www.libtool.com.cn

the effects produced by baths of different strengths and temperatures. The warmer, less strongly saline ones serve to soothe and relieve the weak, irritable heart, whereas those that are strong in mineral ingredients and charged with CO_2, and at the same time of low temperatures (86° to 83° F.), stimulate the heart to increased work. It is clear, therefore, that these last are permissible only after compensation has been re-established, or in cases that have never displayed very obvious weakness. It is not claimed that the balneological treatment of cardiac disease can be given only in Bad Nauheim, but that here the advantages for this form of management are especially good. This is particularly true of the flowing effervescent bath, which, it is said, can nowhere else be given; and as it is powerfully stimulating, this kind of bath is highly beneficial in suitable cases.

Very briefly stated, the following is the method of ordering the treatment. At first, baths are prescribed which are weak in salts (about one per cent. of sodium chloride and one-tenth per cent. of calcium chloride) at a temperature of 95° to 92° F., and for a duration of from five to eight minutes. Carbonic acid is not added in the beginning of treatment, or at most in a very weak percentage of CO_2. As time proceeds and cardiac energy grows, the strength of the baths is increased until the salts mentioned approximate three per cent. of the sodium and one per cent. of the calcium chloride. Carbonic acid is added in the course of time, as determined by the judgment of the physician, and *pari passu* the temperature of the water is reduced and the length of each bath is increased, until at last the patient remains in the tub about twenty minutes.

In the fore part of the treatment the baths are interrupted by an occasional day of rest (one out of every three or four), but toward the end of the course such interruptions come at longer intervals. Patients are also required to lie down and rest after each treatment for an hour or so, in order that the effect of the bath may be retained and opportunity be given for a nap if inclination thereto be felt.

In addition to balneology patients are usually instructed to take exercise either in the form of massage, the so-called resistance exercises, or, as the heart becomes equal to it, by walking on the level or up the gentle inclines prepared for the carrying out of Oertel's terrain-kur. The diet and intake of fluids are also supposed to be carefully regulated.

As has been stated in numerous medical journals, this balneological treatment can be very well given at home by means of artificial waters, and, as my experience has abundantly proved, with excellent results. It is not possible, however, successfully to imitate the current bath, and in addition it is difficult to get patients to make treatment the sole aim of existence as at Bad Nauheim.

In concluding this brief sketch, which by reason of the limitation of space allotted is necessarily cursory and incomplete, I desire to express my sincere thanks to Dr. H. N. Heineman and to Dr. Groedel for valuable assistance rendered by them. I am also indebted to numerous papers by Dr. Schott and others. *Robert H. Babcock.*

NAVAL HYGIENE.—INTRODUCTION.—Naval hygiene may be briefly defined as being that branch of hygiene which applies the principles of sanitation to the conditions peculiar to life at sea, and especially as existing in ships of war. Although, in actual practice, appearing more or less modified to make them meet the peculiar conditions prevalent on board sea-going ships, the laws of general hygiene must remain essentially and fundamentally the same. Adaptation may at times necessitate and require a modification in the practice, but can never be allowed to go so far as to alter the principles of what is known as good hygiene, and so recognized by the best sanitarians the world over.

The importance of the study of hygiene to the naval surgeon cannot be exaggerated. Unless he possesses a profound theoretical as well as a practical knowledge of the essential and fundamental principles and purposes of hygiene, the naval surgeon of to-day can hardly be called "up-to-date," for without that knowledge he is barely able to perform but half his duties as sanitary officer on board a war-vessel. Since these duties must be confined, in form at least, to recommendations, made to his commanding officer, it is hardly to be expected that his recommendations will meet with the approval, required by regulations, unless the medical officer at the same time is able to prove to his captain that he possesses the necessary and requisite knowledge to entitle him and his recommendations to that attention and consideration which alone can make them effective.

To the naval architect the careful and conscientious study of hygiene is likewise of very great importance. At least one of the essential conditions implied in the construction of a warship is that it shall be so designed as to afford a given number of men a wholesome shelter during the performance of their duties; that the conditions on board be such as to preserve the life and health of the men, aiding them in, instead of interfering with, their most effective duties and excluding outside influences that are detrimental to these ends. The naval constructor owes it to himself, to the naval service, and to the people of his country that the best possible arrangements be made, that the best methods be adopted, and that the best work be done to advance the interests of hygienic living on board the ships which he designs and builds, as as far that may be within the range of his power. The ventilating system for a ship of modern construction, for instance, must be considered to be so essential that without it the ship would be of little value and its use limited.

Since the type and details of a ventilating system must be adapted to the type of the ship, it should from the beginning form a part in the design and structure of the ship and not be left to an afterthought. The constructor, realizing the difficulties, may commit them to an expert; but even then it is necessary that he have enough knowledge of the subject and of the results to be aimed at that he can readily and conscientiously accede to the demands of the expert, instead of regarding them as unreasonable; he should, moreover, possess enough knowledge on the subject to enable him to pass a just and proper estimate upon the value of the services of the employed expert himself. Thus, in giving out contracts, he is usually besieged by competitors. Competition leads to low bids and these lead to poor work and material. The result must be prejudicial to the interests of the naval service and to the constructor as well.

Scientific facts are stubborn things: they will not and cannot remain long ignored; mere opinions, whether official or unofficial, cannot sidetrack them, and thus the inevitable conclusion remains that we must bravely face these facts. In so far as the life of the sailor is influenced by the training which he must and can receive only on board a warship in commission and at sea, it is perfectly evident that that life is either increased or impaired in value to the service in direct proportion to the improvements in the hygiene of his immediate environments. These are intimately connected with the improvements in the construction of the ships on which he has his being.

Fortunately, there is abundant proof of the fact that within recent years, at least, a deeper recognition of the importance and of the profound significance of ships' hygiene on the part of all the officers of the naval service has become manifest. It has become clearly recognized that the strength, the power, the health, and the endurance of a ship of war, in action or out of it, whether on a mission of peace or one of war, can be but those of all its inmates combined, and, consequently, every man individually either adds or detracts from the sum total of the ship's power and endurance in direct proportion to the standard of his physical health. But the highest aims and objects of hygiene are not merely to preserve, but to raise the average standard of the health of our men to its maximum capacity. All training is more or less useless unless done on that basis.

Having once recognized these things, it becomes our

Digitized by Microsoft®

Naval Hygiene.

next duty to examine into the conditions, to consider some of the facts, upon which the successful solution of so high a problem depends. The three mainstays of all living things that people this earth are air, water, and food. An efficient ventilation, a good water supply, and an abundance of good and wholesome food must ever remain the principal subjects of our study and claim our first care and consideration. But before entering upon a more detailed study of these, we are impelled at least to call attention to what seems a most necessary preliminary to the successful administration of all hygienic laws in every organized body of men such as constitutes the navy. By that we mean the instruction of the men under training in the laws of the hygiene of our daily lives.

www.libtool.com.cn

It has been found repeatedly and constitutes an almost daily lesson of the sanitarian that one of the greatest and ever-present dangers from disease, on the part of the men in both the army and navy, is the ignorance of the most simple and elementary laws of health that must govern the every-day conduct of their lives. Examples of this might be cited *ad infinitum*, but we need go no further than merely call attention to the lessons that have been taught us, during our short war with Spain, by some of our volunteer regiments. Many of our bravest sons, because untrained and uninstructed in these things, died within a few weeks of going into their first encampment. Hence the warning finger, fortified and supported by an experience that should never again be allowed to lapse into forgottenness, points directly and unwaveringly to the necessity for instructing the men in the simple and elementary laws of health. This is clearly and distinctly the duty of the medical officers of the navy, the only officers in the service who, by the very nature of their training and education, should and can be held responsible for initiating reforms and improvements in this direction.

> "Nous sommes si zélés partisans de la ventilation que nous n'hésitons pas à la considérer comme le premier facteur de l'hygiène des navires, plus important à lui seul que tous les autres réunis."—ROCHARD ET BODET.

I. VENTILATION.

To supply a ship's complement of men with a pure, good, and wholesome atmosphere at all times and under the most varying conditions of activity, rest, and climate, is a problem which as yet has not been completely solved. The different climates through which men-of-war have to pass within a short space of time, and the conditions which these impose upon our problem, would alone be sufficient to demand the greatest possible elasticity in the range of adaptability from any ventilating system that is known, while the large number of small water-tight compartments into which the interior of a modern warship has been systematically reduced would make it seem almost next to impossible to keep the air inside all of these in a desirable state of purity and in constant and measured circulation. While, therefore, we agree with the distinguished French hygienists whom we have quoted above as regards the very great importance, to the hygiene of war-vessels, of an efficient ventilating system, we must also recognize and acknowledge that in no other department of naval hygiene do we find ourselves confronted with as great and perplexing difficulties as we do in the ventilation of warships of recent construction. We may accordingly be pardoned for devoting to this subject more time and space than to any of the others.

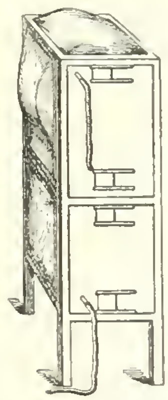

FIG. 3499. Recknagel's Model Paper Box. (From Karl Schmidt.)

Ventilation means to produce currents in the air. Currents are produced (1) by rarefying a column of air at some place, through heat or suction, and (2) by condensing at some other place, through either cold or compres-

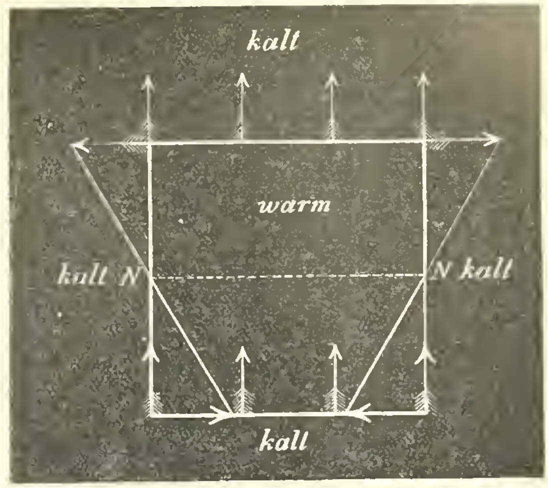

FIG. 3500.—Illustrating Distribution of Pressure in Heated Rooms. (From Rubner.)

sion. An excellent illustration of the effects of heat and cold upon the creation of aërial currents is furnished, in nature, by our regular winds. Along the equator we have a belt of calms, several degrees in width, over which the air is rarefied and expanded, rendered specifically lighter under the influence of a vertical sun, and consequently a constant current ascends into the higher regions of the atmosphere; then this current flows north as well as south from the equator, passing over the cooler trade-winds which flow in beneath them from either hemisphere. The warm equatorial currents descend toward the surface of the earth in about the thirtieth degree of latitude. The same currents cross the winds coming from the poles and proceed converging toward them as surface winds, whence they again ascend and, now, proceeding in a direction toward the equator, they descend through the calms of Cancer and Capricorn, become surface winds, and form the trade-winds already alluded to, thus completing their figure-of-eight form of circulation.

A similar process, though on a much smaller scale, may be seen daily in the large chimneys of some of our great manufacturing establishments. Through the fires, the column of air contained inside of them is heated and rarefied. The rarefied column of air, consequently, rises very much as a stick of wood forced lengthwise under water will rise, and the specifically heavier air, outside the chimney, will press inward from below. The cause of this movement is the difference in temperature between the inside and outside columns of air, for if this difference disappears equilibrium is re-established and the movement ceases.

In houses and dwellings of all kinds, these same physical forces are constantly at work, tending to bring about a change of air within them. The porous nature of our building materials, the winds, and the differences in temperature between inside and outside air are the efficient causes of this natural ventilation. In an experiment by von Pettenkofer it was found that in a room of 75 cubic metres' capacity one complete change of air was produced in one hour through a difference in temperature between inside and outside, of 20° C.

In order to illustrate the working of the principles of this natural ventilation, Recknagel made a box of thin paper (see Fig. 3499) perfectly cubical in shape, leaving the bottom side uncovered. Through this uncovered lower side he heated the air by means of an alcohol lamp,

Digitized by Microsoft ®

Naval Hygiene.

thus imitating the conditions under which natural ventilation occurs in any heated space in which doors and windows are closed. It was shown by manometrical measurements that in the upper portion of such a box there was overpressure, while in the lower portion of the box there was underpressure. In the upper portion the walls were pressed outward, in the lower portion they were pressed inward. About the middle part the pressure was = 0, and the line of this zero pressure was called the neutral zone. (See Fig. 5300, line *N N*).

www.libtool.com.cn

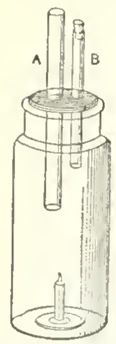

FIG. 3501.—Illustrates the Principle of Natural Ventilation of Ships. (From Munson.)

It will easily be perceived that wherever ventilation is effected by suction or exhaustion there must be underpressure, produced throughout the entire enclosure. The neutral zone will rise up to the ceiling or near the place where the exhaustion is done. The region of underpressure will rise until it prevails throughout the entire space. Under such conditions air tends to press into the enclosure from below, through cracks in the sides, or wherever underpressure extends. In case the adjoining rooms are kitchens, closets, stuffy cellars, galleys, pantries, engine- and firerooms, bilge or store-rooms, as would be the case on board ship, all the effluvia from these would be bound to pass into any of the living spaces that are ventilated after that fashion.

These facts would hold good everywhere, although a ship is vastly different in its material construction from any building on shore. A ship's bottom and sides, unlike those of a house or building, must practically be made both water- and air-tight; hence, whatever fresh air gets into a vessel must come from the top side and thence find its way, as best it can, to the various parts below. It represents a Recknagel's box with its inside air heated, but with its partly open side on top, instead of at the bottom. Whatever natural ventilation occurs in a ship can best be illustrated by the classical experiment with the unstoppered bottle. If we lower a lighted wax taper attached to the end of a wire down to the bottom of a wide-mouthed bottle, the little flame will burn brightly for a short time, then grow gradually dimmer and dimmer and finally die out altogether. If we now change the conditions of our first experiment by inserting a piece of cardboard into the neck of the bottle so as to divide the cylindrical opening into two nearly equal parts vertically, and now again introduce our lighted taper to the bottom, it will burn brightly to the end. The heated air charged with carbon dioxide will ascend through the neck on one side of the cardboard, while a current of air, pure and cold, will descend on the other side of it and support the life of the flame. As long as the hot air alone came through the neck, fresh air was prevented from entering, and whatever little did find its way into the bottle was returned before it reached the candle at the bottom.

The same principle is also well illustrated by Fig. 3501. Here the fresh air enters through the long tube *A*, and the foul air passes out through the short tube *B*.

A single central tube, being equivalent to a septum, will answer the same purpose. In this arrangement the warm-air current passes up through the central tube, while the fresh, cool current will descend outside of the tubular septum. In case, however, this central tube should be provided on top with a hood which is turned to the wind, then the cold air will pass down it and the warm air ascend around and outside it. As long as nature has her choice, the column of hot air will be found to occupy the centre and the cold-air currents will arrive from the periphery. These simple principles explain the method of ventilating ships by means of wind-sails, of no matter what construction they may be, through hatches. The essential difference in the methods of ventilating houses and ships is that, in the former, fresh air can be admitted, in fact presses in from below, with the greatest ease, while in the latter it must first be drawn from above downward, which is a matter of some difficulty, therefore also requiring special means for its accomplishment. *It should never be drawn down at a place where it meets with an ascending current of warm air.* Fresh air having arrived at the lowest compartment of the ship, its distribution to other parts of the vessel can, of course, only be effected on the same principles and by the same means that are employed in the ventilation of houses on land.

After the air has left the ventilating pipes and entered the smaller compartments and living spaces, its further distribution follows the laws of temperature and pressure differences, either existing naturally or being produced artificially. Whenever a ship happens to run against the wind, its inside temperature will be found considerably higher in the after-part of the vessel than in the forward part; with the wind on her side, the leeward side will show a higher temperature than the windward side. These differences are of course greater in the interior of the ship than on the upper deck.

These simple principles of natural ventilation would not have been dwelled on at such length, were it not that daily experience has abundantly shown that an undue lack of appreciation of them in putting them into practice is almost equivalent to entire ignorance of them, and hence their having been emphasized. The problem of ventilating ships on the best principles deserves our most serious study and devotion.

Natural-Air Currents in Steamships.—The student of ships' ventilation will do well to begin with familiarizing himself with the movements of natural-air currents within ships of different types, both under varying and under average conditions. In doing this, he will at first meet with many rather startling surprises. The currents move in quite unexpected directions and seem difficult to explain. Thus, in sailing vessels, a number of canvas wind sails are in use (see Fig. 3502); these wind-sails are usually suspended from some point high above the upper deck and have their heads turned to the wind. The air is led down into the deepest portions of the ship by the wind sail which passes straight down through the different hatches which are usually superimposed. Under these conditions, the foul air rises outside of the wind-sail to escape into the open. When, however, either by accident or design, the open heads of the wind-sails are turned away from the wind, these currents will be found to be exactly reversed, the wind-sail becoming an uptake for the foul air and the remaining space in the hatch, outside the wind sail, becoming a down-take for fresh air. In sailing vessels the temperature and pressure differences are, comparatively speaking, slight and, consequently, a rather trifling circumstance suffices to reverse the air currents within them.

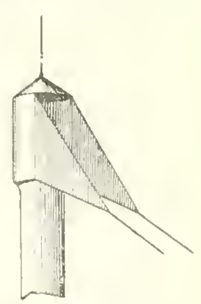

FIG. 3502.—Shows a Canvass Wind-sail of the Ordinary Pattern.

In a steamer of modern construction, such as a cruiser or battleship, with enormous fire- and engine-rooms, large steam pipes and a number of auxiliary engines, situated for the most part in the middle or central compartments of the ship's body and radiating considerable amounts of heat, air currents from all parts of the vessel would, under average conditions, move in their direction, that is, from the colder lower and peripheral parts toward the warmer higher and central compartments. Local heat-producing centres and open hatches will, however, here also produce interference currents which are sometimes difficult to explain, although perfectly natural when traced to their cause. The natural currents in steam vessels are not so easily diverted

Digitized by Microsoft®

Naval Hygiene.

as those in sailing vessels, for reasons that must now seem obvious.

From the consideration and study of these normal air currents in ships, we derive one very important lesson with regard to the subject of the artificial ventilation of vessels in general, namely: That any air currents established by artificial means and intended for purposes of ventilation must be so directed as to have *concerting* rather than *conflicting* action with the normal ship's currents. It must be clear that the most effectual as well as the most economical plans for ventilating ships by artificial means, after natural ventilation has been found insufficient, consist in providing means intended to aid and increase the ventilating capacity of the natural currents.

A supply of fresh air, directed in separate air shafts to the lower and most peripheral compartments of a steamship, would be the first step to be taken and quite in harmony with the general principles of ships' ventilation. Hollow masts, hatches, engine- and fireroom gratings and chimney casings, owing to the high temperature existing about these places and the consequent tendency of a strong upward current, would send the foul air out of the ship without the aid of any other power directed to effect this end. By such a system alone will it be possible to realize the nearest practicable approach to that continuous mass movement of air so desirable in artificial ventilation. The air, fresh and cool, sent into the extreme peripheral parts of a ship and starting from these parts on its way through the ship, in a direction converging toward the various natural outlets, would do the most efficient ventilating work attainable and without being turned back. Its flow can be so graded that there will not be the slightest danger from too great a draught.

Economy in Ventilation.—The best principles of economy in ventilation are met, when the arrangements are such that the air-contaminating substances are gotten rid of without becoming mixed with the incoming fresh air. The nearest possible approach to such economical mass movement, in a continuous flow, which can be realized in the ventilation of a ship, is in the vertical movement of air, when, for instance, fresh air is admitted below and foul air passes up through hatches or other natural vents. This condition clearly demands that the supply of fresh air be directed into the lowest and most peripheral compartments of a ship through channels other than those operating as the natural outlets for foul air. To cause downward currents of fresh air through these natural outlets of foul air, by creating various degrees of underpressure in the lower compartments of a ship, through exhausting the air there, must, in view of these facts, be considered contrary to every good principle involved in ships' ventilation so far considered.

Different Methods of Ventilation.—In the words of Woodbridge ("Lecture Notes") "ventilation is by the vacuum or the plenum method according as the greater motive power is in the discharge or in the supply part of the system. That power may be solely in either one or the other of the two parts, or it may be shared between them. Its predominance in the one or the other determines the vacuum or the plenum character of the ventilation."

Vacuum Method.—This method causes a movement of air into an enclosure by creating a partial vacuum within it. Into such an enclosure the air then flows through every available channel both provided and accidental. From whatever points, therefore, the pressure may be greater than in the enclosure, ventilated by the vacuum method, from thence it will move toward that enclosure. Each such space, therefore, is more or less at the mercy of its surroundings and of conditions beyond the control of its occupants. The vacuum method of ventilation on board ship puts the breather at the point of discharge of foul air and sends into the living spaces specimens of air from every part, near or remote, whether filled with good or foul air.

Plenum Method.—This method puts each compartment under a slight pressure and thus prevents leakage of air from adjoining compartments. It tends to accelerate the flow of air through natural outlets and gives the occupants control over the source and velocity of their air supply. This method puts the breather at the point of supply and consequently in position to breathe the best of air. It is recommended as the best by Rubner, Kirchner, Karl Schmidt, Notter, Harrington, and Munson. As it applies to ships, it is more nearly a method of removal than the other, and this constitutes the highest degree of efficiency for any ventilating system. We have seen that it answers to the best principles of economy. The method is the one best adapted to warm climates in which men-of-war spend at least ninety per cent. of their time. It will supply a steady current of fresh air to all the compartments in the ship alike, and, by tending to produce even conditions of temperature and pressure, it will prevent currents and counter-currents between the different enclosures in spite of free communication existing between them.

The usual objections made to the plenum system of ventilation are that it gives rise to sensible draughts and causes dangerous colds. This is very true for houses in a cold northern climate with a temperature difference between inside and outside air of from 60° to 70° F. and in which the air coming into the rooms is not sufficiently warmed. These dangerous draughts of northern climates can, however, not be taken into account when designing a ventilating system for a ship of which it is known beforehand that it will spend ninety per cent. of its time in the tropics. We heat the air by artificial means in our northern climates before admitting it into the living rooms, in order to enable us to take in a larger supply of it without becoming sensible of it. But, in the tropics, as must be evident, we need not resort to such artificial means of heating the incoming air in order to diminish existing temperature differences, and, consequently, the dangers due to sensible draughts. Ventilation here must, on the contrary, be designed for the double purpose of having a cooling as well as a ventilating effect. Besides, a dry atmosphere of low temperature is here borne with greater ease and comfort than a moist atmosphere with a high temperature, on account of physical heat regulation being more prominently active in the warmer climates than in the colder climates. It is the common experience of hygienists and sanitarians that air currents of a temperature and velocity pronounced dangerous in northern climates must be considered well within the range of perfect safety in ships cruising in the tropics. An efficient supply of air to the lower decks of a ship in the tropics rarely, if ever, gives rise to a dangerous draught or even a noteworthy feeling of discomfort. The colds are generally caught on deck while the men are asleep in an exposed part of the ship. Many people fear draughts, and attribute to this cause not only all the colds they catch but also all their other ills into the bargain. Some are so acutely sensitive, especially within doors, that they feel air currents that are beyond being measured by the most delicate instruments of precision. The same people will sit out of doors, where the air moves at the rate of 10 metres a second, without either complaint or harm.

Of one thing I am daily growing more assured, namely: that the limits to the velocity of air currents, given in works on ventilation, for houses and buildings, do not apply to ships. To live on board ship is more like living out of doors than living within a room.

Air currents that would be both disagreeable and dangerous in rooms of houses on land are still borne with comfort and without danger on board ship; hence, also, a much larger supply of fresh outside air can be provided for in the case of ships than in that of houses and buildings on land without overstepping the safety limits.

Dilution or Removal in Ventilation.—The ideal aim of any ventilating system, in theory at least, must be the getting rid of the foul air in an enclosure and the replacing it with fresh air, without the two becoming mixed. In practice, however, and as Rubner has long since

Digitized by Microsoft®

pointed out, we are obliged to take the air for inspiration from the same reservoir into which we send our expiratory air. It would, therefore, seem impossible for any ventilating system to separate the one from the other, and all ventilation must www.libtool.com.cn after the manner of a process of dilution and be so arranged as to keep the enclosed air from reaching a composition very much different from the outside air.

According as to whether we remove the foul air and replace it with fresh air without the two becoming mixed, or whether we maintain in the air of an enclosure a composition not dangerously far from that found outside by the constant and continuous introduction of fresh air, we may be said to ventilate either by the method of *removal* or by that of *dilution*. The removal method reaches its maximum applicability and efficiency in such cases as the fireplace, the chemical hood, the kitchen range bonnet, and the blacksmith's forge. The nearest practicable approach to this method on shipboard is effected by the escape of foul air through an open hatch. Whenever and wherever air is warmed in transit, as it is in steamships in passing from the cooler peripheral compartments toward the warmer central ones, economical and effectual escape of foul air occurs by an upward movement through a hatch. The foul air, under such circumstances, makes a direct escape into the open and does not return to mix with the incoming fresh air, providing, of course, the proper outlets are free and unobstructed and it meets or passes no compartment on its way in which underpressure exists. In such ventilation, economy, efficiency, and excellence reach their maximum. What the chemical hood is to the laboratory, what the range bonnet is to the kitchen, that the vertical foul-air shaft or hatch is to the ventilation of a ship. Providing the proper number of fresh-air inlets has been provided and distributed in such a manner as to allow the incoming air to do the most effectual ventilating work, such would be the natural air currents on board every ship of the type represented in the above description.

Would any one with the full knowledge and appreciation of these principles of natural ships' ventilation choose a ventilating system at variance with them? Let us confess that it would be difficult for any one to believe that such a one exists. Ventilation by natural means having been found insufficient, let us without hesitation, and basing our arguments upon the above grounds, put the fresh air directly where it is most needed, place our power on the supply side of our system and thus give it the plenum character; let us aid rather than antagonize natural currents, and we shall have the satisfaction of coming nearer to a perfect method of ventilating a ship than by any other known means.

Perflation signifies a blowing through. When the wind moves across the deck of a ship that has its ports open on both sides, as is sometimes the case on the decks that are above the water line in fine smooth seas with light winds, such decks may be said to be ventilated by perflation. No method of either natural or artificial ventilation is comparable to this in the volume of air moved and in the ventilating effect produced. It should, therefore, be taken advantage of and used at every favorable opportunity that offers itself for the purpose of directly aërating parts of ships not generally accessible to such direct ventilation.

Relation between Size of Hatches and Tonnage of Ships.—Notwithstanding the great importance of the hatches in their relation to the ventilation of the interior of ships, there seem to exist no fixed rules for a definite relation between the square area of them and the tonnage of vessels which the constructor is bound to follow. Thus, Rochard and Bodet mention several very striking instances, illustrating this very important point, as existing in the French navy: *L'Océan* of the French navy has hatches of a total square area of 64^{m2}, 40 and a displacement of 8,000 tons. The *Forbin* has only one-fourth of the displacement of the *Océan*, while her hatches have but one-tenth of the square area of that vessel. The *Hoche* displaces nearly one-third more than the *Océan* but her spardeck hatches have a square area of only one-half that of the *Océan*. A number of similar instances could be cited concerning ships in the American navy and showing the same lack of proper relation between the square area of the hatches and the tonnage, but the above examples suffice.

Nor are the number, size, and location of these hatches and their relation to each other on the different decks of the same vessel matters of minor importance to the interests of the ventilation of the vessel. Thus, superimposed hatches favor the natural ventilation of the lower compartments, while alternating hatches favor the circulation of air through the 'tween-deck compartments. The location of a hatch often determines its function as an up-take for foul air or a down-take of fresh air. Turrets, railings, and other obstacles in the way toward hatches and ventilators divert a large quantity of air, preventing it from going into the ship. Moreover, with the wind ahead, the forward compartments are the best ventilated, the hatches in this part becoming inlets, while the after-ones become outlets. The velocity of a head wind is increased by the speed of the vessel, so far as its ventilating effect is concerned. The opposite is true for a wind going in the same direction as the vessel. With the wind on either side, the best ventilating work is done by perflation.

Wooden gratings with which hatchways and air-shafts are covered reduce the area for ventilating purposes three-fourths of their capacity. Perforated iron gratings are recommended and come into use more and more, because they have been found superior to wooden ones. Thus, simple hexagonal openings in iron plates in which the arms, separating the openings, are just one-half the width of the openings themselves, decrease the ventilating capacity by only one-half instead of three-fourths.

Ventilation is not equally important to all compartments, and from this point of view they have been divided into four classes:

1. There are the cells of the double bottoms. These are rarely opened, and whenever opened for inspection they are never entered without the air enclosed within them being changed by means of portable ventilators. Their influence upon the hygiene of the vessel is practically nil.

2. There are the various storerooms for cordage and sails, provisions and clothing, water, ammunition, engineer's stores and others. In these it is only necessary that the air should not absolutely stagnate.

3. The 'tween-deck compartments that are inhabited by the crew are, of course, of the greatest importance and ventilation here must be ample, safe, and constant.

4. The various workshops, engine- and firerooms in which men stand watch or are kept at work for stated periods night and day. The rooms in which are located the steering, pumping, hydraulic, circulating, and condensing engines, and which in protected cruisers and battleships are found below the protective deck, need a sure and steady air supply. Ventilation of these places has the double purpose of cooling the air as well as renewing the oxygen. Inlets in these compartments should be distributed all around, in order to avoid the dangerous effects that would be produced by a single strong current.

Sources of Contamination of the Ship's Air.—The composition of the air on board ships of war is influenced: (1) By human life and activity; (2) by various nuisances of an industrial origin; (3) by the bilge water.

1. Human life and activity change both the physical and the chemical composition of an atmosphere in several ways, namely: (*a*) they take from it oxygen and replace the same with carbon dioxide; (*b*) they increase its humidity; (*c*) they add to its temperature.

From the physical side, the processes of life have been likened to the phenomena commonly observed about a steam-engine. Neither animal life nor steam-engines can be kept going without food or fuel; both do a definite amount of work, the energy for which is derived from the oxidation or combustion of substances put inside of

Digitized by Microsoft®

Naval Hygiene.

them, and both produce certain effete end-products that are similar, namely: carbon dioxide, water, heat, and the various products of excretion (ashes).

An efficient ventilation to an overcrowded ship is as necessary and has the same significance as forced draught for a furnace overloaded with coal. A deficient ventilation is attended by the elimination of a series of products that are not normally present in either expired air or perspiration; to this class of compounds belongs the anthropotoxin of Brown-Séquard. These poisonous substances, produced under the influence of a deficient ventilation, may well be compared to the products of an incomplete combustion produced in a furnace and consisting of both invisible poisonous gases and visible smoke. Since a state of overcrowding must be looked upon as the normal condition of life on a warship and as a necessary accompaniment of all activity there, an efficient ventilation on board a ship becomes a much more serious problem than on shore.

www.libtool.com.cn

If we assume with Rochard and Bodet that, under normal conditions, a man with his respiration vitiates 1 cubic metre, or about 36 cubic feet, of air in one minute, he vitiates in one hour 60 cubic metres, in twelve hours 7,200 cubic metres. A group of 500 men, the usual number on board a battleship, would then vitiate in twelve hours 360,000 cubic metres, or about 12,960,000 cubic feet. Such a group of men living in a space of 2,500 cubic metres capacity would vitiate their available air quantum 150 times, and, to keep it pure and within respirable limits, it would need to be renewed 12.5 times per hour. How overcrowding increases, apparently in geometrical progression, the carbon dioxide, organic matter, and the number of germs in an atmosphere is shown by Carnelley, Haldane, and Anderson (Kirchner) in the following table:

TABLE I.

Living in—	Carbon dioxide. Per minute.	Organic matter. Per minute.	Number of germs. Per litre.
One room	1.12	0.0157	60
Two rooms	.99	.0101	46
Three rooms	.77	.0045	9

No wonder that the mortality tables show a corresponding increase. People living in one room show a mortality of 23.3; those living in two rooms a mortality of 18.8, and those living in three rooms 17.2, while those who live in four or more rooms have a mortality of only 12.3 per cent, out of a general mortality of 20.7 per cent. These conditions are directly applicable to life on board ship.

But human life and activity add also heat and moisture to the atmosphere. An adult man produces in his body in twenty-four hours 2,300 large calories, an amount of heat sufficient to increase the temperature of 23 litres of water from 0° to 100° C. Through the skin, by evaporation, he loses from 600 to 2,400 c.c. of water in twenty-four hours, the exact amount depending upon the temperature, relative humidity, and the amount of movement of the atmosphere surrounding him. This would correspond to a heat loss of from 343,320 to 1,373,280 calories. The total heat loss is distributed as follows:

TABLE II.

	von Helmholtz. Per cent.	Vierordt. Per cent.
Through skin	77.5	86.9
Through lungs.........................	19.9	11.1
Through bowels and kidneys........	2.9	2.0

2. Industrial nuisances. The modern battleship may be said to combine within its sides all the varied industries of a manufacturing town pressed into the smallest possible space with all its accompanying nuisances in a concentrated form; the principal ones among them being those which come from the engine- and firerooms, in the form of gases, heat, and moisture. The products of incomplete combustion of coal may find their way into living spaces through processes of diffusion or the wrong kind of ventilation such as the vacuum method. Heat may accumulate owing to faulty construction or imperfect covering of heat-radiating surfaces in certain living spaces, close to engines and steam pipes. Steam escapes more or less constantly from imperfect or worn-out joints. The mean loss of water from escape of steam through pipes alone in a modern protected cruiser has been estimated to be about four tons daily. Plumert mentions a case of poisoning with carbon monoxide which occurred in one of the compartments of a torpedo boat, and which shows how dangerous gases may be diverted and get into living spaces. A hole was bored through one of the bulkheads separating the smoke-room from the living spaces, for the purpose of laying electric wires, and through this small opening, the carbon monoxide had made its way from the smoke-room to the men. In an empty ammunition room which had remained closed up for some time on board the *Sachsen*, Gärtner found up to 51 parts per 1,000 of carbon dioxide. The men who entered this compartment became suddenly asphyxiated.

3. The bilge is a constant source of air contamination. This fluid accumulates perpetually near the keel, along the bottom of the very lowest compartment of a ship and corresponds to the ground water, surface water, or sewage of our buildings on land. It is sea water mixed with the off-fall from all sorts of cargo, provisions, wash water, coal, ashes, grease from machinery, dead rats, the organic matter from everything living in the sea, in short a portion of everything that finds its way sooner or later into ships, will gravitate finally into the bilge.

In iron ships the sea water comes in through the shaft alley alone, while in wooden ships it may at times press in through every seam below the water line. The bilge is therefore less abundant in the former than in the latter. Dr. Nocht found from 3,000 to 15,000,000 germs in 1 c.c. of bilge water. Fermentation is very naturally the normal condition, and the gases constantly produced pass either into the ship's atmosphere or accumulate within spaces not ordinarily included in the general atmospheric circulation. The farther away we pass from the keel of a ship, the higher we ascend the ship's ladder the purer, the drier, and the cooler becomes its atmosphere.

Besides the above-described sources of contamination there are others which are, however, not remedied, as are these, by an efficient ventilation, and hence they were not included in the above enumeration. These are dirty personal habits and dirty clothes as well as a dirty ship. Nothing short of water, soap, the brush, and strenuous work will reach these.

Influence of Vitiated Air on Human Life.—There is besides sudden death due to asphyxia from the inhalation of air overcharged with carbon dioxide, a process of *slow* dying, due to living in badly ventilated rooms, which is not so clearly and so generally recognized nor so directly and clearly traceable to its cause. Non-medical observers and the victims themselves do not realize the causal connection between bad ventilation and this condition, hence also the lack of complaints with regard to poor ventilation from that source. The usual and immediate effects of breathing foul air are pallor of the skin, disturbances of digestion, impairment of assimilation, loss of muscular and mental vigor, and a tendency to physical break-down and disease. The difference in the complexion between the deck-hands and the fire- and engine-room men on board a man-of-war may well be seen at a muster, when the two classes of men are drawn up in line on opposite sides of the deck of the ship. On one side you may see the ruddy and rosy faces of the deck hands, on the other the pale, sallow features and sunken eyes of the men who work below.

Anthropotoxins in Air.—Determinations of carbon dioxide often fail to give information in all respects satis-

Digitized by Microsoft®

factory as regards the degree of atmospheric contamination, and an air must often be pronounced unfit for respiration, especially on board ship, before either lack of oxygen or the undue accumulation of carbon dioxide, and even watery vapor, can be accused of being the causes thereof.

www.libtool.com.cn

What exactly these poisonous substances are and whence they originate, what their nature and chemical composition may be, we do not as yet know with certainty. In their effects they are like poisons. Since they are known especially to accumulate in places overcrowded by human beings, an exact knowledge of their origin and composition would be of great interest to naval hygiene.

Brown-Séquard and d'Arsonval once believed that they had discovered in stagnant expired air a toxic alkaloid which, consequently, they named *anthropotoxin*, and which, indeed, when injected under the skin of mice, killed them within a few hours. Rauer repeated but did not confirm the experiments of Brown-Séquard. The problem has recently been taken up again by Formanek (*Archiv f. Hygiene*, Bd. xxxviii., Heft 1), who makes it appear likely that the problematic substance is an ammonia compound, not so much the result of the decomposition of expired air as it is of the decomposition of urine, fæces, and of the buccal contents of the animals experimented on. He concludes that the distress, the nausea, and the fainting fits which occur in overcrowded enclosures under poor ventilation cannot be attributed to a single and always uniform factor. It seems, therefore, that Formanek likewise has failed to confirm the results of Brown-Séquard and d'Arsonval. According to the experiments of Lübbert and Peters on guinea-pigs, the poison, if it exists at all, is not an organic, that is, not a carbon-containing or combustible substance. Wolfhügel insists that it is not contained in normal but always only in stagnant and decomposed expired air. The presence of a well-defined, well-characterized chemical poison in bad air would form one of the most convenient means of determining the degree of its contamination. Such a substance is as yet unknown. Nor is it definitely known whether these substances do their harm through being inhaled or whether their presence in the atmosphere simply inhibits the further elimination of them from our bodies, and thus gives rise to poisoning by the retention of an excretory product. Certain it is, according to Rubner, Seegen, and Nowak, that when animals are kept in closed spaces, in which care is taken to remove the expired carbon dioxide and to re-supply the used-up oxygen, the animals nevertheless succumb after a time.

Estimation of the Quality of Air.—Since, as we have just seen, chemistry has as yet failed to find a convenient chemical compound in the air by the determination of which we might standardize a normal atmosphere, we must resort to less direct methods. Experience seems to hold the chemical determination of the amount of carbon dioxide as the most reliable method for estimating the quality of a specimen of air. The method for the determination of the amount of organic matter in air with potassium permanganate has been found very inaccurate by Archarow and Emmerich, and the method proposed by Rietschel, of using the temperature as an indicator of the degree of contamination of the air, could hardly find application on board ships which produce heat in such enormous amounts as do the modern battleships and protected cruisers.

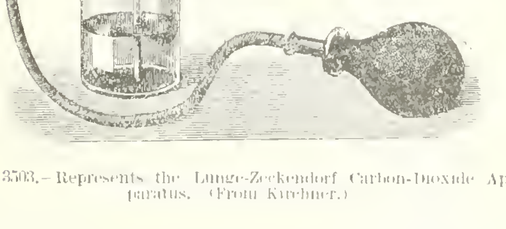

FIG. 3503.—Represents the Lunge-Zeckendorf Carbon-Dioxide Apparatus. (From Kirchner.)

Determination of Carbon Dioxide in Air.—It is known that barium oxyhydrate combines with CO_2 according to the formula, $Ba(OH)_2 + CO_2 = BaCO_3 + H_2O$. Pettenkofer proceeds as follows: A bottle containing 5 litres of the air to be examined receives 50 c.c. of baryta water. After thorough shaking and allowing to stand for a few minutes, all the CO_2 that was in the air of the bottle is now supposed to have combined with the barium oxyhydrate. The uncombined barium is now converted into an oxalate according to the formula: $C_2O_4H_2 + Ba(OH)_2 = C_2O_4Ba + 2H_2O$. From this the amount of CO_2 in the specimen of air may easily be computed. Although accuracy is decidedly in favor of Pettenkofer's method with baryta water, other considerations will sometimes cause us to sacrifice accuracy and to decide in favor of another method on account of its convenience. Several methods of this kind have been published recently. Thus, "A Rapid Method of Determining Carbonic Acid in Air" has appeared in a recent number of the *Journal of Hygiene* (University Press, Cambridge, England) by John Haldane. The apparatus, neatly fixed in a wooden portable box, represents a simple form of Haldane's gas analysis apparatus; it is so arranged that the CO_2 is absorbed by a potash solution. The final reading indicates the parts of CO_2 contained in 10,000 parts of air. The whole observation can be made in five minutes. Lunge (see Fig. 3503) ("Zur Frage der Ventilation," Zurich, 1877) uses a bottle of 50 c.c. capacity, closed by a double perforated cork and containing 7 c.c. of a 6 to 1,000 baryta solution. Through one of the holes in the cork a long glass tube reaching to the bottom of the bottle is introduced; the outer end of this tube is closed with a piece of rubber tubing and a clamp. The second hole in the cork is provided with a short tube, the outer end of which is connected with a bulb. This rubber bulb has a slit which serves the purpose of a valve, permitting the air in the bulb to be pressed out without going into the bottle, but not to re-enter the bulb, except with the air that passes through the baryta water in the bottle by way of the long tube. To this end the clamp, of course, is taken off. The bulb having a capacity of 25 c.c. the air quantum, sent through the baryta water, can be easily estimated. When the test is made, the air is drawn through the bottle until a lead-pencil mark on the side of the bottle, opposite the eye of the observer, becomes invisible through its contents. The table below gives the values. To the number of fillings must be added two volumes representing the capacity of the bottle.

TABLE III.

Number of fillings.	Volumes per 10,000.	Number of fillings.	Volumes per 10,000.
4	22.0	8	11.0
5	17.6	9	9.8
6	14.8	10	8.8
7	12.6	11	8.0

This method has more recently been greatly improved by Lunge and Zeckendorf (*Zeitschrift f. angewandte Chemie*, 1888, Heft 14, and 1889, Heft 1). Instead of baryta water, a decinormal solution of soda is used. To 1 litre of the solution there is added 0.1 gm. of phenolphthalein which colors the solution dark blue. Two cubic centimetres of this solution are mixed with 100 c.c. of air-free distilled water. The empty bottle is now filled with the air to be examined and 10 c.c. of the dilute solution are added. The bulb is now worked once and the bottle shaken for a minute. This process is repeated until the color of the fluid has changed from blue to yellow.

The values may be seen in the next table:

www.libtool.com.cn

More recently still a neat and handy method similar to the preceding, and based on practically the same principles, has been devised by Dr. G. W. Fitz. This method is carried out by shaking a small quantity of dilute lime water, colored pink with phenolphthalein, with successive portions of air until the solution is decolorized. The method has of late been made still more practicable by Woodman and Richards (*Technology Quarterly*, vol. xiv., No. 2, June, 1901). Since I have used this method quite a little and have found it to answer every purpose on board ship, being easy of application, also sufficiently accurate, a detailed description, given by Woodman and Richards, will here follow:

Description of Method of Using the Shaker for Determining the Amount of Carbon Dioxide in the Air.—"The method of preparation of the solutions and the manner of making the tests which have been found to give the best results will be described in detail, since experience has shown that these directions cannot be too minute.

"*Preparation of the Test Solution.*—The solution used is a dilute solution of lime water colored with phenolphthalein. To freshly slaked lime add twenty times its weight of water in a bottle of such size that it is not more than two-thirds full. Shake the mixture continuously for twenty minutes, and then allow it to settle over night or until perfectly clear. The resulting solution is the stock lime solution, or 'saturated lime water.' If made in the manner indicated, each cubic centimetre of it ought to be very nearly equivalent to 1 mgm. of carbon dioxide. If, however, it is desired to know the strength of it more exactly, it may be determined by standard acid.

"To prepare the 'test solution,' pour into the 1-litre bottle of the testing apparatus one measured litre of distilled water, and add 5 c.c. of solution of phenolphthalein (made by dissolving 0.7 gm. of phenolphthalein in 50 c.c. of alcohol and adding an equal volume of water). Stand the bottle on a sheet of white paper and add the 'saturated lime water,' drop by drop from a pipette, shaking the bottle thoroughly after each addition, until a faint pink color is produced which is permanent for one minute. Now add 12.6 c.c. of the 'saturated lime water,' shake, and immediately connect the bottle again to the apparatus.

TABLE A.

Standard test solution. CO_2 in 10,000.	Cubic centimetres of air.	"Half solution." CO_2 in 10,000.	Standard test solution. CO_2 in 10,000.	Cubic centimetres of air.	"Half solution." CO_2 in 10,000.
22.2	50	15.6	5.9	270	4.1
18.0	70	12.4	5.6	290	3.95
15.1	90	10.2	5.4	310	3.8
13.0	110	8.7	5.1	330	3.7
11.3	130	7.5	4.8	350	3.6
9.9	150	6.6	4.7	370	....
8.8	170	5.8	4.5	390	....
8.0	190	5.2	4.4	410	....
7.3	210	4.8	4.2	450	....
6.8	230	4.5	4.0	490	....
6.3	250	4.3	3.9	530	....

"To shorten the time required in testing air which is low in carbon dioxide, it may be found advantageous to use a solution only half as strong as the above. This 'half solution' is prepared in precisely the same way, using 2.5 c.c. of the phenolphthalein solution and 6.3 c.c. of the 'saturated lime water.'

"While this procedure does not give an exact volume of solution, it is believed to be the best for the preparation of this dilute test solution, since it obviates the necessity for pouring the prepared solution from the measuring flask into the bottle in which it is kept; 12.6 c.c. of the stock lime solution is added rather than 10 c.c., in order to keep the values obtained with the resulting solution more nearly comparable with the older values calculated on the supposition that 10 c.c. of 'saturated lime water' was equivalent to 12.6 mgm. of carbon dioxide.

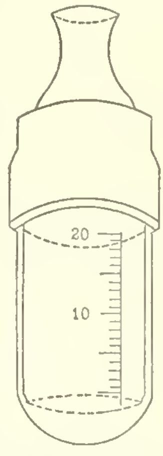

FIG. 3504.—The Fitz Shaker. Full Size. (From Woodman and Richards.)

"*Method of Making the Test.*—See that the inner tube of the shaker slides readily in the outer one, moistening the rubber collar slightly if necessary. Have the inner tube pressed down to the bottom of the larger one, and measure into the apparatus 10 c.c. of the test solution from the automatic pipette. Pull the inner tube up to the 5 c.c. mark (the bottom of the inner tube serving as the index) and close the end of the tube with the finger. Hold the apparatus horizontally, and shake it vigorously for exactly thirty seconds.

"The amount of air which is thus brought in contact with the solution is equivalent to 30 c.c., as there are 25 c.c. of air above the liquid when the small tube is forced to the bottom of the larger. Remove the finger, press down the small tube again to the bottom of the larger and draw it up to the 20 c.c. mark. Shake the apparatus again for thirty seconds. The amount of air brought in contact with the solution is now 30 + 20 = 50 c.c. Repeat the shaking, using 20 c.c. of fresh air each time until the pink color is discharged. The amount of carbon dioxide corresponding to the number of cubic centimetres of air used will be found in Table A.

"*Notes and Precautions.*—Care should be taken that the finger used to close the end of the tube is perfectly clean, since on a warm day the free acid in the perspiration might easily vitiate the results.

"If greater accuracy is desired, the shaker should be filled with the air to be tested before running in the test solution. This may be done readily by filling the shaker with water and emptying it or by forcing air into the tube by means of a small rubber bulb.

"The apparatus should be shaken vigorously and continuously during the thirty seconds in order to absorb practically all of the carbon dioxide in 20 c.c. of air. The number of shakings ought not to be less than one hundred during this time.

"Care should be taken not to contaminate the air while the sample is being taken. The breath should be held momentarily while the air in the apparatus is being replaced, and the sample should be collected as far to one side of the body as possible. It ought not to require over ten seconds to replace the air, and the entire test, with air containing, say, 8 parts of carbon dioxide per 10,000, should not require over six minutes.

"If less than 90 c.c. of air is required to discharge the pink color, the test should be repeated, using 10 c.c. of air each time after the first 30 c.c.

"It is not necessary to rinse out the shaker after making each test, but it should be carefully washed and dried after using, and the parts kept separate when not in use.

"The 'half-solution' is used in exactly the same manner and amount as the regular test solution, reference being made to the appropriate portion of the table."

Air Quantum Needed.—The ventilating plant to be designed for a place or ship must be given a ventilating

Digitized by Microsoft®

Naval Hygiene.

capacity of power sufficient to do the work which it is intended to do. The air quantum needed depends upon the amount of atmospheric vitiation that may be expected to occur in the place to be ventilated. Thus, the changes that occur in a given www.libtool.com.cn single act of respiration may be seen in the following table:

TABLE V.

	Contains in Volume per Cent.	
	Dry air.	Expired air.
Oxygen	20.96	16.03
Nitrogen	79.02	79.02
Carbon dioxide	.03	4.38

According to this table, the nitrogen of the air is the only one of its constituents that remains unchanged in quantity; oxygen is decreased about one-fifth and carbon dioxide has increased a hundredfold by the respiratory act. The following calculation will serve as an example of the method that is generally employed to determine the air quantum which the ventilating system must supply to a place in a given time, before our system can be pronounced satisfactory: Given an enclosure, hermetically sealed, of 40 cubic metres capacity, filled with fresh air, originally found to contain 0.5 part per 1,000 of carbon dioxide. Every cubic metre of this air contains, consequently, 0.5 litre of carbon dioxide. An average person confined in this space would produce 22.6 litres of carbon dioxide within one hour. This quantity, when added to that normally present in the above 40 cubic metres of air, would bring the total amount of CO_2 at the end of one hour up to 42.6 litres or 1.065 per thousand.

The maximum limit of CO_2 allowed by Pettenkofer for a good quality of air is 0.7 per 1,000, and this we see has been seriously surpassed. Roth and Lex have adopted 0.6 per 1,000 for their maximum limit, and Carnelly, Haldane, and Anderson want 1.0 per 1,000 adopted for dwellings. If we adopt for the sake of illustration the limit of Pettenkofer, and further assume that fresh outside air contains, on an average, never more than 0.5 per 1,000 or every litre 0.5 c.c. of CO_2, then every litre of air may take up 0.2 c.c. of CO_2 before the normal carbon dioxide maximum limit is exceeded. Consequently, we need 113 litres or 113×0.2 c.c. = 22.6 of CO_2; we need 113 cubic metres (3,991 cubic feet) of fresh air in one hour and for an average person, in order to keep the air of a place within respirable limits. Notter quotes Roth and Lex as estimating the amount of CO_2 produced by an average person per hour at 20 litres and the hourly quantity of air required at 100 cubic metres. If we state this quantity of air, with Notter, as 3,600 cubic feet per hour, it is just one cubic foot per second.

It will be seen that we can vary our calculations considerably either by extending our maximum limit of CO_2 or by starting with an air of a higher standard of purity to begin with. If, for instance, we would ventilate our test enclosure with an air that contained only 0.3 of CO_2 per 1,000, we would require only 56.5 cubic metres to take up the above 22.6 litres of CO_2 exhaled by an average person in one hour.

The needed air quantum is generally calculated according to the following simple rule of three: (1) $n : 1 = k : (p-q)$; (2) $n = \frac{k}{p-q}$; (3) $n = \frac{22.6}{0.7-0.5} = 113$ cubic metres; (4) $n = \frac{22.6}{1.0-0.5} = 45.2$ cubic metres (Märcke and Schultze, by Kirchner). Table VI. shows how the amounts vary within the limits of purity demanded.

Some of the medical officers of the French navy appear to be keenly aware of the needs of their service from a hygienic point of view. Thus, Rochard and Bodet, in their excellent work on "Naval Hygiene" (p. 113) make a strong and timely appeal for the introduction of more scientific methods in the investigation of naval sanitary

TABLE VI.

Maximum limit CO_2 allowed per 1,000.	Air Required per Man and per Hour.

problems, an appeal which United States naval medical officers might take seriously to heart, very much to their advantage. They say: "Nous demandons instamment qu'on munisse les médecins-majors de tous les bâtiments de guerre d'un anémomètre de Cassella," etc., and they deplore the departmental penury in not providing naval surgeons with the instruments necessary for better research work.

For the determination of the air quantum they propose to employ what they have termed the "coefficient of ventilation." In this, the hour is taken as the unit of time. Any air space, no matter what its cubic capacity, in which the air is renewed once in an hour, has a coefficient of 1. Where the air is renewed twice in an hour, that enclosure has a ventilating coefficient of 2. Wherever it takes two hours, that place has a coefficient of $\frac{1}{2}$ etc. The coefficient is expressed by the fraction $\frac{R}{H}$ in which R represents the number of times the air is renewed and H is the time required to do it in. According to this plan, the facts in ventilation could be intelligently recorded. Thus, for instance, 5 cubic metres (176 cubic feet) is the average air space allotted to one man in the French navy. This space is so small that the air in it would have to be renewed 22.6 times, *i.e.*, it would have to receive a coefficient of $\frac{22.6}{1}$ in order to bring the air quantum up to that required by our average adult in the preceding example, which was 113 cubic metres.

But almost every work on ventilation tells us that the air in any enclosure cannot be renewed more than three and at most five times, lest there be danger from draught. If we allow the French sailor to breathe into his allotted air space of 5 cubic metres for one hour, assuming that the air originally contained 0.5 CO_2 per 1,000, then that air would contain 5 CO_2 per 1,000 at the end of the first hour. If we allow the air to be renewed three times, or employ a coefficient of $\frac{3}{1}$, it would contain 2 parts CO_2 per 1,000; with a coefficient of $\frac{5}{1}$, it would reach only 1.1 CO_2 per 1,000.

A sailor on active duty generally turns into his hammock at 9 P.M. and is called at 5 A.M., when not called out for a watch before. He would sleep for eight continuous hours in a space the air of which, at the end of that time, would scarcely keep a candle burning, even under a coefficient of $\frac{5}{1}$. It is difficult to imagine that he would wake up again, as we all know he does, unless actually supplied with more air than our calculation allows him. Can any one doubt that, in practice, he somehow gets much more air, draught or no draught, than our theory allows him to get? There are ships in the United States navy, and training ships at that, in which the average air space per man is only two-thirds that allowed in the French navy, which apparently shows much more strongly than does the above instance, that more air *must* get into living spaces than even a coefficient of $\frac{5}{1}$ could put there.

The more the question is studied and the better we are becoming acquainted with the facts, the more it is found that the rules that have been worked out to govern the ventilation of houses and buildings on land do not and cannot be made to apply to ships without considerable modification. We shall have to break with fixed standards as regards the number of times we are allowed to renew the air in enclosures and part company with dangers from draughts, when going to sea in ships.

The coefficient of Rochard and Bodet may be said to

Naval Hygiene.

be a simple, convenient, and accurate means of recording the ventilation of an air space. It might with great advantage be used in company with the "air cube." The air cube is expressed by the fraction $\frac{1}{M}$. 1 stands for cubic space, M for the number of men in it. Thus a space of 100 cubic metres capacity with four men in it, has an air cube of 25 cubic metres.

www.libtool.com.cn

Testing the Sufficiency of a Ventilating System.—This is done (1) by determining the cubic capacity of the living spaces with the air quantum supplied to each in a given time, and (2) by examining the air both chemically and bacteriologically. For the measurement of the cubic capacity of ships' spaces, the three simple rules given by MacDonald are still sufficiently accurate and answer all the purposes of the sanitarian: (1) Take the largest measurements of length, breadth, and height that the space will admit of, for the determination of the main cubic capacity. (2) Take the cubic capacity of all irregular spaces and recesses in communication with the principal space, and add their sum to the latter. (3) Take the measurements of all obstructive bodies and projections and of everything that impinges upon the available air space and subtract the sum from the gross capacity already obtained. Since it will greatly facilitate calculation to take down the measurement in feet and tenths of feet rather than in feet and inches, the following table may prove useful:

TABLE VII.

Inches.	1	2	3	4	5	6	7	8	9	10	11	12
Decimals of a foot........	0.08	0.17	0.25	0.33	0.41	0.5	0.58	0.67	0.75	0.83	0.92	1

A few simple rules will satisfy the requirements of the sanitarian. For example, the area of the segment of a circle equals two-thirds of the product of the chord and height, plus the square of the height divided by twice the chord $(Ch \times H \times \frac{2}{3}) + \left(\frac{H^2}{2Ch}\right)$.

The area of the triangle equals the base multiplied by one-half the height. The circumference of a circle equals $D \times 3.1416$. To ascertain the area of an ellipse, multiply the product of the two diameters by 0.7854. The cubic capacity of a cylinder equals area of base multiplied by height.

The total number of cubic feet, with additions and deductions made, must now be divided by the number of berths or hammock swings in the different crew spaces and the result is the cubic space per head or air cube.

The total air quantum that passes through a space can be determined only by means of an anemometer and the area of the ventilating trunks. The velocity of an air current in metres per second is ascertained in accordance with the formula $v = a + b\frac{n}{z}$ where a and b are constant; a refers to internal friction and b to vane inclination; n is the number of turns and z the duration of the observation in seconds. The air volume is then calculated by the formula: $L = f.\ v.\ 3{,}600$, where f is the area of the intake in square metres. For example: The hands of the anemometer stand at the beginning of the observation at 3,420, and after operating $z = 120$ seconds, the reading of the hands indicates 3,900. The instrument had made $n = 480$ turns. The constants are $a = 0.18$ and $b = 0.14$, and thus we get $v = 0.18 + \underbrace{0.14\frac{480}{120}}_{0.56} = 0.74$.

The measurements of the inlet area gave 0.26×0.38 m. or $f = 0.0988$, consequently the pipes propelled $L = 0.0988$, 0.74, $3{,}600 = 263.2$ cubic metres of air per hour.

Pressure differences existing between different compartments of a ship are ascertained by differential manometers; these serve chiefly to indicate inequalities of ventilating power in different compartments with relation to each other and to determine the direction of the air currents existing between adjoining compartments from one with more into the one with less pressure.

An ingenious method for determining the amounts of air discharge which occurs in an enclosure—a method which can be applied to ships—was devised by Pettenkofer. After closing all openings into a room, he generates CO_2 by burning stearin candles. The candles furnish a definite amount of CO_2 per hour and the CO_2 of the air is also known. When the power of the ventilating system is to be ascertained, the blowers are started and the air from the centre of the enclosure is examined at intervals for CO_2. The rate at which the CO_2 disappears gives testimony of the efficiency of the ventilating capacity of the system under investigation.

Carbonic-acid examinations by any one of the above-described methods will complete the test of the ventilating sufficiency. Bacteriological examinations of the air of ships have not yet been made to my knowledge. The difficulties of preserving or making culture fluids are alone to blame for this serious omission. Special research work has, however, shown that the number of germs in a cubic metre of air decreases at sea in direct proportion to the distance from land, until, in midocean, the air is found absolutely sterile but a few feet above the upper deck of a ship. Fischer (*Zeitschrift f. Hygiene*, Bd. 1, 1886, p. 421), in examining sea air, found one germ in 44 litres of air; at a distance of one hundred and twenty miles from the coast, it was found to be sterile.

Ventilation of Different Types of Vessels.

1. *Battleships "Kearsarge" and "Kentucky"* (see Plate XLVI. and description of figures).—Most excellent examples of ventilation on the plenum principle are furnished by these two battleships of recent construction. They are practically sister ships and the ventilating system is the same in both. The *Kearsarge* and *Kentucky* are the best ventilated ships in the United States navy (see Plate XLVI.).

The United States Steamship *Kearsarge* is a twin-screw armored sea-going battleship with a displacement of 11,526 tons; she was built at Newport News, Va., and was first commissioned on February 20th, 1900. She has an upper deck, main deck, berth deck, splinter deck, protective deck, holds, and double bottoms. There are in all ten fifty-inch electrically driven fans, of twelve horse power each, and giving each a speed of 500 revolutions per minute with an output of 160 volts. Every fan forms an independent supply system for a certain part of the vessel and is located as near as practicable to that part of the vessel which it is intended to supply with air. All the air is drawn from above the spar deck and propelled down below the main deck; from thence it is driven through a system of branches into the various compartments into which these are made to open through numerous small outlets, provided with adjustable cowls or terminal trumpets that can be turned in any desired direction or closed at will by shutters.

The ten supply systems are distributed about as follows: (1) Two systems, supplying all the forward compartments of the vessel, have the blowers located symmetrically on each side of the centre line of the vessel in the blower room, on the splinter deck, and underneath the conning tower. (2) Two systems, supplying the dynamo-rooms and ammunition passages on splinter deck, with blowers symmetrically located on each side of centre line of vessel, on berth deck over dynamo-room; they receive their fresh air through two ventilators, situated between the smokestacks and outboard of the two ventilators supplying the berth deck. (3) Two systems supplying compartments in midship portion of splinter deck, including passages, also upper and lower dynamo-rooms; blowers symmetrically located on each side of centre line of vessel, in upper dynamo-room; they take the air through two ventilators situated between the smokestacks and inboard of the ventilators that supply

Digitized by Microsoft®

the dynamo-room. (4) Two systems supplying the engine-rooms; blowers located in the engine-room hatch on main deck and taking their fresh-air supply through two ventilators abaft the after-smokestack, and in the engine-room hatch. (5) Two systems, supplying all the after-compartments of the vessel; blowers symmetrically located on each www.libtool.com.cn blower-rooms on spar deck abaft the main mast.

The fresh air supplied in this manner, after doing its ventilating work, finds its way out of the ship through the various hatches and the exhaust-leads of the smokestack. There are besides some special exhaust blowers of three horse power each for the steering engine-room, officers' water-closets and lavatories, crew's and petty officers' lavatories and closets. The large vertical exhaust-trunks from the fire- and engine-rooms are made to extend high above the upper deck in order to increase their draught and so as to prevent the escape of hot and foul air from these compartments into the living spaces.

The eight firerooms are supplied with air for forced-draught purposes. There are eight steam-fans located underneath the firerooms' ventilating trunks, each fan supplied with air by means of a separate smaller trunk, coming from above the upper deck, and fitted with a portable cowl. When forced draught is being used in any fireroom, that fireroom is kept closed and all the air that is forced in finds its way out through the furnaces and thus goes up the smokestack. Incidentally, of course, this forced draught furnishes fresh air to the firemen, stokers, engineers and others who may happen to be in the fireroom. When the forced draught fans are not running, the same ducts furnish fresh air, by natural means, such as temperature differences, to the men in the fireroom.

No fans or other artificial means are provided for forcing air into the coal bunkers. The free admission of air into these is effected by separate inlets; while the outlets are connected with the exhaust leads of the smokestack system. With regard to the working efficiency of this system on the U. S. S. *Kearsarge*, Medical Inspector J. C. Boyd, in his annual report to the Surgeon-General, 1901, says: "The total volume of air that is brought into the ship per minute has never been accurately determined, but estimating the probable capacity of the blowers, based upon the cubic feet of air per minute that can be delivered for each horse-power, it will be readily seen that the air throughout the ship can be changed within a few minutes. The cubic capacity of the ward-room is 5,376 feet, and it has been found that the air is changed 15.6 times per hour, or every 3.8 minutes."

2. *Battleship "Illinois."*—The ventilation of the *Illinois*, like that of the *Kearsarge* and *Kentucky*, has the power on the supply side of the system, and is, therefore, effected on the plenum principle. The following description is from a few notes taken during her speed trial and will only give the leading points: There are, on the *Illinois*, eight large square air shafts, serving as inlets and taking the fresh air from above the upper deck. Four of these inlets are distributed about the forward side of the forward turret of the ship and four of them are distributed similarly about the after-turret of the ship. Of the four forward ventilating shafts, two supply the dynamo-rooms and two supply the quarters, storerooms, and magazines below the protective deck, as also those of the compartments above this deck which are located forward of the diagonal armor. The four after-ventilating shafts supply the staterooms above the protective deck and the storerooms and magazines which are below this deck. They also supply those compartments of the ship above the protective deck which are included between the diagonal armor and the sides of the after-part of the ship. All the fans are driven by steam except the two that supply the dynamo-rooms; these are driven by electricity.

The discharge of foul air is effected: (1) through two large shafts, leading from the engine-rooms high above the spar deck; (2) through gratings in both the protective and the splinter decks, and (3) through the military mast which has the outlet immediately beneath the first gun platform. The exhaust side of the system has no fans and does not seem to need any.

The mid-ship section of the *Illinois*, which includes the engine- and firerooms, is supplied with four large supply shafts on each side of the centre line. The air is taken from above the spar deck and driven by strong steam fans through the fire- and engine-room spaces. Foul air escapes through hatches and gratings as well as through the fires and smokestack.

The steam steering-room is ventilated on the combined plan, having driving fans on both the supply and exhaust sides of the system, while the W.C.'s have the power on the exhaust side only. To judge by the smell that hovered about these, they did not seem to be sufficiently ventilated. Besides the above, there are two separate shafts, also provided with steam fans, which supply all the quarters located above the protective deck and between the diagonal armor and the sides of the ship.

The maximum temperature observed in the fireroom during the entire trip was 110 F. The adjoining table shows temperature in the engine-room:

TABLE VIII.—TEMPERATURES, DEGREES FAHRENHEIT.

	Engine-room, port.			Upper grating, starboard.		
Forward	121	122	122	114	116	116
Outboard	116	120	118	118	119	120
Inboard	116	116	115	109	110	111
Aft	114	118	119	106	106	108
Average	114	119	119	112	113	114

All temperatures were taken at 11, 12, and 1.

3. *The French Battleship "Hoche."*—This ship deserves special mention in connection with the subject of ventilation, because it presents a novelty in not showing a single windsail above the upper deck. All the air is taken into the ship through eight hatchways, extending from the upper deck down to the protective deck. The system has the great advantage of allowing the air to pass between decks before reaching the lowest compartments, much to the advantage of these compartments between decks during the night. The eight large hatchways of the *Hoche* on the upper deck have an areating surface of 42 square metres (see Fig. 3505); to this must be added the openings of the smoke boxes, and those of the ammunition hoists of the four turrets, which may in reality be regarded as hatchways. The access of air down to the protective deck is assured in sufficient quantity by three large hatchways, arranged like air pits between the upper and the protective decks.

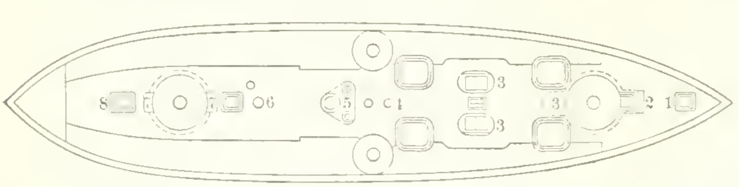

FIG. 3505.—Shows the Plan of the Upper Deck of the *Hoche* with its Eight Hatches, Marked by Treble Lines. Four small ones are in the centre line of the deck, and the four large ones (engine-room hatches) are arranged symmetrically by twos on each side of the centre line of the deck. (From Rochard et Bodet.)

There are in all twelve large inlets (see Fig. 3506), each section of the ship having its own; the last three sections alone are ventilated by a common hatchway. This last one is very large, because the spaces which it is intended to ventilate are the steering engine-room, that of the pumping engine, etc. The various firerooms

Digitized by Microsoft®

Naval Hygiene.

have their own inlets, each opening being 7 metres square.

The fortunate position of the exits (see Fig. 3507) for vitiated air permits the inlets in the protective deck to have their full effect. The fourteen sections into which the vessel is divided are not, however, equally well cared for in this respect. The three forward sections being for the most part storerooms, are merely aerated by one circular opening, which serves both as a supply and an exhaust at the same time. The last two sections, which include the steering engine-room, have likewise but one hatchway. Everywhere else, a large number of conduits is arranged so as to take the hot air out from the compartments below the protective deck and conduct it above the spar deck. These are (1) the military mast system, which exhausts the forward turret, the section for the wounded, and the forward pumping engine-room; (2) the chimney mantle system, which exhausts the four firerooms; (3) the protective casing of the conning tower, through which escapes a portion of the air from a space between the engine-room and the fireroom; (4) the great central shaft, divided into several smaller trunks, lets out (*a*) the hot air from the engines, the exhaustion of which is effected by a fan through a perforated deck ceiling; (*b*) the air of the midship pumping engine-room, steam pipes, store- and ammunition-rooms; (5) an isolated conduit for the after ammunition-room; and (6) the after military mast, through which escapes the air from the after pumping engine-room and ammunition storeroom. It is interesting to note that the exhaust pipes are placed inboard of the supply shafts.

www.libtool.com.cn

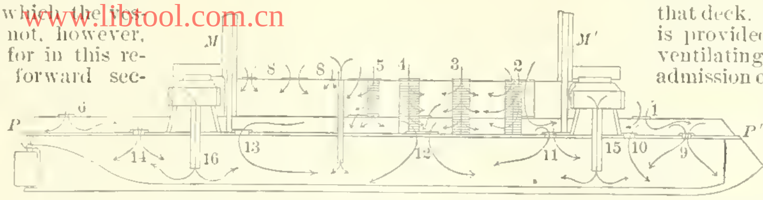

FIG. 3506.—Shows all the Supply Shafts of the *Hoche*, Especially the Three Great Superimposed Hatchways Extending from the Upper Clear Down through the Main Deck to the Protective Deck. (From Rochard et Bodet.)

3a. *H. M. SS. "Glatten" and "Devastation."*—According to MacDonald the plenum system of ventilation has been adopted without exception in Great Britain ever since the earlier seventies. Examples are H. M. SS. *Glatten* and *Devastation*. The *Glatten* has a rectangular supply shaft, five feet six inches by six feet four inches, beginning twelve feet above the upper deck and reaching down to the level of the main deck, just abaft the smokestack. At the bottom of this shaft there are four fans connected with two transverse trunks, the upper of which is sixteen by twelve, and the lower sixteen inches square. The fans, driven by steam, take the fresh air from the shaft and send it into the trunks, through which it is propelled by means of smaller pipes into every cabin and compartment of the ship, fore as well as aft, by goosenecked funicular ends that open a few inches from the floor of the deck. There are in the *Glatten* one hundred and thirty-three of these outlets. All the fans are provided with distinct sets of engines which work independently, but in the *Devastation* the arrangement is such that, in case one or two shafts get accidentally blocked or otherwise rendered useless, the third can be made to supply all the compartments whose ventilation would be thus interfered with.

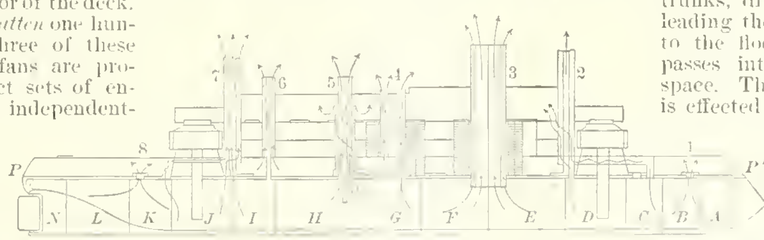

FIG. 3507.—Longitudinal Section of the *Hoche*, Showing all the Passages for the Evacuation of Foul Air, also the Independence of the Different Compartments from one another. (From Rochard et Bodet.)

The following table, IX., shows the relative number of supply and exhaust fans in some of H. M. ships; it clearly shows how even the combined system is gradually giving way to the plenum system of ventilation in the royal navy.

4. *The Austrian Coast Defence Vessels "Monarch," "Wien," and "Budapest."*—All these ships have a very large number of water-tight compartments, one hundred and forty-two of which are located beneath the protective deck and thirteen are above that deck. Each compartment is provided with its own two ventilating pipes, one for the admission of fresh air, the other for the discharge of foul air. The two pipes reach above the main deck and are themselves water-tight.

As a general rule, all efforts at ventilating water-tight compartments do in a measure endanger the purpose which these compartments are designed to serve. In all English vessels of this type the protective deck is left intact, while in French and in Austrian ships the bulk-heads are almost never perforated.

The engine-rooms on all these ships are ventilated on the plenum principle. The air is taken from above decks and pressed into horizontally arranged ventilating trunks, divided into branches leading the air down the sides to the floor deck, whence it passes into the engine-room space. The escape of foul air is effected through one large shaft, located amidships over the engine-room and provided with an electric exhaust fan with cowl on top.

The boiler-rooms are supplied with air through eight air shafts, four of which have fans, while the foul air escapes through the chimney, the hatch openings, and several special exhaust pipes. All the other compartments are ventilated through a large number of electrically driven fans which act on the plenum principle. The coal bunkers are

Digitized by Microsoft®

merely connected with the system of exhaust pipes which lead into the chimney casing and the military masts. The various cells for the confinement of prisoners are traversed by the ventilating pipes intended as supplies for the ammunition storerooms. The air escapes into the cells through s[illegible] pipes and leaves the cells through openings in the bulk-heads.

www.libtool.com.cn

The forward station for the wounded has one, the after station two fresh-air inlets with cowls, while the foul air escapes through separate outlets. Most of the officers' cabins are dependent for their air supply on perflation, and this must be considered an important flaw in the whole system. All three of the above-named vessels are also provided with steam ash ejectors, which contribute largely toward keeping the ship's air clear of finely divided particles of inorganic matter.

5. *U. S. Training Ship "Prairie."*—We will conclude the chapter on ventilation with a description of the *Prairie's* system of ventilation, giving at the same time the results of some investigations into the working efficiency of the latter. The present training-ship *Prairie* is the converted steamer *El Sol* of the Morgan Line Steamship Company. She has a length of 404 feet over all and a beam of 44 feet; she has a gross tonnage of 6,782 tons, and is provided with a single screw, driven by a vertical, inverted three-cylinder triple-expansion engine of the ordinary marine pattern for commercial use, built at the Cramps' shipyard in 1890, and last commissioned at the Boston navy yard on November 9th, 1901; she has a spar deck, a gun deck, and a berth deck with the usual holds and storerooms below.

Since the berth deck compartments are the only ones which have artificial ventilation, all her other compartments depending upon ventilation by perflation, the former will be the only ones included in the following description. The berth deck of the *Prairie* is divided by the large engine- and fireroom hatch into a forward and an after section of nearly equal dimensions, and between them there is no communication, the two iron bulkheads of the hatch reaching clear across from one side of the ship to the other.

The forward section of the berth deck is again divided by two cross bulkheads into three compartments with two communicating doors, symmetrically placed on each side of the two dividing bulkheads. The most forward of the three compartments is used for sick-quarters, the one next to this comprises the petty officers' quarters, and the third gives berthing space to a large number of men.

The after-section of the berth deck is likewise divided into three compartments, the most forward of which accommodates the dynamos, the next gives berthing space to the marine guard, and the last is for the chief petty officers.

There are three large square and three small oblong and rather narrow hatches in her decks, all superimposed and therefore well intended to send both light and air directly down into the deeper parts of the ship. The two electric fans of 110 volts each are both on the gun deck, just fore and abaft the fire- and engine-room hatches respectively. Each of the two large ventilating trunks, after passing through the gun deck, bifurcates, and the two branch trunks with their inlets run along the sides of the various compartments which they traverse, at a height above the berth-deck flooring of six or seven feet.

The two tables, showing the results of the anemometrical observations, are intended to exhibit at the same time in a diagrammatic manner the relative position of the different compartments, their cubic capacity, the number of inlets, and also the relative distance of the inlets from the fans or blowers. As may be seen in the columns of "cubic feet exhausted per hour," the amounts of air taken up by the different inlets decrease very rapidly and directly with their distance from the blowers. Inasmuch as the observations on the inlets and outlets rarely agree exactly, the largest figure is always taken as indicating the true value of the amount of work done by the fans.

TABLE X.—ANEMOMETRICAL OBSERVATIONS ON THE VENTILATION OF THE BERTH-DECK COMPARTMENT, MADE ON U. S. S. *Prairie*, AT SEA, ON JANUARY 5TH BETWEEN THE HOURS OF 1 AND 3 A.M. NUMBER OF INLETS TWENTY-SIX, WITH AN AVERAGE SQUARE AREA OF 0.1 FEET.

I. Forward of engine- and firerooms; average difference in number of turns of anemometer between the inlets is eighty-five per minute.

Number inlets, port.	Cubic feet exhausted per hour.	Bow.	Cubic feet exhausted per hour.	Number inlets, starboard.	Sum.
13	15,900	Sick-quarters, cubic air space, 4,700 feet, exhausted 22 times per hour; available air per head and per hour, 5,370 cubic feet.	15,900	13	
12	17,880		17,880	12	
11	19,920		19,920	11	107,400

The after berth-deck compartments of the *Prairie*, by reason of their relatively smaller cubic capacity, are much better ventilated than the forward compartments, both fans doing about the same amount of ventilating work. The blowers are run at night only.

The tests for the amount of atmospheric carbon dioxide, exhibited in Tables XI. and XII., were made according to the method of Fitz, as modified by Woodman and Richards and described in the preceding pages. In making these examinations, it was the intention to get, as nearly as that was possible under the circumstances, a true and absolutely fair estimate of the amount of carbon dioxide present in the atmosphere of the different parts of the ship. None of the dark places in which the air naturally stagnates, such as storerooms and holds, and where the carbon dioxide was found up to 22 to 40 parts in 10,000, were included in these observations. The tests shown in

the tables represent the compartments that are included in the general circulation of the area ventilated by the blowers. The results show what the carbon-dioxide content of the ship's atmosphere available for breathing purposes may be expected to be, when the ship is at sea and is sailing under the *most favorable* conditions of weather and climate. The influence of hatches, whether open or closed, of gunports, of the direction of the winds and of the blowers upon the carbonic-acid content, may be seen in the tables and studied in connection with the column of remarks.

As the blowers operate on the vacuum principle, it must, of course, be expected that the air, when it reaches the breather, is at its worst. The differences between the night and day averages in series I. were rather large, as compared with those shown in series II. The colder climate at Hampton Roads made it necessary for the comfort of the men sleeping below to keep the hatches covered and the ports closed. Under such conditions the vacuum system of ventilation shows its weak points. The fans arranged in accordance with the plenum principle would easily remedy these defects and convert a very faulty system of ventilation into an efficient one.

In concluding the chapter on ventilation we would emphasize two leading and important factors influencing a ship's ventilation, namely: (1) The plenum system of ventilation for ship's purposes is unqualifiedly recommended. (2) That the high atmospheric temperatures and humidities prevailing in warm climates, together with the prominent part played by physical heat regulation on the part of the men, make it possible that the air in ships may be renewed from fifteen to twenty times per hour, without danger from draughts.

II. WATER.

Every living organism, every single microscopic cell of this organism, has its normal amount of water under which alone it can perform its proper function, and the slightest departure from this normal percentage amount of water peculiar to its composition begins to initiate the series of changes that can have but one ending, namely, the death of the organism. The human body has in its composition sixty-five per cent. of water, of which it loses 2,500 gm. daily. As it receives from 500 to 800 gm. in the food, the remaining loss must be made good by drink. In experimental animals death inevitably ensues whenever the loss of water amounts to from twenty to twenty-five per cent. Those of us who live in temperate climates, in which water is found everywhere in sufficient quantity to supply our daily needs, hardly ever think of the possibility of dying of thirst; but those who live in the tropics know well how pressing and dangerous thirst can become as compared to hunger. As a means of personal cleanliness, it has become well recognized that it is economy to be lavish with the water supply, especially among soldiers and sailors, who must be so trained that cleanliness of person becomes to them a necessity and a habit.

With regard to the water-supply of ships, the last fifty years have brought about great changes. The general introduction of steam has made not only the voyages shorter, but it has been the means of making ships almost entirely independent of the shore as regards their water-supply. In times of wooden ships and long passages across the seas under sail alone, the water question was one of most serious concern to all seafaring men. Besides this, the generally prevalent lack of knowledge at that time of the importance of cleanliness in collecting, storing, and distributing the water on board ship was the cause of untold misery and long suffering, due to poor water and to the separation from a base of supply. The water was carelessly collected and then stored in tanks or barrels down in the dark holds of the ship. Often neither the water nor the barrels were examined, and consequently they left much to be desired as regards cleanliness. After a time the water began to emit a disagreeable odor, the essence of which was sulphureted hydrogen. This gas was produced by the decomposition of the sulphates in the water. In the course of time this gas was reoxidized and the disagreeable odor disappeared. This periodical reduction of the sulphates and oxidation of sulphureted hydrogen recurred several times during a voyage, and it was a common saying among sailors that the water had to putrefy three times before it became potable.

It certainly was true that the water did cease fermenting after a time, and consequently it was often better at the end of a voyage than at the beginning. We now are perfectly well acquainted with the causes of this fermentation and make use of this very property of water to purify it before filtration. It is the septic-tank method which has been found so effective in removing a large percentage amount of germs and fermentable organic matter, and which makes subsequent sand filtration so much more effective in producing a pure and potable water than it would be without it.

Although most of the naval vessels are supplied with distillers for the production of drinking-water from sea-water, it cannot be said that all ships of the navy are absolutely independent of water supplies from natural

Digitized by Microsoft®

sources on shore. Circumstances arise on every naval vessel, and arise often, under which the water tanks are filled with water coming from shore. Naval sanitarians can, therefore, not yet afford entirely to disregard the hygiene of water supplies as found in nature.

The question of the water supply to naval vessels would, accordingwww.libtool.com.cn the supply from natural sources, and (2) the supply through distillation from sea water.

1. Supply from Nature's Reservoirs. (*a*) *Rain Water.*—The quantity of water which a cubic kilometre of air is able to take up, when saturated at a temperature of 15° C. (60° F.), is no less than 15,990,000 litres. In the tropics the atmosphere covering a square mile of surface, at a temperature of 30° C. (85° F.), takes up two and a half millions of cubic metres of water. This water is driven by the wind to the different parts of the world, and returns to the earth in the form of rain, snow, or hail. The water, when it evaporates, is pure, but when it returns to the earth in the form of meteoric water it shows various forms of contamination, having absorbed not only the gases of the air, but carrying down also more substantial impurities with it. It is easily seen that rain water must differ in character with the quality of the atmosphere through which it falls; it must differ with the season of the year, and whether it falls in town or country. As rain purifies the air by taking down dust and smoke, it must become purer the later it is collected.

Of the water which is thus returned to the earth by precipitation, a small portion evaporates again immediately; the greater portion sinks to certain depths from the surface, becoming what is known as surface water; while still another portion runs off into rivers, brooks, and lakes, and the rest returns by way of the rivers and streams to the great sea whence it came.

In its passage through the atmosphere, it takes up, in the first place, a certain volume of air. The oxygen of the air being more easily soluble in water than is nitrogen, the air dissolved in water is richer in oxygen than the atmospheric air. Besides oxygen, rain water absorbs carbon dioxide, ammonia, and nitric acid. The farther above the surface of the earth rain water is collected, the more nitric acid it contains; and the nearer to the earth's surface it is collected, the more ammonia is found in it. The reason for this is that the ammonia emanating from the soil is gradually oxidized into nitric acid as it rises into the higher regions of the atmosphere. Thus 1 litre of water contains: Ammonia at 7 metres, 5.94 mgm.; at 47 metres, 2 mgm. Nitric acid at 7 metres, 5.68 mgm.; at 47 metres 7.36 mgm. Rain water contains from seven thousand to twenty thousand bacteria in 1 c.c., which explains why it undergoes rapid fermentation on standing. Bujwid, who examined a hailstone 6 cm. long and 3 cm. thick, found twenty-one thousand bacteria in 1 c.c. of melted ice. Fontin, at St. Petersburg, discovered in a hailstone a coccus that proved pathogenic to mice.

Schmeich, in examining some ice from high mountains, in high latitudes, where organic life is not abundant, found but two microbes in a cubic centimetre of ice from Iostedlasbrü in Norway. Rain water is a soft water and very good for washing purposes; when used for drinking purposes, the first portions of it should always be rejected.

(*b*) *Surface Water.*—The term surface water is applied to the water contained in rivers, brooks, and ponds, into which the earth's surface is drained, especially after heavy rains. The composition of such water is influenced by local conditions, depending partly on the geological formation of the place, partly upon the character and amount of sewage washed into it and furnished by the towns in the vicinity. Epidemics of typhoid and cholera, traceable to infected river water, continue to recur with frequency, and these would be still more frequent than they are, were it not for the self-purification of river water and the nitrifying action of a certain class of saprophytic water bacteria. Such water, therefore, needs a thorough chemical and bacteriological examination before being taken on board, unless it comes from a place where sand filtration is used, and where all sewage is thus filtered before it is allowed to pass into the river, brook, or lake.

(*c*) *Ground Water.*—That portion of rain water which neither evaporates immediately nor flows off into rivers and brooks, but which gradually drizzles down into the deeper layers of the soil, until it strikes an impermeable layer of clay, upon which it accumulates, is known as ground water. As such it may feed a neighboring well or find its way to the surface again in the form of a spring. Borings often reveal the existence of several such subsoil lakes superimposed. The water, while drizzling through the permeable layers, gives up suspended matters, but takes up soluble ones instead, and hence its composition is essentially different from that of either rain or surface water. All those particulate impurities which rain water washes down from the atmosphere it loses in the uppermost layers of the permeable soil and before it becomes ground water; the organic matters are destroyed by oxidation, furnishing carbonic and nitric acids. Ground water, when obtained at a depth of 20 metres below the surface and well protected, has an agreeable taste and should possess a temperature representing the mean annual temperature of the place, which temperature is accepted as the most favorable temperature which a good drinking-water should possess. All the superfluous ground water finally flows off into subterranean rivers and lakes, which in turn are drained into the all-engulfing sea to start on a new round in its circulation. Such water is probably the best that can be obtained from natural sources.

In the royal navy of England and in the navy of the United States, the rule is that no water is to be taken or used on board until it has been examined and passed by the surgeon. In home ports, the water is either directly pumped on board from the city mains or it comes alongside the ship in a water boat. The latter method is usually bad and the water is often found contaminated, owing to leaky bottoms and leaky decks. No wooden water barge should be allowed to bring drinking-water on board a ship. In many foreign ports, recourse is had to fetching the water from shore by clearing the ship's boats of all removable gear and then filling them with water directly from the main; finally towing the boats back to the ship and pumping the water on board. All these methods are objectionable, because no boat is absolutely water-tight and sea water is bound to leak into it.

A time may come when it becomes necessary to take a battalion of men on shore and quarter them in a town for some time. Under such circumstances experience has shown the following rules to be worthy of adoption: (1) Let the men take their water from the same places from which the inhabitants draw theirs; these places should be plotted down by the officers arranging for quarters for the men. In case the water supply of the town is not free from suspicion, avoid taking water from wells in sloping streets and from those which are located in the neighborhood of poor dwellings, factories, dungheaps, and avoid likewise, if you can, water flowing through the town; take it, if possible, from a point above the town. (2) Make provision against the contamination of the town water by the men themselves, who should be instructed in how best to avoid dangers from such a cause. (3) Mark the good wells from the bad ones. (4) Wells that have been out of use for some time must first be pumped out before they can be used again. (5) Contaminated wells must be placed under guard. (6) The too frequent and too copious use of a well is to be avoided because large draughts would cause a too rapid flow of the neighboring ground water in the direction of the well, through the subsoil, which might seriously interfere with the filtering capacity of such a soil, resulting in drawing impurities in with it. (7) In the case of wells, small rivers, and brooks, dams can be built in several places, of which the highest may be used for drinking purposes for the men, the lower for the animals and for cleansing purposes. (8) In case of rivers and shallow lakes, small bridges and waterways

Digitized by Microsoft®

Naval Hygiene.

should be constructed so as to enable the men to get their water farther away from the shore and prevent them from stirring up the sediment at the bottom, which may harbor pathogenic germs. (9) In case the water has been rendered turbid by heavy rains, small wells may be sunk near the river and the filtering action of the soil or sand be taken advantage of, which should be protected and covered over by boards. (10) If the soil permits, tubular wells may be bored.

www.fbtool.com.cn

In France, Pasteur filters have been most generally introduced into all barracks. The water runs through these filters under a pressure of 10 metres, and, in places where this pressure cannot be obtained by natural means, it is produced by artificial means.

The great danger to troops is, as we all know, typhoid fever. No army seems to escape a certain amount of it. The typhoid bacillus respects neither race nor climate and is practically ubiquitous. Extensive experiments are now under way in England and other parts of Europe on the subject of the possible chances of vaccinating soldiers against typhoid, cholera, plague, and other diseases. The mortality from typhoid among the English troops in South Africa has been so great as to induce some of the best English bacteriologists to engage in serious experimentation in that direction.

For the purpose of sterilizing a suspected water in the field, in the absence of means for boiling large quantities of it, the method of Schumburg is the best. He uses bromine to render the water germ-free and removes the bromine afterward by the addition of ammonia. The apparatus comes conveniently packed in a box with the chemicals ready for use, and in quantities weighed out so as to sterilize any given amount of water in five minutes.

2. Supply Through Distillation from Sea Water.—If rivers, brooks, and lakes are the drainage basins into which flows the surface water of certain small circumscribed geographical areas, the great oceans may be said to receive the combined drainage of all the continents of the globe. From a chemical viewpoint, perhaps one of the principal differences between ground water and sea water is found in the large percentage of salts that are contained in the latter. These salts perform an important function which it is well to keep in mind. They assist in the penetration of solar heat, which otherwise would act on the surface only; salts also retard evaporation. Sea water teems with living organisms which, but for the preserving action of the brine, would die, and the products of their decomposition would render a life at sea practically unbearable if not altogether impossible. The salts in sea water also are the efficient causes of some of its circulating currents. Those, for instance, from the Mediterranean into the Atlantic, according to Maury, owe their main strength to this agency. The freezing point of sea water is put down as 27.2° F. The specific gravities, according to location, are as follows: (1) North Atlantic, 1.02676; (2) South Atlantic, 1.02664; (3) North Pacific, 1.02658; (4) South Pacific, 1.02548.

The temperature of the sea water is higher than that of the ground water of the same region. It varies, of course, with the latitude and the depth, and is greatly influenced by the circulation of the various currents coming from different localities. The Atlantic is the coldest, the Indian Ocean the warmest.

Table XIII.

	Total solids.	Organic carbon.	Organic nitrogen.	Ammonia.	Nitrogen as nitrites and nitrates.	Total combined nitrogen.	Chlorine.	Hardness. Total.	Hardness. Fixed.
Hastings, two miles from shore	3.955	0.291	0.135	0.005	0.013	0.152	2.050	698	646
Gulf of Paria	....	....	....	.003	.027	....	1.350	580	

The composition of sea water has been found to vary somewhat in different places and at different depths. In the vicinity of the poles, the percentage amount of salts is somewhat less than at the equator, while in certain parts of the Mediterranean more salt is found than in the great oceans. The average composition of sea water is given in the preceding table from Notter, to which has been added an incomplete and partial analysis made of the water in the Gulf of Paria.

According to Hales, it was Jean Antoine Gadesden who, as early as 1516, proposed distillation as a means of rendering sea water potable, and in 1560 Sebastien de la Pallière, of Sicily, proposed to the Duke of Moedina Coeli, while the latter was besieged by the Turks, in a fortress in which the cisterns had run dry, to distil sea water. He succeeded in producing thirty-five barrels of potable water in twenty-four hours. In 1717 Gauthier made an unsuccessful attempt to introduce distillers on board ship. After him, Lind proposed to utilize the steam coming from cooking utensils and condense it by leading it through cold-water tanks. Three years later, Poissonier designed a distiller which was similar to that of Lind, but which again failed of adoption on account of its taking up too much room on board! Finally Irving designed a distiller for which he received a pension of £500 from the English Government. All this shows how much the necessity for an apparatus of this sort was felt. A rather long time, however, had yet to pass before distilling became as general and practicable as it is now. There is perhaps no seagoing man-of-war at the present day that is not provided with one or more of these distillers, of which there are a large number of patterns.

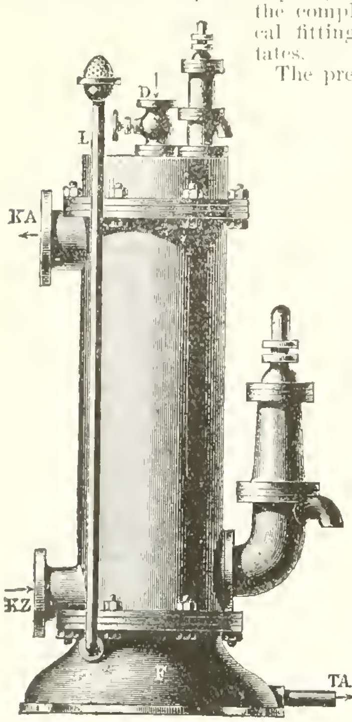
In the French navy the "Cousin," modified by Mouraille & Co., and the "Normandy," which latter has the evaporator and condenser united into one apparatus, are generally in use. A special refrigerator by Perroy and a condensor by Fraser are also in common use. In the English navy the "Normandy," "Kirkaldy and Caird," and "Raynor" are employed. In the Austrian navy the French distillers have been adopted. The United States Naval Standard Evaporator is made of several sizes, the largest of which possesses a productive capacity of ten thousand gallons of distilled water per diem. The general design is identical for all sizes. The apparatus consists of two parts, namely: (1) the evaporator and (2) the distiller, sometimes called the condenser. The evaporator consists in a hollow cylindrical shell, made of steel and placed horizontally. The lower half of this cylinder is partially or loosely occupied by tubes running lengthwise, and fixed in their position at either end to a pair of plates which permit of the tubes being removed for scaling in their entirety. The tubes are connected with the main boilers, from which steam is run into them generally at a pressure not exceeding forty pounds. The sea water intended for distillation fills that portion of the lower half of the cylinder which is outside the tubes, but not quite reaching the upper level of the highest tubes. It is indeed the intention that the tubes shall not be completely immersed in the salt water, the upper level of which is, on the contrary, maintained considerably below the top of the tubes. The customary pressure within the shell is about ten pounds. By the use of the valves, the density of the sea water is generally maintained at $\frac{1}{32}$. The tubes of the distiller are made of tinned copper or brass; the joints are soldered. Thus we see that the evaporation of the sea water is caused by the heat imparted to it through the steam in the pipes which the sea water surrounds. The steam itself does not mix with the sea water. The distiller or condenser is a cylinder, made of brass or iron in various sizes, placed vertically and fitted with straight tubes for circulating cooling water, which is made to enter at the bottom and discharge at the top. The steam to be condensed passes through the condenser in the inverse sense.

On vessels which are equipped with very large plants for distilling water, the apparatus is arranged differently from the above. The work of distilling is divided into two or three stages and the working efficiency of the plant is thereby correspondingly increased. Under this

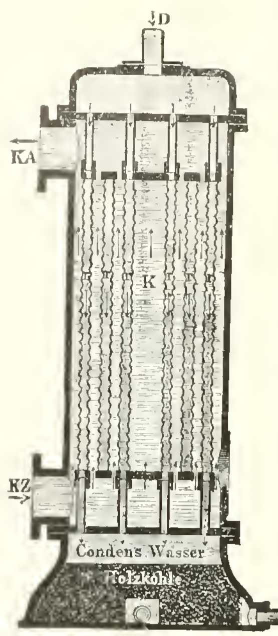
Digitized by Microsoft®

Naval Hygiene.

system, steam from the boilers is used to evaporate the water in the first set of evaporators; this evaporated steam is used to heat and evaporate the water contained in the second set of evaporators, and this in turn is made to evaporate the water contained in a third set. This last steam is finally condensed to water in a distiller of the above description. This system more than doubles the actual thermal efficiency of the distilling apparatus, but it is not installed except in very large ships, on account of the complications in mechanical fittings which it necessitates.



A.



B.

FIG. 3508.—(From Kirchner.) The Transatlantic liners of the North German Lloyd are equipped with distillers of the "Acme" patent. These were preferred on account of their combining great efficacy, small space and ease with which they can be handled and worked. The condenser is shown in the adjoining two figures A and B. The steam generated in an auxiliary boiler is made to enter, at D, into the condenser, which consists of a vertical cylinder, 110 cm. long and 36 cm. in diameter. The steam now passes into a number of tubes, made of thin copper r r, outside of which a constant and rapid stream of cold sea water passes from below upward, entering at KZ and leaving the cooler at KA. The distilled water, at the lower end of the condenser, enters a charcoal filter, F, where it is purified, and, at the same time, aërated by the air coming in through the tube L, with which it is here in communication. The water, both filtered and aërated, is finally collected at TA. The apparatus furnishes 18 cubic metres of good potable water in twenty-four hours. The warships of the imperial German navy are all equipped with distillers made on the same principle as those of the "Acme" patent.

The precautions usually observed are as follows: (1) The plant is operated only when pure sea water is obtainable. (2) For drinking-water, the plant is not operated to its full capacity, in order to reduce priming or carrying salt water directly over into the distillate. (3) Tests of the complete plant are made daily to insure tightness of all the joints. (4) The water level in the evaporators is kept low. (5) When the ship is under way and rolling heavily, the plant is worked at its lowest capacity. (6) The pressure of the cooling water in the distiller is limited by departmental order to thirty pounds, which is to minimize the danger of salt water leaking into the distillate. (7) Tests of the distillate are made every fifteen minutes.

The process of distillation, however, always involves an expense which sometimes may be considerably greater than the price at which good drinking-water can be bought on shore, and then it becomes the duty of commanders of vessels to secure such water when of good quality and whenever practicable. Besides, the process of distilling is not always faultless and the product occasionally needs looking into.

Water Distilled from Sea Water.—Although the water obtained from sea water by distillation may not be absolutely pure, it has nevertheless stood the test of many years' practical experience, and hence must be considered to be harmless. The mineral salts, contained in sea water, sodium and magnesium chloride, lime, alkalies, acids, bromine, iodine, etc., especially magnesium chloride, in decomposing during the process of distillation, vitiate the product to a certain degree. In order to obviate these objectionable features, Rubner ("Lehrbuch d. Hygiene") proposes the following preliminary treatment of salt water before distilling: The salt water is to be mixed with milk of lime in special tanks and kept, being constantly stirred up, for fifteen minutes; it is then heated up to a temperature of about 60° C. by steam. All organic matter is thus destroyed and coagulated. Magnesium chloride is decomposed by the lime and the magnesia is precipitated. After all has settled the water is siphoned off and distilled. This preliminary treatment, if it could be carried out practically, would no doubt result in a more uniform product of distillation; it would, however, necessitate a reconstruction of all the evaporators and condensers at present in use.

That sea water under the present system of distillation does not furnish a uniformly pure product may be seen from Table XIV., which represents an almost daily though partial analysis of such water, continued for nearly a month. Free ammonia was determined with Nessler's reagent; the nitrites were qualitatively determined with the sulphanilic acid and naphthylamine test; the nitrates with brucine and sulphuric acid; chlorine with a volumetric solution of silver nitrate, potassium chromate as indicator; hardness with standard soap solution; and the organic matter, represented in milligrams of oxygen, was determined by a standard solution of potassium permanganate. All these solutions were made on board ship and according to the methods given in Harrington's excellent manual of "Practical Hygiene." The analyses show that the water produced in our distillers always contains quite appreciable quantities of chlorine, lime, and magnesium salts (represented by hardness), and also organic matter; less frequently ammonia, and still less frequently nitrites and nitrates. All these, in the above quantities, must be considered harmless. With few exceptions the water was free from odor and perfectly colorless.

An important point, to which it is necessary to call attention in connection with the chemical composition of water distilled on board ship, is the hygienic significance of it. It will be seen at once that we must judge this from a standard entirely different from the one in accordance with which we would judge a surface or a ground water. Ammonia, nitrites, nitrates, as also chlorides, when found in a properly collected sample of river or well water, would justly arouse great suspicion, while the same chemical compounds in the water distilled from sea water arouse no such suspicion. These stand simply for a certain amount of nitrogen in different stages of oxidation and are otherwise perfectly harmless in the quantities in which they appear. No living organism, neither an animal nor a vegetable parasite, capable of producing disease could possibly survive such a process of distillation.

The following table is interesting from quite another point of view; it shows that, while a small quantity of organic matter is constantly present in the distillate, ammonia, nitrates, and nitrites are almost as constantly absent. This would indicate an almost absolute absence

Digitized by Microsoft®

Naval Hygiene.

of all oxidation during distillation. When, however, we consider that the salt water, from which our distillate is obtained, does not come directly from the sea, but has already been used as condense water and gone through the distiller in which it has been heated up to a high temperature, then this is easily explained. By the time such water arrives in the evaporator as feed water, all the air has been driven out.

The Storage and Distribution of Water on Board.—If, notwithstanding the fact that, as we have seen, no reasonable objections can be entertained from a sanitary point of view against the water distilled on board ship, complaints, and very pressing ones, are still often heard against the drinking-water supplied to officers and men, what are they due to? In almost every instance to unclean tanks and faulty pipe connections, as perhaps the following instance from my own experience will best serve to illustrate. It was not many days after our ship had been placed in commission and her officers and men had begun to live on board, that the presumably pure and distilled water was found absolutely non-potable and everybody refused to drink of it. The water was undoubtedly and indescribably bad. A sample of it was immediately collected from one of the spigots in the galley, under the usual precautions, and analyzed, with the following results:

November 26th, 1901, sample of water supposedly distilled:

1. *Color.*—Distinctly yellowish, very turbid, depositing on standing a brownish flocculent sediment.
2. *Odor.*—On being heated in a flask and shaken, a very perceptible, strong, musty odor is present.
3. *Residue.*—On evaporation grayish-white, turning black on being heated to redness.
4. *Free* as well as *albuminoid* ammonia present in large amounts, forming brownish precipitate.
5. *Nitrites.*—Positive reactions with the starch iodine test as well as with the sulphanilic acid and naphthylamine test.
6. *Chlorine.*—NaCl, 2.5 gm. per litre.
7. *Hardness.*—Equal to ninety parts of calcium chloride in ten thousand parts.
8. *Nitrates.*—Positive reaction with brucine.
9. *Lead.*—Grayish discoloration with hydrogen sulphide and acetic acid.
10. *Organic Matter.*—In abundance and not determined quantitatively.

Based upon the results of the above analysis, the probable source of contamination was put down as being dirty salt water from the harbor in which the ship was lying; also improperly cleaned tanks and pipes, as was made apparent by the water giving reactions for lead. When the result of this analysis and the inevitable conclusions it led to were communicated to the commanding officer, an immediate inspection of the entire water-supply system of the ship was made, and the source of the contamination quickly and decidedly traced to a very faulty system of pipe connection existing between the sweet and the salt water reservoirs on board. Owing to this connection, it was impossible to draw either sweet or salt water from any of the spigots without getting a mixture of both in varying proportions.

The bacteriological examination of a sample of this water, made at the Bacteriological Laboratory of the Harvard University College of Medicine, showed the presence of liquefying bacteria in large numbers, while that of a sample of water collected from the distiller proved absolutely sterile.

A more common source of lead in ship's drinking-water is found in the pipe joints, especially in newly made ones, of which several instances have recently come to our notice. The red lead used for the purpose of making joints water-tight should be forbidden and asbestos used instead, in all pipes used for water distribution. Early in the history of distilling water on board ship and the laying of pipes for its convenient distribution, A. Le Fèvre, of the French navy, discovered lead in the water; and quite recently Dr. Cautellauve (1891–92), also of the French navy, has again reported several cases of lead poisoning from the same cause, during his cruise in the East on board the *Troude*.

Time and space do not permit here to go into a detailed description of the various methods of modern water analysis. Nor is it necessary to mention the characters that a good drinking-water should possess. These are matters of general hygiene and can easily be found in every work on that subject. There is no doubt that the naval surgeon, equipped with a practical knowledge of the laboratory methods used in water analysis, will be well able to make such a selection of apparatus and reagents, before going to sea, as will enable him to make a very satisfactory water analysis, wherever and whenever called upon to do so. There may be some difficulties as regards accommodations on board some ships, but there are none that cannot be overcome. His difficulties certainly cannot be greater than are those of the army surgeon in the field.

The water-supply systems and the chemical composition of the water supplied by them, of every one of the islands near our coast, including all the Antilles, should be systematically investigated. The composition of every important well in common use and out of use on every island should be known, recorded, and plotted on geographical maps for immediate reference. With some encouragement and the necessary means and apparatus, this work could easily be done by naval medical officers.

III. THE RATION.

FOODS AND NUTRITION IN GENERAL.—While it cannot be expected, in the limited space allotted to this paper, that we enter at all into the special physiology of nutrition or into the chemistry of foods, it is, on the other hand, absolutely necessary and unavoidable briefly to touch upon those of the leading principles and methods according to which the nutritive values of those of the food substances in common use on board all sea-going vessels and included in the navy ration, are ordinarily determined.

Daily experience and observation have sufficiently acquainted us with the fact that the physical part of our existence consists in a perpetual and constant effort on the part of the living organism to adapt itself to an ever-changing series of outside conditions. In this supreme effort the organism uses up constantly part of its own organized substance, expending it as, or converting it

Digitized by Microsoft®

into, mechanical work and heat. If the body weight is to be maintained and the life of the organism is to continue successful in the struggle, this expenditure in organized substance must be made good. The products of wear and tear incident to the process must also be promptly removed.

www.libtool.com.cn

Since the source of the energy thus expended by a living animal organism can be restored only through the introduction and the assimilation of certain definite quantities of organic and inorganic food substances, their supply, preservation, preparation, digestion, assimilation, and dissimilation have been among the principal subjects of study and investigation on the part of physiologists. Since, moreover, the supply of these substances and their assimilation must vary directly with the energy expended by the organism in a given time and under varying conditions of environment, a balance between supply and expenditure must be maintained and the influence upon it of different conditions be known, as well as the relative value of the food itself. We must be able to measure the energy expended and to ascertain its food equivalent, if we are to make no mistake in our provisions.

Since, finally, it is of coequal importance to the life of the organism that the products of wear and tear should be as promptly and as completely eliminated as new material is appropriated, the maximum working efficiency of the living machine is conditioned not only by a proper balance between supply and demand, in accordance with different environmental and subjective conditions, but is, moreover, determined by the individual capacity for maintaining a high balance between assimilative and dissimilative functions. The latter determine the difference between two individuals and between different races of mankind. This functional capacity on the part of both the individual and the race can be developed and increased through systematic training.

According to Verworn, tissue metamorphosis (Stoffwechsel) comprises a long series of complicated chemical processes, beginning with the entry of nutritive substances into the living cells of the body and ending with their exit. These processes follow each other like the links of an unbroken chain, and might not inaptly be represented by a binomial curve. In this curve the ascending arm would then represent all those processes which lead to the repair of living matter; the top of the curve, those highly complicated processes leading to the synthesis of protoplasm itself; and the descending arm, the processes leading to, and finally ending in, the decomposition of living matter into the simplest end-products (urea, carbonic acid, water, etc.). With the beginning and the ending of the highly complicated process and the materials found at these two points we are fairly well acquainted; the rest is as yet wrapped in darkness.

Foods, in the physiological sense, are classified into nitrogenous, also called proteids, and non-nitrogenous, in which are included the fats and carbohydrates. While fats and carbohydrates may, to a certain extent, be substituted for one another, non-nitrogenous substances can never be made to take the place of proteids in nutrition. The latter must be regarded as by far the most important food substances and as absolutely indispensable parts of a complete and perfect diet.

The *proteids* form the chief components of the cells in the tissues of all plants as well as animals, and, according to the researches of Voit and Pettenkofer the absorption and ozonization of oxygen and its effect upon all the chemical processes within the cells, are entirely under the direct control of the nitrogenous part of their tissues. Without the participation of the nitrogenous tissues, neither oxidation nor any manifestation of energy is possible. Mechanical motion and heat may be evolved through the oxidation of both fats and carbohydrates, but the initiative to the manifestations of these must be given by the tissues containing nitrogen. Proteids have, moreover, been found to produce fats and possibly also carbohydrates under certain conditions.

Fats are chemical compounds consisting of a trivalent alcohol, glycerin, and three molecules of a monobasic acid, chiefly stearic acid, palmitic acid, and oleic acid in different proportions. They all contain hydrogen and oxygen as well as carbon, but no nitrogen, their general formula being represented by $C_{16}H_{18}O$. The formula suggests that the fats need oxygen in large quantities for their complete conversion into water and carbon dioxide.

The *carbohydrates* comprise the sugars and the starches which are for the most part of vegetable origin. It has been shown that the formation of starch granules in the green plant goes on hand-in-hand with the decomposition of carbon dioxide by the chlorophyl granules, under the influence of sunlight. On the hypothesis of von Baeyer, the carbon (C) of the carbon dioxide, the moment it is set free, combines with the water (H_2O), taken up by the roots of the plant, and forms one molecule of formaldehyde (CH_2O). Six of these molecules of formaldehyde now link together by polymerization and form one molecule of a monosaccharid ($C_6H_{12}O_6$) and through further polymerization of the monosaccharids thus formed, and with the loss of one molecule of water by each, starch finally results ($C_6H_{10}O_5$). This hypothesis has met with the most general acceptance. In the group of the carbohydrates also belong cellulose and pectin. Cellulose forms the solid skeleton and, when boiled with dilute sulphuric acid, it gives dextrin and glucose. Pectin is the vegetable jelly found in various ripe fruits.

All living organisms must, moreover, have a certain amount of *oxygen*, without which life is impossible; and, lastly, *water* and *salts*. Indispensable are sodium, potassium, magnesium, calcium, and iron, and their combinations with phosphoric, sulphuric, carbonic, and hydrochloric acids.

Food Value.—The food value of an eatable substance is generally expressed by the number of calories or heat units which 1 gm. or any other definite quantity of it will develop, when completely burned in a calorimeter. The amount of heat that is developed during the combustion of, for instance, 1 gm. of substance in a calorimeter is exactly the same as that which is produced when 1 gm. of the same substance is completely oxidized within the body. In a living organism about thirty per cent. of this value can be put out in the form of mechanical work, while the remainder passes off in the form of heat. We know, thanks to the researches of Voit, that an average adult laborer, performing his daily work, puts out in mechanical work and heat the equivalent of about three thousand calories. In order, therefore, that the man shall not lose in weight, his daily diet must be such as to balance his loss and have a combined caloric value of at least three thousand units. If we, furthermore, will take into calculation that about four hundred of the units at least must come from proteids, five hundred from fats, and the remainder from carbohydrates, we have the most necessary data for the calculation of the man's diet. Thanks to the labors of Voit and Rubner and their numerous pupils, these determinations have been greatly simplified in recent years.

Outside conditions, personal and racial habits, climate, age, and sex may alter the relative proportions of proteids, fats, and carbohydrates in a certain diet, but the above proportions must stand as answering to the average requirements of an adult workingman in a temperate climate. In calculating the dietary value of a ration, we must also allow for an unavoidable loss in the preparation of the different parts of it. In meats, a loss of twenty per cent. of the raw material is generally allowed for bones; with salted herrings, thirty-seven per cent.; pickled herring, twenty-nine per cent.; potatoes boiled and then peeled, seven per cent.; potatoes peeled raw, thirty per cent.; if eggs be used, ten per cent. in weight is deducted for the shell, etc. Another source of loss from the gross weight is in the different degrees of digestibility of foods, for which allowance must also be made. As a general rule, animal foods are much more completely digested than foods of vegetable origin. Rubner has shown that proteids from meat and milk disappear almost entirely, while those from bread and espe-

cially vegetables reappear in the fæces in quite considerable proportion.

A simple and approximately accurate method for calculating the nutritive value of a diet has recently been published by Schumburg. Schumburg makes a slight difference in the food value between animal and vegetable proteids, giving the former a value of 3.5 and the latter a value of 3.1 per gram. The fats have a value of 8.8 and the carbohydrates one of 3.7. Given, then, the various constituents of a diet, expressed in proteids, fats, and carbohydrates, their weight stated in grams, multiplied by their respective values, the several amounts added together would give a sum corresponding to the total food value of a diet in numbers of calories or nutrient units. Remembering that a sufficient diet for an adult workingman must have at least 3,000 nutrient units, and that the proportion of proteids, fats, carbohydrates, and salts in a complete diet should be as 150, 100, 500, and 35, we would have an easy and simple method of ascertaining and controlling the dietary value of any meal.

The adjoining Table XV. has been compiled from many sources, notably, Koenig, Rubner, Kirchner, Schmidt, Plunert, Ranke, Notter, Harrington, Munson, the reports of the United States Fish Commission and of the United States Department of Agriculture. The first five columns give the percentage composition of each food in proteids, fats, carbohydrates, etc.; the next three columns give the number of nutrient units contained in 100 parts; the next two columns give the sum of nutrient units in 100 gm. and one ounce respectively.

There are a few food substances of vegetable origin,

Digitized by Microsoft®

Naval Hygiene.

not included in this list, such as the tomato, cucumber, squash, pumpkin, egg plant, and vegetable marrow; they have about the same nutritive value as celery and lettuce. The jellies and jams are semi-solid glutinous preparations, made by boiling fruit juices with sugar and allowing to cool; jams are similar preparations which include the pulp of the fruit as well as the juice. Their nutritive value must be determined by taking their ingredients separately in each case. Tea, coffee, and chocolate owe their nutritive value more to the stimulating effect of the alkaloids which they contain than to anything else; they are condiments rather than nutritious substances.

www.libtool.com.cn

The caloric values, originally assigned to the several proximate principles of foods, by Rubner and Stohmann, were as follows: 1 gm. of proteids, 4.8 calories; 1 gm. of fats, 9.5 calories; 1 gm. of carbohydrates, 4 calories. It was soon found, however, that, while the fats and the carbohydrates were as completely oxidized within the tissue cells as they were when burned in a calorimeter, namely, into water and carbon dioxide, the proteids left an unconsumed remnant. If, for instance, 1 gm. of proteid material is decomposed within the organism, it leaves a remnant of urea, uric acid, and a few other nitrogenous substances, excreted by the kidneys and the intestines. The 4.8 calories, therefore, that were assigned to 1 gm. of proteids, as their food-value in calories, represent only a part of that value in calories which we would obtain if 1 gm. of proteids was burned in a calorimeter, where it would, of course, be completely consumed by oxidation. According to Rubner, the unconsumed remnant amounts to 22 to 28 per cent. of the original quantity of proteids ingested. In other words, if 1 gm. of proteid material is decomposed within the body, is converted into water, carbon dioxide, urea, etc., only so much of its potential energy is converted into heat as will raise the temperature of 4.8 kgm. of water 1° C., while if 1 gm. of proteid is completely assimilated within the organism, the amount of energy added to the latter is equal to 5.7 calories, or its full caloric value. The above values for proteids, fats, and carbohydrates, in their practical application to the calculation of the food values of a certain diet or ration, have had to be modified still further. Allowance had to be made for a certain percentage amount of indigestible matter peculiar to the different articles of food, as well as for the energy that had to be expended on their digestion, in order not to overestimate their net value. After making these necessary deductions, Schumburg gives, as the net values, the following numbers in calories: 1 gm. proteids (animal), 3.5 calories; 1 gm. proteids (vegetable), 3.1 calories; 1 gm. fats, 8.8 calories; 1 gm. carbohydrates, 3.7 calories. It is on the basis of Schumburg's figures that the food values in table XV. have been calculated.

Voit's original standard requirements in proteids, fats, and carbohydrates, for a moderately hard-working adult man, are: 118 gm. of proteids, 56 gm. of fat, and 500 gm. of carbohydrates. These standard requirements have stood the test of many years of scientific controversy and have proved themselves practically unassailable.

The following table is intended to show the number of calories obtained from Voit's standard by using both Rubner's and Schumburg's figures:

TABLE XVI.

Name.	Grams.	Multiplied by—	
		Rubner's figures.	Schumburg's figures.
Proteids.........	118	× 4.8 = 566	× 3.5 = 413
Fats.............	56	× 9.5 = 532	× 8.8 = 492
Carbohydrates...	500	× 4.0 = 2,000	× 3.7 = 1,850
		Total, 3,098	Total, 2,755

(In a paper on the "Hygiene of the Navy Ration," published by me in the Proceedings of the United States Naval Institute, vol. xxv., No. 3, the total caloric value of the ration was estimated as amounting to 2,696 calories. This number was obtained after making all due allowance for indigestible matters as well as taking into account the losses incurred in cooking and the general preparation of the food; it agrees so nearly with Voit's standard, multiplied by Schumburg's figures, that this agreement is considered an additional proof of its correctness. Unfortunately, the proof of this paper not having been submitted to the writer, a few errors have crept in, owing to the wrong position of the decimal points in the numbers there given; they are, however, so easily perceived as hardly to need any correction.)

From the point of view of their digestibility, food substances vary quite considerably, and, since only that portion of a food substance which is absorbed is of any good to the organism, it cannot be immaterial in what form food is taken. The following table XVII. by Rubner is intended to show the indigestible and, consequently, unabsorbed remnant in per cent., of some of the more common articles of food.

TABLE XVII.

Remained unabsorbed.	Dry substance.	Proteids.	Fats.	Carbohydrates.
Meat, dried	5.3	2.6		
Fish........................	4.3	2.5		
Eggs, hard-boiled	5.2	6.6	4.4	
Milk	8.8	7.1	5.3	
Bread, baker's, wheaten...	4.2	21.8	....	1.1
Bread, inferior quality	6.7	21.6	...	2.6
Bread, coarse meal	12.2	30.5	....	7.4
Bread, peasants' rye.......	15.0	32.0	....	10.9
Macaroni, poor in egg......	4.3	17.1	....	1.2
Rice (Risotto)..............	4.1	20.4	....	0.9
Corn (Palenta).............	6.7	15.5	....	3.2
Peas (dried)	9.1	17.5	....	3.6
Beans (dried)	18.3	30.2		
Beans, fresh................	15.0			
Potatoes mashed	....	19.5	....	0.7
Potatoes, mashed, different preparations..............	9.4	30.5	....	7.4
Carrots......................	20.7	39.0	....	18.2

The table shows that those articles of a diet which have an animal origin and upon which we mostly depend for the necessary proteid part of our diet, such as meat, fish and eggs, are best digested and absorbed. Of the vegetables, rice, corn, and macaroni seem to be much more digestible than the vegetables properly so-called. The digestion and absorption of all kinds of fats is generally favorable.

The different composition of foodstuffs, as regards proteids, fats, and carbohydrates, in itself makes it necessary that an appropriate mixture of them be taken in order to maintain a certain necessary equilibrium in the composition of our own bodies.

For, although Pflüger has kept dogs alive and in a thriving state of health and activity for long periods at a time, man cannot live forever on an exclusively animal diet, much less on one of fats and carbohydrates to the exclusion of all proteids.

Volume of a Diet.—Regarding, as we must, our digestive organs as muscular as well as secretory organs, we shall have to admit, that, like other muscles, their strength in grinding up and propelling food material must have a maximum limit, beyond which they become liable to fatigue and exhaustion. This limit has been reached whenever we become conscious of a feeling of overfulness after taking a meal. While a feeling of satiety is, up to a certain limit, stimulating to digestion, overfulness has the very opposite effect and ought to be avoided. Experience and experimentation have shown that the volume of an average diet should not exceed 2,100 gm. nor fall below 1,500 gm. The daily volume is, of course, to be distributed among the several customary meals.

It has been found a most suitable plan, in a temperate climate at any rate, to make the following distribution of the daily ration between the different meals of the

Digitized by Microsoft®

day: For breakfast, 12 per cent.; for midday meal, 47 per cent.; for supper, 31 per cent.

In warm climates, however, it will be found a good rule, especially on board a ship-of-war where drilling is done morning and afternoon, not to overfill the stomach of the men at midday, but to make the heavy meal the 5 P.M. meal of the day. The above percentage distribution would have to be slightly modified in accordance with these requirements.

The Dietary Value of One Week's Ration.—In order to obtain an approximately correct estimate of the dietary value of the meals as they are actually served out on board a ship in commission, the commissary yeoman of one of them was requested to furnish us with a list of the articles included in one week's allowance and divide that up into the customary three daily meals. With the aid of table XV., the food value of each meal in proteids, fats, and carbohydrates was then calculated and expressed in terms of nutrient units, obtained after the manner found described in the preceding pages. In this estimate no deductions were made for indigestible matters nor for the work expended on digestion, because these values, as will be remembered, had already been deducted in the various multiples used in the calculation of the numbers of nutrient units which each article represents. But a loss of twenty-five per cent., in round numbers, had to be allowed for the usual and unavoidable waste made in the preparation of the raw material for cooking, as well as for a less necessary but always notable waste incurred in serving.

The results of this work are exhibited in table XVIII. A careful study of this table is of some interest. It shows, for instance, that while the sum of nutrient units for almost every single day comes up to and often exceeds the required number, there is quite a considerable lack of uniformity in the several corresponding meals of the different days of the week. The number of nutrient units for one day is almost doubled on another day. It also shows that our sea ration as well as our port ration was deficient in carbohydrates, while the proteids were two per cent. below the standard in the sea ration and three per cent. above the standard in the port ration.

In table XIX., which has been borrowed from Plumert, the proteid content of the United States navy ration is given as 69.2 per cent. This estimate, obtained from our printed allowance-list, puts its dietary value on top of all the other naval rations. According to our present calculation, the dietary value of our port ration is but twenty-three per cent. in proteids, or just one-third of that given by Plumert. Although we must admit that the two estimates are not strictly comparable, this exceedingly large difference between the two nevertheless shows that there are instances in which discrepancies occur between what is found on paper and what the men, in actual practice, get on their table and inside their stomachs.

Proposed New Navy Ration.—The Secretary of the Navy, recognizing the needs of the service and the importance of a well-appointed ration, on July 15th, 1901, ordered a board of officers to examine the ration and the system of messing in the navy. This board, to which the writer was originally ordered a member, but was prevented from attendance by illness, held its sessions in Newport, R. I., and completed its labors September 4th, with a report, which has not yet been made public. A very complete abstract, however, appeared in the *Army and Navy Journal* of January 25th, 1902, from which we

take the following. This board recommends legislation as follows:

"Hereafter the navy ration shall consist of the following daily allowance of provisions to each person: One pound and a quarter salt or smoked meat, with three ounces of dried or six ounces of canned fruit, and three gills of beans or peas, or twelve ounces of flour; or one pound of preserved meat, with three ounces of dried or six ounces of canned fruit and twelve ounces of rice or eight ounces of canned vegetables, or four ounces of desiccated vegetables; together with one pound of biscuit, two ounces of butter, four ounces of sugar, two ounces of coffee or cocoa, or one-half ounce of tea and one ounce of condensed milk or evaporated cream; and a weekly allowance of one-half pound of macaroni, four ounces of cheese, four ounces of tomatoes, one-half pint of vinegar, one-half pint of pickles, one-half pint of molasses, four ounces of salt, one-quarter ounce of pepper, and one-half ounce of dry mustard. Five pounds of lard or a suitable substitute, will be allowed for every hundred pounds of flour issued as bread, and such quantities of yeast as may be necessary.

"The following substitution for the components of the ration may be made when deemed necessary by the senior officer present in command:

"For one and one-quarter pounds of salt or smoked meat or one pound of preserved meat, one and three-quarter pounds of fresh meat; in lieu of the article usually issued with salt, smoked, or preserved meat, fresh vegetables of equal value; for one pound of biscuit, one and one-quarter pounds of soft bread or eighteen ounces of flour; for three gills of beans or peas, twelve ounces of flour or rice, or eight ounces of canned vegetables; and for twelve ounces of flour or rice, or eight ounces of canned vegetables, three gills of beans or peas.

"An extra allowance of coffee or cocoa, two ounces of sugar, four ounces of hard bread or its equivalent, and four ounces of preserved meat or its equivalent, will be allowed to enlisted men of the engineer and dynamo force when standing night watches under steam."

The Board has also recommended some other changes to be made in the system of messing and has suggested some much needed reforms in the organization of the personnel of the commissary department on board ships, but, the above changes in the food-supply being the only ones of interest in connection with the study of the actual food value of the ration, we cannot here consider them.

The same commissary yeoman who had previously furnished us with a written weekly allowance list, divided into the customary three daily meals, made up from the old ration, was now requested to do the same with this proposed new ration. This he very kindly did, after having been thoroughly advised of the promised additions to the present ration, and the following table XX. shows the food value for this new ration in nutrient units, expressed in terms of proteids, fats, and carbohydrates, which the new ration would yield *in his hands*.

While, in our opinion, the ration is very ample, the table shows that both in the port ration and in the sea ration we have an excess in fats and a deficiency in carbohydrates, while the proteids may be regarded as just about up to the standard. We also notice the same lack of uniformity as regards the distribution of the quantities between the different days of the week as well as between the three meals of the day that has been previously noted. The importance of the personal equation of the yeoman and its influence upon the whole subject of rationing on board ship is well brought out. A very natural suggestion, therefore, would seem to be that either the commissary yeomen of the navy be given a great deal more instruction as regards the value in nutrient units of the different classes of food which it is their duty to distribute, than they now possess, or that this distribution be supervised on board ship by the class of men whose training and education ought to be a guarantee of the fact that they possess the required knowledge to do so in accordance with the best principles.

The Influence of Climate upon Nutrition.—Any discussion of the navy ration would be incomplete without some consideration of the influence of the various climatic factors upon nutrition. The problem of what constitutes a proper ration for a definite climate can be solved only on the basis of an exact knowledge of the physiology of general nutrition, as modified and influenced by the different climatic conditions. When we shall be in possession of a full and complete knowledge of this, then the proper ration for almost any climate will become a matter of exact calculation and a mere application of principles to practical life. We must, in the first place, find out what climate is, and in the second place ascertain its influence upon nutrition.

Since some very important and fundamental work has, within recent years, been done in this line of research by German hygienists, which must hereafter be taken into account whenever the questions of climate and nutrition become subjects for further research or discussion, it is absolutely necessary in this connection briefly to call attention to a few of the leading points in this great work. In doing this, only so much of it will be reviewed as seems necessary for a better understanding of the subject under discussion; for a fuller and more detailed account the reader is respectfully referred to a most excellent monograph by K. E. Ranke.*

* "Ueber die Einwirkung des Tropenklimas auf die Ernährung des Menschen auf Grund von Versuchen im tropischen und subtropischen Südamerika," von Dr. Karl Ernst Ranke, München.

The physiological process, known as heat regulation or heat economy, consists, on the one hand, in the production of heat within the living organism through oxidative changes; and heat-dissipation, through conduction, radiation, and water evaporation, on the other. The remaining balance between these two phases of the process finds expression in the normal temperature of the animal under observation. That this heat-regulating process is influenced by a great variety of both environmental and subjective conditions has long been known, but a more exact knowledge of it has only recently been gained through the researches of Voit and Rubner and their numerous co-workers.

Environmental Conditions.—*Climate.*—Ranke has recently defined climate as being "the total mean thermic effect exerted upon a living organism, at a certain point on the earth's surface." This comprehensive definition of climate covers every point on the earth's surface, both at sea and on the continent. The total mean thermic effect is made up of several factors, namely: atmospheric temperature (direct solar rays, reflected and radiated heat), humidity, air currents, barometric pressure, and rainfall.

Against the untoward influence of these combined agencies the organism possesses certain physiological defences that are summed up in the term heat regulation, and, within a certain number of degrees of atmospheric temperature, the organism is able to accommodate itself to its environment, without losing control of its own normal temperature. This number of degrees of temperature has, accordingly, been called by Ranke the "temperature range." This range has an upper and a lower limiting point, beyond either of which the regulating influence of our physiological mechanism does not extend, and where our physiological defences begin to break down. When, therefore, the limits are surpassed, the normal temperature of the organism will either be raised or lowered, according as either the upper or the lower limiting point in the range is exceeded. We leave our normal ground and enter the pathological arena.

(*a*) *Atmospheric Temperature.* One of the most important factors in a climate is its temperature. Complete and accurate sets of experiments on the influence of atmospheric temperature on the temperature range have, so far, been made on animals only. A sufficient number of observations, however, has been made on man to enable us to summarize the different reactions thus observed into a connected whole. Thus Voit, in 1878, made the important discovery that the several factors concerned in the mechanism of heat regulation did not all act alike when followed through the whole of the temperature range. Proceeding from the lower in the direction of the upper limit, there soon comes a point on our scale where, for instance, heat production refuses to take any further part in heat economy. This point was likewise observed by Rubner and noted to occur in all his experiments on the heat regulation of animals. Ranke now proposes to designate the point "the critical point" in heat regulation. By it the whole temperature range is naturally divided into two great groups. According to the present state of our knowledge, the reactions of the different factors concerned in heat regulation, within the several groups and subdivisions of the temperature range, are about as follows: At the lowest limit of the range, we meet with the highest amount of heat production; from here on up to the critical point,

Digitized by Microsoft®

Naval Hygiene.

heat production is found to be gradually diminishing. Heat regulation, then, between the lower limit of the range and the critical point, occurs principally through changes in chemical heat production. Water evaporation behaves so indifferently here that no regulating function can be attributed to it. From the critical point on upward, no further decrease in heat production depending upon temperature occurs. In place of changes in heat production we now notice changes occurring in heat elimination. This second great group of the temperature range is again divided into two subdivisions, distinctly marked out by important changes in the reactions of the regulating mechanism. In the lower of these two divisions we find conduction and radiation actively increased. Although a slight increase in heat production is noticeable within this section, due to quickened circulation and respiration, this is exactly counterbalanced by a simultaneous slight increase in water evaporation. This kind of regulation extends, in the dog, to about 5° C. above the critical point.

In the upper of the two subdivisions of physical heat regulation we find that radiation and conduction cease to be actively or reflexly increased and are considerably diminished instead. In place of these factors, water evaporation suddenly sets in.

Rubner has shown that, when active perspiration begins in man, the influence of conduction and radiation ceases to be exerted upon heat economy, but that the work of the sweat glands here causes a further slight increase in the amount of heat production.

These somewhat complicated relations will be made clear by a glance at the accompanying chart, constructed from one of Rubner's experiments on the dog and intended graphically to illustrate the essential points in the mechanism of heat regulation under the influence of varying degrees of atmospheric temperature.

The next table (table XXI.) shows the experiment of Rubner on the dog which the chart is intended to represent graphically.

TABLE XXI.—RUBNER'S EXPERIMENT.

Atmospheric temperature.	Latent heat in calories in water vapor.	Conduction and radiation in calories.	Total heat production.	Atmospheric temperature.	Latent heat in calories in water vapor.	Conduction and radiation in calories.	Total heat production.
7.6	11.8	71.7	83.5	25.0	16.9	37.3	54.2
15.0	14.0	49.0	63.0	30.0	26.2	30.0	56.2
20.0	16.2	37.3	53.5				

In the chart, the ordinates indicate the number of calories, the abscissa, the degrees of temperature. *W.E.* stands for water evaporation; *C. and R.* for conduction and radiation, and *H.P.* for heat production; all else is self-evident.

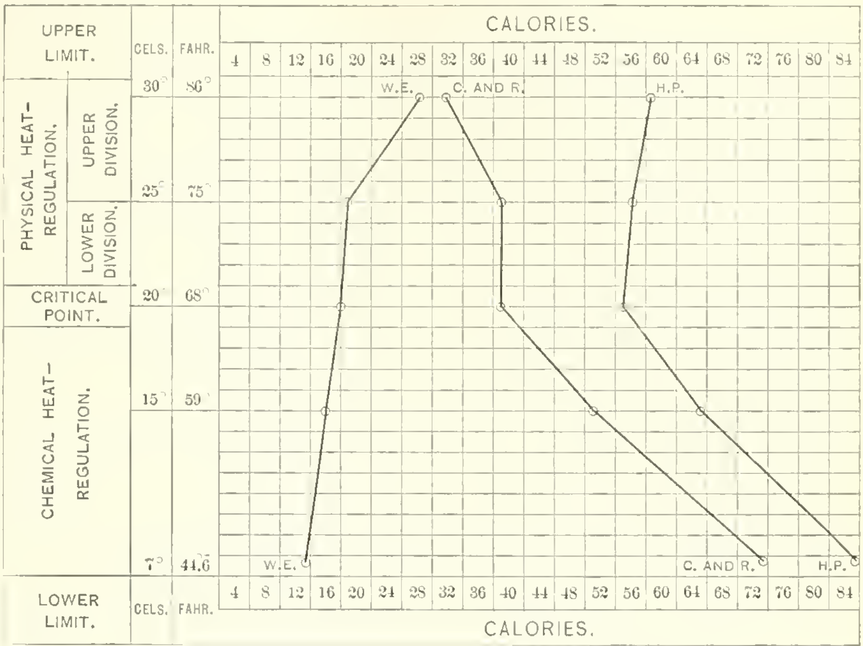

FIG. 3509.—Chart Showing Temperature Range and Heat Regulation.

(*b*) *Air Currents.* Air in motion has a very important influence upon heat economy. Rubner sums up its influence by stating that air currents cause physical heat regulation to begin at a few degrees higher temperature than during a calm. Ranke expresses the same thing by stating that air currents cause the critical point in the temperature range to move a few degrees upward.

(*c*) *Humidity.* The thermic influence of atmospheric humidity is twofold. It diminishes water evaporation and improves conduction. By increasing conduction it causes the lower limit of the temperature range to move upward, and by retarding water evaporation it moves the upper limit downward, thus narrowing the entire range. Moist cold is colder than dry cold and moist heat hotter than dry heat. It will be seen, then, that the organism possesses no defences against the combined influence of excessive humidities and temperatures.

II. SUBJECTIVE CONDITIONS.—(*a*) *Food and Feeding.*—That amount and variety of food which an organism is required to take in order to maintain its present weight is called its *need.* If more food is taken than is required for this purpose, the smaller part of the surplus only becomes converted into tissue; the greater part is decomposed and eliminated. Consequently, an increased heat production always follows the introduction of an amount of food beyond the needs of an organism to maintain its weight, and the consequence of that is that the entire range is moved downward. This is well shown in one of Rubner's experiments (also quoted by Ranke). In the experimental animal of Rubner, when it was in a state of hunger, this sudden water evaporation began at a temperature of 32.5° C.; when 200 gm. of meat were given, the sudden water evaporation began at 19.1° C., and when 320 gm. of meat were given, it began at 13.4° C. This shows the enormous influence of feeding upon the temperature range; it moves the entire range a considerable number of degrees downward. Under the influence of high temperatures, therefore, every increase in the food allowance beyond the mere need must materially increase the difficulty of heat elimination and cause the critical point to move a corresponding number of degrees downward. The proteid food substances are the

Digitized by Microsoft®

most powerful in this respect, the fats the least effective, and the carbohydrates stand between the two.

(*b*) *Muscular Work.*—Numerous experiments have shown that the influence of muscular work upon the temperature range is a most powerful one. Since heat production is greatly increased by all kinds of muscular work, its influence upon the temperature range is, briefly stated, that it moves it downward. Near the upper limit of the range we may reach a point where a man may be able to exist while at perfect rest, but where every attempt at work will lead to heat accumulation and heat stroke and other pathological conditions.

(*c*) *Clothing* influences the temperature range by pushing it a certain number of degrees downward; it has, then, upon it an influence similar to that exerted by eating and muscular work.

The salient points of our subject have now been brought forward as thoroughly, we believe, as the scanty allowance of space will permit. We will simply add the conclusions arrived at by Ranke from a most self-sacrificing set of experiments which he made upon himself and published in the monograph already referred to. They are:

1. The temperature optimum of the European, in moderate clothing, lies between 15° and 18° C. (59°-64.4° F.), providing that the other climatic factors exercise no undue influence at the time.

2. In a climate with an atmospheric temperature between the optimum and 22° C. (72° F.) an increased water evaporation begins to show itself, but no decided influence upon nutrition is yet noted.

3. In a climate of a temperature of 25° C. (77° F.) and on the assumption that other climatic factors are without great influence, a diminished desire for food begins to become manifest; the amount of food taken sinks to that of a man doing very light work.

4. The climatic effect still rising, the amount of food taken sinks below the need of an adult at rest and in a state of hunger. The proteids remain constant, and every further diminution occurs at the expense of fats and carbohydrates.

5. If, against the instinctive diminution in the desire for nourishment, food is forcibly taken in greater amount than is desired, pathological changes in the general health, rises in the temperature, and a decreased resistance to infectious diseases will occur.

6. If, on the other hand, the quantities of food taken are permanently diminished in accordance with the demands of a tropical climate, as is usually the case, a deficient nutrition of the organism is the inevitable result, with all the dangerous consequences that follow in its train.

From these conclusions and from the preceding discussion, the leading principles that must govern the composition of a ration or the diet of a man who has transferred his residence from a temperate to a tropical climate may be easily inferred. The details of it are subjects of special research.

A sea climate is perhaps more nearly a purely solar climate than any land climate can ever be. A solar climate is defined as a climate which would be characteristic of every degree of latitude, if the earth was a mathematically perfect spheroid without unevenness, and had throughout the same composition. This is true at least for the great oceans. Although the value of the total mean thermic effect of the climate, which the seaman is exposed to as long as he confines himself to the limits of his ship, has not yet been determined with scientific accuracy, it may be safely said that that value is less than one found over a corresponding latitude on land. It would most undoubtedly be modified by the ship, especially one of the modern battleships, in which every part has a climate of its own and which must be regarded as a heat producing body; nevertheless, the total mean effect on deck will be found to be considerably less detrimental than the corresponding shore climate. With the aid of a few thermometers, psychrometers, anemometers and some interest and experience in scientific investigations, this work should present no difficulty. Until it shall have been done, any expression of opinion on the influence of the climate in which the seaman lives, upon his heat economy, and upon the composition of his ration, would be premature.

IV. Recruiting.

Recruiting for the navy signifies the separation by a medical officer of the physically fit from the physically unfit, of the mentally sound from the mentally unsound, of good timber from bad timber, for a most serious and important service, the common defence of the land and its people against a danger threatening their commerce and their liberty from the direction of the sea. Every physician in the land should be familiar with the principles and practice of recruiting, and recent experience has demonstrated the fact that every medical man in the country is liable to be called upon to do this duty. Whatever else there may be connected with the process of enlisting a man in the navy or army, the point of gravity in the duty of recruiting lies in the medico-physical examination of the recruit; but to perform this duty properly requires some knowledge as well as practice. We shall be obliged to limit ourselves here to giving a very brief outline of some of the more important principles involved.

To begin with, it is a mistaken notion to presume that any individual with a normal heart and a good pair of lungs must necessarily be a fit candidate for the navy. There are indeed many other points of equal importance which the examiner must keep constantly in mind while scrutinizing a candidate. Besides seeing to special parts in the anatomy of an individual, he must look at the man as a whole. Generally speaking, a fine form symmetrically proportioned, good development, regular features, a good clear eye, a frank and open countenance, convey an impression that is rarely misleading; they form an index to the inner life of the man, usually favorable. On the other hand, asymmetry of face and body, irregular development and features, the stigmata of degeneration, in at least fifty per cent. of the cases are unfavorable in this respect. They would indicate an abnormal deviation from the average, the juvenile offender in the young, the hardened criminal and repeater in the adult. The navy can no longer be considered a reform school for the juvenile offender nor a prison for the cure of the hardened adult criminal. Neither the time nor the training can be given in the service to such objects, however noble, and there are other institutions, maintained by the state, the special function of which is to attend to these duties.

Besides good physique, the man, to be of any real and permanent value to the service, must bring with him right from the start a good will, a high sense of duty and responsibility capable of further training, all of which he must be prepared and willing to maintain during the entire term of service to his country and his flag. This may be aiming high, but many years' experience, both in recruiting and in surveying the unfit, have proved to my satisfaction that the service is not benefited but injured by anything below such a standard.

The British Navy.—The only other navy with which our own can be compared as regards the system of recruiting is the British navy. Although the system of conscription for the army has—until recently at any rate—always been considered in England to be a detestable and insufferable encroachment on individual liberty, sailors have at all times been regarded as bound to serve in the royal navy. If they did not enter the service voluntarily, they were simply pressed into it by the press-gang, often very ruthlessly and cruelly. These press-gangs, commanded by officers, were sent into the ports to seize all available seamen. The man, thus forcibly enlisted, had a small coin (the Queen's shilling) pressed into his hand, and it is from this circumstance that the name press-gang is said to have been derived.

This peculiar method of recruiting the navy, scorning, as it did, all law and humanity, had nevertheless taken such firm root in the habits and modes of thought of the

Naval Hygiene.

people of England that, even during the long period of peace after Waterloo, when humanitarian principles were taking a strong hold on all civilized communities, no attempt was made to abolish the press-gang. Down to the middle of the nineteenth century English admirals declared that the press-gang was one of the props of the greatness of England and absolutely indispensable.

www.libtool.com.cn

By that time public opinion resolutely and persistently objected to this forcible enlistment, so that in 1852 the Admiralty was forced to adopt new methods for the recruiting of seamen for the navy—methods which turned out to be highly beneficial, leading as they did to a thoroughly beneficial reform in the manning of the navy and to a very superior personnel at the same time. The royal navy of Great Britain and the navy of the United States are now both recruited on the voluntary system, while in the continental naval services the system is by conscription.

The average of volunteers has invariably been found superior to that derived from those who were driven into the service either by force or by necessity or who entered for reasons of convenience. So far as the navy of the United States is concerned, its personnel has markedly improved during the last twenty-five years, and the general public is beginning to look upon the naval uniform with both pride and affection instead of as a mark of degradation.

For the details and the nature of the physical examination required in both services, the reader is referred to Appendices I. and II., at the end of this article. Every physician may well be supposed to be familiar with the technique of the examination.

The Recruitment of Officers.—This presents several rather interesting as well as instructive differences in the two services. In the English service, considerable stress is laid upon the circumstance that the young naval candidate possesses a good family origin and connections. Under the more democratic form of government of the United States, this principle of selection does not prevail. Then, again, the promotion to the higher grades or command rank does not proceed by seniority in England as it does in the United States, but by selection.

There is, then, a certain amount of selection at both ends of the line in the British service that does not exist in the United States naval service. Besides, the cadet as well as midshipman in the British service is obliged to defray not only all his private personal expenses but also to pay from fifty to seventy-five pounds a year for his schooling. Thus there is, in addition to the above, a money qualification. In both services alike there is a physical and a competitive mental examination, in both of which the candidate must be successful before he can become a cadet.

Granting that a certain amount of this selection which characterizes the British service as distinct from the United States service is done from motives of interest other than the best of the service, we must perhaps admit that the resulting average, thus carefully selected, may in the end be for a steady and constant improvement of their service after all. Even the least important of the qualifications, the money qualification, may not be altogether without a certain value as a principle of selection. If we regard, for instance, the possession of a certain amount of this world's treasure by the lad's father or other relatives as representing a certain amount of brain power which must have been expended at some time in order to accumulate it, the natural conclusion would be that the boy had inherited a part of this same brain power, in a facultative state, in the same natural way as he will some day inherit the accumulated ancestral possessions. We may, moreover, further assume that early training might do much to divert this power into other channels; in other words, turn the lad into a successful naval officer as his ancestor had proved himself successful in other ways.

In the free and unhampered competition in the civil life of a republic like that of the United States and in the general scramble or struggle of the masses for social preferment, high official position, professional distinction, or financial betterment, almost any individual will in the end find his level, in accordance with his natural and inherited endowments, his abilities, acquired through education, and the use which he makes of them. The gifted, industrious, physically and mentally fittest will easily rise to the top, while the physically weak and the mentally deficient will, as naturally and according to the same law, gravitate to the bottom of this sea of human life and of the multitude. The process of natural selection in the social sphere of human existence has full sway here.

In naval and military life, in countries where all are supposed to be born equal but are not, and in which selection on the principle of true merit and ability has been found either inconvenient, impracticable, or impossible, where artificial barriers are created and placed in the way of the advancement of organized merit and ability, the results must very naturally be somewhat different. While, perhaps, a high and uniform level of efficiency on the part of the individual members of such a body of men may not be inconsistent with such methods, an extremely dangerous dearth of leaders must, nevertheless, remain the inevitable result of such a system, a dearth most keenly felt at the most inopportune moments of national trials and tribulations.

In view of the above facts and considerations the process known as recruiting, being practically the only generally recognized and accepted method of selecting those who are fit for the service from those who are not, becomes of an importance all the greater. From this view-point the physical examination of the recruit, more especially, however that of the cadet, must appear in an entirely new light and one which, in its far-reaching importance, it would indeed be difficult to exaggerate.

The Significance of Selection by Means of a Physical Examination.—With the aid of a physical examination, as this is understood at the present day, the scientifically trained and practically experienced examiner is able to select, from a given number of candidates, a group not only superior in physique, but also, and at the same time, one superior in mental qualifications to the remainder. He can, moreover, by the same means exclude the criminals, criminaloids, and the degenerates.

It has been shown by a series of observations in different parts of the United States and other countries, made by Porter, Christopher, Hastings, Beyer, and others, that children and youths who have inherited an exceptionally good physique almost invariably also manifest mental qualifications that are likewise superior. All these observations, made by different observers and by means of different methods, have led to such uniform results that the correlation must seem unavoidable to any unprejudiced observer and the application of the principles involved to the process of recruiting follows as a most natural corollary.

A necessary preliminary step to the application of these principles to recruiting is the preparation of tables according to the percentile grade system of Francis Galton from as large a number of subjects as possible and from subjects (men and boys) of as nearly the same type as those with whom the candidates under consideration are to be compared. Such tables may include any number of measurements and tests. While height, weight, and chest circumference must be regarded as absolutely essential, other dimensions are very desirable.

The tables published in "The Growth of United States Naval Cadets," United States Naval Institute No. 74, include a number of tests and measurements in various dimensions; they will, therefore, do good service in the examination of cadets. The adjoining three tables (XXII., XXIII., and XXIV.) were made from 6,901 sailor-men and boys, and may, consequently, be said to be fairly representative of the physique of that class of people who have at all times applied for enlistment in the naval service. Since, however, the averages must be preponderatingly made up from the descendants of Anglo-Saxon and Teutonic stock, the examiner will still have

Naval Hygiene.

to use his judgment as regards the type of man before him in adjudging his relation to the averages given in the tables. Such tables are to the examiner what the compasses are to the navigator. One or two examples will perhaps help to make this clear.

Example I. A boy presents himself and his nearest birthday makes him fifteen years old. The measuring rod gives his height as 63.4 inches, the scale shows that he weighs 109 pounds nude, and the tape measure around his chest, taken at the level of the nipples, shows that his chest circumference is 30 inches. Looking now at the tables, along the line of averages obtained from boys of his age (fifteen) we shall find that all these figures fall under the fifty percentile grade. What does this indicate and what is his physical relation or standing when thus compared to the rest of the boys of his age? It means that out of one hundred boys of his age, our candidate is taller than forty-nine and not so tall as the remaining fifty above him; the same is, of course, true for weight and chest circumference. In other words, our boy is an average, or mean, boy for his age.

www.libtool.com.cn

Example II. Our second boy is sixteen years old, his height is recorded as five feet and one inch, his weight as 105 pounds, and his chest circumference as 29.5 inches. Our tables show him to be ten per cent. in height, twenty per cent. in weight, and thirty per cent. in chest circumference. These several percentages added together and averaged make him a twenty-per-cent. boy: $10 + 20 + 30 = \frac{60}{3} = 20$. In this manner a boy's physique in its relation to that of all the other boys of his age and type is brought out and the physical examiner gains an idea of the probable relation of his candidate to the rest of the community. Although it is, comparatively speaking, a rare occurrence that a recruit is found to have all his measurements fall under the same percentile grade, it is nevertheless also a fact that, whenever such is the case, our candidate shows a perfectly symmetrical development.

It has been found over and over again that the curves constructed from a number of children and youth, measured and averaged in this manner, when compared with the curves from their mental examination marks received at school, run very nearly parallel. An undoubted correlation between the physique and the mental performances of children and youths is hereby fully established and the application of the principles involved to the selection of recruits made apparent.

The minimum standards of height, weight, and chest circumference required from boys intending to enter the navy, as given in Appendix II., are all of very low percentage, when compared with the percentile grade tables, and cannot, therefore, be said to serve any purpose of selection. If notwithstanding these low limits we get a class of men into the service that is better than our requirements would indicate, this would seem to have been obtained in spite of and not with the aid of our examinations.

There seems to be nothing better established and recognized by prominent army surgeons—*e.g.*, Greenleaf, Woodhull, Munson, Woodruff, Tripler, and others—than that the lowering of the physical standard is invariably followed by a lowering of the moral standard.

Notter also believes in the correlation between the physical and the moral standards. Men of defective development are noted for the time which they spend on the sick list, in confinement; they are also known to furnish by far the greatest number of deserters.

The following table (XXV.), showing, as it does, that the percentage number of deserters has steadily increased since 1895, except during the war of 1898, would, if attributable to faulty recruiting alone, indeed be a revelation. But, although recruiting undoubtedly has its share in the production of such a large percentage of deserters, a careful and unbiassed inquiry would no doubt result in tracing such wholesale desertions to a variety of causes. Such an inquiry, if it were made without fear or favor, would throw valuable light on the subject.

Mr. Arthur H. Lee (*Nineteenth Century Magazine*, 1901),

TABLE XXV.

Year.	Naval Force.		Total.	Number of deserters.	Same in per cent.
	American.	Foreign.			
1895	....	....	10,000	888	8.8
1896	5,720	5,280	11,000	1,041	9.5
1897	6,126	5,219	11,345	1,357	12.0
1898	14,838	4,990	22,828	1,317	5.8
1899	11,446	5,386	16,832	2,452	14.6
1900	....	....	18,000	3,100	17.2

treating on the "recruiting question," says of the English army, where the standard had been lowered several years in succession: "Owing to the poor quality of the recruit enlisted, it ensues that less than 47 per cent. ever serve their full term; the remaining 53 per cent. are completely lost to the service and the country after an expensive training and a few years' inefficient service." "Owing to the same cause, the annual number of desertions has risen from 3,357 to 6,378." "Owing, moreover, to inefficient recruiting, at least 10,000 men disappear annually from the ranks of the army, for no valid cause beyond moral and physical unfitness." "The pecuniary loss to the nation from this cause alone is over 100,000 pounds sterling per annum, which, in my opinion, might be entirely obviated if the proper men were enlisted to begin with."

Mr. Lee's fundamental contention is, that the physically and mentally developed man is not only incomparably the better soldier, but is much the cheaper in the end.

Lord Kitchener has several times loudly complained of the poor and useless quality of recruits sent him to South Africa, and Kulp, from his recent experience, remarks, "The undersized, underfed, and underdeveloped boys one sees invalided from South Africa are not at all representative of the sturdy English race."

Thus it would seem that a lowering of the physical standards in order to increase the number of enlistments does not add to the value, the strength, or the efficiency of an army and is an unnecessary waste of public money.

Since there has been at all times a large percentage of men of foreign birth in the navy, it is interesting to note the difference in physique between that class and the native-born American. The adjoining table (XXVI.), calculated from—as nearly as that could be done—an equal number of both groups and of the same age (twenty-one) shows that, while the Americans have a slight advantage in height in almost all the percentile grades, the foreign-born American seaman has a more decided advantage in both weight and chest circumference.

TABLE XXVI.—AVERAGES OF 350 AMERICAN AND 316 FOREIGN BORN (ALL TWENTY-ONE YEARS OLD) COMPARED.

Per cent.	Height Inches.		Weight, Pounds.		Chest Circumference.	
	American.	Foreign.	American.	Foreign.	American.	Foreign.
5	62.91	62.61	113.2	115.4	29.4	30.3
10	63.50	63.40	116.9	119.5	30.2	31.0
20	64.48	64.30	121.5	124.5	31.0	31.7
30	65.27	64.86	125.0	128.5	31.5	32.3
40	65.96	65.40	128.0	131.5	31.9	32.8
50	66.52	65.93	131.4	134.7	32.3	33.3

70	67.61	67.34	139.1	142.2	33.2	34.3
80	68.21	68.05	143.5	147.5	33.7	34.9
90	68.94	68.88	149.4	153.9	34.5	35.9
95	69.86	69.52	157.2	159.2	35.2	36.7

The Significance of War to the Nation and the Race.—It is said of physicians that a large portion of their work is directed toward the prevention of disease rather than to the cure of it, and medical men have the rare distinction of being perhaps the only workmen known who make it

Digitized by Microsoft®

www.libtool.com.cn

their first duty to stop the sources of supply whence they derive their income. To prevent disease and suffering is, nevertheless, the highest function of hygiene and one of the noblest aspirations of modern medicine. If we look upon wars as preventable causes of disease and suffering and of death, it would seem to be one of the functions of naval and military hygiene not only to modify if not altogether to exterminate bullets, as we are trying to annihilate germs, mosquitoes, and other disease-producing agencies, but also to try to devise means for the final abolition of war itself. The gradual reduction in the calibre and the change in shape of the new small-arm projectile seem to be a step in this direction. In the same sense, arbitration may some day fill a chapter in a work on hygiene, and the great peace conference at The Hague, called into being by the august ruler of all the Russias a few years since, would then constitute historically speaking, the first great international attempt at promoting the fundamental interests and purposes of naval and military hygiene. War undoubtedly is the greatest and most merciless destroyer of the best there is of human life. The history of every war-like nation usually ends in the extinction of the best of that nation. Greece died because the men who had made her glory had all passed away; leaving none of their kin, they left none of their kind. The Greeks of to-day are the sons of those of whom she could make no use in her conquest of Asia. Indeed there is strong ground for the statement that there was more of the old heroic blood of Hellas in the Turkish army of Edhem Pacha than in the soldiers of King George who fled before them five years ago.

The cause of the fall of Rome has been traced to the extinction of the best of her race through her numerous conquests, only cowards remained and from their brood came forward the new generations, and even Cæsar noted the dire scarcity of real men, and "vir" the real man, became "homo" a mere human being.

"Send me the best you have," said Napoleon; "I want men, not boys." Since the time of the French Revolution and the Napoleonic wars, French skulls may be found piled up in Italy, Austria, Germany, Russia, Egypt, and Spain. They are the skulls of the best men that France had sent into the field. It was only after these were gone that the great general began to call for boys, saying, "A boy will stop a bullet as well as a man," and these died without leaving any offspring. From that time onward the men of the Loe became the fathers of the present men of France. M. Legoyt thinks it will take long periods of peace and plenty before France can recover the tall statures mowed down in the wars of the republic and of the first Empire.

Mr. Arthur Knapp, in his work entitled "Feudal and Modern Japan," says: "It is astonishing to find that after more than six generations or more than two hundred years of peace in which physical courage has not been demanded, these virile powers in the Japanese should be found unimpaired!" The student of history, however, finds that this is just what he would expect, for, in times of peace there is no slaughter of the strong, no sacrifice of the brave and courageous. It is in accordance with the laws of natural history and is proven by all the records of human history that the nation which has seen the least of war always develops the strongest battalions.

Germany, always systematic and thorough, taking advantage of the lessons taught by scientific research and, guided by the best principles of the times, spends her men and reduces the waste in war to a minimum by the strictest attention to scientific hygiene. She is military rather than warlike. In modern times the greatest loss to Germany has occurred through emigration, not through wars. The tendency of all emigration, whether from country districts into towns in the same country or from one country to another, has always been to weaken those left behind. Ammon has shown, for Germany, by measurements, that the average of those who emigrate is superior to the average of those who stay behind. Quetelet has shown that in some towns of Belgium the average stature was a little higher than in the country. Dunant found this to hold good with respect to the inhabitants of Geneva as compared with the country people around. Villermé, Manouvrier, and others have shown that the stature of the Parisian conscript is higher by 8 or 9 mm. than that of the men belonging to the rural arrondissement of the Seine. Germany has long since recognized this, and hence her struggle for colonies, the possession of which alone can save her ever-increasing population to her flag. It is want of room and lack of opportunity that drive her sons to foreign shores, not fear of military service!

Holland has become a nation of old men. Her sons have died in the fields of Java, and Batavia alone is said to have one million of Dutch graves. Dutch armies are to-day recruited elsewhere. Holland will not waste any more of her own blood.

"Spain died of empire years ago. She has never really crossed our path, it was only her ghost which walked at Manila and Santiago. The warlike nation of to-day is the decadent one of to-morrow" (David Starr Jordan, *Forum*, 1901).

As long as the physician cannot prevent the occurrence of disease, he will have to continue trying to do his best to cure it; as long as war will continue to recur, a nation will have to face the foe. Since, however, the most skilful physician for the care and treatment of disease will in the end prove the least expensive to the family, so the best sailor and soldier will invariably prove the more remunerative to the state. To bring a war to a speedy and successful termination, a nation must offer as recruits, and be willing to sacrifice, the best she breeds.

Henry G. Beyer.

APPENDIX I. *Requirements for Enlistment in the British Navy.*—The British navy is enlisted upon the Voluntary System. The seaman must have a good physique, though height, apart from a good development, is considered of no advantage. While no physical examination is required for the mercantile marine, none but promising lads are accepted for the training ships of His Majesty's navy, and persons of whatever age or class found to be laboring under any of the undermentioned physical defects or deformities are, by Article 1154 of the Admiralty Instructions, 1899, considered unfit for the service:

(*a*) A weak constitution, imperfect development, or important malformation or physical weakness, either hereditary or acquired.

(*b*) Skin disease, temporary or trivial; extensive marks of cupping, leeching, blistering, or of issues.

(*c*) Malformations of the head, deformity from fracture or depression of the bones of the skull, impaired intellect, epilepsy or paralysis or impediment of the speech.

(*d*) Blindness or defective vision, imperfect perception of colors, or any chronic disease of the eyes or eyelids.

(*e*) Impaired hearing, discharge from or disease of one or both ears.

(*f*) Disease of nasal bones or cartilage and nasal polypus.

(*g*) Disease of throat, palate, tonsils or mouth; cicatrices of neck, whether from scrofula or from suicidal wounds; unsound teeth or seven teeth missing or defective in persons under seventeen years of age; ten defective or deficient teeth in persons above the age of seventeen.

(*h*) Functional or organic disease of the heart or blood-vessels, deformity of chest, phthisis, bronchitis, hæmoptysis, asthma, dyspnœa, chronic cough, or any evidence of lung disease or tendency thereto.

(*i*) Undue swelling or distention of the abdomen; disease of liver, spleen or kidneys, hernia or tendency thereto, incontinence of urine, syphilis or gonorrhœa.

(*j*) Non-descent of either or both testicles, hydrocele, varicocele, or any other serious defect or malformation of the genital organs.

(*k*) Fistula of anus, hemorrhoids, or any disease of stomach and bowels.

(*l*) Paralysis, weakness or impaired motion, or deformity of either extremity, including varicosity of veins, especially of the leg, and distortion or malformation of hands, feet, fingers or toes.

(*m*) Distortion of spine, of the bones of pelvis, no matter whether from injury or disease, or from constitutional defect.

APPENDIX II. *Requirements for Enlistment in the United States Navy.* Briefly stated, the physical requirements for enlistment in the United States navy are as follows: The candidate must be of good physical proportions, and, if accepted, is required to take oath before enlistment that he is not subject to fits and has no concealed diseases. Any of the following conditions are sufficient to cause the rejection of an applicant: Greatly retarded development; feeble constitution, inherited or acquired; permanently impaired general health; depraved condition of general nutrition; liability to any disease; chronic diseases or results of injuries sufficient permanently to impair efficiency, such as weak or disordered intellect; epilepsy or other convulsions within five years; impaired vision or chronic disease of the ears; chronic or offensive nasal catarrh; tumors of the nasal passages or great enlargement of the tonsils; marked impediment of speech; decided indications of liability to pulmonary disease; chronic heart affections; rupture; non-appearance of testicles; dropsy of testicle or cord; stricture, fistula or hemorrhoids; large

Digitized by Microsoft®

varicose veins of lower limbs, scrotum or cord; chronic ulcers; cutaneous and communicable diseases; unnatural curvature of the spine; wryneck or other deformity; permanent disability of either of the extremities or articulation from any cause; defective teeth; the loss or extensive caries of four molar teeth.

In addition to the above, candidates for enlistment as apprentice must at least fulfil the requirements of the following table of minimum measurements:

www.libtool.com.cn

Age in years.	Minimum height.	Minimum weight.	Minimum chest circumference.
14	4 feet 9 inches.	70 pounds.	25 inches.
15	4 feet 11 inches.	80 pounds.	27 inches.
16	5 feet 1 inches.	90 pounds.	28 inches.

NAVAL MEDICAL SERVICE.—I. NAVAL MEDICAL DEPARTMENT.—*Historical Notice.*—"The Marine Committee" of the Continental Congress made provision at an early date for a medical department of the navy, and declared "the care of the sick and wounded to be objects of great solicitude." In the "Rules for the Regulation of the Navy of the United Colonies," adopted November 28th, 1775, this service was defined. After the completion of the revolutionary struggle slow progress was made, until 1794, when the entire naval service was augmented; yet at this time the medical departments of the army and navy were one, under an officer who bore the title of physician-general. Not until 1828 were the medical departments of the army and navy divided. In 1842 the bureau of medicine and surgery of the navy department was created, and W. P. C. Barton was nominated its chief. By the act of 1871 the entire service was reorganized, the grades of medical director, and medical inspector created, and the title of surgeon-general, with the relative rank of commodore, conferred on the chief of bureau. In March, 1898, this officer was given the rank and title of rear-admiral.

The organization of the medical corps of the navy is essentially that created by the act of 1871, and amended by the acts of 1898 and 1900.

The grades, ranks, and titles in the medical corps of the navy, compared with that of the line of the army and navy, is shown in the table prepared by Medical Director Gihon, as modified by existing law.

U. S. ARMY.	U. S. NAVY.	
All Officers.	Line.	Medical Officers.
....	Admiral.	
Lieut.-General.		
Major-General ...	Rear-Admiral	Surgeon-General.
Brigadier.		
Colonel	Captain............	Medical Director.
Lieut.-Colonel....	Commander	Medical Inspector.
Major............	Lieut.-Commander.	Surgeons (Senior).
Captain...........	Lieutenant.........	Surgeons (Junior). Passed Asst. Surgeon (Sr.).
1st Lieutenant....	Lieutenant (Junior Grade)...........	Passed Asst. Surgeon (Jr.). Assistant Surgeon.

By the act of 1898 positive rank was conferred on all officers of the medical corps of the navy, and in 1900 assistant surgeons were given the rank of lieutenant (junior grade), corresponding to first lieutenant in the army.

The titles, grades, and numbers in the medical corps of the navy are as follows, viz.: 15 medical directors, 15 medical inspectors, 55 surgeons, and 105 in the combined grades of passed and assistant surgeons.

The number of officers in the grade of passed assistant surgeon is not limited, the law providing for promotion of assistants after three years' service.

The surgeon-general does not constitute an extra number, but is chosen from the grade of director or inspector for a term of four years, being eligible to reappointment. All officers of the navy retire on reaching the age of sixty-two years.

Examination and Appointment.—A candidate for entrance into the medical corps of the navy must be between the ages twenty-one (21) and thirty years (30). He appears before a board, which is under oath to report on his physical, mental, moral, and professional qualifications.

Appointments are made in the order of merit reported by the board.

The examination is: (1st) physical; (2d) mental, consisting of (*a*) written, (*b*) oral, (*c*) clinical, (*d*) practical, and embraces about six days.

The board of medical examiners sits permanently at the Naval Hospital, New York. Prior to 1897 no examination was required from the grade of passed assistant to that of surgeon, but under present law examinations occur with each promotion. The examination for the grade of surgeon relates largely to an officer's experience attained in the lower grades. It comprises the following subjects: (*a*) Naval regulations, in so far as they pertain to the medical department; (*b*) thesis on general and naval hygiene; (*c*) thesis on clinical medicine; (*d*) practical bacteriology and chemistry; (*e*) microscopy and microbiology; (*f*) military surgery.

The flow of promotion is dependent upon resignations, dismissals, retirements, and deaths.

Officers reaching the grade of surgeon at this time (1900) have been in the service about ten years. The disposition of officers entering the corps depends upon the exigencies of the service; if these permit, they are ordered to receiving ships, and gain some preliminary knowledge of the duties and life at sea. The percentage of those given permission to appear before the board of examiners, who pass, is small. Thus, of the twenty-two candidates who presented themselves during the fiscal year ending in 1896, four were rejected physically, twelve were rejected professionally, and six were found qualified for the position of assistant surgeon. It cannot be concluded from this statement that the examination is unduly rigorous, but rather it is indicative of insufficient academic study and a lack of thoroughness in the professional equipment, which we fear is far too common a condition among the graduates of a large number of medical schools in the United States.

The compensation of officers of the medical corps is that of their corresponding rank in the line, and is shown as follows:

PAY TABLE.

	At sea.	On shore.	Allowances,* per annum.
Assistant Surgeons: Rank of Lieutenant (Junior Grade)......................	$1,650.00	$1,402.50	$288.00
Passed Assistant Surgeons:			
Rank of Lieutenant (Junior Grade)...	1,650.00	1,402.50	288.00
After five years in the service........	1,800.00	1,530.00	288.00
Rank of Lieutenant	1,980.00	1,683.00	432.00
After five years in the service.......	2,160.00	1,836.00	432.00
After ten years in the service........	2,340.00	1,989.00	432.00
Surgeons:			
Rank of Lieutenant: After ten years in the service....................	2,340.00	1,989.00	432.00
After fifteen years in the service......	2,520.00	2,142.00	432.00
Rank of Lieutenant-Commander: After ten years in the service.........	3,250.00	2,762.50	576.00
After fifteen years in the service......	3,500.00	2,975.00	576.00
Medical Inspectors, rank of Commander:			
After fifteen years in the service......	4,000.00	3,400.00	576.00
Medical Directors, rank of Captain:			
After fifteen years in the service......	4,500.00	3,825.00	720.00
Surgeon-General, rank of Rear-Admiral.	5,500.00	5,500.00	720.00

The hospital corps of the navy was authorized by an act of Congress, June, 1897, thus securing for the service skilled men for the care of the sick and wounded.

The hospital corps consists of the following grades and rates: (*a*) Pharmacists, warrant officers; (*b*) hospital stewards, chief petty officers; (*c*) hospital apprentice, first class; (*d*) hospital apprentice, second class.

* Only when quarters are not furnished by the Government. Eight cents a mile is the allowance when travelling under orders.

Digitized by Microsoft®

An examination, physical and professional, before a board of medical officers, is required for enlistment and for promotion in each of the above grades.

The naval medical department maintains hospitals at the following places: Widow's Island, Me.; Portsmouth, N. H.; Boston, Mass.; Newport, R. I.; Brooklyn, N. Y.; Philadelphia, Pa.; Washington, D. C.; Annapolis, Md.; Norfolk, Va.; Pensacola, Fla.; Mare Island, Cal.; Yokohama, Japan; Cavité, P. I. The hospitals provided by the original act of Congress were those at Boston, New York, Philadelphia, and Norfolk. That at Philadelphia has been converted into the Naval Asylum, and a fine modern structure has taken its place.

The naval hospitals of the United States and other powers have been fully described by Surgeon J. D. Gatewood, U. S. N.*

At a comparatively recent date most of these hospitals have been modernized in construction, and their equipment has been raised to present requirements.

Although the hospital ship *Maine* has done efficient service in South Africa, the floating hospital of the future will be the *Ambulance Ship*, such as was the *Solace* during the late war with Spain. The object of such a ship is to collect the sick and wounded in a fleet after an engagement, render immediate succor, and transfer the wounded to a base hospital. While the presence of such a ship amid hostile fleets had been previously proposed, the desirability of such a step was formally advanced, and earnestly advocated by the present chief of bureau, Surgeon-General W. K. Van Reypen, in a paper read before the Twelfth International Medical Congress, held at Moscow in 1897, and in less than a year it was this officer's privilege to commission the *Solace*, a ship such as he had described, which rendered such excellent service in the war with Spain.

The *Solace* had a displacement of thirty-six hundred tons, was three hundred and seventy feet over all, with an average speed of fourteen knots; she carried steam launches and barges for the transfer of the sick and wounded. Hoisting and lowering were accomplished by steam winches. A complete aseptic outfit, formaldehyde generators, disinfecting chambers, laundry, and drying room were provided. The *Solace* accommodated three hundred and fifty patients. Ventilation was accomplished by means of powerful blowers and electric fans. The ship flew the Red Cross, and was under the protection of the Geneva Convention. Indeed everything which could be suggested to make this floating, travelling hospital a success was done. The excellent results accomplished justified all expectations, and established a decided advance in the humanitarian aspect of modern war.

Hospital ships may still serve a useful purpose as before stated, when the base of a fleet is too remote to permit of the transfer of the disabled. When conditions obtain, such as those at Santiago, or such as prevail at present (1900) in Manila and China, the *Ambulance Ship* will be of inestimable value so long as Japan can be used as a base.

Service at Sea.—The progress made in the past twenty-five years in the betterment of conditions making for health on shipboard are only equalled by the advance in the sciences of medicine and surgery themselves; yet the former condition is not largely due to the latter, but rather to the improvement of naval construction and a higher appreciation of sanitary principles, which have been so persistently inculcated. Medical Director Gihon has drawn a graphic picture of this change; and since this officer's active service closed, the improvement has continued, the modern man-of-war presenting the most striking object-lessons, showing how an observance of the prime principles, involving a supply of fresh air, good lighting, and scrupulous cleanliness, has so far succeeded as to render a most unnatural life and environment a comparatively healthy one. In this connection, it must be borne in mind what a radical change has been wrought in the life of a man-of-war's crew by the change from sail to steam power; and to overcome the deleterious effect thus brought about has been the most important problem which the naval medical officer has been called upon to consider; and the splendid results obtained in our service during the late war are most creditable alike to commanding and to medical officers. We have every reasonable hope that the lessons of the past are now heeded, and that the inutility of a ship, however powerful, with a crew living in unhealthy conditions, has been amply demonstrated. Such was Admiral Vernon's expedition against Carthagena, in which the crew were crowded into dark, ill-ventilated sleeping quarters, and were fed upon salt and often decomposing food with bad water. Surgeon-General Tryon has pointed out that when iron and wood supplanted steel as the material for the construction of ships, a destructible organic substance was substituted by an indestructible, inorganic substance, and this change worked the most important reform in naval hygiene. The sequels of this change were broad inlets for the admission of air, and light, systematic ventilation, the distillation of water, its preservation in iron tanks, and the improvement of the rations by the art of preserving foods. Thus were accomplished the conditions which have made prolonged life at sea not only possible, but one closely approaching the natural. A discussion of such questions belongs to the domain of naval hygiene; they have been alluded to here, and give the reader an idea of the broader lines of duty which will engage the attention of a medical officer at sea. The details and daily rounds are soon mastered, and are important or unimportant, much more in the way in which the sanitarian of the ship conceives of his duty than in any other. The naval medical officer will soon learn that it is in the broad realm of preventive medicine that he will find his sphere of greatest utility; that to ameliorate the effects of environment and to reduce the potency of pathological factors should be his chiefest aim.

The daily duties are defined by regulation; and besides attention to and report upon the condition of the sick, they embrace an inquiry into that of the living spaces, cells, closets, pantries, and an examination of food and water issued or coming on board. A duty peculiar to army and naval medical service is that of determining whether in a given case of disease or injury it is the result of causes incident to service; on this decision rights to pension are based, and in it also are involved the rights of the individual and the Government alike, both of which are to be respected.

The facilities of the medical department on shipboard have in late years been greatly improved, involving a comfortable hospital, or sick-bay, usually supplied with bath and closet. When we consider that the primal object of a battleship is the destruction of life, we must admit that the humanitarian side of the question has had as a rule fair treatment. Medical officers at times complain of an insufficiency of accommodation, yet a generous consideration is accorded, and any agencies seriously affecting the interest of the department are, if possible, remedied. The medical supplies, including hospital stores, furnished by the naval laboratory located at New York, are usually of good quality; and this held good during the stress of the Spanish-American war. The supply table is varied and the allowance liberal. Complete antiseptic outfits are supplied, and the instrument cases are now so complete that when hospitals are inaccessible, major operations can be performed with confidence.

Inasmuch as the naval medical officer visits all climates, he should be an authority on climatic diseases, and consequently the reports of the bureau of medicine and surgery contain frequent descriptions of such maladies. Indeed, since the late acquisition of territory by the United States, the great need of more exact knowledge of diseases foreign to our own nomenclature has been greatly emphasized.

The accompanying table exhibits the amount of disease in the naval service for the years 1893–94.

Recruiting for the naval service is a matter of the greatest importance, as we have here an opportunity to shut out predisposing and hereditary tendencies as well as existing disease. This work for the navy is usually done on shipboard (receiving ships) and for the marine corps at a rendezvous located in our large cities. As far as possible examination for entering the naval service should be discouraged on shipboard.

It is to-day incumbent on the naval medical officer to be familiar with the duties involved with bluejackets and marines landed to co-operate with the army. This service is becoming more than occasional, especially in the operations in the Orient.

The number of medical officers detailed for a ship of war depends principally upon her size, third and fourth rates carrying one, second and first rates two, the flag-ship as a rule carrying but three officers, the senior being the fleet-surgeon, who is on the staff of the commander-in-chief, and is by the regulations entrusted with duties largely supervisory in character.

The disposition of the medical department on a ship in action is provided for only in a general way by the regulations. The type of the ships varies to such an extent that the matter is wisely left to the discretion of the commanding and medical officers. The care of the wounded in action will be considered in the next section.

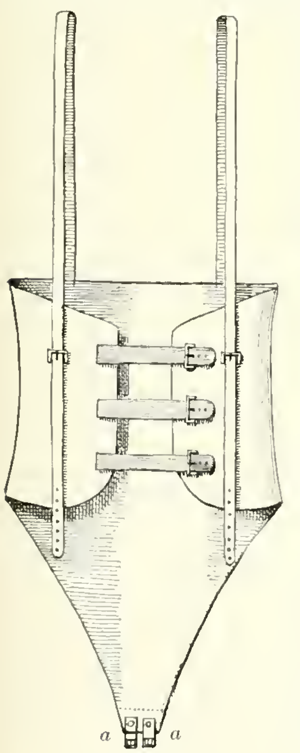

FIG. 3510.—Lowmoor Jacket.

Service on Shore.—Medical officers of the navy serving on shore are detailed, according to their rank, as members of boards, in charge of hospitals, at navy yards, recruiting rendezvous, on receiving ships, or on some form of special duty. The length of a shore detail is from one to three years (usually the latter), according to the requirements of the service. Recent law makes retired officers eligible for duty on shore and at sea.

Not since the Civil War has the lowest grade of the naval medical corps had the full number allowed by law. This condition has been attributed to various causes, such as the fact that an assistant surgeon, upon entering the service, is ranked as a steerage officer and is not admitted into the ward-room, and the further fact that he has entered a grade lower than in the army. Doubtless these facts may have exerted an influence in some cases, but they cannot, in the opinion of the writer, have operated to any considerable extent. The standard of the examining board has been a strong factor, as is evidenced by the percentage of rejections. The first two objections have been removed by recent law.

The life of a naval medical officer at sea is one of practical isolation; and, despite the literature so liberally supplied, he inevitably gets out of touch with the great mass of the profession. In discharge of the duties required of him by the regulations he may have been fully occupied, but this fortunately does not occur in so far as strictly medical or surgical work is concerned. The greatest need of the medical service of the navy is an opportunity to avail of post-graduate instruction, and it is much better, with the present numbers of the army and navy, that such instruction be followed in a civil school. It may be that in the future the importance of the interests involved will justify an army and navy medical school, such as that at Netley in England; but until then the medical officers of the two services must look to the great metropolitan hospitals for advance in the more strictly professional aspects of their duty, and some plan by which this can be more systematically accomplished will greatly enhance the efficiency of the naval medical service.

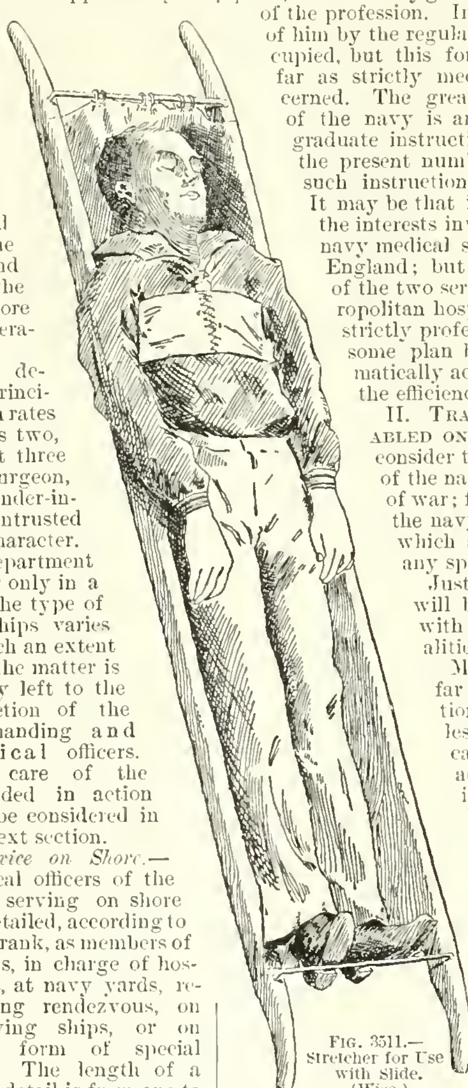

FIG. 3511.—Stretcher for Use with Slide. (Wise.)

II. TRANSPORTATION OF THE DISABLED ON SHIPBOARD.—It is proposed to consider this question as it relates to ships of the navy, and more especially in time of war; for in the merchant service and in the navy in time of peace the difficulties which are encountered do not call for any special consideration in this place.

Just what the fate of the wounded will be in a maintained naval action, with its inevitable high rate of casualities, no one can foretell.

Mr. Archibald Forbes has gone so far as to say that since the introduction of modern firearms and smokeless powder the wounded will not, cannot, be cared for until after the action (this statement was made in reference to engagements on land), or on the succeeding day; but the war in South Africa and the Philippines has totally disproved this position, as never before has the medical department been so much exposed or the wounded more scrupulously cared for.

In the old style man-of-war we had, in all ships, to deal with the same general type,—we had broad hatches, wide ladders, easily removed, and flush decks. To-day the decks are cut up and subdivided indefinitely. There is such a demand for space that great ingenuity is necessary to get the requisite equipment and all the quarters within the hull. This state of affairs is greatly accentuated in the battleship. The turrets, tops, and fire-rooms are practically isolated.

For the care and transport of the wounded on a ship like the *Brooklyn*, an armored cruiser, or the *Oregon*, a battleship, there are from two to three medical officers, an apothecary or hospital steward, and two or three hospital apprentices—an average of five persons. From each gun-crew two men are detailed as aids, numbering from eight to twelve ordinarily. With this force the wounded in a crew of six hundred must be relieved.

Digitized by Microsoft®

A most conservative estimate of the number of wounded in naval actions of the future is thirty-three per cent; in the action between the *Bonne-Homme Richard* and the *Serapis* it reached fifty per cent. on each side. Long before thirty-three per cent. of a crew are placed *hors de combat*, no aid will be available from the guns.

www.libtool.com.cn

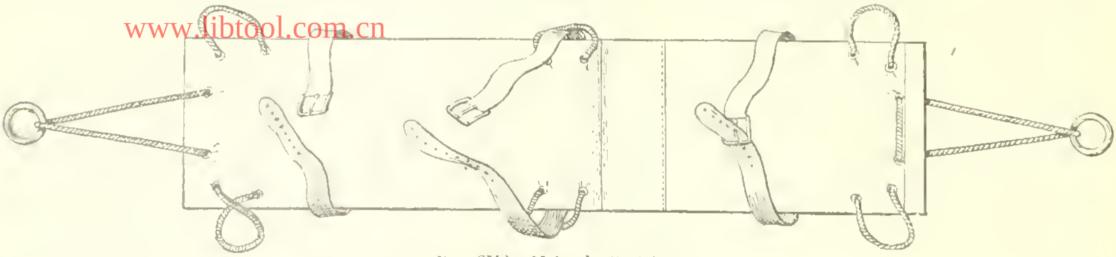

FIG. 3512.—Mahan's Stretcher.

The careful medical officer, before an action, will have studied this question as applying to his own ship. He will have established the stations for the wounded and the base of supplies. He will have indicated points of temporary shelter about the decks and will have distributed first-aid packages. In all probability there will be no systematic transport of the wounded during an action at sea. In the turrets, tops, and fire-rooms the wounded will be given emergent aid, and will be allowed to remain where they fall, or they will be pushed aside into temporary shelter.

For the dark, narrow, acute-angled passages hand portage is alone available; and this method will prevail in those heated contests in which time cannot be taken or aid secured to send all the wounded below.

During the late war with Spain the navy gained little experience in this respect, for the number of casualties on the American ships was insignificant, while on the vessels of the enemy the destruction of life was so great and the conditions were so frightful that no systematic relief could be attempted.

For the removal of the sick or injured from the hold or fire-room, or for sending them down from the tops we can conceive of no better device than the Lowmoor jacket (Fig. 3510), which may be briefly described as follows:

This jacket is T-shaped, and adapts itself to men of different sizes. The arms of the T surround the body, and extend from the axillæ to the waist, fastening in front by three leather buckles and straps; the leg of the T, passing down behind the body and over the perineum, comes up and fastens in front by two straps and buckles. Two leather straps are stitched to the back of the jacket for its whole length, and their free ends are then brought high up above the shoulders (in the form of loops) and carried down to points where they can be fastened by buckles to the front of the jacket. The ends which extend beyond these first buckles are to be passed through two other buckles which are fastened to the ends of the two perineal straps (cut off at *a*, *a*, in Fig. 3510).

The transportation of the disabled along the deck, or between decks, from above below, can be accomplished by by several different stretchers. The writer devised a stretcher and slide for this purpose, which has been favorably reported upon by a board of officers for use in the naval service (Fig. 3511). This stretcher consists of two poles seven feet eight inches in length, and a piece of canvas six feet two inches long, into the sleeves of which the poles run. Two steel stretcher-bars, three-quarters of an inch in diameter, join the poles (at points where the canvas terminates), and passing through them are secured by nut and screw. Two canvas bands are fastened to the frame on either side so as to cross the chest of the occupant at the axillæ and fasten in front with hooks and lacing. When the patient is put upon the stretcher, his insteps take upon the lower bar, preventing his slipping downward. The slide to be used with this stretcher is made of ordinary boards, battened together, and may be placed in a hatchway, extending from the coaming to the deck below, over the ladder, or it can be used without the ladder. Upon this slide the stretcher is sent below.

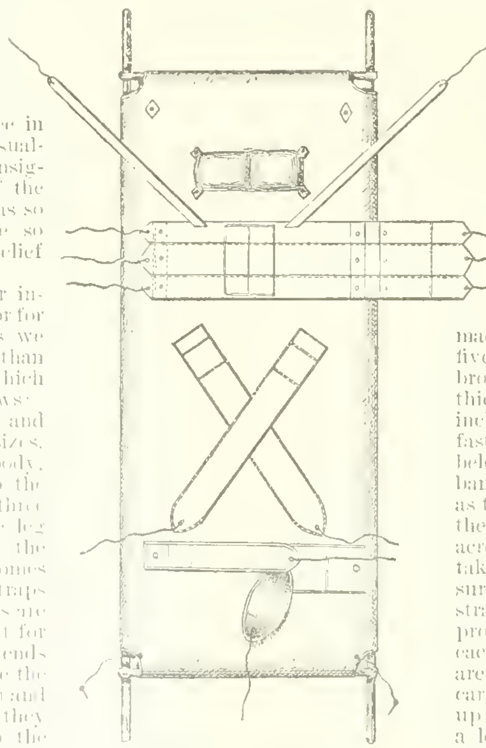

Fig. 3513.—Gihon's Stretcher.

The advantage of this stretcher is, that it does not involve suspension of the body; and it is immaterial whether or not a ladder is in place in a hatchway.

When not in use the bars are removed at one end, laid parallel with the poles, and the whole is neatly rolled. This form of stretcher is available for landing parties. Lieutenant-Commander Mahan has devised a stretcher which is described by Medical Director Gravatt, U. S. N., as follows (Fig. 3512): "This stretcher is made of light pine boards, six feet five inches long, fourteen inches broad, and one and one-half inches thick, with a wooden batten several inches in height and thickness, firmly fastened across each end and a little below the middle. Three canvas bands, four inches broad, are made so as to buckle just across the chest at the armpits, over the abdomen, and across the leg. The middle batten takes under the buttock, 'and gives surprising support.' A man so strapped can be put in any position, prone, upright, or at any angle. Near each end of the board, rope handles are made, by which it can easily be carried through narrow doors and up and down ladders. By means of a loop across the head-end it can be lowered through hatches or over the side."

The suspension of sick or wounded men on shipboard is a very unusual occurrence, and it will probably never be attempted in action. For bearers to carry a man down a ladder in a stretcher is a very awkward procedure; and a device like Mahan's, when sending below, will be most serviceable when used with a slide.

Digitized by Microsoft®

Objections urged against this stretcher are, that it would be injurious in case of thigh fracture, and that it cannot be availed of for landing parties. Medical Inspector Gravatt, U. S. N., reports that he has used Mahan's device in cases of thigh fracture without detriment.

There are many other forms of stretcher available for the purpose under consideration. Wells' ambulance cot is in use in the United States naval service, but, as is true of other devices of this kind, men cannot be sent below upon it conveniently without the slide. This is an excellent form of stretcher for landing parties. "The improved cot" of Gorgas, or the "ambulance lift" of McDonald are seldom used. Gihon's "naval ambulance cot" is a secure and excellent device (Fig. 3513) and adapted to any ordinary need of transportation. Most of the stretchers devised for the old type of ship contemplate the suspension of the wounded, with hoisting or lowering; but, as hitherto remarked, this is a rare procedure. During an action at sea, if a hatchway is cleared, it will, as a rule, be used for militant purposes, and it is only where the ladder is taken away that suspension can be practised. If the ladder remain, one of the forms of stretcher already described, and with a slide, will be found the simplest and best procedure when hand-portage is not desirable.

For an improvised stretcher Lieutenant Mason, U. S. N., suggested the use of a ship's hammock, which is stretched and laced to a wooden frame, made of poles and cross-bars.

John C. Wise.

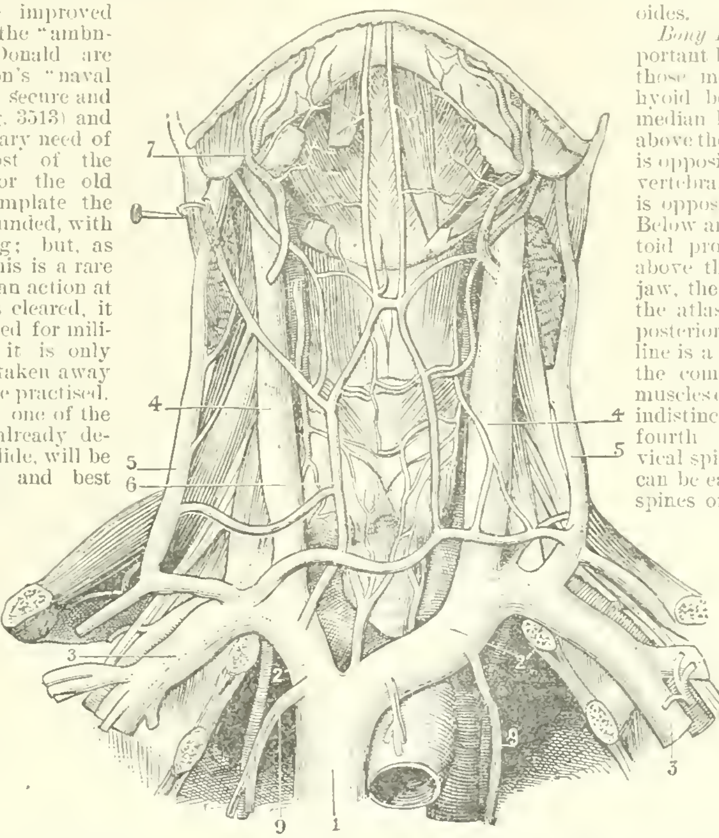

FIG. 3514.—Superior Vena Cava and Its Affluents. (From Testut.) 1, Superior vena cava; 2, trunk formed by the union of the brachial and cephalic veins on the right side; 2', the corresponding venous trunk on the left side; 3, 3, subclavian veins; 4, internal jugular vein; 5, external jugular vein; 6, anterior jugular vein; 7, facial vein; 8, thyroid veins; 9, internal mammary vein.

NECK, SURGICAL ANATOMY OF THE.—By the neck we usually mean the space between the occipital bone and lower jaw, above, and the upper aperture of the thorax, below. For convenience of description it is advisable to divide the neck into regions, viz., two lateral, an anterior median, and a posterior.

The *lateral* region represents a quadrilateral which is divided diagonally by the great sterno-mastoid muscle into two triangles, the anterior (carotid) and the posterior. Each of these is again subdivided into two by the omohyoid muscle. The anterior triangle is subdivided into a superior and an inferior carotid triangle, and the posterior into an occipital and a subclavian triangle.

The *anterior median* region is divided into two spaces by the hyoid bone, the upper being called the suprahyoid or submaxillary, and the lower the infrahyoid or hyosternal region.

The *submaxillary* region is bounded posteriorly by the posterior belly of the digastric and stylohyoid muscles, and contains the submaxillary gland.

The *posterior region* includes the portion commonly known as the nape of the neck.

SURFACE ANATOMY.—The outline of the neck varies much in different people; in stout individuals it is round and full, and the various landmarks are not easily distinguished; in thin people, on the other hand, every landmark stands out prominently, and can be made out by even the most inexperienced. The neck is, as a rule, fuller and rounder in women and children, and the *pomum Adami* is less marked. In muscular males the prominences are well seen; in old people who are thin the sterno-mastoid muscles and superficial veins stand out well, as does also the internal border of the platysma myoides.

Bony Points.—The most important bony point, and one of those most easily felt, is the hyoid bone, which is in the median line, a finger's breadth above the thyroid cartilage. It is opposite the fourth cervical vertebra. The cricoid cartilage is opposite the sixth cervical. Below and in front of the mastoid process, and behind and above the angle of the lower jaw, the transverse process of the atlas can be felt. In the posterior region in the middle line is a depression formed by the complexus and trapezius muscles of each side; here can be indistinctly made out the third, fourth, fifth, and sixth cervical spines, while the seventh can be easily felt, and also the spines of the first two dorsal vertebræ. These become more prominent when the head is bent forward; occasionally, when the spine of the sixth cervical vertebra is well developed, it is quite as prominent as the seventh. The transverse process of the sixth cervical vertebra can be felt on deep pressure opposite the cricoid cartilage, in the course of the carotid vessels. This is called the "carotid tubercle," and here the carotid may be easily compressed against it.

Anterior or Median Region.—In the receding angle below the chin is the hyoid bone, which can be easily felt in the fattest necks, it divides the anterior part of the neck into the suprahyoid and infrahyoid regions. In the median line of the suprahyoid region the anterior bellies and the digastric muscles cause a slight convexity; on the outer side of each anterior belly of the digastric muscle is felt the submaxillary gland lying on the mylohyoid muscle, which helps to form the floor of the mouth. This region is commonly cut into in self-inflicted wounds of the throat. About half an inch below the hyoid bone is the prominent thyroid cartilage (pomum Adami). This cartilage is prominent in deep-voiced men and people with thin necks, but in women and children it is not so distinctly seen; the notch at its upper border can be easily felt, and is commonly situated to one side of the median line. The superior cornua of the thyroid cartilage can be traced with the finger.

Digitized by Microsoft®

The space between the thyroid cartilage and the hyoid bone is called the thyrohyoid space, a membrane connecting these two structures; this membrane is covered by the muscles going to the hyoid bone from below, and is pierced by the superior laryngeal nerve and artery of each side. A cut made through the thyrohyoidean space would sever the lower part of the epiglottis. The rima glottidis is opposite the middle of the thyroid cartilage. Below this cartilage the finger sinks into a slight depression, the cricothyroid space; this is the space in which the operation of laryngotomy is performed, the opening here being well below the vocal cords. Across this space ramify two small vessels, the cricothyroid branches of the superior thyroid arteries. The next landmark of interest is the cricoid cartilage; it is a guide to many operations on the neck and air passages, and can be distinguished in the youngest and fattest neck. The cricoid cartilage is opposite the sixth cervical vertebra, and the narrowest part of the gullet is behind it; at this point foreign bodies are most likely to be arrested. The omohyoid muscle crosses the carotid vessels on a line with the cricoid cartilage, immediately above which line is the point usually selected for tying the common carotid artery. The middle cervical ganglion of the sympathetic is also on a line with this cartilage, and a little below and outside of it is the point where the vertebral artery enters the transverse process of the sixth cervical vertebra.

Below the cricoid cartilage the finger passes on to the trachea, the separate rings of which cannot be easily felt, because they are covered by the isthmus of the thyroid gland above, and below the trachea recedes from the surface. At the upper border of the sternum the trachea is one inch and a half from the surface. The isthmus of the thyroid crosses the second and third rings of the trachea.

In front of the trachea, below the isthmus, lie the inferior thyroid veins, which give so much trouble in tracheotomy. Occasionally an artery is found lying upon

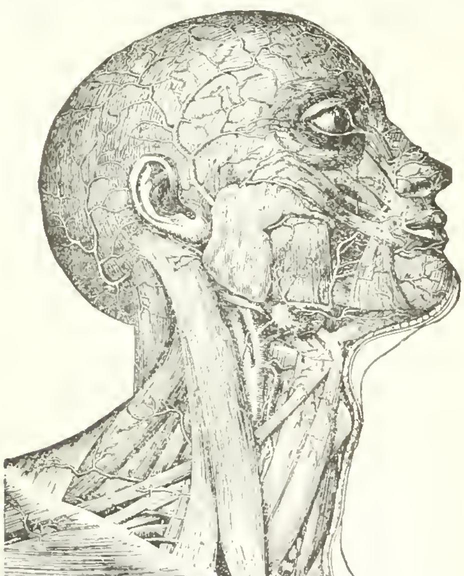

FIG. 3515.—Dissection of the Neck, showing the Triangles and their Contents. (Tiedemann.)

the trachea, on its way to the thyroid gland; it is called the thyroidea ima and generally arises from the innominate. The episternal notch is felt at the top of the sternum, and is opposite the second dorsal vertebra.

Lateral Region.—The sternomastoid muscle is the prominent landmark in this region; in thin subjects, especially, it is well seen, and stands out distinctly when the face is turned to the opposite shoulder. The inner border, which covers the carotid artery, is more strongly marked than the posterior, which is thin, only the lower portion

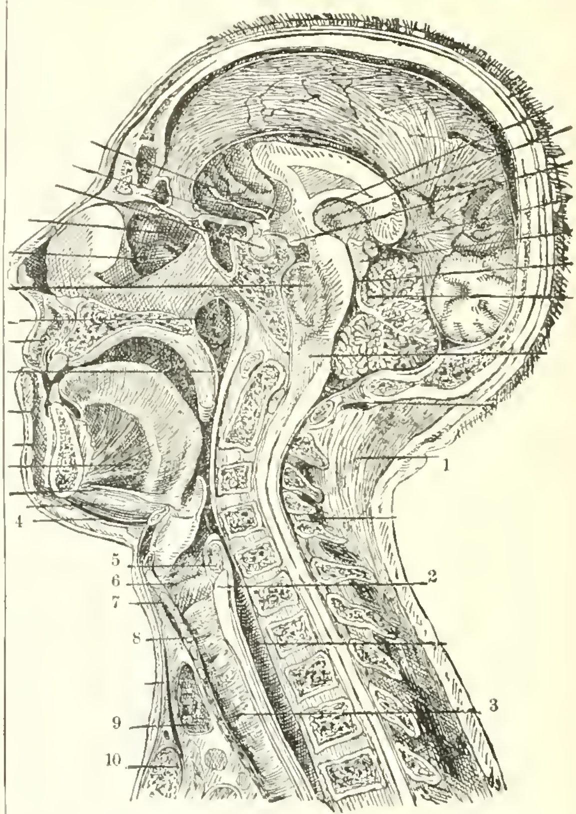

FIG. 3516.—Vertical Median Section of the Head and Neck. 1, Ligamentum nuchæ; 2, cricoid cartilage; 3, trachea; 4, hyoid bone; 5, musculus arytenoideus; 6, ventricle of larynx; 7, thyroid cartilage; 8, cricoid cartilage; 9, thyroid body; 10, sternum. (After Braune.)

showing through the skin. The sternal tendons are well seen in nearly everybody, the depression between them being named the suprasternal fossa. In some necks this fossa is absent, owing to the space being filled with fat. The space between the sternal and clavicular portions of the sternomastoid can usually be made out; in thin necks it is well marked. The internal jugular vein and carotid artery lie behind this space; deeper down still, we have the apex of the lung, which sometimes rises an inch and a half above the clavicle.

The sternoclavicular articulation is an important landmark; immediately behind it, on the left side, is the common carotid artery and the division of the innominate; on the right, it is opposite the point where the internal jugular joins the subclavian vein to form the innominate. The division of the innominate artery in children is higher up than the articulation; in some cases it divides in front of the trachea (see *Arteries, Anomalies of*).

The depression above the clavicle, between the trapezius and the clavicular origin of the sternomastoid, is called the supraclavicular fossa. In this fossa the external jugular vein terminates in the subclavian, after piercing the deep cervical fascia. Here also may be felt, in thin persons, the brachial plexus of nerves and the omohyoid muscle, and in the angle formed by the sternomastoid and clavicle the third part of the subclavian artery may be felt pulsating. At this point it can be compressed against the first rib. The central point of the greatest convexity of the clavicle is opposite the third portion of

Digitized by Microsoft®

the subclavian artery. This is a more certain landmark than the muscle, the extent of attachment of which to the clavicle varies considerably.

The posterior border of the sternomastoid corresponds pretty closely to the outer border of the scalenus anticus muscle; this point should be borne in mind in tying the subclavian artery.

www.libtool.com.cn

Behind the sternomastoid the chain of lymphatic glands, when enlarged, can be easily felt.

The posterior belly of the digastric muscle corresponds to a line drawn from the mastoid process to the body of the hyoid bone. When the chin is extended a prominent fold of cervical fascia can be felt going from the angle of the lower jaw, downward and outward.

The position of the tonsil corresponds externally to the angle of the jaw.

Veins (Surface Marking of).—The most important of these is the *external jugular*, which can always be seen. Its course is marked out by a line drawn from the angle of the jaw to the middle of the clavicle, at which point it pierces the deep cervical fascia to join the subclavian vein. It is occasionally joined by a vein which runs over the clavicle (see *Veins, Anomalies of*). By pressing above the clavicle, the vein is distended, and its course is easily traced.

The *anterior jugular* vein lies on the sternohyoid muscle and in front of the inner border of the sternomastoid. When the external jugular is small this vein attains considerable size.

The surface marking of the *internal jugular* corresponds to a line drawn immediately external to the line of the artery. The *facial vein* runs from the anterior border of the masseter muscle downward and backward, and joins the internal jugular opposite the upper border of the thyroid cartilage.

The *middle thyroid vein* crosses the carotid artery opposite the cricoid cartilage.

Arteries (Surface Marking of).—The *carotid* artery corresponds to a line drawn from the sternoclavicular articulation to a point midway between the mastoid process and the angle of the jaw. The *common carotid* reaches as high as the upper border of the thyroid cartilage. It can be compressed against the sixth cervical transverse process ("carotid tubercle"), which is opposite the cricoid cartilage. The *superior thyroid* artery comes off from the external carotid a little above the upper border of the thyroid cartilage. The *lingual* artery runs forward from the external carotid to the upper border of the great cornu of the hyoid bone, to which it is parallel. The hypoglossal nerve lies above the artery. The course of the *facial* artery in the neck corresponds to a line drawn from the tip of the great cornu of the hyoid bone to the outer border of the masseter muscle.

The *occipital* arteries can be felt pulsating immediately below and a little in front of the tip of the mastoid process.

Nerves (Surface Marking of).—The *spinal accessory* nerve passes beneath the anterior border of the sternomastoid muscle an inch below the tip of the mastoid process, and emerges from the posterior border at a point on a level with the upper border of the thyroid cartilage; it then crosses the posterior triangle obliquely and enters the trapezius muscle on a level with the sixth or seventh cervical spines.

The *phrenic* nerve commences in the neck about the level of the hyoid bone, and runs obliquely downward over the scalenus anticus to its inner edge. In the neck the phrenic nerve is covered by the sternomastoid.

The *superficial cervical* nerves all emerge at a point corresponding to the middle of the posterior border of the sternomastoid. The *great auricular* crosses the sternomastoid on its way up to the ear; the *lesser occipital* runs along the posterior border of the sternomastoid; the *superficial cervical* crosses the sternomastoid at right angles and reaches the middle of the neck, and lines drawn from the point of emergence to the sternum, middle of the clavicle, and the acromion would mark the course of the *suprasternal, supraclavicular,* and *supra-acromial* nerves.

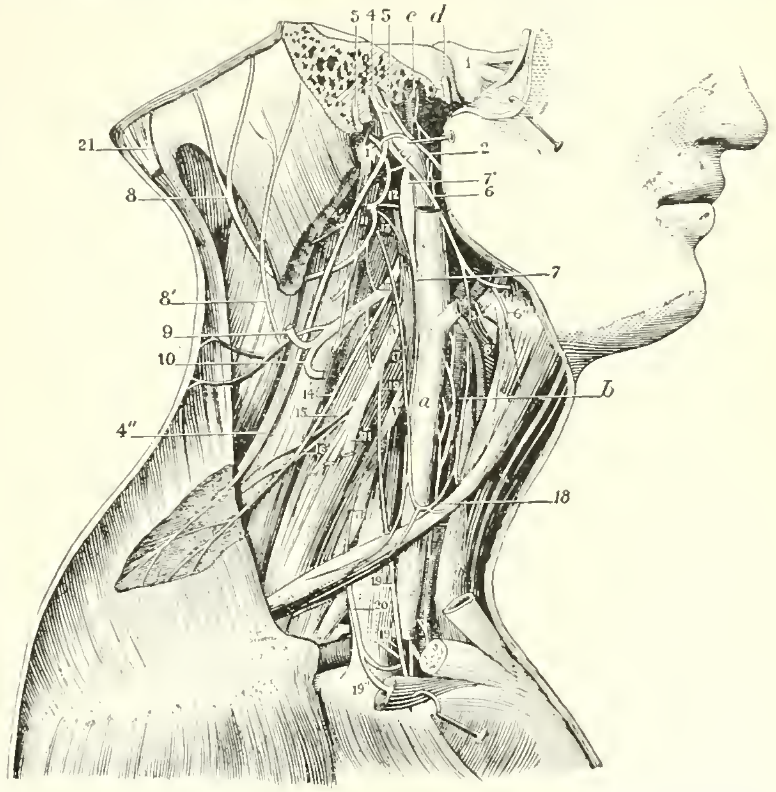

Fig. 3517.—Deep Cervical Plexus of Nerves. (From Testut.) *I, II, . . . VIII*, Anterior branches of the eight cervical nerves. 1, trigeminal nerve, with its three branches; 2, glossopharyngeal; 3, pneumogastric, with, 3', its branch, the superior laryngeal; 4, spinal accessory, with its two branches—4', that which supplies the sterno-cleido-mastoid muscle, and, 4", that which goes to the trapezius; 5, facial nerve; 6, the main trunk of the hypoglossal, with its two branches—6', the descending ramus, and, 6", that which supplies the thyrohyoid muscle; 7, the great sympathetic, with, 7', its superior cervical ganglion; 8, the larger mastoid branch of the cervical plexus; 8', the little mastoid branch; 9, the auricular branch; 10, the transverse cervical branch; 11, the subclavian and subacromial branches; 12, point of anastomosis with the great sympathetic; 13, nerve of the large anterior rectus muscle; 14, trapezian branch of the cervical plexus; 15, nerve of the levator ang. scap.; 16, nerve of the rhomboideus; 17, internal descending branch; 18, bend of the hypoglossal, with its efferent branches that supply the subhyoidean muscles; 19, phrenic nerve, with, 19', its anastomosis with the great sympathetic, and, 19", its anastomosis with the nerve that supplies the subclavius muscle; 20, the nerve of the subclavius muscle; 21, great occipital nerve.

The cutaneous branches of the cervical plexus are widely distributed, supplying the ear, back of scalp, cheek, parotid gland, side and front of neck, and upper part of chest and shoulder.

Digitized by Microsoft®

The facial nerve sends a branch to the neck, which supplies the platysma myoides muscle.

TOPOGRAPHICAL ANATOMY.—The skin over the anterior and lateral regions of the neck is thin and lax, and in

www.libtool.com.cn

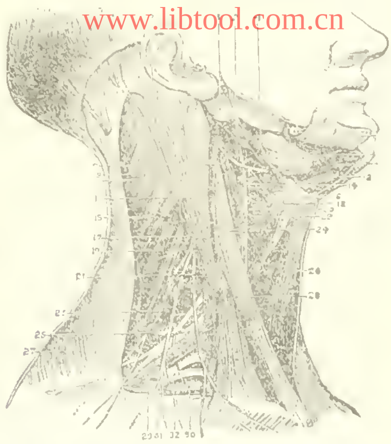

FIG. 3518.—Superficial Dissection of the Neck, showing the Distribution of the Branches of the Superficial Cervical Plexus of Nerves. (Heath.)

plastic operations is of great value in making flaps. The platysma is closely connected with the skin of this part of the neck. There is frequently some transverse wrinkling of the skin above the hyoid bone, and in this region in fat people there is much fat, giving rise to what is called a double chin; here also the sebaceous follicles are very abundant. In adult males this part is covered with beard.

The skin of the posterior region is very thick and adheres closely to the deeper structures; this is due to the large number of short fibrous connections between the skin and fascia. Carbuncles and boils frequently occur here and cause great pain, owing to the density of the parts and their free nerve supply.

The *nape* of the neck is often the seat of pustular and vesicular eruptions, which are due almost invariably, when localized in this part, to the presence of pediculi, these parasites finding a safe habitat in the thick hair under the prominent portion of the occipital bone. The glands in this region are frequently enlarged in sympathy with eruptions of the hairy scalp. The nape of the neck was the favorite site, in olden times, for the application of setons and issues.

Fatty tumors are often seen at the lower part of this region.

CERVICAL FASCIA.—It is the custom to divide the deep fascia of the neck into *superficial* and *deep* processes. The superficial fascia invests all the muscles, with the exception of the platysma; and some of the veins, as the external jugular, are also superficial to it. It is attached posteriorly to the spinous processes of the cervical vertebræ and ligamentum nuchæ; passing forward it splits to enclose the trapezius and then crosses the posterior triangle; at the posterior border of the sternomastoid the fascia divides into two layers which enclose that muscle, these layers unite at the anterior border of the muscle, and the fascia passes on to the middle line of the neck, where it is continuous with that of the opposite side. It covers the anterior triangle, being attached above to the lower jaw. In the posterior triangle the fascia is attached below to the clavicle and above to the mastoid process and the superior curved line of the occipital bone; in this triangle it is pierced by the external jugular vein and some of the superficial cervical nerves. In the anterior triangle the fascia is attached above to the body of the lower jaw, and continues backward and upward over the parotid gland to be attached to the zygoma. It sends a process (the stylomaxillary ligament) between the parotid and the submaxillary glands. In front the fascia is attached to the hyoid bone and covers the thyroid gland, below which it splits into two layers; the deeper covers the sternohyoid and sternothyroid muscles, and is attached below to the posterior edge of the first piece of the sternum, behind the sternoclavicular joint; the superficial and thinner layer passes down over the sternomastoid muscles, and is attached to the anterior edge of the manubrium and interclavicular ligament. The space between these two layers is filled with cellular tissue and fat, and sometimes a small gland is found here. In this compartment are also found the sternal head of the sternomastoid and the anterior jugular vein. In tenotomy of the sternomastoid this space must be opened, and the vein is avoided by keeping the knife close to the tendon of the muscle.

This space is also cut through in performing the operation of tracheotomy, and air is sometimes driven at every inspiration into the cellular tissue beneath the deep layer, an occurrence which complicates the operation exceedingly. The process of fascia covering the posterior belly of the omohyoid and binding it down to the clavicle and first rib, is continuous with the fascia covering the depressors of the hyoid bone.

The deeper processes of cervical fascia are important; one comes off from the anterior border of the sternomastoid and forms a sheath which encloses the carotid artery, jugular vein, and pneumogastric nerve. The vein is separated from the artery by a thin septum of fascia.

A process of fascia also invests the thyroid body, passes behind the depressors of the hyoid bone, and lies in front of the trachea and deep vessels of the neck; below, this layer is continuous with the fibrous pericardium.

The *prevertebral* fascia is a layer which descends on the prevertebral muscles, separating them from the pharynx and œsophagus; laterally it joins the carotid sheath and then proceeds outward covering the scalene muscles, brachial plexus of nerves, and subclavian vessels, becoming continuous with the axillary sheath. It is also connected with the costocoracoid membrane.

Although the cervical fascia influences to a certain extent the growth of tumors and collections of matter, this influence has been much exaggerated, and tumors grow and matter collects and distributes itself often quite irrespective of this fascia.

Pus in front of the trachea would tend to gravitate into the anterior mediastinum and on the side of the neck

FIG. 3519.—Transverse Section of the Neck through the Fifth Cervical Vertebra, showing Cervical Fascia. (Braune.)

might perforate the apex of the pleural sac. An abscess in front of the vertebræ would lie beneath the prevertebral fascia, and if it did not burst into the gullet, might extend laterally and present itself outside the sternomastoid, or descend to the posterior mediastinum. In some cases these collections of pus have been known, after reaching

Digitized by Microsoft®

the posterior triangle of the neck, to follow the course of the brachial plexus and present themselves in the axilla. Pus pent up between the layers of the cervical fascia has destroyed portions of not only the jugular vein, but also the carotid artery, and when the abscess cavity was opened the patient has died of hemorrhage from these vessels. Dr. S. W. Gross (*American Journ. of the Medical Sciences*, April, 1871) has collected twelve cases of ulceration of the jugular veins, with hemorrhage into the sacs of closed abscesses, or into abscesses several days after their contents have been evacuated, or into acute or chronic ulcers. The majority of cases were in children who had cellulitis of the neck following scarlet fever—all the cases proved fatal.

www.libtool.com.cn

Dr. Erichsen (*St. Petersburg. med. Woch.*, December, 1877) reports a case of suppurative angina which broke of itself, and several days afterward a profuse and fatal hemorrhage occurred. The autopsy revealed ulceration of the internal carotid artery. In such cases the lesson to be learned is to prevent the destructive effects of diffuse cellulitis by early and free incision, and, if hemorrhage does occur, not to rely exclusively on packing, but to ligature the affected vessel.

In opening abscesses in the neck, there is some danger of wounding some of the great vessels if a too free incision be made with the knife, the vessels being pushed out of their normal position by the abscess; their exact course is difficult to determine. In such cases at first the skin only should be incised; after this the knife should be laid aside and a director should be pushed through the fascia; and when pus runs along the groove of the director, a pair of dressing forceps should be introduced, opened in the abscess cavity, and withdrawn open. This method has the advantage of being perfectly safe, and is especially adapted for opening deep-seated abscesses. It is known as Hilton's method.

ARTERIES OF THE NECK.—The two large arterial trunks which are seen in the neck are the *carotid*, which lies in the anterior triangle, and the *subclavian*, which lies in the lower part of the posterior triangle (subclavian triangle).

The *carotid* is included in a sheath of deep cervical fascia with the internal jugular vein and pneumogastric nerve. The vein lies to its outer side, and in the living subject overlaps the artery at the lower end and especially on the left side. To the inner side of the artery lie the trachea and œsophagus, larynx, and pharynx, and low down the recurrent laryngeal nerve. The thyroid gland also lies to its inner side. The vagus nerve lies to the outer side and posteriorly above, and rather more in front below.

Lying on or in the sheath of the vessels is the descendens noni nerve. The great sternomastoid muscle covers not only the common, but also the internal and external carotid arteries. In the undissected subject it is impossible to puncture the common carotid from the side of the neck without piercing the sternomastoid muscle (Richet). This fact is not sufficiently dwelt on in anatomical works, the descriptions given being applicable to dissected subjects only. The omohyoid muscle crosses the artery and vein obliquely and on a line with the cricoid cartilage. The most important structures behind the artery are the sympathetic trunk, the inferior thyroid artery, and the recurrent laryngeal nerve. The common carotid normally gives off no branches in its course. It divides into external and internal carotid opposite the upper border of the thyroid cartilage. The right and left common carotid arteries are so similar in their course in the neck that one description will answer for both. The left, however, it is well to bear in mind, arises from the arch of the aorta, and is somewhat longer than the right, which arises from the innominate opposite the right sternoclavicular articulation. The right common carotid is generally larger and not so deeply placed in the neck as the left; it is also farther away from the trachea.

As the vessels ascend the neck they become more superficial, and, having a direction somewhat backward, get farther apart as they reach their termination. The surface-marking of the carotid has already been described.

The artery may be easily compressed against the transverse process of the sixth cervical vertebra.

Ligature of the Common Carotid.—A ligature may be applied to any part of the artery, except near its origin or termination. The usual point of ligature is either im-

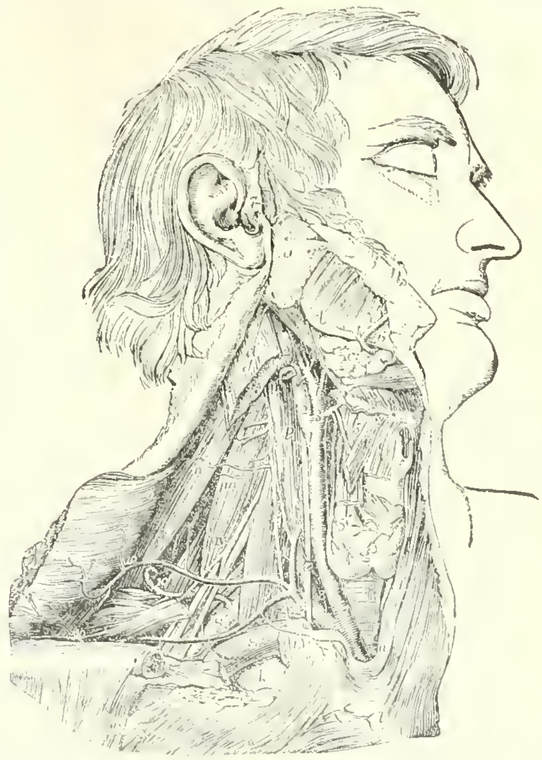

FIG. 3520.—View of the Common Carotid and Subclavian Arteries, with the Origin of their Branches and their Relations. (R. Quain.)

mediately above or below the omohyoid muscle. It is usually ligatured above the omohyoid, as here the artery is more superficial, and the operation is, in consequence, easier. An incision should be made along the inner border of the sternomastoid muscle, and the parts carefully divided until the sheath of the vessels is reached. The operation is much facilitated by drawing the sternomastoid outward and (if the superior operation be chosen) pulling inward the omohyoid. Should any veins or small branches of the superior thyroid artery come in the way, they should be divided between two ligatures. The sheath of the vessels should be opened on its inner side, so as to avoid the jugular vein, and the descendens noni nerve should be held aside to avoid injury. The aneurism needle with the ligature should be passed from without inward; in this way the vein and vagus nerve are most easily avoided.

The lower operation is the more difficult one, for, to expose the sheath of the vessels it is often necessary to divide some fibres of the muscles covering it. Again, the vein, if large, overlaps the artery; this renders the passing of the aneurism needle a proceeding of some difficulty. On the left side the internal jugular vein is much closer to the artery than on the right, and so the difficulty of passing a ligature around the artery is much increased. Ligature of the carotid is performed for wounds of the vessel or some of its branches, also for aneurism. It has been ligatured for pulsating orbital tumor. Mr. W. Rivington (*British Medical Journal*, October, 1885) records an interesting case of a boy, aged nine years, who swallowed a fish bone; this was followed

Digitized by Microsoft®

by pyrexia, stiff neck, salivation, and a tender lump on the left side of the neck opposite the cricoid cartilage. Three days later, the boy had two severe attacks of hemorrhage from the mouth. Wound of the carotid was diagnosed, and the artery cut down upon and ligatured. The fish bone was found in the centre of a clot, and it had ulcerated in[illegible] www.libtool.com.cn [illegible]ent died of abscess of the brain ten days after the operation. A common site of carotid aneurism is at the bifurcation of the common carotid, and the treatment is ligature of the vessel below. In aneurism at the root of the neck the carotid has been ligatured with success above the tumor. Ligature at the distal side of an aneurism was first proposed by Brasdor, and practised by Warddrop. The treatment of aneurism of the arch of the aorta or innominate artery by simultaneous ligature of the carotid and subclavian arteries has been attended in a few cases with benefit.

Aneurism at the root of the neck frequently gives rise to "pressure symptoms." When the great venous trunks are compressed there is œdema and lividity, not only of the side of the face and neck, but also of the upper extremity of the same side. Not infrequently cough is produced by pressure on the recurrent laryngeal nerve, and if the pressure be great, then paralysis of the vocal cords of that side will ensue and cause a marked alteration of the voice. Dilatation of the pupil may also occur from pressure on the sympathetic trunk.

When the common carotid reaches the upper part of the larynx, it divides into two trunks, one of which, the

external, gives off a number of branches, and is distributed to the superficial parts of the head and face and the tongue; the other, the *internal*, furnishes blood to the brain and eye. As a rule, the internal carotid has the deeper course, and lies behind the external, but not infrequently the two arteries lie side by side for some distance, the internal lying more posteriorly, and being recognized by the accompanying pneumogastric nerve. The two vessels are separated by the styloid process and stylohyoid ligament, also the styloglossus and stylopharyngeus muscles and glossopharyngeal nerve. The external trunk has two muscles and a nerve in relation to it anteriorly, viz., the digastric and stylohyoid muscles, and the hypoglossal nerve which hooks round one of its branches, the occipital. After passing behind the angle of the lower jaw the external carotid becomes embedded in the parotid gland.

Ligature of the external carotid is not a very easy operation owing to the number of branches given off from it, and the large venous trunks which lie over the lower portion may much increase the difficulties. The artery is reached by an incision in the line of the vessel, having its midpoint about the level of the hyoid bone. It is usually ligatured immediately below the digastric. It occasionally requires ligature in the course of operations for the removal of tumors about the angle of the jaw and neck.

Branches of External Carotid.—The most important branches in the neck are the superior thyroid, lingual, and the cervical portion of the occipital and facial.

The *superior thyroid* arises near the origin of the main vessel and curves downward, forward, and inward, beneath the depressors of the hyoid bone. It is distributed to the upper part of the thyroid gland, and can be readily exposed by an incision between the omohyoid and sterno-mastoid muscles. It sends a branch along the cricothyroid membrane which is sometimes wounded in the operation of laryngotomy. The superior thyroid artery has lately been tied with success for the purpose of arresting the growth of an enlarging thyroid body.

The *lingual* artery arises from the external carotid nearly opposite the great cornu of the hyoid bone (it may however, arise in common with the superior thyroid and cross the hyoid bone). It runs above and parallel to the great cornu and beneath the hyoglossus muscle. It is frequently necessary to ligature the lingual previous to extirpation of the tongue.

In ligaturing this vessel the one guide which the operator must rely on is the great cornu of the hyoid bone—it can always be felt and its relation to the artery is nearly always constant. The best place to expose the artery is immediately above the great cornu. Some authorities advise ligature of the artery near its origin from the carotid; but here, owing to the large veins which cover it, the operation is more difficult, and besides we have no absolute guide as to the exact point of origin of the artery, which frequently varies. On the other hand, the relation of the vessel to the great cornu of the hyoid bone is nearly always constant. The incision should be a curved one, and should extend from near the symphysis menti to near the angle of the lower jaw. The convexity of the curve should be downward, and its lowest point ought to reach the hyoid bone. After dividing the skin, platysma, and deep fascia, the tendon of the digastric muscle should be searched for, and in the angle which the tendon forms with the hyoid bone the artery will be found running beneath the hyoglossus muscle; the hypoglossal nerve is seen running over this muscle. If the submaxillary gland cover the parts, it should be held aside with hooks. After carefully dividing the hyoglossus muscle the artery will be felt pulsating at the bottom of the wound. If the incision be carried too far back the facial vein may be wounded.

When it is necessary to remove the submaxillary gland the facial artery must be ligatured. The operation presents no difficulties and requires no special description.

The *subclavian artery* is, surgically, a very important vessel. The left subclavian lies deeper than the right and arises directly from the arch of the aorta, while the right is one of the terminal branches of the innominate and commences opposite the right sternoclavicular articulation. Each artery curves upward into the neck

Digitized by Microsoft®

under the anterior scalenus muscle, and then descends into the subclavian triangle under the clavicle and over the first rib. The subclavian vein lies in front and somewhat below the artery, from which it is separated by the anterior scalenus.

The artery is divided into three portions by the scalenus anticus muscle, viz., first, portion internal to the

www.libtool.com.cn

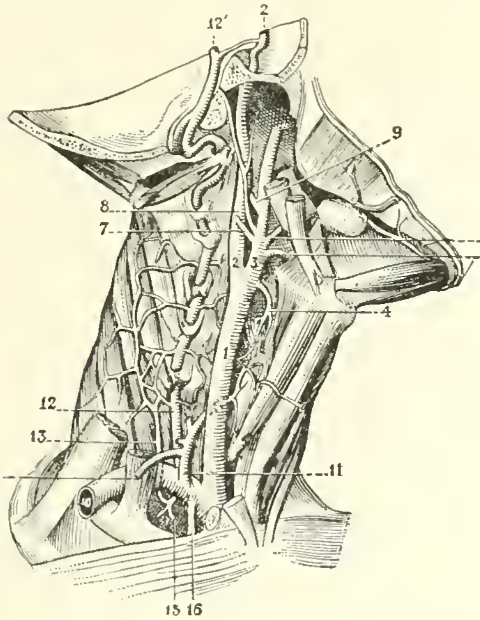

FIG. 3522.—Inferior Thyroid and Vertebral Arteries. muscle; second, portion beneath the muscle; and, third, portion external to the muscle reaching to the lower border of the first rib. Surgically, the third portion is most important. The external jugular vein crosses the artery, and the sternomastoid and the deep fascia which binds down the omohyoid muscle to the clavicle are in front of it; the brachial plexus of nerves lies above and to the outside of the third portion of the artery. Posteriorly the artery lies on the pleura and on the scalenus medius, and finally it rests on the first rib. The third portion of the artery can be felt pulsating above the clavicle, in the supraclavicular fossa, and here it may be readily compressed against the first rib with the thumb or the handle of an old-fashioned door-key wrapped in lint. The direction of the pressure should be vertical to the axis of the body; before attempting compression the shoulder should be lowered as much as possible. In compressing this vessel pain is sometimes caused by pressing on the lowest cord of the brachial plexus, which usually lies behind the artery; this may be easily avoided by rolling the nerve away from the artery, and then the proceeding is quite painless.

Some individuals (the writer among them) can arrest the pulse at the wrist by forcibly carrying the shoulder downward and backward. In this case the artery is compressed against the first rib by the subclavius muscle and clavicle.

Ligature of the subclavian is, as a rule, confined to the third portion, or that part lying in the supraclavicular space between the sternomastoid and trapezius muscles; the other portions are so deeply placed, so thickly studded with branches, and so closely connected with such important structures as the phrenic and vagus nerves, the junction of the internal jugular and subclavian veins, and, on the left side, with the thoracic duct, that ligature is rarely attempted. On the right side it is possible to ligature the vessel between the common carotid and the internal jugular vein.

The third portion of the vessel is comparatively superficial, being covered above the clavicle by no other soft parts than the skin, fascia, and fat. In at least fifty per cent. of subjects it is branchless, and when a branch is given off from the third portion it is almost invariably the posterior scapular.

To reach the artery an incision is made between the sternomastoid and the trapezius. The skin should be drawn down and the first incision should be made upon the clavicle to avoid wounding the external jugular, which pierces the deep fascia immediately above the clavicle. The vein should be held aside, or, better still, divided between two ligatures, and the deep fascia attached to the clavicle cut through; the finger should then be introduced and the scalene tubercle of the first rib searched for; this tubercle is usually found by following down the scalenus anticus muscle, which runs in the direction of the posterior edge of the sternomastoid. Having made out the scalene tubercle, the surgeon will feel the artery pulsating beneath the finger immediately outside the scalenus anticus muscle. The aneurism needle should be introduced from below upward to avoid the vein; it must hug the artery closely so that the lowest cord of the brachial plexus may not be included.

The operation is performed for aneurism of the axillary artery, and also of the innominate; also before amputating the whole upper extremity. In the latter case the common carotid is also tied. In axillary aneurism the operation is much complicated by the great distention of the veins and the great elevation of the clavicle.

Branches of the Subclavian.—The subclavian is rich in branches which are distributed in three different directions, viz., the vertebral and inferior thyroid, upward; the transversus colli and transversus humeri, outward; and the internal mammary and superior intercostal, downward. Most of the branches arise internal to the scalenus anticus; three of them, the transversus colli, transversus humeri, and inferior thyroid arise from a single trunk, the thyroid axis. The posterior scapular is frequently given off from the third part of the artery in place of from the transversus colli. The branches of the subclavian artery are subject to innumerable variations both as to their number and origin (see *Arteries, Anomalies of*). When the subclavian is ligatured, there being free anastomosis between its branches and those of the axillary artery, the nutrition of the arm is not interfered with.

The *vertebral artery*, which is the largest branch of the subclavian, arises from the upper and posterior part of

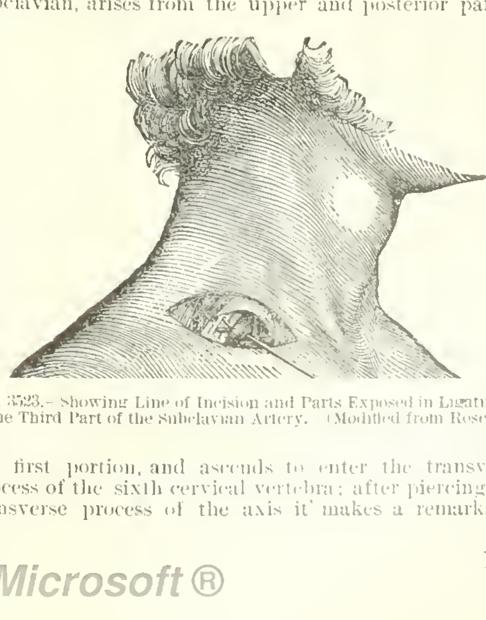

FIG. 3523.—Showing Line of Incision and Parts Exposed in Ligature of the Third Part of the Subclavian Artery. (Modified from Roser.)

the first portion, and ascends to enter the transverse process of the sixth cervical vertebra; after piercing the transverse process of the axis it makes a remarkable

Digitized by Microsoft®

curve (Fig. 3524, 5) outward and upward to reach the foramen in the transvere process of the atlas, and bending backward, runs in the deep groove on the upper surface of the atlas.

Immediately above the clavicle this vessel lies very deeply between the scalenus anticus and longus colli muscles. It has frequently been ligatured here for the relief of epilepsy; the operation is a difficult one, owing to the many important structures in close relation with the vessel. An incision is made along the posterior border of the sternomastoid muscle immediately above the clavicle, the transverse process of the sixth cervical vertebra (carotid tubercle) is now searched for, and the artery is found lying between the scalene and longus colli muscles.

www.libtool.com.cn

Drs. Bright and Ramskill state that disease of the vertebral artery, immediately before it enters the skull, may lead to pain at the back of the head. The fact that the artery is here in close relation with the suboccipital nerve, which communicates with the great occipital nerve, may explain this symptom. (Treves.)

The vertebral artery is sometimes wounded by stabs in the neck; not a few cases are reported in which the artery was injured by stabs below the mastoid process. Dr. King (*Lancet*, November, 1885) records a case of injury of this artery in a young man, aged twenty-five, due to a deep wound below the left mastoid process; there was severe bleeding, so the wound was enlarged and the transverse process of a cervical vertebra was found broken; the finger placed between two transverse processes stopped the hemorrhage; the wound was plugged with strips of oiled lint, and in four weeks the patient had perfectly recovered. The plug was removed on the fourth day.

Hemorrhage from wounds of the vertebral artery between two transverse processes is difficult to arrest; wooden plugs have sometimes succeeded; occasionally the artery has been successfully tied by snipping away

Fig. 3524.—Deep Dissection of the Neck, showing the Course and Origin of the Vertebral Artery (5). (Tiedemann.)

the transverse process and applying a ligature. If this cannot be done the bleeding vessel may be secured by artery forceps, which should be left in the wound.

Traumatic aneurisms of the vertebral artery may occur after a stab in the neck; the writer on one occasion saw this follow a wound of the vessel between the second and third cervical transverse processes. These aneurisms are commonly mistaken for aneurism of one of the branches of the carotid—as, for instance, the occipital—and the common carotid has been tied on this supposition, without avail, of course. The mistake has arisen from the surgeon finding that pulsation in the aneurism ceased on compressing the carotid in the neck. Of course, if it is compressed below the "carotid tubercle," the circulation in the vertebral is arrested as well as in the carotid; and even if pressure is applied at this point, the vertebral may be compressed, for it frequently fails to enter the foramen in the transverse process of the sixth cervical vertebra.

The ligature placed on the carotid should be first tightened, and, if this arrests the pulsations in the aneurism, the ligation may be completed; but if pulsation is not arrested, then it is probable that the vertebral is the artery affected, and ligature of the carotid is a useless proceeding.

The treatment of such aneurisms is very unsatisfactory; cases of cure are reported from continuous compression with shot-bag, but if this fail operative measures are of little avail; it is useless to ligature the artery low down, as the anastomosis above is so free; and if the aneurism is cut down upon, ligature at the seat of the aneurism is rarely satisfactorily completed. The writer once saw the carotid tied for vertebral aneurism due to a stab with a knife below the mastoid, and afterward the sac of the aneurism cut down upon; but the hemorrhage could not be arrested by plugging, or otherwise, and the patient died. In this case pressure on the carotid against the sixth cervical transverse process arrested pulsations in the aneurism, and it was supposed that the affection was connected with the occipital artery.

The inferior thyroid artery is sometimes ligatured at the same time as the superior thyroid for enlarged thyroid in exophthalmic goitre (Graves' disease). Any of the arteries may be temporarily ligatured during an operation by tying the ligature over a piece of rubber tubing placed on the vessel. The writer has done this with both the carotid and the subclavian arteries with success.

Veins of the Neck.—The *anterior jugular* vein has already been mentioned as lying along the inner border of the sternomastoid. It varies somewhat as to its course, and is sometimes double. Occasionally, the veins of the two sides are connected by a large transverse branch, which is a source of trouble in the operation of tracheotomy. The anterior jugular, if large and placed nearer the median line than usual, is liable to be wounded in tracheotomy. It might also be wounded in tenotomy of the sternomastoid for wry-neck. The two anterior jugulars may be replaced by a single trunk.*

In front of the trachea and thyroid gland is a large vein, the *inferior thyroid* (vena thyroidea ima), which, when large, complicates operations on the trachea.

The *external jugular* vein corresponds to a line drawn from the angle of the jaw to the middle of the clavicle; it runs beneath the skin and platysma and over the sternomastoid muscle, and ends by piercing the deep fascia above the clavicle to join the subclavian vein. In the operation of tying the subclavian in its third part, it (the vein) must be held aside or ligatured.

The *internal jugular* vein lies to the outer side of the common carotid artery, and when distended partially overlaps it. In operations for the removal of tumors or enlarged glands of the neck, this vessel may be wounded; ligature in such accidents is the proper procedure, and is not attended by any evil after-effects. The writer has on three occasions ligatured the internal jugular with the most happy results.

The *subclavian vein* is a continuation of the axillary, and is in close relation with the clavicle; it lies in front of and below the subclavian artery, from which it is

* The anatomy of this region has been ably described by Dr. Pilcher in the Annals of Anatomy and Surgery, vol. iii., 1881.

the subclavian vein adheres closely to the fascial sheath by which it is invested; this sheath is connected anteriorly with the costocoracoid membrane and the clavicle, and when the shoulder is carried forward the vessel becomes expanded. (Quain.) In operations at the root of the neck great care should be taken to avoid wounding the large veins, for air is very apt to be sucked in during inspiration. These veins are so firmly united to the bones and muscles, that when wounded they do not collapse, but, on the contrary, gape. It should be remembered that the risk of air entering is increased by movements of the upper limb, which still further open the wounded vein.

THYROID BODY.—This is a highly vascular organ consisting of two lateral lobes, one on each side of the larynx and trachea, connected by an isthmus which crosses the second and third rings of the trachea. The lobes are pear-shaped, and reach from the fifth and sixth rings of the trachea to the upper border of the thyroid cartilage; the lateral lobes are covered in front by the depressions of the hyoid bone, and posteriorly are in contact with the sheath of the great vessels of the neck. Each lateral lobe measures about two inches in length, one and one-fourth inch in breadth, and from three-fourths to one inch in thickness. The weight of the thyroid body is from one to two ounces, and is greater in females than in males. The isthmus is occasionally absent, the lateral lobes being connected by fibrous tissue only, as is the case in some animals, viz., the horse, donkey, etc.

Owing to the fact that the thyroid body lies over the great vessels of the neck, when enlarged it derives from them a visible pulsation, and a distinct thrill may be felt. Such pulsating tumors have been mistaken for aneurism, but as the thyroid body is closely connected with the larynx and trachea, it rises and falls in deglutition, and so is easily diagnosed from aneurismal or other tumors, which are not disturbed by deglutition. When hypertrophied the tumor resulting from an enlarged thyroid is called a "*bronchocele*" or *goitre*. When a goitre grows rapidly respiration is often interfered with, and operation has to be undertaken for its relief. It is not necessary to remove the whole gland to relieve the obstructed respiration, for division and removal of the isthmus only often gives very good results. Mr. Sidney Jones (*Lancet*, vol. ii., 1883) reports cases in which excision of the isthmus not only relieved the dyspnœa, but a month after the operation the lateral lobes had almost disappeared.

Since the advent of antiseptic surgery the extirpation of large bronchoceles by the knife has become most common, but the operation, owing to the very important structures in relation to it, is always a most formidable one. It is very important in this operation first to ligate the vessels supplying the gland, viz., the superior thyroid above, and the inferior thyroid below, and if present, the middle thyroid. In ligating the inferior thyroid artery, care must be taken not to injure the inferior laryngeal nerve, which winds among the branches of that artery. Simple cysts may be removed by enucleation. Owing to the conditions which follow complete removal of the thyroid, viz., myxœdema, and cachexia strumipriva, partial removal is the more common operation except in cases of malignant disease or when the growth becomes dangerous from pressure.

The ŒSOPHAGUS commences opposite the cricoid cartilage; it lies between the trachea and the vertebral column. At the lower end of the neck it inclines a little to the left, and for this reason œsophagotomy is performed on the left side. Strictures most commonly occur at its upper part, and foreign bodies are most apt to be arrested behind the larynx. Foreign bodies, such as fish bones, mutton or beef bones, have occasionally ulcerated through the œsophagus and perforated some of the large vessels with which it is in contact.

In performing *œsophagotomy* for the removal of an arrested foreign body, the incision is made between the sternomastoid and trachea, the middle point being opposite the cricoid cartilage. The inferior thyroid artery and recurrent laryngeal nerve must be carefully avoided. The carotid artery is in no danger of being wounded if proper care be taken.

In *œsophagostomy*, when a stricture exists high up, the incision into the œsophagus is made for the purpose of feeding the patient by a tube, and so avoiding gastrostomy. The fact that the operation is performed low down makes it much more dangerous than œsophagotomy, and nearly all the reported cases have ended in death within a short time of the operation from diffuse inflammation of the neck.

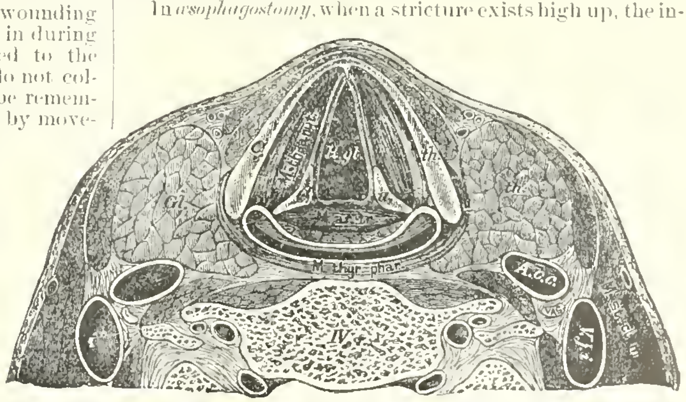

FIG. 3526.—Transverse Section of Neck, Opposite Fourth Cervical Vertebra, showing Thyroid Body (*Gl. th.*).

Digitized by Microsoft®

HYOID BONE.—This is one of the most important landmarks in the neck, and one which can always be felt in the stoutest neck. It is the best guide for ligature of the lingual. In old age the different portions of the bone become ossified into one piece, and in consequence it is more easily broken by direct violence due to blows or throttling. Cases are reported of fracture of the hyoid from yawning and sudden extension backward of the head. The symptoms of fracture are pain, difficulty in speaking, in movements of the tongue, and in swallowing.

www.libtool.com.cn

LARYNX AND TRACHEA.—The *larynx* is connected above with the hyoid bone by means of the thyrohyoid membrane, and is continuous below with the trachea. Posteriorly it helps to form the wall of the pharynx. It consists of several parts, which are closely connected together by ligamentous structures, muscles, and mucous membrane; these parts are the thyroid cartilage, epiglottis, cricoid, and arytenoid cartilages. On the upper margin of the thyroid cartilage is a bursa which prevents friction as the larynx ascends beneath the hyoid bone in deglutition. This bursa is sometimes enlarged, and has to be incised. The larynx is occasionally wounded in cases of attempted suicide by cutting the throat. Between the lower border of the thyroid and cricoid cartilages is the cricothyroid membrane, where the operation of laryngotomy is performed. A small lymphatic gland is occasionally found here, which may become enlarged. (For description of interior of larynx see *Larynx*.)

Foreign Bodies.—Children not infrequently swallow articles which are sucked into the larynx during inspiration; these may be arrested by the cords at the rima, or may lodge in one of the ventricles. If they pass the rima they usually lodge in the right bronchus. These bodies can frequently be seen with a laryngoscope and extracted with forceps, but very often the operation of tracheotomy is necessary to remove them.

The TRACHEA extends from opposite the sixth cervical vertebra to its bifurcation opposite the third dorsal, where it is crossed by the arch of the aorta. It measures from four to five inches in length, and from three-fourths to one inch in breadth. It is covered by the depressors of the hyoid bone, and has on each side at its upper end the

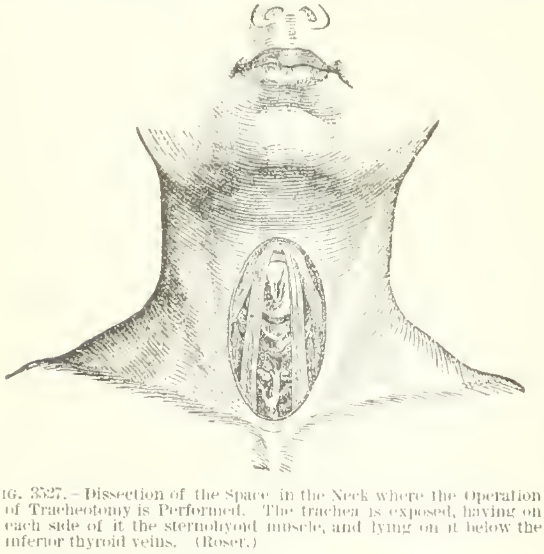

FIG. 3527.—Dissection of the Space in the Neck where the Operation of Tracheotomy is Performed. The trachea is exposed, having on each side of it the sternohyoid muscle, and lying on it below the inferior thyroid veins. (Roser.)

thyroid body. It is crossed by the isthmus of the thyroid gland opposite its second and third rings, and has also in front the inferior thyroid veins, and sometimes a transverse branch connecting the two anterior jugulars. When the middle thyroid artery is present it also lies upon the trachea in its course up to the isthmus of the thyroid. In children the thymus gland covers its lower portion. Laterally the trachea is in relation with the carotid artery and recurrent laryngeal nerve; posteriorly it is in contact with the œsophagus. The innominate artery crosses the lower end of the trachea; this occurs higher up in children than in adults.

The operation of *tracheotomy* is performed above or below the isthmus. It is required for the extraction of foreign bodies and for any obstruction to respiration having its seat in the larynx, as from diphtheritic membrane, new growths, etc. It is also performed as a preliminary to certain operations in the neck and mouth.

The distance between the cricoid cartilage and the upper border of the sternum, in ordinary individuals is about one inch and a half (4 cm.); when the head is thrown back three-fourths of an inch more is gained; so in performing tracheotomy the neck should be extended as much as possible by placing a hard round pillow under it, and the incision should be exactly in the middle line, so as to come between the two sternohyoid muscles and anterior jugular veins. In operating there is a choice as to where the trachea is to be opened, either above or below the isthmus. Above, the parts are more superficial and blood-vessels fewer, but the space is limited and the cricoid cartilage has often to be cut; below, although the trachea is deeper and the veins are more plentiful, still there is more room for incision, and we get farther away from the disease, which is an important point in diphtheria. With our present means of arresting hemorrhage the low operation is to be preferred.

Laryngotomy is performed in cases in which it is necessary rapidly to relieve suffocation, and in adults who have chronic affections of the larynx. It is performed by cutting the cricothyroid membrane transversely.

(For a more complete description of these operations see *Tracheotomy*.)

LYMPHATIC GLANDS OF THE NECK.—These are large and numerous. They frequently enlarge and become inflamed, and if not excised break down and suppurate, leaving unsightly scars. In scrofulous subjects the glands of the neck are the ones most frequently enlarged. The enlargement is always the result of some irritation, either of the mucous membrane of the throat, nose, ear, etc., or of the skin of the scalp, face, or neck. The glands are more liable to enlarge in persons of a scrofulous diathesis, and in them the amount of involvement of the glands is out of all proportion to the irritating cause; this may be an eczema of the scalp or a simple sore throat. In non-scrofulous individuals the glands are frequently enlarged from some special irritating cause, as a diseased tooth, tonsillitis, malignant disease of the tongue, lip, etc., but in these individuals the affection of the glands is not so widespread, nor is the enlargement so great, and the glands do not tend to suppurate.

In syphilitics the *glandulæ concatenatæ* in the posterior triangle of the neck are frequently enlarged and indurated, but they do not tend to suppurate. In tonsillitis an enlarged gland is always felt beneath the angle of the lower jaw; this is erroneously supposed by many to be the enlarged tonsil which cannot be felt from the outside.

In eczema of the scalp the glands of the neck are frequently enlarged, especially if the eczema be of the pustular variety. In delicate children pediculi not only often cause an eczema of the nape of the neck, but the irritation frequently causes enlargement of the glands in the suboccipital and mastoid regions.

Occasionally a single gland becomes enlarged over the carotid artery, and this has been mistaken for aneurism on account of the strong pulsation communicated to the tumor by the artery; these tumors, however, cannot be emptied by lateral pressure, and when lifted away from the artery all pulsation, of course, ceases.

When one or several glands of the neck have become enlarged and show no tendency to diminish, it is much better to remove them with the knife. This can be easily done before the gland breaks down and suppurates, and so forms inflammatory adhesions to the surrounding parts. In cases of "scrofulous necks," in which nearly all

Digitized by Microsoft®

the glands are enlarged, their removal is advisable, for if left to themselves they break down and suppurate, and after months and perhaps years of discomfort, heal, leaving unsightly scars. An argument in favor of early excision is that foci of infection are removed, and the patient's chance of good health is much greater. Frequently thirty or forty glands have been removed at one operation, and the result is almost invariably good, the patient recovers rapidly, and the amount of scarring is very trifling. In dissecting out the glands in close relation to the large vessels, great care should be taken.

When the glands have suppurated and sinuses are left which will not heal, scraping the sinus and removal of the remains of the gland with a sharp spoon give very good results. Mr. Treves recommends puncture of softened caseous glands with a cautery; he also advises opening gland abscesses by the cautery highly heated.

The lymphatics of the neck are enlarged, with those of other parts of the body, in leukæmia and Hodgkin's disease, and care should be taken not to confound scrofulous glands with enlarged glands in these diseases. Removal of enlarged glands in Hodgkin's disease is, except for diagnostic purposes, of course, perfectly useless.

The lymphatic glands of the neck are arranged in the following groups: *Submaxillary* (ten to twelve in number), situated beneath the base of the inferior maxilla; these also include the *suprahyoid*, which are situated between the two anterior bellies of the digastric muscle in the middle line of the neck. *Superficial cervical* (four to six) situated along the external jugular vein beneath the platysma and deep fascia. *Deep cervical* (twenty to thirty). These are subdivided into *superior* and *inferior*. The *superior* are situated about the bifurcation of the common carotid, and reach to the base of the skull, lying along the internal jugular vein. The *inferior* are grouped around the lower part of the internal jugular vein, and extend outward into the supraclavicular fossa, becoming continuous below with the axillary and mediastinal glands.

The following table, from Sir F. Treves' book on "Scrofula and Its Gland Diseases," showing the relation certain glands bear to the periphery, will be found useful:

Scalp: Posterior part = suboccipital and mastoid glands; frontal and parietal portions = parotid glands; vessels from the scalp also enter the superficial cervical set of glands.

Skin of Face and Neck = Submaxillary, parotid, and superficial cervical glands.

External Ear = Superficial cervical glands.

Lower Lip = Submaxillary and suprahyoid glands.

Buccal Cavity = Submaxillary and deep superior cervical glands.

Gums of Lower Jaw = Submaxillary glands.

Tongue: Anterior portion = suprahyoid and submaxillary glands; posterior portion = deep cervical glands (superior).

Tonsils and Palate = Deep cervical glands (superior).

Pharynx: Upper part = parotid and retropharyngeal glands; lower part = deep cervical glands (superior).

Larynx, Orbit, and Roof of Mouth = deep cervical glands (superior set).

Nasal Fossa = Retropharyngeal glands and deep cervical (superior). Some lymphatics from the posterior part of the fossa enter the parotid gland.

PAROTID GLAND.—This gland lies on the face in front of the ear, and extends deeply into the space behind the lower jaw; its inferior portion is situated partly in the neck behind the angle of the jaw, lying on the digastric muscles in the submaxillary region. It is connected with very important structures, being pierced by the external carotid artery and facial nerve. This gland not infrequently becomes inflamed and suppurates after fevers (as typhoid) and operations on the abdominal viscera. Cases are reported in which it has become inflamed after ovariotomy, and the writer has twice seen abscess of the parotid follow severe blows on the abdomen. These abscesses are very painful, owing to the tension caused by the investing fibrous capsule. In opening abscesses here the incision should be transverse, to avoid cutting the facial nerve, and should be in front of the line of the carotid artery. Abscesses of the parotid gland frequently burst

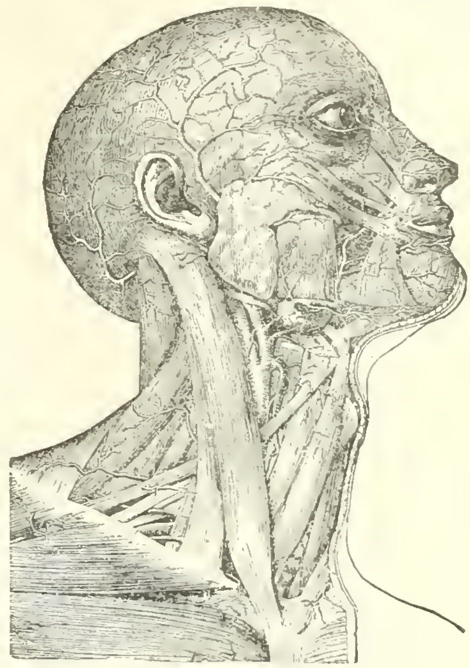

FIG. 3528.—Dissection of the Neck, showing the Triangles and their Contents. (Tiedemann.)

into the external auditory meatus. There are a number of lymphatic glands in relation with the parotid, which receive vessels from the scalp, pharynx, etc. Tumors are not infrequently found in this region, the extirpation of which gives rise to very severe hemorrhage. The facial nerve is frequently unavoidably injured in the removal of these tumors, and the external carotid artery sometimes requires ligature.

SUBMAXILLARY GLAND.—The submaxillary gland is situated in the submaxillary region, between the anterior and posterior bellies of the digastric muscle. It lies partly on the mylohyoid and partly beneath it. The facial artery grooves the back part and upper border of the gland. The gland is sometimes involved in malignant diseases affecting the mouth and tongue. It is separated from the parotid gland by a fold of deep cervical fascia, the stylomaxillary ligament.

NAPE OF THE NECK.—The superficial anatomy of this region has already been described. The most superficial muscle is the trapezius, which is covered by a layer of thick and tough fascia and is pierced by the great occipital nerve. To the outer side of the trapezius, and separated from it as it descends, is the sternomastoid muscle; crossing obliquely the interval between them are the splenius capitis and colli muscles. On removing the trapezius, which in this region is usually very thin, the complexus muscle comes into view, also pierced by the great occipital nerve; deeper down still are seen the muscles bounding the suboccipital triangle (rectus capitis anticus major, superior and inferior oblique), where are seen the suboccipital nerve and vertebral artery. In the central line is the ligamentum nuchæ. It extends from the seventh cervical spine to the external occipital protuberance. In some animals this ligament is a very powerful elastic band which suspends the head; to it are attached muscles and fascia. The occipital artery becomes superficial midway between the mastoid process and external occipital protuberance. It runs along the outer border of the superior oblique and is

www.libtool.com.cn
Digitized by Microsoft®

accompanied by the great occipital nerve. The lesser occipital nerve winds round the posterior border of the sternomastoid, and supplies the lateral region of the occiput; the suboccipital, being a purely motor nerve, rarely reaches the skin.

Spinal Cord and Vertebral Column.—The accompanying figure (3530) shows well the situation of the spinal cord in the neck vertebræ. It is not so well protected against injury as in other parts, for in the space between the several arches, any sharp instrument piercing the muscular tissue could easily wound the cord. The vertebral artery, as has already been mentioned, is also liable to injury on its way from one vertebra to another. From the great mobility of this part of the spine dislocation occasionally occurs and death is caused by pressure on the cord. In caries of the upper cervical vertebræ, sudden death has taken place from the destruction of the ligaments between the atlas and axis. When this occurs—the head with the atlas inclining forward and leaving the axis in its proper position—the medulla oblongata is crushed against the odontoid process, and so instant death is the result. (Hilton.)

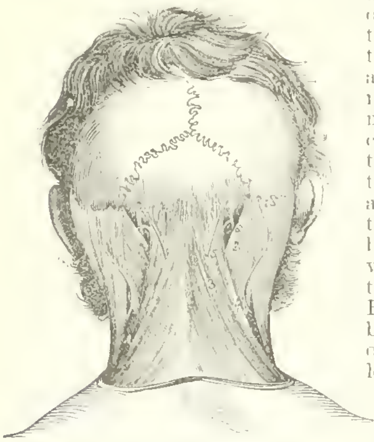

FIG. 3529. The Skin and Fascia have been Removed, and the Superficial Muscles Exposed. 1, Sternomastoid; 2, splenius capitis; 3, trapezius; 4, small occipital nerve; 5, great occipital nerve; 6, occipital artery. (After Roser.)

Caries of the spine in the cervical region is not uncommon. In its early stages the symptoms are somewhat obscure, the chief complaint being of pain in the course of the great occipital nerve, due to its implication in inflammatory exudation. The peculiar stiff way in which the patient carries his head, and the presence of a slight prominence which is excessively tender, enables the surgeon to recognize the disease. These cases occasionally result in a post-pharyngeal abscess, which has to be opened. This may easily and safely be done by an incision along the posterior border of the sternomastoid. Some advise tapping it with a trocar through the mouth.

BRANCHIAL FISTULÆ AND CYSTS.—In the mammalian embryo, at the fourth week, there are on each side of the head, behind the oral cavity, four fissures which communicate with the anterior part of the alimentary canal. These are the homologues of the clefts found in branchiate vertebrates. The third and fourth fissures in the human embryo disappear about the sixth week, and only the first remains at the end of the ninth week. This persists as the Eustachian tube, tympanic cavity, and external auditory meatus. The structures developed in the folds between the clefts (branchial arches) are as follows:

First Arch (*Mandibular*): Meckel's cartilage, the anterior portion of which is developed into the lower jaw, and the mandibular arch is completed by the malleus bone of the ear.

Second Arch (*Hyoid*): Incus, stapes (Parker), styloid process, stylohyoid ligament, and lesser cornu of the hyoid bone.

Third Arch: Great cornu and body of the hyoid bone.

Fourth Arch: No permanent remains.

Sometimes the clefts between these arches remain more or less open, and this fact explains the occurrence of congenital fistulæ of the neck, as well as that of cysts and diverticula from the œsophagus and larynx.

Paget says (Proc. Royal Med. Soc., 1877): "Cervical branchial fistulas occur as two or three minute orifices on one or both sides of the lower part of the neck, and they lead upward to the œsophagus and pharynx; the lowermost being near the sternal end of the clavicle in front of the sternomastoid muscle, the next opposite the thyroid cartilage, and the highest between the thyroid cartilage and hyoid bone." When two in number, they are often symmetrical; they vary in length from one-half to one and a half inches, and barely admit a probe. They have a smooth lining membrane, which secretes a clear mucous fluid. These fistulæ can be cured by cauterizing them with the galvanocautery. It is probable that many cysts and so-called hydroceles of the neck are due to imperfectly closed embryonal fissures.

Sanguineous cysts of the neck are probably originally branchial cysts, which have communicated with the internal jugular vien. Cases are on record in which, before removal of the cyst, the vein had to be ligatured (Glück: *Deutsche med. Woch.*, No. 5, 1886).

BRANCHIAL DERMOIDS.—These are occasionally seen in the neck, the most common situation being between the geniohyoglossi muscles, where the swelling projects into the submaxillary space and also into the mouth. They can usually be enucleated. A dermoid sometimes is seen under the deep fascia close to the carotid arteries.

THYROLINGUAL FISTULÆ AND CYSTS.—These are met with on the tongue, at the hyoid bone, and lower down over the thyroid cartilage, cricoid, and upper rings of the trachea. They grow slowly with the growth of the individual, and are very difficult to eradicate. The cyst wall is thin and lined with columnar epithelium, perhaps ciliated. Their contents are mucoid. They sometimes burst, leaving fistulous openings which are difficult to close. Unless the cyst be entirely removed, it will recur, for if any part of the epithelial lining be left it will secrete and cause a persistence of the trouble. Thyrolingual cysts and fistulæ are the remains of the thyrolingual duct, which passes up the neck to the tongue behind the hyoid bone. The lower part becomes the isthmus of the thyroid gland while the upper part persists as the foramen cæcum of the tongue.

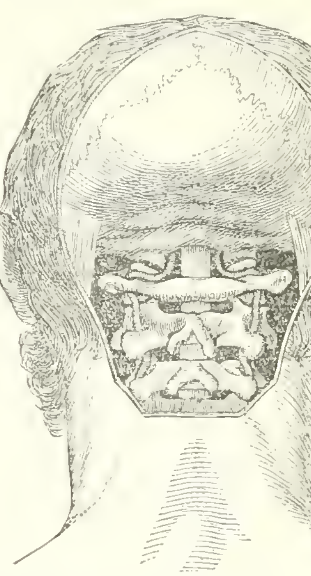

FIG. 3530. The Superficial Tissues have been Removed to show the Vertebral Artery Passing Through the Transverse Processes of the Vertebræ, and also the Relation of the Cord to the Spinal Canal. (Roser.)

TUMORS OF THE NECK.—The neck is a favorite site for tumors, fibrous, sarcomatous, and others. Sarcomatous tumors in the early stages can be removed, but they nearly always recur. Tumors of the neck, which are

Digitized by Microsoft®

apparently so freely movable that their extirpation would seem to be an easy matter, are found, when cut down upon, to be intimately connected with the deep vessels and nerves. In these cases the tumor is freely movable laterally, the vessels going with them, but there is no freedom of movement in the vertical direction. It is remarkable with what impunity large tumors may be removed from the neck, especially if they are benign. It is not uncommon in these cases to ligature both the internal jugular vein and the carotid artery, and to cut through the sternomastoid muscle, and yet have the patient make a rapid recovery from the operation; the tumor, as mentioned above, if sarcomatous, almost invariably returns, for it is impossible in the neck in such cases to remove sufficient of the surrounding healthy structures.

Aneurismal tumors at the root of the neck are comparatively common, and although in many cases these tumors may have the appearance of being connected with the subclavian or innominate arteries, yet they almost invariably proceed from the aortic arch, and push their way upward under the clavicle into the neck. Fusiform aneurisms of the aorta frequently simulate aneurism of one of the great branches.

Tumors in connection with the thyroid gland have been alluded to in the description of that body.

Francis J. Shepherd.

NECROBIOSIS.—The gradual death of tissue due to slowly acting injurious agents is known as *necrobiosis* or *indirect necrosis*, in opposition to *direct necrosis* or *immediate death*. In necrobiosis the death of the cell is preceded by some other retrograde change, such as atrophy, cloudy swelling, mucous, hydropic or fatty degeneration, or by one of the pathological infiltrations. In the case of direct necrosis death of the tissue takes place rapidly without the occurrence of preceding abnormal changes in cellular structure. The preceding retrograde change in necrobiotic processes is by some writers regarded as constituting the necrobiosis; but a distinction should be made between the preceding atrophy, degeneration or infiltration, and the molecular disintegration which constitutes the essential feature of necrobiosis. The retrogressive changes preceding this disintegration usually occur so gradually, and in themselves present such definite characteristics, as to be classed by themselves. The use of the term necrobiosis is more theoretical than practical, inasmuch as a practical distinction between direct necrosis and necrobiosis is at times very difficult or impossible. Necrobiosis is, therefore, best conceived of as a slowly progressive or incomplete necrosis. The gross appearances of necrobiotic tissues vary according to the nature of the preceding retrograde change and the degree of necrosis present. Microscopically, in addition to the characteristic changes presented by the accompanying retrograde change, the nuclei of the affected tissue show karyorrhexis and a greater or less degree of karyolysis. The ultimate picture of necrobiosis is that of necrosis; if the necrobiotic process has been characterized by cloudy swelling, simple necrosis follows; if by fatty degeneration, soft caseation (fatty necrobiosis) occurs; if by hydropic degeneration, liquefaction necrosis results. The sequelæ of necrobiosis are essentially those of necrosis: regeneration, repair, cicatrization, calcification, and cyst formation. Likewise the causes producing necrobiosis are the same as those leading to direct necrosis: mechanical, thermal, chemical, infectious, and nutritional. The injurious agents may act separately or coincidently. As a general rule it may be stated that harmful agents of slight power but of long-continued action are more likely to produce necrobiosis than direct necrosis. Disturbances of blood supply, deficient nutrition and oxygenation, as in the case of chronic anæmia, are among the most important factors leading to necrobiotic processes. Chronic intoxications and infections also play a leading rôle in the production of necrobiosis. Clinically a neuropathic necrobiosis may be distinguished.

Aldred Scott Warthin.

NECROSIS, PATHOLOGY OF.—The condition of local death, the death of individual cells or groups of cells within the living body, is known as *necrosis*. If such local death occurs immediately or very quickly after the action of some injurious agent, it is termed *direct necrosis;* if, on the other hand, the death of tissue is of a slowly progressive nature preceded by other retrograde changes, the process is designated *necrobiosis* or *indirect necrosis*. The use of the word necrosis without modifying designation is usually taken as referring to direct necrosis.

Inasmuch as we have no definite knowledge, either chemical or histological, of the condition of cell life, the essential nature of cell death or necrosis is also unknown to us. The cellular change which marks the exact moment of the passage of life from the cell is at present beyond our knowledge; the slight histological changes taking place in cells at this moment do not permit us to determine with certainty the definite boundary between the states of cell life and cell death. Our conception of necrosis is, therefore, based upon the changes which follow necrosis rather than upon those taking place at the moment of cessation of life. The development of modern microscopical technique has, however, so perfected methods of tissue fixation that it is now possible to fix and preserve definitely the histological characteristics of the cells as they exist at the moment the tissue is placed in the fixing fluid. Our knowledge of the structure of normal living cells has been obtained from the study of cells killed and fixed by such means; and likewise our conceptions of pathological conditions are based upon the relative appearances of cells so treated.

As a result of such study certain pathological criteria have been created. Of these the condition of *necrosis* is that state of the cell which is characterized microscopically by the disappearance of the nucleus and certain molecular changes in the cytoplasm. The disappearance of the nucleus or its failure to respond to nuclear stains is to be taken as the most striking feature of necrosis, inasmuch as the nucleus is to be regarded as the most essential vital element of the cell. Cells may be dead and yet retain their nuclei, but necrosis becomes evident to us microscopically only when certain changes in cell structure have occurred to distinguish the dead cell from living ones. The loss of the nucleus may occur at the moment of death or subsequently; in either case it becomes the criterion of necrosis. To the disappearance of the nucleus and its loss of staining power the terms *karyolysis* and *chromatolysis* have been applied. These changes are very frequently preceded by fragmentation of the nuclear chromatin. This change is known as *karyorrhexis;* it has been shown to consist of regular and definite movements on the part of the chromatin elements. Small masses and granules of chromatin may leave the nucleus and pass into the cell body. With the disappearance of the cell membrane fine chromatin granules may be scattered throughout the cell detritus of the necrotic area. As a result of such diffusion of the chromatin areas of necrosis in the early stage may stain diffusely blue. In other cases the nucleus before its disappearance contracts and becomes smaller, at the same time staining more deeply than normal (*pyknosis.*) Very frequently the nucleus retains its normal form and size, but gradually loses its staining power and fades away, both nucleus and protoplasm being converted into a homogeneous hyaline mass.

Sooner or later, changes take place in the protoplasm of dead or dying cells. The normal granulation of the cytoplasm may disappear and the cell undergo a hyaline change. The cell membrane ultimately disappears and the outline of the cell becomes irregular or lost altogether. Often the cell protoplasm becomes coarsely granular, the cell ultimately breaking up into a granular débris. Vacuolation may take place and the cell become enlarged and swollen from the inbibition of fluid. As the result of such swelling, breaks in the continuity of the protoplasm may occur. On the other hand, the dead cells may under certain conditions become inspissated.

Digitized by Microsoft®

Extrusion and constriction of portions of the protoplasm may occur during the process of dying. Ameboid cells usually assume a globular form. The disintegration of the protoplasm is termed *plasmoschisis*. The ultimate result of the necrotic process is the conversion of both nucleus and cytoplasm into a granular débris; when such appearances are found microscopically the condition is to be regarded as one of complete necrosis

Causes of Necrosis.—The causes which may lead to local death of tissue may be classed as follows: nutritional, mechanical, thermal, chemical, toxic, infectious, and neuropathic.

Disturbances of nutrition through interruption of the circulation are among the most frequent causes of necrosis. Local anemia due to arterial occlusion as a result of thrombosis, embolism, compression, ligature, or arteriosclerosis may be the direct cause of local tissue death (anæmic and hemorrhagic infarction). Likewise stasis due to mechanical, thermal, chemical, or trophic changes in the vessel walls or to weakened heart's action may be a primary or secondary factor of necrosis. Local asphyxia from any cause may result in cell death.

Traumatic violence may through crushing or tearing cause direct death of cells, or through damage to the blood-vessels it may cause necrosis through disturbed nutrition. Cells separated from their normal environment as a rule soon die.

Elevation of temperature from 54° to 68° C. for a short period of time causes the death of tissue; excessive cold produces the same result.

The prolonged action of *x*-rays may lead to necrotic changes. This has been explained as due to the destruction of nerves, but this point has not been definitely settled

Chemical and toxic substances of various kinds may act directly upon cells and cause their death. The poison may destroy the cells directly or, through chemical anion with the cell protoplasm or intercellular substance, render life impossible, or by producing changes in the blood-vessels give rise to necrosis secondarily. Most important of all as agents of necrosis are the bacterial toxins, particularly those of tuberculosis, typhoid, cholera, staphylococcus, and streptococcus infections. Chemical substances, originating within the body, may also give rise to necrosis under certain conditions.

The bile acids, uric acid, metabolic products in diabetes, pancreatic ferments, etc., may under certain pathological conditions give rise to necrotic processes. Fat necrosis is a striking example of necrosis arising from the action of a normal body product under abnormal conditions. The pancreatic juices are absorbed into the lymph and blood streams, the fat-splitting ferment, steapsin, causing necrosis of fat cells in the neighboring fat tissue, or even in such distant regions as the pericardium and fatty marrow.

The direct action of bacteria or other forms of vegetable and animal parasites may also produce necrosis of cells.

Primary lesions of the central nervous system and the peripheral nerves are considered by many writers to give rise to a trophic or neuropathic necrosis. The changes following such lesions are much more to be regarded as dependent upon circulatory disturbances than as trophic manifestations. As a result of lowered nutrition the normal resistance of the affected parts may be diminished and bacterial infection favored.

The causes mentioned above may act separately or coincidently. The degree of necrosis depends not only upon the nature and severity of the exciting cause, but also upon the condition of the tissue at the time of injury. Tissues of lowered vitality, in conditions of general anaemia, marasmus, and cachexia, die more easily than normal tissue; hence long-continued pressure of slight degree, which under normal conditions would produce no effect, may in such conditions as typhoid fever, chronic valvular disease, etc., bring about necrosis (*decubitus, marasmic necrosis*). Necrosis occurs also in the tissues of the aged as a result of slight injuries (*senile necrosis*).

Varieties of Necrosis.—Though the loss of the nucleus and a greater or less disorganization of the cytoplasm form the essential features of necrosis, these changes may be more or less modified, or so associated with other processes as to give rise to different varieties of necrosis, recognizable either by gross or by microscopical appearances. The kind of necrosis depends upon the location and nature of the affected cells, the character and severity of the destructive agent, and the nature of the surrounding tissue, particularly with reference to the absence or presence of fluids. If the dead cells are on a surface exposed to evaporation, inspissation may take place; on the other hand, if there is an abundant supply of fluid, the cells may become hydropic and ultimately liquefy; if the factors necessary for the formation of fibrin are present, coagulation may occur either in the cells or between them. The character of the necrosis may be further modified by infection with putrefactive bacteria. It becomes therefore possible to distinguish the following varieties of necrosis, each form presenting distinct macroscopical and microscopical characteristics when occurring alone. Between these different varieties there is, however, no distinct boundary line. They are very frequently combined or may follow each other in certain cases, so that the practical diagnosis as to the original form may be difficult.

Varieties of necrosis.	1. Simple.		Caseation.
	2. Coagulation.	Intercellular. Intracellular.	
	3. Liquefaction.		
	4. Mummification.		
	5. Moist gangrene.		

Simple Necrosis.—This form of necrosis is characterized microscopically by the disappearance of the nucleus and a hyaline or granular change in the cytoplasm, the original outlines of the tissue being preserved to a greater or less extent. Usually the dead cells are somewhat larger than normal, the protoplasm being more granular and staining heavily with eosin. Less frequently the cells are hyaline and homogeneous. By some writers this variety of necrosis is regarded as a form of coagulation necrosis, but it seems better to restrict the latter class to those forms

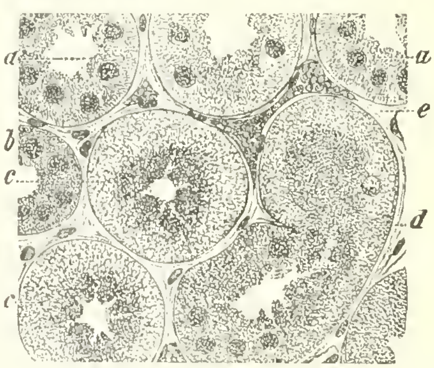

FIG. 3531.—Simple Necrosis of the Epithelium of the Uriniferous Tubes in a Case of Icterus Gravis. of necrosis in which fibrin or fibrinoid substances are formed. Simple necrosis usually follows cloudy swelling; indeed, it may be regarded as a late stage of this degeneration advanced to such a degree that the nucleus has entirely disappeared Early stages of simple necrosis may often be recognized by the presence of diffuse chromatin. The gross appearances of simple necrosis

www.libtool.com.cn
Digitized by Microsoft®

are yellowish or grayish discoloration and lessened consistency. Simple necrosis is one of the most common forms of necrosis; it occurs very frequently in the epithelium of the kidneys and liver as the result of intoxica-

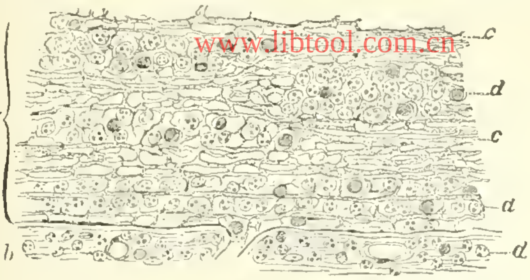

FIG. 3532.—Coagulation Necrosis. Croupous membrane from the trachea. (From Ziegler.) *a*, Transverse section of the membrane; *b*, uppermost layer of the mucous membrane with pus cells, *d*, scattered throughout its substance; *c*, fibrin threads and granules; *d*, pus cells. Magnified 250 diameters.

tions and infections, but may be found in any of the tissues. It is the most common form of necrosis found in anæmic and hemorrhagic infarcts, and in focal necroses due to various forms of intoxication and infection (typhoid, tuberculosis, diphtheria, scarlatina, etc.). A further change in tissues showing simple necrosis, so that all tissue outlines are lost and only a finely granular mass is left, results in the condition known as caseation.

Coagulation Necrosis.—This form of necrosis is characterized by the production, in the necrosed tissue, of fibrin or substances allied to fibrin, the so-called "*fibrinoid degeneration.*" The variety of necrosis described above as simple necrosis is by some writers regarded as a coagulation necrosis, but there is no positive evidence that it represents a coagulation process, and the resulting substance is not allied to fibrin. Coagulation necrosis occurs only in tissues rich in proteids and under conditions favorable for the production of the factors necessary for the formation of fibrin. Two forms are distinguished—*intercellular* and *intracellular*. In the intercellular form fibrin is formed between the dying or dead cells, the granular débris of the latter finally lying in a more or less dense network of fibrin threads. By the use of the Weigert's fibrin method this network of fibrin may be easily demonstrated. The fibrin may exist also in the granular, fibro-granular, or hyaline form. The chief source of the fibrin is most probably an exudate from the blood-vessels, but some of the factors necessary for the formation of fibrin may be supplied by the disintegration of tissue cells or leucocytes. The cells may become hyaline or granular, and ultimately completely disintegrate. This form of necrosis is most frequently seen in the fibrinous inflammations of mucous and serous membranes, and is hence also called *diphtheritic*, *croupous*, or *membranous* necrosis. The diphtheritic membrane may be taken as the typical example of this variety of necrosis. In all so-called diphtheritic inflammations there is more or less extensive necrosis of the mucosa with the formation of granular or fibro-granular fibrin between the granules of cell detritus. Intercellular coagulation necrosis may also occur in deeper tissues, as in the follicles of the spleen or lymph glands, in the liver, kidney, etc. It is of very common occurrence in the focal necroses of toxic and bacterial origin, and is almost constantly present to some degree in tubercles. It occurs much less frequently in anæmic and hemorrhagic infarction. Many chemicals cause coagulation by direct action. The toxæmia of superficial burns is associated with a form of coagulation necrosis in the splenic follicles and lymph glands similar to that seen in infectious processes. The coagulation of the blood and the process of thrombosis may be regarded as a form of coagulation necrosis. Tissues showing coagulation necrosis are firmer and paler than normal, more opaque, and show slight elevations above the cut surface. The source of the fibrin in the different instances of coagulation necrosis mentioned above is not entirely clear. A portion may result from the coagulation of vascular exudates and from escaped blood cells. In other cases it has been assumed that fibrinogenetic substances are derived from the necrosing cells or from bacterial products. The small quantity of fibrinogen found in the lymph may give rise to a portion of the fibrin produced during the necrotic process.

The intracellular form of coagulation necrosis is characterized by the coagulation of the cell protoplasm into a solid or semi-solid albuminous body more or less resembling fibrin. The most common example of this process is the so-called waxy or hyaline necrosis of striped muscle, commonly known as *Zenker's necrosis*. In this change the muscle loses its striations and becomes converted into a hyaline homogeneous substance which sometimes stains like fibrin, but often does not. To the naked eye such muscle appears pearly white or grayish, semitranslucent, resembling fish flesh. The condition occurs most commonly in cases of long-continued fevers as typhoid, and is found also in anæmic, thermal, and toxic necrosis of muscle. In the fevers the abdominal recti and the adductors of the femurs are most often affected. The exact chemical nature of the coagulated protoplasm is unknown. The simple necrosis which occurs in anæmic infarcts is regarded by some writers as being a similar form of intracellular necrosis (hyaline coagulation), but the process is of a very different nature from the change seen in striped muscle; and, as stated above, there is no definite proof that it is of the nature of a coagulation. Other writers look upon it as an inspissation process. In some instances intracellular coagulation may result from the imbibition of fibrinogen-containing fluids and their subsequent coagulation.

Liquefaction Necrosis.—In this variety of necrosis the dead cells undergo liquefaction; the dissolution may follow a hydropic degeneration or the necrotic cells may be dissolved in the tissue fluids. As a rule liquefaction necrosis occurs primarily in tissues freely bathed in lymph, but containing little of the fibrin-forming substances, as in the brain, cord, and skin. Burns of the second degree (blisters) are very common examples of this form of necrosis. Anæmic infarction of the brain, tissue suppurations, simple softening of thrombi, atheromatous softening in blood-vessel walls, and the digestion of necrotic areas of stomach and duodenum by the gastric juice are all processes characterized by softening and liquefaction. Liquefaction is also of frequent occurrence in certain tumors. In other cases liquefaction is a secondary process following simple or coagulation necrosis. The fibrinous exudates of inflammatory processes become liquefied during the later stages of the inflammation or during the process of healing, as in the case of the resolution of croupous pneumonia. Areas of caseation necrosis and moist gangrene may undergo a secondary liquefaction. On the other hand, coagulation may follow liquefaction, the fibrin-forming substances being produced from leucocytes. In the blebs which

appear in gangrenous skin there may occur a coagulation of the fluid, and the coagula may later be dissolved. Macroscopically, liquefaction necrosis is characterized by the formation of blebs on free surfaces, or by cavities filled with softened tissue débris, varying in appearance from a thin watery fluid, as in the case of brain cysts, to thick creamy fluid in abscess cavities. The earlier stages are shown by softening and increase in the amount of tissue juices. Microscopically, the presence of fluid is shown by clear spaces or vacuoles, stringy disintegration, etc. Both gross and microscopical appearances may be altered by the presence of blood or blood pigments.

Magnified 150 diameters. (Ziegler.)

Mummification Necrosis.—Necrotic tissues exposed to the air lose their fluids quickly through evaporation, and become leathery, dry, hard, shrivelled, brownish, or black, resembling mummy tissue. The condition is also known as dry gangrene; the amount of decomposition which takes place is, however, very slight, the dryness rendering the growth of saprophytic bacteria impossible. In the very early stages before the fluids are entirely removed there is some putrefaction usually present, as shown by the fact that there is almost always some odor about mummified tissue. The process may be regarded as a moist gangrene in which the processes of decomposition are cut short by the evaporation of fluid. Senile diabetic gangrene, gangrene of the extremities following freezing are examples of this form of necrosis. Microscopically, dry gangrene is characterized by the disappearance of the nuclei, the cells being flattened or contracted into hyaline masses. Cornification may be taken as a physiological example of this form of necrosis.

Moist Gangrene.—If necrotic tissues containing fluids become infected with saprophytic organisms with resulting decomposition, the condition is known as moist gangrene (*sphacelus, gangræna humida, gangræna putrida*). The formation of gas bubbles due to the presence of gas-forming bacteria gives rise to emphysematous gangrene (*gangræna emphysematosa*). The different forms of moist gangrene, though distinguished by various names, are in their essence identical, since bacteria develop only in moist tissues. As mentioned above, moist gangrene may be changed to the dry form through evaporation. Gangrenous tissues are black, greenish, or brownish in color, according to the amount of blood pigment present. If there was much blood in the tissue before death the gangrene may be *black*; if the tissues were anæmic the condition is sometimes designated *white gangrene*. Such forms are also distinguished clinically by the terms *hot* or *cold gangrene*. In hot gangrene the heat may come from an abundant blood supply in the neighboring tissues. The odor of putrefaction is always present in moist gangrene, and various gases may be formed. Ptomaïns and other poisonous substances are formed in the gangrenous area, and the absorption of these may lead to sapræmia. Softening and liquefaction are always present to a greater or less degree. Microscopically, moist gangrene, in addition to the essential features of necrosis, is characterized by the presence of products of decomposition in the form of fatty acid crystals, tyrosin, leucin, triple phosphate, blood pigment, etc. The general picture may be that of a simple coagulation or liquefaction necrosis, or a combination of these forms may be present. Liquefaction is always present in a greater or less degree according to the stage of the process; all elements of the tissues, even bone and fascia, ultimately becoming dissolved. Moist gangrene may be caused by external injuries, chemical action, freezing, burns, *x*-rays, pressure, disturbances of circulation with impaired nutrition, intoxications, and infections. Lesions of the central nervous system and peripheral nerves are also regarded as direct or indirect causes of gangrene (*neuropathic gangrene*). The tissues usually affected are those most likely to be infected with saprophytic organisms, viz., the extremities, skin, lungs, external genitals, uterus, and intestines. (See also *Gangrene*.)

Caseation Necrosis.—The term caseous is used as a gross descriptive designation for necrotic processes in which the dead areas bear more or less resemblance to cheese in color and consistency. Two forms may be distinguished, the *hard* or *firm* and *soft caseation*. Either simple or coagulation necrosis or moist gangrene may be followed by caseation; the latter condition is to be regarded as a post-necrotic change representing a more advanced stage of cellular disintegration. If coagulation necrosis is present, the caseation is usually of the firm variety; if there is much fluid in the part or if the necrosis had been preceded by fatty degeneration, soft caseation will result. Caseous areas are yellowish or grayish-white, more or less firm, dry, or viscid, and on section resemble cheese in consistency. Microscopically, the outlines of tissue elements are entirely lost, nuclei are absent, and the cells broken into fine granules. Fibrin threads may be shown by proper staining; fat droplets and vacuoles may be present. Early stages of caseation may stain diffusely blue from diffused chromatin; old caseation stains red with eosin, but shows no trace of chromatin. The chemical nature of caseous material is unknown; it probably includes many different substances derived from the breaking down of proteids. Caseation is a constant change in tubercles and gummata, and is of frequent occurrence in old infarcts, focal necroses, rapidly growing tumors, etc. Caseous areas not infrequently become liquefied. It is probable that diffusion processes take place between the area of caseation and the surrounding tissue; in this way the former may become infiltrated with fluid.

According to clinical or macroscopical characteristics the various forms of necrosis are also described as *focal, diffuse, spreading, central, circumscribed*, etc. Of these varieties *focal necrosis* deserves special mention. The term is applied to small necrotic foci, occurring very frequently in the course of various intoxications and infections, such as typhoid, diphtheria, scarlatina, smallpox,

Digitized by Microsoft®

puerperal eclampsia, tuberculosis, toxæmia of burns, etc. The foci are found chiefly in the liver, spleen, lymph glands, and kidneys. The form of the necrosis is usually simple, but fibrin is often present in the necrotic material. The later stages present the appearance of caseation. Focal necroses may not be visible to the naked eye, or they may resemble miliary tubercles or abscesses, for which they may be mistaken. At other times they may appear as small pale yellow or grayish spots barely distinguishable from the surrounding normal tissue. Microscopically, small islands of simple coagulation or caseation necrosis are found. When the necrosis has been recent, diffuse or fragmented chromatin may be present and the areas may stain deep blue. About the necrotic areas there is often a leucocyte infiltration. Many of the leucocytes become involved in the necrotic process; their chromatin becomes diffuse, giving rise to a deeply staining periphery. In the liver focal necroses are often limited to the central zone of the lobule about the central vein; hence the designation *central necrosis*. The same term is also applied to central necroses of bone. Focal necroses are due to the direct action of bacilli or to poisons acting directly upon the cells or to local asphyxia. The changes in the small capillaries of the affected tissue play a very important part. Fibrin may be first formed in the capillaries and lymph vessels, and thus shutting off the supply of nutrition cause cell death. In other cases changes in the capillary walls may be first produced by the injurious agent; capillary thrombosis follows, and to this the cellular necrosis may be secondary. Transudation of serum through the injured capillary walls may also lead to necrosis of the surrounding cells. The sequelæ of focal necrosis are the same as those of necrosis in general.

Fat Necrosis.—The necrosis of the fat-containing cells of adipose tissue forms a condition so striking in its clinical and pathological aspects as to warrant special mention. The condition occurs most frequently in the abdominal fat in connection with pancreatitis. The necrotic areas appear in the fat as grayish or yellowish, or in some cases black, opaque areas, soft or gritty, slightly elevated and usually circular in outline. The appearance sometimes is such as to suggest that the fat had been seared by a hot iron. Microscopically, the fat cells are enlarged, the nuclei absent, the contents granular or presenting the appearance of fine needles radiating from the centre of the cell. Osmic acid has no effect upon the altered fat cells. With ordinary stains the necrotic fat cells react in a variety of ways. The granular detritus in the fat cells consists of a combination of lime salts and fatty acids. If the process is old, the amount of lime salts may be great. It has been definitely shown that fat necrosis is due to the fat-splitting ferment of the pancreas, which under certain inflammatory conditions of that organ gains access to the tissues through the blood or lymph. Experimentally, fat necrosis may be produced by injection of pancreatic extract, by ligature of the pancreatic vessels, by introduction of pieces of pancreas into adipose tissue or into the peritoneal cavity, and by the direct action of steapsin in fat tissue. Not only may the abdominal fat be affected in cases of pancreatitis associated with fat necrosis, but also the fat of the pericardium, liver cells, retroperitoneal region, and bone marrow. In the majority of cases the condition is fatal, but recovery has been noted, the dead fat cells becoming calcified.

Hæmolysis, the destruction of the red blood cells, and *leucolysis*, the disintegration of leucocytes, are discussed by some writers under the head of necrosis. The exact nature of these processes is not at present definitely determined. Bacterial products, various poisons, the blood sera of animals of different species, or of the same species under certain conditions, are the chief factors in the production of these conditions. Normal hæmolysis occurs in the spleen, lymph glands, hæmolymph glands, and bone marrow. In pernicious anæmia, sepsis, and many of the acute infections and intoxications hæmolysis occurs in these organs to a greatly increased extent. Pathological destruction of the red cells in the circulating blood occurs also in a variety of infections and intoxications. The term *hæmocytolysis* is more properly applied to this condition, but has been largely superseded by the word hæmolysis.

Sequelæ of Necrosis.—The course of the necrotic process depends upon the anatomical nature and location of the affected tissue, the course and manner of the injurious influence causing the necrosis, the condition and environment of the affected part, the amount of blood and lymph, the nature of preceding changes, the opportunity for the access of air and putrefactive agents to the part, etc. About the necrotic area there is always a more or less marked inflammatory reaction in the surrounding living tissue. As a result of such inflammation the necrotic area becomes isolated and sequestered. The process is called *sequestration*, and the area of necrotic tissue so shut off a *sequestrum*. The ultimate sequelæ will be: (1) *Regeneration* following the absorption or casting off of the dead tissue, new tissue resembling the normal being formed; (2) *cicatrization*; (3) *calcification*; (4) *cyst formation*, the dead tissue being liquefied and encapsulated; (5) *chronic abscess* or *ulcer*.

Aldred Scott Warthin.

NECROSIS OF BONE. See *Bone, Pathology of.*

NEMATODA.*—The class of the Nematoda or round worms constitutes a large, rather uniform, and clearly demarcated group, which by many recent authors has been regarded as of the rank even of a phylum, in which case the name Nemathelminthes has been applied. The group is characterized by a cylindrical body, often filiform even in its attenuation, and by the heavy cuticular investment which carries in some cases small bristles, hooks, or spines, but which is consistently without appendages and manifests at most surface striation, but never true segmentation. The body cavity is extensive, but unprovided with a peritoneal epithelium, and the sexual and excretory systems do not stand in any connection with it. Another striking feature is the entire absence of cilia in all stages of development.

An alimentary canal is present, at least in some stage of the life history of all forms. It is with rare exceptions a permanent structure in the members of the sub-class of true round worms, or Eunematoda; but in the sub-class of the hairsnakes or Gordiacea, the alimentary canal is greatly reduced in the adult, in that the mouth is closed and a delicate solid string of tissue is the only vestige of the anterior portion of the canal. The posterior region still retains its cavity and functions in connection with the reproductive organs of both sexes, which have with it a common outlet. In the Eunematoda, on the other hand, the male organs join the alimentary canal to form a common cloaca, but the female system is entirely unconnected with the alimentary system, and the vulva occupies a variable position in the midventral line. The sexes are separate, though in rare instances parthenogenesis or hermaphroditism modifies the usual balance.

By far the largest number of forms belongs to the Eunematoda, which will be considered first, while the Gordiacea and, as an appendix, the Acanthocephala will be discussed subsequently. Among the Eunematoda the better known forms are parasitic, though some are free living and an occasional species is capable of making use of both types of environment. The free living species are uniformly insignificant, but among parasitic forms one finds the microscopic blood parasites and the meter long guinea worm. In respect to location also there obtains great variety; and one finds these parasites in all regions of the alimentary, respiratory, circulatory, excretory, and muscular systems, and in connective tissue and serous cavities.

The greatly elongated cylindrical form tapers as a rule more or less toward both ends, though generally speak-

* A general discussion of parasitism and its effects will be found under the heading *Parasites*.

Digitized by Microsoft®

ing the head is truncated and the tail acute. The chitinous cuticula invests the entire body, and is introverted a short distance at all orifices. It bears rarely unjointed spines and bristles and is marked often by delicate surface striations. In cross section (Fig. 3537) the body appears circular, and shows beneath the cuticula a thin hypoderma layer, which is prominently thickened at four points. Of these the lateral lines, fields, or areas, as they are called, are largest, and are visible in surface view as delicate longitudinal stripes (*c*, Fig. 3535). The dorsal and ventral median lines are much less prominent and are distinguishable ordinarily only in sectional views.

www.libtool.com.cn

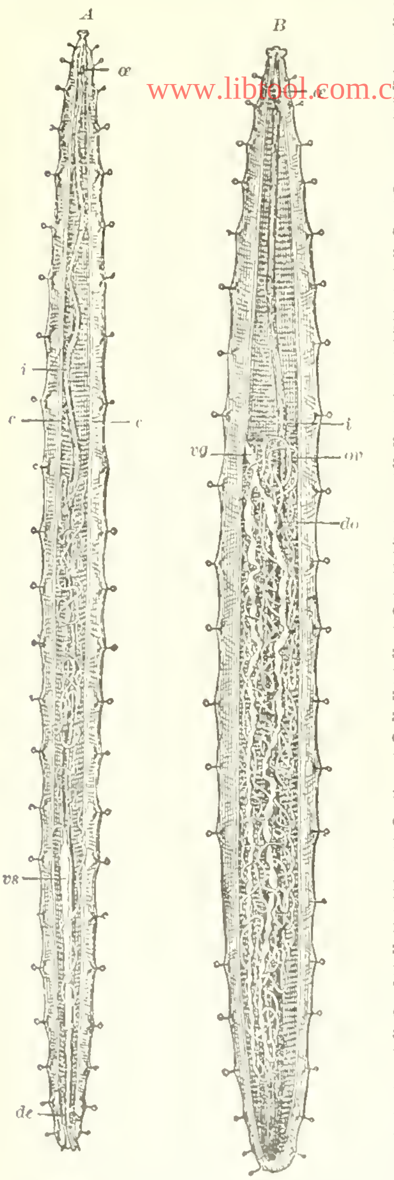

FIG. 3535.—Internal Anatomy of *Ascaris lumbricoides*, opened along dorsal line. *A*, Male; *B*, female; *c*, lateral line; *de*, ductus ejaculatorius; *do*, uterus; *i*, intestine; *oe*, œsophagus; *ov*, coiled ovary; *vg*, vagina; *vs*, seminal vesicle. (After Delafond.)

Directly below the hypodermis is the muscular layer which is interrupted by the lines already noted, and hence appears as four muscular fields. The muscle cells (*m*, Fig. 3536) are of a peculiar type in that a protoplasmic body is distinct from the contractile fibrillar portion. The main trunks of the nervous system occupy the dorsal and ventral areas, while the lateral areas contain each a delicate canal, which has been interpreted as part of the otherwise unexplained excretory system; with the latter are associated, however, certain stellate cells of peculiar character, which project from the lateral fields into the body cavity and are known as phagocytic organs.

The alimentary canal (*i*, Fig. 3535) is a straight simple tube extending from the mouth, which is always terminal, to the anus, which varies in location from the posterior end to a position on the ventral surface, some little distance removed from it. Various features connected with the canal are of great systematic importance. About the mouth are found a number of lips and papillæ characteristic of the genus or family. The buccal or pharyngeal cavity, an enlargement at the outset, the muscular œsophagus with a triangular lumen (Fig. 3537) and a terminal enlargement which may be indistinctly marked, or may partake of the form of a distinct bulb, or even two such, with a valvular apparatus, the intestine proper followed by the rectum and cloaca in the male—these constitute the distinct parts of the alimentary system.

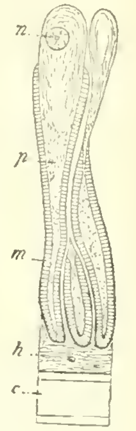

FIG. 3536.—Section of Body Wall. Highly magnified. *n*, Nucleus and *p*, protoplasmic body of muscle cell, *m*.

The sexual organs have the form of a long coiled tube, in the attenuated distal end of which the sexual cells are produced, while the proximal portions afford storage for the perfected germ cells before they are discharged from the body. In the female the system is regularly bifid, although one horn of the uterus may be undeveloped to a greater or less extent, while in the male only a single tube is present. The varied debouchment of the system in the two sexes has already been noted. About the vulva chitinous lips often of notable thickness are developed, and on the external surface near the male orifice numerous papillæ characteristic of the genus or species, and at times a sucker also are to be found; these function as accessory copulatory apparatus, while in the same category are included expanding folds of the body wall known as the bursa and awl-shaped chitinous structures called spicules. The bursa varies from a pair of simple folds lateral to the cloaca to a cup or bell surrounding it and the posterior end of the body. The spicules, either one or two in number, with an accessory guiding piece in some instances, are developed in a dorsal evagination from the cloacal wall and provided with special musculature for extrusion and retraction. Their form varies greatly in different species, and with the bursa and circumanal papillæ constitutes the means for determination of the species.

The Eunematoda are oviparous, but in some cases the eggs are retained long enough in the uterus to contain when laid a partly or fully developed embryo; and in a

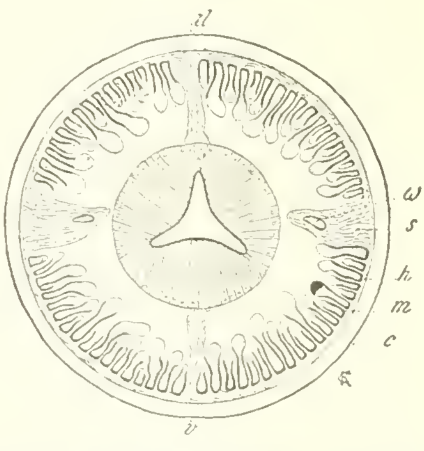

FIG. 3537.—Transsection of *Ascaris lumbricoides* at level of œsophagus. *c*, Cuticula; *h*, hypoderm; *i*, intestine; *m*, muscle layer; *d*, dorsal, *s*, lateral, *v*, ventral lines; *w*, excretory canal. (After Hertwig.)

few species the embryo deserts the shell before it is extruded from the body. All stages in the development of this ovoviviparous habit may be observed.

Ordinarily the eggs which undergo development exter-

Digitized by Microsoft®

nal to the body of the host are provided with a heavy shell to resist the action of an unfavorable environment. In case the eggs undergo development while still in the uterus, the shell is thin. Some species develop directly, *i.e.*, without a change of host, though a certain stage in the life history at least is passed in the outer world; in other cases the immature worm lives in another animal, known as the intermediate host, than that which harbors the adult, or rarely in a different part of the body of the one host. In a few species a parasitic generation alternates with a free living generation of such different form as to have been regarded as another species; and the alternating generations differ radically in method of reproduction. In one case at least (*Trichinella*) the entire life history is passed within the host and transportation to a new host depends upon the carnivorous habit. In other cases also (blood filariæ) the life history is passed within two hosts and no part takes place externally; but in most instances there is a free living stage and infection is brought about primarily through the drinking-water. Some prominent exceptions to this general statement are noted later.

www.libtool.com.cn

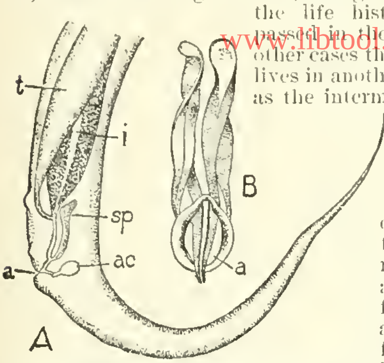

FIG. 3538.—*Anguillula aceti.* *A*, Tail of male; *ac*, accessory piece; *sp*, spicules; *B*, spicules partially protruded from anus. Magnified. (After Stiles.)

The family of the Anguillulidæ, which is difficult to characterize, contains mostly free nematodes of small size, transparent, filiform, and tapering to both ends. The œsophagus is inflated or has one or two bulbs at the posterior end. The female possesses double symmetrical uteri and short reflexed tubular ovaries, with vulva at or behind the centre of the body, with few, large ova, and with development rapid, often ovoviviparous. The male has two equal chitinous spicules, with or without one or more accessory pieces. The type genus is

Anguillula Ehrenberg 1826.—Buccal cavity very minute; œsophagus cylindrical with two bulbs, the posterior having a valve apparatus; vulva behind centre of body; male without bursa; accessory piece single, fan-shaped. The best-known species is the vinegar eel, which has recently been found as a parasite of man.

Anguillula aceti Müller (Fig. 3538).—Cuticula unstriated, body tapering slightly anteriad; tail greatly attenuated. Male 1.35 to 1.45 mm. long by 24–28 μ wide. Spicules 38 μ long, similar, twisted; accessory piece slightly caudad; no bursa; papillæ at least two preanal and one postanal. Female, 1 to 2.4 mm. long, by 40–72 μ in diameter, contains embryos 0.22 mm. long by 12 μ in diameter.

This worm, which is everywhere common in vinegar, has been recently studied by Stiles and Frankland in the rôle of a human parasite. The specimens were taken in great numbers from the urine of a female patient, and were present during a period of thirty-three days. The urine was always very acid and once had a marked odor of vinegar. In this sample the worms lived two months, and individuals then removed to vinegar became vigorous and bred rapidly.

Pathology.—The patient had chronic parenchymatous nephritis of a degenerative type, and the urine frequently contained albumin, but not while the parasites were present. No symptoms traceable to them were observed, and their presence in the bladder remained unexplained. The suspected use of vaginal douches acidulated with vinegar was denied by the patient, and no grounds existed for questioning the truth of the statement. Evidently this parasite might be present in the vagina if such a practice were followed. Billings and Miller have reported two other cases from the United States in which, however, the source of the parasite was not demonstrated beyond question.

Leptodera A. Schneider 1866.—Œsophagus with two bulbs, the posterior with or without valves. Male with or without bursa, often six to ten papillæ on the bursa or on the median line; two short spicules and a single accessory piece. Some species are hermaphroditic. A somewhat indistinct genus, difficult to separate from that last described, and perhaps identical with it.

Leptodera Niellyi R. Blanchard 1885.—(Syn.: *Anguillula leptodera* Nielly; *Rhabditis Niellyi* R. Bl. 1888.)

This species is known only in the larval form, in which it measures 333 μ in length and 13 μ in breadth. The alimentary canal was the only internal organ described; it displayed two enlargements in the pharynx, the second pharyngeal bulb having a dentate armature.

The worms were discovered by Nielly in 1882 in a young man, fourteen years of age, who was born near Brest, and had never been out of that region. A dermal eruption, much like craw-craw, of about five or six weeks' standing, affected chiefly the patient's limbs. In the fluid of each papule were found several worms, and the blood showed on microscopical examination at the outset of the malady many small nematoda, which, however, could not be found later; at no time were they found in fæces or urine.

The method of the introduction of the parasite was unknown; but it was remarked that the lad had been in the habit of drinking from brooks. It is easily surmised that the eggs of the worm were swallowed in drinking, and that the embryos, hatching out in the alimentary canal, bored their way into the circulation and thus reached the skin. Their presence both in the blood and in the papules is thus easily explained. They may have been, however, larvæ of some imported filaria, though dermatosis caused by larval nematoda has been observed in dog, fox and horse in Europe by many investigators.

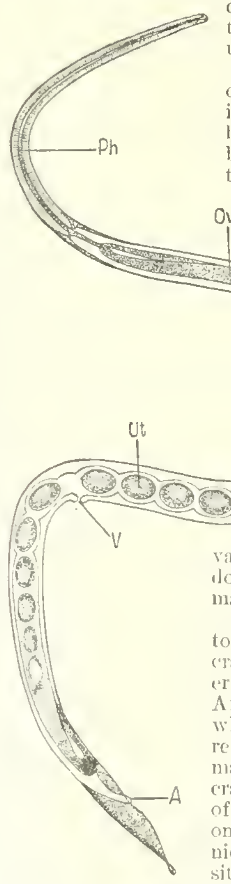

FIG. 3539.—*Strongyloides stercoralis* from Human Intestine. × 80. (After Braun.)

In this connection it is important to note the similarity of this case to craw-craw, a contagious vesicular eruption of the skin, observed in Africa and in South America, in which various investigators have reported the presence of larval nematoda. Manson regards craw-craw as a dermatosis characteristic of the "sleeping sickness," endemic on the west coast of Africa. Moniez has suggested that the parasites to which this case is due may have been imported by some sailor from Africa, and associates with it the case of elephantiasis, also observed in Brittany.

Leptodera pellio (A. Schneider 1866).—(Syn.: *Rhabditis pellio* A. Schneider 1866; *R. pellio* Bütschli 1873; *R. genitalis* Scheiber 1880.)

Male: Length, 0.8–1.5 mm.; bursa with seven to ten ribs on each side; spicules 27–33 μ in length, nearly alike. Female: Length, 0.9–1.5 mm., posterior extremity long

Digitized by Microsoft®

and pointed, vulva a little in front of the middle; ovary not paired; eggs oval, 60 by 35 μ.

Scheiber found this species at Stuhlweissenburg, Hungary, in the urine of a native woman suffering from pyelonephritis, pneumonia, and acute intestinal catarrh. During the entire illness the worms were found in the vagina in all stages of development. Several other authors have found what is closely related, if not the same form, in the urine in cases of hæmaturia; but the parasitism is probably accidental, since Oerley has shown that *R. genitalis* Scheiber must be referred to *R. pellio*, a common free living form found in moist earth and putrefying substances, and also that worms of this species will multiply in the vagina of white rats. There is further to be noted both the habit of Hungarian peasants in employing moist earth for poultices and the record of Scheiber, that patient and clothing were earth-stained, rendering it altogether likely that such a poultice had been applied near the vulva, and that from it the free living worms had successfully colonized the vagina.

www.libtool.com.cn

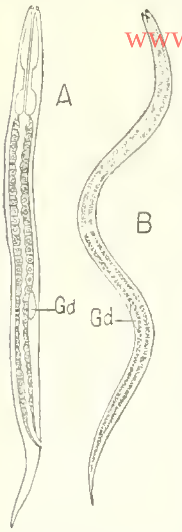

FIG. 3540. *Strongyloides stercoralis.* *A*, Rhabditiform larva from fresh fæces. × 145; *B*, filariform larva from culture; *Gd*, genital cell. 135. (After Braun.)

Leptodera terricola (Dujardin 1845.)—(Syn.: *Rhabditis terricola* Duj. 1845; *Pelodera teres* Schneider 1866; *P. setigera* Bastian 1879; *R. Cornwalli* Cobbold 1879.)

Mouth with six lips, anterior bulb of pharynx fusiform, posterior spherical. Male: Length, 1.3 mm.; tail attenuated, slightly longer than the bursa. Female: 2 mm. in length and over; posterior extremity sometimes regularly attenuated, sometimes sharply rounded and provided with a very fine tail; vulva about the middle of the body; ovoviviparous; eggs 60 by 40 μ.

This typical free living species should be listed as a pseudo-parasite of man by virtue of its occurrence in cadavers, and, in one case at least, its confusion with trichina. The facts in this celebrated case are as follows: The English schoolship *Cornwall* was visited in 1879 by an epidemic which affected many cadets and killed one. The symptoms of the disease were not incompatible with trichinosis, and microscopical examination of the exhumed cadaver, undertaken two months later, demonstrated in the muscles of the abdomen many nematoda, which, with the exception of the first one examined, were dead, but not one was encysted. The epidemic was pronounced therewith trichinosis, and attracted enough attention to be brought before Parliament. Cobbold and Bastian easily showed that the worms in question had nothing to do with *Trichinella*, and Oerley established their identity with *L. terricola*, which had undoubtedly penetrated the body after inhumation.

The family of the Angiostomidæ includes small rhabditis-like nematoda which manifest in development the alternation of two types of sexual generations of which the first is diœcious, free and very similar to Leptodera, while the second is parasitic, hermaphroditic, and of a different structure.

Strongyloides Grassi 1879.—Parasitic generation with simple mouth in which no armature is present; cylindrical pharynx very long. Free generation with small oral cavity; pharynx with two bulbs, the anterior fusiform, the posterior spherical and armed; male with two small spicules similar.

Strongyloides stercoralis Stiles and Hassall 1902.—(Syn.: *Anguillula intestinalis* and *A. stercoralis* Bavay 1877; *Leptodera intestinalis* and *L. stercoralis* Cobbold 1879; *Pseudorhabditis stercoralis* Perroncito 1881; *Rhabdonema strongyloides* Leuckart 1883; *Strongyloides intestinalis* Grassi 1883; *R. intestinale* Blanchard 1885.)

Free generation (Bavay's *A. stercoralis*) both sexes occur; body slender, tapering toward the ends; mouth with three or four indistinct papillæ; œsophagus 0.16 mm. long, with well-developed buccal cavity and two bulbs, the posterior of which is armed with three chitinous teeth; anus with protruding lips on right side of body. Male (Fig. 3541, B): 0.75–1 mm. long, 35 to 66 μ thick, with short recurved tail and two curved, conical spicules, 38 μ long. Female (Fig. 3541, A): 1–1.4 mm. long, 50–75 μ broad, with long slender pointed tail; vulva a little behind the middle of the body and on the right side; uterus double; eggs ellipsoidal, thin-shelled, 70 by 45 μ, segmentation advanced, embryo often hatched within body of mother; embryos at first with tapering tail, bulbous œsophagus, and chitinous teeth, soon changing to filariform stage.

Parasitic generation (Bavay's *A. intestinalis*) (Fig. 3539). Female only, hermaphroditic or parthenogenetic; length 2.1–2.2 mm., breadth 30–39 μ, body slightly tapering anteriorly, but terminated posteriorly by a short bluntly conical tail, with rounded and slightly dilated tip, mouth with three poorly developed lips (or none? Strong); œsophagus cylindrical, with no swellings, one-fourth the length of the body or more, distinguishable readily only in color from the intestine; vulva transverse in posterior third of the body; uterus with five to six (nine to twenty?) ellipsoidal eggs, 50–59, or 65–70 μ by 30–34, or 39 μ, and often joined in strings of two or three. The eggs are segmenting when laid, they develop rapidly and hatch before being ejected with the excrement. Embryos rhabditiform, 0.3–0.6 mm. long by 16–22 μ wide; first molt within twenty hours if in incubator.

Dr. Normand discovered the species in 1876, when examining microscopically the stools of soldiers returned from Cochin China, who were suffering from acute dysentery. Somewhat later he found at the necropsy of a soldier who had died from Cochin China diarrhœa, the other form of the species. Both of these forms were originally studied and described by Bavay. It was in 1883, before the connection of the two was established by Leuckart, who showed them to be phases in the life history of the same species. In life man harbors in the canal the one* form (*A. intestinalis* Bavay) and its young which, reaching the exterior with the fæces, may be transformed then into the other adult (*A. stercoralis* Bavay); the latter transformation may also take place in the intestine after death, as in cultures made in confirming these discoveries. Later authors have added many details, which may be summarized as follows:

The parasitic generation, which recalls a strongylid or a filaria in general appearance, produces eggs so abundantly that from an ordinary infection more than a million embryos may be evacuated in a single stool. The embryos (Fig. 3540, A) measure at hatching 0.2–0.24 mm. long by 12 μ broad, but develop so rapidly that those in the stools have attained a length of 0.30–0.60 mm. by a width of 16–23 μ. The embryos are characterized by a rhabditiform œsophagus, and under normal temperature they soon moult; and then, protected as if by a cyst in the larval skin, await more favorable conditions for further development. If kept, however, at a temperature of 25–35° C. they develop to sexual maturity in fifteen to eighteen hours; they copulate in thirty hours, and the females begin to lay at fifty to fifty-five hours.

After the first moult the structure of the embryos becomes more distinct, and one can see three or four oral papillæ and a buccal cavity, together with an anterior enlarged and median constricted region of the œsophagus, which is terminated by the œsophageal bulb, containing an apparatus for trituration composed of three chitinous teeth. The intestine which follows ends in a slightly protruding anus located on the right side. Also

* It is disputed whether the other form may rarely be found under the same circumstances.

Digitized by Microsoft®

on the right, about one-third the distance from the bulb to the tail, is the whitish lenticular proton of the sexual system.

In most cases studied in temperate regions after a few days in culture, these embryos die or change form, becoming elongate and with more tapering tails, the œsophagus loses its teeth and enlargements and becomes a uniform cylinder; the embryos resemble young filariæ and have taken on the strongyloid form (Fig. 3540, B).

www.libtool.com.cn

Only thirty to forty eggs are deposited by each female of the free generation (Bavay's *A. stercoralis*), which develop so rapidly as to approach the ovoviviparous condition; they hatch out young worms about 0.22 mm. long, in which the œsophagus manifests a distinct rhabditiform character. After the first moult, which occurs when they are about 0.35 mm. long, they acquire in from thirty to thirty-six hours the strongyloid appearance, in that the mouth shows four lips, the œsophagus is cylindrical and has lost its dental armature, the tail is shortened, and bears near its end two small lateral wings. At the end of eight days the free form can no longer be found in the cultures, and all the young have become strongyloid larvæ. If introduced into the intestine, these larvæ develop into the parasitic female, with which the cycle begins anew.

A remarkable modification of this, the normal life cycle of the species, was discovered by Grassi, who found that the development might be abridged since the rhabditiform embryos may transform directly into the strongyloid larvæ without the intervention of any free sexual generation. This direct development has been confirmed by Leichtenstern, who has observed it for weeks in succession, while at other times alternation with the free rhabditiform generation comes in. The causes of this transformation are unknown as yet; it must, however, be regarded as an important etiological factor, since the infection of man may be due to the accidental introduction of either sort of larvæ, or of the adult parasitic form. Stiles has suggested that this abbreviation is a step toward perfect parasitism.

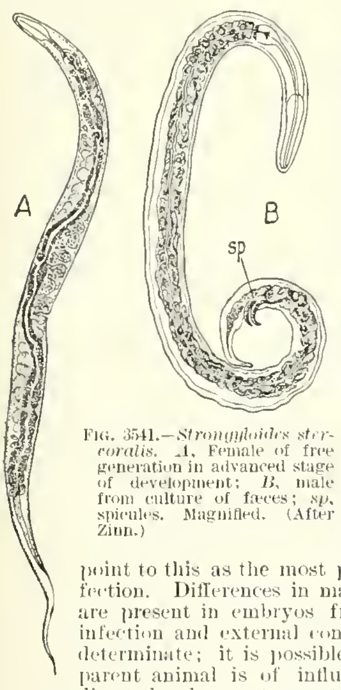

FIG. 3541.—*Strongyloides stercoralis*. *A*, Female of free generation in advanced stage of development; *B*, male from culture of fæces; *sp*, spicules. Magnified. (After Zinn.)

The method of introduction can only be inferred to be impure water or vegetables, salads, etc., which have been contaminated by human excrement. Although Normaud acquired the disease in Cochin China, while having refrained absolutely from drinking any but imported water, and was accordingly inclined to question the part played by water in its dispersal, yet in the absence of further evidence general considerations must point to this as the most probable source of infection. Differences in manner of development are present in embryos from a single original infection and external conditions seem to be indeterminate; it is possible that the age of the parent animal is of influence. Embryos with direct development are at least more resistant, and alone survive under unfavorable environment.

It has been claimed after culture experiments by Wilms that there are not two varieties of the parasite, one developing by the direct, the other by the indirect method, but that embryos from the same lot of eggs may develop in either fashion. Though the number of cases observed is probably too small for definite conclusions, it is striking that cases infected with the tropical strongyloids develop usually with the interpolation of the free sexual generation, while cases infected in temperate regions, both of Europe and America, manifest almost exclusively direct development. It should not be forgotten that there may be concerned here more than one species of closely related and heretofore confused forms, which would account for some of the apparently conflicting statements. Certain it is that the figures of the larvæ, given by various authors, do not agree in the form and proportions of the different regions in the œsophagus, which for individuals in the same moult are ordinarily regarded as constant, and an examination of the adult parasites, as figured by two most recent observers, Strong and Braun, shows numerous differences in detail, which can hardly be errors in observation.

The observations of Grassi, that the alternation of generations described above is not a necessary feature in the life cycle of this species, is still further of importance as explaining the enormous number of worms found in the intestine in some cases. Leuckart records an instance in which prodigious quantities of the worms were evacuated even a year and a half after leaving the locality of infection. Such evidence leaves little reasonable doubt of the multiplication of the parasite in the human alimentary canal, as in fact related species do so reproduce in other animals and as *Anguillula aceti* multiplies in the human bladder as noted above.

Distribution. — *Strongyloides stercoralis* occurs very widely. The entire tropical and subtropical zone of Africa, Asia, the Philippines, and the East Indies form apparently its original home, within which its occurrence is all but universal. It has also been recorded from Martinique, Brazil, Hawaii, and in Europe from Sicily, Italy, and Mount St. Gothard tunnel, Spain, Russia, and among brickworkers along the Rhine and in East Prussia. First reported in the United States by Strong, it has been observed and studied since then twice in Baltimore by Thayer, who showed its probable endemic character. For further data on its occurrence as well as for bibliography and discussion of previous cases consult the splendid paper by the latter author. Stiles has 5 further cases to be published soon.

Pathology.—At first the worm was regarded as the cause of the dysentery in which it was originally discovered and with which it is usually associated; more recent investigations have thrown some doubts upon this view. The rarity of the worm in the intestine at the outset of the disease, its abundance in stools of convalescents, its absence in cases which have freely bilious diarrhœa, and often in severe attacks of Cochin China diarrhœa, and finally its frequent presence in individuals enjoying normal health, all militate against the supposed pathogenic rôle of the species; and both Grassi and Leichtenstern go so far as to proclaim the species entirely innocuous, "innocent commensals of man."

On the other hand, its presence is not regarded by all authors as harmless, even though they do not regard it as the cause of the disease. Sonsino has found that in Italy excessive multiplication of the species may give rise to acute enteritis followed by dangerous anæmia. Golgi and others have observed epithelial lesions which they have attributed probably with justice to the action of this parasite. Its extraordinary multiplication in the human alimentary canal must contribute to the irritation of the mucosa and to the development of the lesions produced by the so-called Cochin China dysentery. Recent observations of Askanazy serve to demonstrate the pathological character of these worms, which he finds to be actual parasites of the intestinal wall in the duodenum and jejunum. Here they penetrate chiefly the mucosa, being often found in the epithelium of Lieberkühn's glands. They may penetrate to the muscular layer or rarely deeper than this. These migrations are in search of food, as the chyle-filled body of the worm shows; but no evidence was found to show that they ever suck the blood of their host.

Digitized by Microsoft®

The female deposits eggs in the galleries of the mucosa, which give rise to embryos that wander out into the lumen of the intestine. In Teissier's case it was claimed that these embryos had taken a different route and had entered the circulation, perhaps by way of the chyle tubes; their presence here was accompanied by high temperature, which abated with their disappearance three days later. More probably this case represents a double infection of *Filaria* with *Strongyloides*. The limited number of *Strongyloides* eggs found in the fæces is to be explained perhaps on their deposition deep in the tissue. More recently Strong has confirmed the presence of adults, eggs and embryos in the epithelium and in the cavity of the crypts of Lieberkühn, in which cases the epithelium is often atrophied and less frequently entirely gone. Infiltrations of small round cells were observed in some cases, but no marked inflammatory changes. This author believes that the parasite is not harmless, though not particularly dangerous; and he finds it capable of producing an intermittent diarrhœa with intestinal disturbances. It certainly causes some mechanical injury from its rapid movements.

FIG. 3542.—*Filaria medinensis*, Rolled on Split Stick. (After Fedtschenko.)

Prevention.—The use of filtered or boiled water and abstinence from eating uncooked vegetables of any sort, as well as the destruction of stools from patients afflicted with the parasite, are evident measures suggested by the life history. Special mention has been made by various observers of the general immunity of natives in Cochin China toward both the parasites and the endemic dysentery, and it has been explained on the basis of their universal use of water boiled or treated with alum sufficient to precipitate the organic matter.

The hydrotactic tendency of the embryos is useful in diagnosis in cases in which they are present in small numbers, since in the centre of a fecal layer spread on a culture plate a small cavity can be made and filled with water; here the embryos collect and are easily found. In pure water the embryos of the free generation are apt to perish, perhaps through lack of food materials. Leichtenstern has also pointed out that a differential diagnosis between this species and *Uncinaria* is not difficult, since in fresh fæces the latter form appears only as eggs, the former only as embryos. The *Uncinaria* embryo is also easily distinguished from that of *Strongyloides*, since the latter has a short thin-walled oral cavity, hardly chitinized at all, and a large spindle-shaped sexual rudiment, 33μ long, while the former possesses a long, heavily chitinized oral cavity and a minute circular sexual rudiment, only 3μ long. If eggs are taken from the canal at a necropsy, those of *Uncinaria* are distinguishable from those of *Strongyloides* by the smaller size and thicker shell.

Treatment.—Turpentine and male fern have no apparent effect. In mild cases thymol with general tonic treatment is successful generally, but in severe infections nothing yet reported is of any apparent value.

A genus which offers evident affinities to both Strongylidæ and Filaridæ, but which is usually included in a separate family, the Gnathostomidæ, is represented among human parasites by a single rare species:

Gnathostoma siamense (Levinsen 1889)—(Syn.: *Cheiracanthus siamensis* Lev. 1889.)

The genus is easily recognizable by the numerous spines which cover the entire body, or at least the anterior region. Several species occur in the Felidæ, and in swine and cattle. This form is known only by a single female specimen, length 9 mm., breadth 1 mm.; about the head eight circles of spines. The anterior third of the body alone is covered with spines, the anterior of which are three-pointed, and the posterior simple. The vulva lies behind the centre of the body.

The specimen was collected in Siam and came from a small tumor; when this disappeared there were found on the skin nodules the size of a pea, from one of which this worm emerged. The same symptoms were observed in two other cases, and in one of these five or six worms were expelled, but were not preserved.

Family of the Filaridæ.—Body greatly elongated, filiform; mouth variable, often papillate, sometimes with lips and even with a buccal capsule; œsophagus slender and without a bulb; male, with somewhat coiled tail and a single spicule or two unequal ones. Female, with double ovary and vulva near the anterior end of the body. Many species are ovoviviparous.

Filaria O. F. Müller 1787.—Very slender worms of nearly equal calibre throughout. Males notably smaller than the females, with coiled posterior end, which possesses in some cases alar appendages. Spicules ordinarily very different in size and form. Four preanal papillæ are almost constant; the number of postanal papillæ is, however, variable. Vulva always near the anterior end.

These forms are parasites of the serous cavities and subdermal connective tissue; in general the development, though not well known, appears to be indirect with an intermediate host from Crustacea or Insecta. Railliet justly remarks that for the physician this genus is a sort of "catchall" into which he throws all round worms, old or new, of which the structure is poorly known.

Filaria medinensis (Linnæus 1758)—(Syn.: *Gordius medinensis* Linn. 1758; *F. medinensis* Gmelin 1789; *F. dracunculus* Bremser 1819; *F. æthiopica* Valenciennes 1856; *Dracunculus medinensis* Cobbold 1864.)

Female: 30–100 cm. long (ordinarily 50–80), 0.5–2 mm. broad; body uniform in diameter, white or yellowish-brown; the anterior end smooth, rounded, with cephalic shield, and small mouth surrounded by six papillæ; alimentary canal atrophied in adult and with all other internal organs replaced by enormously developed uterus; vagina has disappeared. Uterus filled with larval filariæ, 0.5–0.75 mm. long and 15–25μ wide.

Male doubtfully observed, said to be much smaller than female, only 4–10 cm. long, found fixed to the female by its posterior extremity, about 14 cm. from the anterior end of the latter. If the observation is substantiated, the male follows the female into the tissues and perishes soon after copulation there. The vagina atrophies subsequently to this.

The so-called "guinea-worm" is the subject of the oldest records dealing with any parasite. Doubtless the fiery serpents which plagued the children of Israel in the wilderness were this species. The writings of the Egyptians and those of early classical times, as well as later authorities, make definite references to it. The Arabian physicians knew it well, and Rufus, of Ephesus, not only gives a good description of the disease and its cause, which he designates as a little snake, but recounts the commonly accepted opinion that "the Arabians suffer from it, and many strangers acquire the disease *if they drink the water*, for that is the chief cause."

Life History.—The adult female is met with in the connective tissue, particularly of the legs and feet. It appears here in eighty-five per cent. of all cases, and pierces the derma; a blister forms in the epidermis over this orifice, and on rupturing shows a small ulcer at the centre of which is a minute opening. If cold water is dashed on the surface here, a drop of a milky fluid exudes or a small tube (the uterus?) is protruded and bursts, setting free the opaque fluid. This fluid contains multitudes of embryos 0.5–0.75 mm. long and 15–25μ wide; they are flattened, terminate in a long pointed tail, and have a striated cuticula and a complete alimentary canal. They swim actively but intermittently, and live six days in pure water, but from two to three weeks in muddy water or moist earth.

Digitized by Microsoft®

As may be followed experimentally they enter the body cavity of small aquatic animals (*Cyclops*, Fig. 3543) through the joints in the exoskeleton, and there with two or three moults, occupying five or six weeks, they metamorphose into a more cylindrical form with a tripartite posterior end. The further life history is unknown. Fedtschenko tried to infect cats and dogs with these infested *Cyclops*, but without result. Manson and Blanchard have successfully repeated these experiments. Some further changes may easily be necessary before the parasite is fitted for its final host, which may be cattle, horse, dog, wildcat, or jackal as well as man.

www.tbtool.com.cn

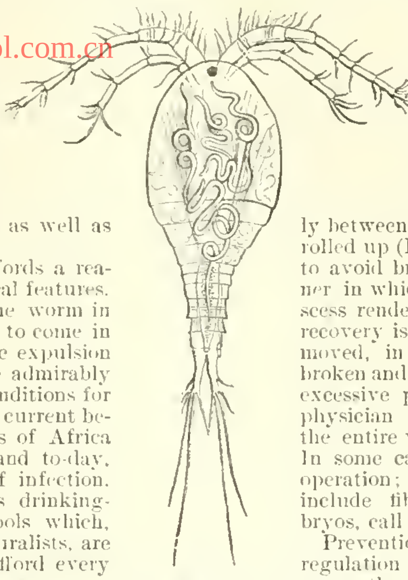

FIG. 3543.—Embryos of *Filaria medinensis* in body cavity of *Cyclops*. (After Fedtschenko.)

The life history, as given above, affords a reasonable explanation of some biological features. Both the preferential location of the worm in legs and feet which are most likely to come in contact with standing water and the expulsion of the embryos on such contact are admirably adjusted to secure for the young conditions for further development. It is a widely current belief among natives in different parts of Africa and Arabia, both in ancient times and to-day, that drinking-water is the source of infection. In the majority of infected districts drinking-water is obtained from surface pools which, according to the observations of naturalists, are swarming with *Cyclops*, and hence afford every opportunity for the spread of the disease.

Distribution. — The guinea-worm is rather widely distributed in tropical and subtropical countries. Most abundant in Deccan (India) and on the west coast of Africa, where in some seasons from one-half to nearly the entire population is affected, it is found more or less from India westward through Southern Asia and tropical Africa, and in a limited area of Brazil, where its introduction may probably be attributed to the slave trade. In Curaçoa and Surinam, where it was formerly endemic, and where it was no doubt introduced with negroes, it has now entirely disappeared. Records of its occurrence in Europe and North America are from natives of the infected area or visitors to it, and though frequently introduced it has never gained a footing in either place. Records of its occurrence in Africa and Arabia are found in historical and medical works of all ages. It is also known to occur in Persia, Turkestan, and Hindustan.

Pathology.—The seat of the adult females is the subcutaneous connective tissue, and they occur most com-

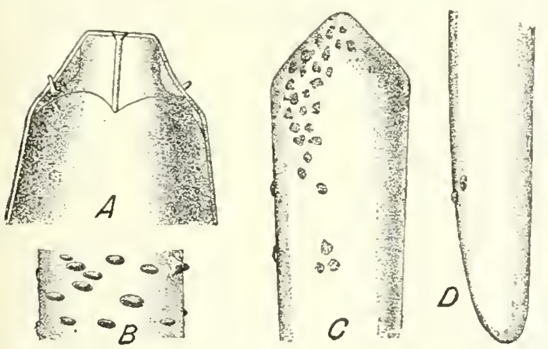

FIG. 3544.—*Filaria loa*. *A*, Head of male; *B*, mid body of male with cuticular bosses; *C*, head of female with bosses; *D*, posterior end of female with two bosses. Magnified. (After Blanchard.)

monly in the lower extremities, especially in the foot and ankle, but have been found in the arm, tongue, eyelid, scrotum, perineum, and trunk. As many as five or six in a single host is not uncommon. The presence of the worm is not detected ordinarily until it approaches the skin, where it produces a swelling, at first painless but later painful, and ultimately a running sore. Of itself the worm may be considered comparatively harmless, but the complications incident to a tropical climate often bring about excessive suppuration and gangrene, such as to necessitate amputation of the part infected, or even to be followed by death. The worm is sometimes expelled spontaneously, but in the majority of cases it is extracted by what is known as the Soudanese method. The end of the worm is seized firmly between two splints, on which it is gradually rolled up (Fig. 3542), great care being exercised to avoid breaking the slender body. The manner in which the worm is coiled up in the abscess renders the operation very slow, and while recovery is rapid when the entire worm is removed, in those cases in which it has been broken and a part left behind, the result has been excessive pain and often fatal gangrene. The physician finds it more satisfactory to remove the entire worm at once by a simple operation. In some cases complete cure follows a single operation; in others subsequent growths, which include fibrous tissue with numbers of embryos, call for further operative interference.

Prevention. — Apparently the satisfactory regulation of the supply of drinking-water will prove the means of stamping out the disease. Surface water is particularly suspicious on account of the large number of *Cyclops* likely to be present.

Filaria loa Guyot 1778.—(Syn.: *F. oculi* Gerv. et v. Ben. 1859 (nec. v. Nordm. 1852); *Dracunculus oculi* Diesing 1860; *Dr. loa* Cobbold 1864.)

Female 30–40 (rarely 70) mm. long, by 0.5 mm. broad, of cylindrical form (Fig. 3544) with anterior end blunt, posterior, straight, pointed; cuticula, transparent, yellowish, not striated but marked with minute, chitinous bosses irregularly distributed; uterus bifid, coiled; eggs 30–35 by 20–25 μ; when deposited containing embryos 210–250 μ in length.

Male: 20–30 mm. long, 0.3–0.45 broad; cuticula not striated, but with small papillæ except on first and last fifth; mouth without papillæ; tail (Fig. 3545) slightly incurved, with lateral wings and five ventral papillæ on each side, three being preanal and the first the largest; spicules two, short, unequal.

It was first observed in 1770, though a print of 1597 seems to show an operation for its removal. Nearly thirty cases are now on record; most of these are only notes, but recent descriptions of Ludwig and Blanchard have made its appearance and structure known. The earlier authors were inclined to regard it as identical with *F. medinensis*, but its specific distinctness maintained by others is now clearly demonstrated. Even if the immaturity of specimens eliminates the difference in size, the smooth striated cuticula of the guinea-worm will serve to separate it at once on careful examination from *F. loa* with its non-striated, embossed surface. The embryos differ also.

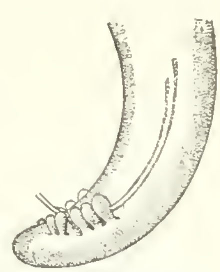

FIG. 3545. Tail of Male *Filaria loa* with Spicules and Papillæ. (Author's specimen.)

In distribution *F. loa* is limited to an area on the west coast of Africa (Guinea, Gold Coast, Gaboon), where it is not uncommon, and cases reported from other regions, which are largely among slaves of earlier days, have been those of persons who had come more or less recently from that region. Such are on rec-

Digitized by Microsoft®

ord from Brazil, Trinidad, St. Domingo, France, England, and the United States.

Naturally the majority of records affect negroes, but physicians in Africa maintain that the parasite attacks blacks and whites alike, and the number of cases reported among missionaries supports this view. One of the latter has recently been reported in the United States by Ward and Milroy.

www.libtool.com.cn

Life History.—From the scattered facts on record Blanchard has outlined the course of development as follows: Introduced into man in the larval form with drinking-water, the form becomes adult in the alimentary canal. Either before or after copulation it penetrates the tissues where its development is slow, as shown by a residence of from four to ten years or more in the body. It appears beneath the conjunctiva of the eye or the skin at the last phase of its existence, but it may reach the surface of the body without having acquired its full development. That unlike *F. medinensis* it does not deposit eggs in dermal abscesses is clear from the entire absence of pus formation and of eruption in cases of its occurrence. It is a prisoner in the body, and the embryos must escape independently of the mother. They probably penetrate the blood, and are drawn from it by some blood-sucking parasite, from which in some unknown way they reach running water and in it a new host, or are inoculated directly when the intermediate host is feeding. Manson has conjectured that the well known *F. diurna* is the larva of *F. loa*, with which it agrees in geographical distribution. The opinion is generally accepted among inhabitants of the affected region that the source of infection is to be found in drinking-water.

Pathology.—The parasite is an active migrant through the connective tissue, but comes often into the region of the orbit. Its appearance in the tissue of the lid or beneath the conjunctiva is made known ordinarily by itching or even by slight pain which may disappear with the withdrawal of the worm, only to recur with its subsequent return at irregular intervals of days, weeks, or even months. An individual has been seen to pass rapidly from the one eye to the other over the bridge of the nose. In one case only has an immature specimen been found actually within the eye. In addition to itching, transient œdematous swellings accompany its appearance in various parts of the body. Fugitive tumefactions, known as Calabar swellings, are not uncommon in lower Nigeria. They are half the size of a goose egg, painless, sudden in appearance, disappearance, and recurrence, and may be found in any part of the body. They are thought to be produced by rubbing when a *F. loa* approaches the surface.

Treatment.—The negroes drive it from the eye by dropping a grain of salt into the conjunctival sac or by extracting the worm with a thorn. Deftness in operating is necessary, and if after cocainizing the eye the worm be grasped with a pair of forceps, a cut in conjunctiva or lid gives an opening through which it usually starts to escape, or may be withdrawn by a second forceps.

Filaria volvulus Leuckart 1893.—Body tapering uniformly, head rounded. Male 30–35 cm. long, 40–140μ in diameter, tail incurved; one postanal, two adanal, one preanal papilla on each side, two spicules 0.08 and 0.177 mm. long. Female 40–70 cm. in length. Embryos 250μ long, 5–6μ wide, resembling *F. nocturna* and *F. diurna*, but shorter and thicker and without sheath, head rounded, tail very sharp, clear spot in anterior fourth of body.

Leuckart received two dermal tumors from Gold Coast negroes containing several worms coiled in a ball and surrounded by a fluid containing embryos. A somewhat similar tumor excised from the arm of a French soldier, who had been in Dahomey, showed that the worm occupied a lymph vessel and was surrounded by a mass of connective tissue. Its identification as the same species has been questioned. Prout has recently described two other cases from Sierra Leone. Like *F. loa*, it is viviparous and found in subdermal tissue; but unlike that species it is sedentary and produces a circumscribed subcutaneous tumor.

F. conjunctivæ Addario 1885.—(Syn.: *F. palpebralis* Pace 1867, nec Wilson 1844; *F. peritonei hominis* Babesiu 1880; *Filaria inermis* Grassi 1887.)

Female: Length 10–16 cm., width 0.5 mm.; cuticula striated not embossed or papillate; mouth terminal, unarmed, vulva near anterior end; uterus double, with eggs and embryos measuring 350 by 5.5μ. Male unknown.

Dubini first found this species in Sicily in a tumor of the conjunctiva, and it has been recorded as a human parasite also in Italy and Hungary. The species is, according to Grassi, a normal parasite of the horse and ass, and is only occasional in man.

Filaria lentis Diesing 1851.—(Syn.: *Filaria oculi humani* von Nordmann 1832.)

With the case of von Nordmann, in which immature nematode worms were found in the lens, have been associated various poorly known and often doubtful cases of later observers, in several of which it is probable that the object was a vestige of a vessel or filament and not a filaria. In three cases the parasite was in the lens, in three also in the vitreous humor, and in two in the aqueous humor. The most recent, by Drake and Brockman, at Madras, has been assigned by Blanchard to *Filaria equina*, which is abundant in India. The character of other species is likely to remain permanently doubtful. Some of them are very likely young forms of the preceding species, *F. inermis*.

Filaria restiformis Leidy 1880. Length 66 cm., width at head 0.375 mm., at centre 1.5 mm.; anterior end pointed, posterior blunt; mouth without papillæ; œsophagus 1.125 mm. long.

Passed in West Virginia from the bladder of a man, fifty years of age. The patient had been suffering some days from hæmaturia. Raillict regards it as evidently a pseudoparasite. While it was not extracted by the attending physician, he maintained that no doubt existed as to the correctness of the patient's statements that the worm had actually been passed.

Filaria hominis oris Leidy 1850.—Length 14 cm., width at head 0.1 mm., at centre 0.38 mm. Mouth terminal, posterior end provided with an epidermal spine, 0.05 mm. long.

Leidy found the single specimen in the collection of the Philadelphia Academy labelled, "Obtained from the mouth of a child," and queried if it might be the young or the male of *F. medinensis*. Leuckart shared the opinion which has, however, been questioned by some later investigators.

F. labialis Pane 1864.—Length 30 mm.; pointed anteriorly; mouth with four papillæ, posterior end slightly inflated; vulva in posterior tenth; uterus double, but in posterior branch rudimentary.

A single specimen only from a pustule on the upper lip of a man in Naples, Italy. Not reported since 1864.

F. lymphatica Treutler 1793.—(Syn.: *Hamularia lymph.* Treutler 1793; *Filaria hominis bronchialis* Rud. 1819; *F. hominis* Dies. 1851; *F. lymph.* Moq.-Tandon 1860; *Strongylus bronchialis* Cobbold 1879.)

Length about 26 mm.; brownish spotted with white; transparent and pointed anteriorly; thickened and blunt posteriorly; two short spicules.

First found in 1790 in the hypertrophied bronchial ganglia of a man of twenty-eight years of age; it has been reported since then by Brera and by Zürn, who discovered another specimen at Geneva in 1879, under conditions like those of the first case. The view of Diesing and Weinland, that it was probably *Strongylus longevaginatus* (= *S. apri*) is improbable according to Railliet, who views it as a male of *F. inermis*. The view of Braun that it is *F. equina*, a common parasite of horse and ass in Europe, seems more probable.

Filaria immitis Leidy 1856.—Mouth with six papillæ. Male: 12–18 cm. long, 0.7–0.9 mm. wide; posterior end with low lateral wings and eight preanal as well as nine to ten postanal papillæ; posterior end rolled in several turns like a corkscrew, spicules unlike. Female: 25–30

Digitized by Microsoft®

cm. long, 1–1.3 mm. wide, posterior end shortly blunt; vulva in posterior fourth; ovoviviparous embryos 0.28–0.30 mm. long and 5 μ wide, with a greatly attenuated posterior extremity.

Originally found by Leidy in the heart of a dog, it is now known to inhabit the entire venous system. The

www.libtool.com.cn

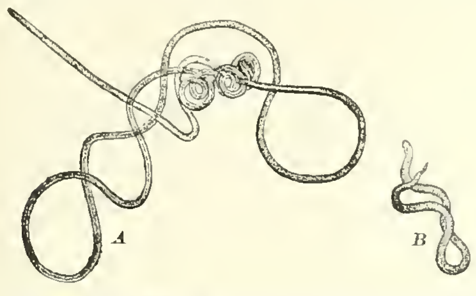

FIG. 3546.—*Filaria Bancrofti.* *A*, Adult male × 7.5. *B*, Embryo from hydrocele fluid × 200. (After Lothrop and Pratt.)

embryos are to be found in the peripheral circulation during the period of rest. With growth they retire to the larger vessels and escape from the kidneys or in excrement. Their normal method of exit is unknown. The parasite is most common in dogs living in the open.

The parasite is common in the United States, especially in the South and in South America. It seems to be very abundant in China and Japan, and is reported also from Italy, France, Germany, and Denmark.

As Moniez has shown, Braun was apparently in error in citing Bowlby as authority for the occurrence of this species in man; and Braun's own case is too uncertain in determination to be accepted as evidence in absence of other instances. If *F. immitis* is even occasionally a human parasite, it should be found as such in the United States, where it occurs commonly. No case has been found on record.

Filaria Bancrofti Cobbold 1877.—(Syn.: *Trichina cystica* Salisbury 1868, non Filaria cystica Rud. 1819; *F. sanguinis hominis* Lewis 1872; *F. sang.-hom. ægypt.* Sonsino 1874; *F. dermathemica* Da Silva Araujo; *F. Wuchereri* da Silva Lima 1877; *F. sanguinis hominis nocturna* Manson 1891; *F. nocturna* Manson 1891.)

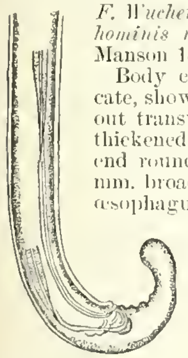

FIG. 3547.—Tail of Male *Filaria Bancrofti.* Magnified. (After von Linstow.)

Body elongated, white, opaque, very delicate, showing tendency to coil; cuticula without transverse striation, anterior end slightly thickened, without lips or papillæ, posterior end rounded. Male 35–40 mm. long; 0.1–0.12 mm. broad, head 51 μ, neck 43 μ, in diameter; œsophagus 0.13 mm. long; tail (Fig. 3547) slightly bent, 1 mm. long; papillæ undescribed; spicula 0.2 and 0.6 mm. long. Female 75–95 mm. long, 0.21–0.28 mm. broad, head 68 μ, neck 51 μ in diameter, vulva 0.72–1.27 mm. from head, anus 0.282 from tail. Eggs 25–28 μ or 35 (Lothrop and Pratt) by 15 μ. Embryos 0.127–0.2 mm. (or 0.2–0.33 mm.) long by 8–10 (7–11) μ broad, with unstriated cuticula, but enveloped in a delicate sheath (Fig. 3546, *B*).

Although first reported as early as 1863 by Demarquay, this form has been very generally confused with other species of the group, especially *F. Magalhaesi*, and even now only a little can be given beyond the data contained in the general characteristics which are taken from Maitland and Manson's account, and from that of Lothrop and Pratt. The discrepant measurements given by different authors are due, in part at least, to the fact that different species were under consideration.

The male (Fig. 3546, *A*) is much shorter than the female, and the posterior end exhibits a strong tendency to twist like a tendril. Both sexes manifest a proclivity to curl into a knot, and various observers note the difficulty of disentangling the individual worms from such a mass. In the female, which alone has been examined, the anterior end is traversed by four deep grooves, giving the transsection much the form of a maltese cross. The thick-walled vagina extends posteriorly a short distance from its external orifice, and splits into two thin-walled uterine tubes, which occupy the entire cavity of the body, forcing the intestine against the muscular wall at one side. These tubes are filled with ova and embryos in all stages of development. The smaller embryos are coiled within a thin structureless chorion. Preserved specimens may assume a brownish tint, owing to a change in the color of the uterine walls.

The embryonic filariæ in freshly drawn blood or in hydrocele fluid are rounded at the anterior end and pointed at the posterior. Though in constant motion, twisting and coiling, they never (?) exhibit a true progressive movement. In freshly drawn blood they are covered by a delicate sheath, which is indistinguishable normally except as a flagellum following the tail at some distance, 0.3–0.4 mm. (Fig. 3548); rarely, when the movement of the body is reversed, this disappears from the tail and becomes evident at the head (Fig. 3548, *A*). It is evidently the collapsed sheath, which Manson regards as a vitelline membrane, and in such specimens as have undergone endosmotic changes it appears like a distended sac enveloping the entire worm; such an appearance, though frequently figured, is entirely unnatural. The embryos of other species, *e.g.*, *F. immitis*, are without this sheath. These embryos may be kept alive five or more days in a cover-glass culture of blood, and after forty-eight hours many empty sheaths may be observed. Attached to the tip of the head is a minute spine, which at times is protruded in rapid succession with a peculiar "pouting" movement.

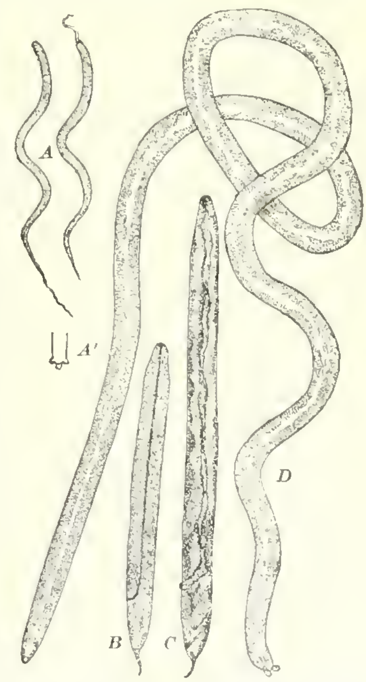

FIG. 3548.—Metamorphosis of *Filaria Bancrofti* in Thorax of Mosquito. *A*, Just ingested; *A'*, posterior end; *B*, five days old; *C*, ten days old; *D*, sixteen days old. (After T. L. Bancroft, except *A'* after Manson.)

Life History.—The female is viviparous, and the embryos, which are produced in enormous numbers, are evacuated into the lymph stream and ultimately pass from it into the blood current, where they are often found in extraordinary abundance. They measure 0.2–0.33 mm. by 7–11 μ (Lothrop and Pratt, 0.26–0.3 mm. by 6–8 μ). Twelve hours after being taken into the stomach of a mosquito one finds side by side free embryos and empty sheaths. By the next day the embryos have traversed the wall of the stomach and are in the thoracic muscle. At the end of eleven days they are 20–25 μ broad and more than 580 μ long. At seventeen to eighteen days they begin to leave the muscles and migrate into connective tissue in front of the prothorax. Such larvæ are

Digitized by Microsoft®

more slender than before, 18–20 μ in diameter. These larvæ show an alimentary canal with œsophagus well differentiated and rudiments of the reproductive apparatus. While some remain in muscles even up to the fiftieth day, the most are gone. By even the twentieth day larvæ have penetrated the head and proboscis in sections of which they appear crowded into the cavity headed toward the point (Fig. 3549). Like the malarial organism they are inoculated directly. The last stage of development occurs in the skin; they become adult and copulate there; thus the variable position of lesions of elephantiasis are explained. In *Anopheles* James finds that the transformation requires only from twelve to fourteen days, and the activity of the embryos does not cease. According to the same author the broad inactive form measures 71–53 μ long and the slender active form 151–132 μ long and 2.6 μ broad; in this latter stage the œsophagus is two-fifths and the tail one-third of the entire length.

www.libtool.com.cn

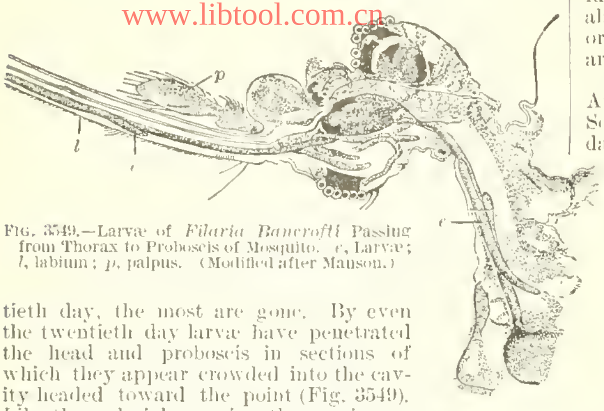

FIG. 3549.—Larvæ of *Filaria Bancrofti* Passing from Thorax to Proboscis of Mosquito. *c*, Larvæ; *l*, labium; *p*, palpus. (Modified after Manson.)

Bancroft and Manson suggested almost simultaneously that the mosquito might serve as a carrier of the embryonic filariæ in the blood. Manson, however, first observed the changes which these embryos undergo in the mosquito. He allowed mosquitoes to suck the blood of filarial subject, and found at first that the embryos are within a delicate sheath or membrane, apparently almost structureless; later, there becomes evident a marked transverse striation, and the sheath is ruptured by the worm forcing its cephalic end against it. Once free from the sheath, the embryo bores through the stomach wall of the insect and wanders into the thoracic muscles. The embryos which emigrate to the thoracic cavity do so as soon as they are withdrawn from the human host; those found some hours later in the mosquito's stomach are such as by immaturity or injury are not destined to metamorphose, and changes in such are retrogressive.

According to one view the worm escapes by boring its way out at the time the mosquito is depositing her eggs on the water, or by breaking out from dying mosquitoes which fall into a pool, and that the infection of the human host is brought about by drinking such water as contains well-developed embryos. It is further supposed that these young worms then bore their way through the human intestinal wall and attain maturity at some suitable point. Copulation here is followed by the production of swarms of embryos. In objection it may be urged that Bancroft has shown water to be fatal to the embryos in the course of three or four hours, and that hence it cannot be the medium by which they reach the human subject. He also says the embryos never escape naturally from the mosquito's body even if in water. The other hypothesis as to later development is that the infection takes place when the mosquito containing the fully developed embryos is sucking blood, and Bancroft has proved the migration of such embryos from the thoracic muscles into the labium, from which he believes they escape at a definite point at the tip to penetrate the body of the new host. Grassi believes that the larvæ escape from the bent labium in the act of biting by rupture of the cuticula. This part of the life history has not been cleared up as yet.

In the transmission of embryos certain species of mosquito only are culpable; among such are *Culex fatigans* in Australia, *Anopheles Rossii* in India, probably also *Anopheles musivus*; this genus James regards as the proper intermediate host, since in it the development is more rapid. In case the embryos are taken up by any unsuitable species of mosquito they are digested in the stomach; or if a few individuals succeed in wandering out, they are absorbed in the muscles.

Distribution.—Tropical Asia, Africa, America, and Australia are all infected. In Samoa and some other South Pacific Islands this parasite is particularly abundant, as much as fifty per cent. of the population being infected.

The first mention of this parasite in the United States was made by Salisbury in 1868, who found the ova in the urine. Some years later (1886) Guiteras called attention to the presence of the embryos in the South, reporting four cases from Key West and one from Charleston, S. C. Only a little later De Saussure published a clinical history of twenty-two cases, also from Charleston. Since then many cases have been reported in the Gulf and South Atlantic States, many of which have been undoubtedly imported, but indigenous cases are not wanting, and one concerns a woman who had always lived in Pennsylvania. The last account by Lothrop and Pratt gives a most extensive and valuable study of two cases in Boston imported from the Barbadoes, and includes important new data on the characteristics of the adult worms.

Pathology.—The adult worm was first found in 1876, by the elder Bancroft, in a lymphatic abscess of the arm and subsequently in a hydrocele. The two sexes are found coiled together, and probably live for some time. Since then this discovery has been abundantly confirmed. Manson has shown that the species normally occurs in the lymphatic vessels, and that the embryos, as well as the adults, rarely also gain the circulation by way of the thoracic duct. The embryonic blood filariæ were first observed by Demarquay, of Paris, in a man from Havana, who was suffering from chylocele. The name *F. sanguinis hominis*, first used for these embryos by Lewis in India, has been applied to several different embryos, which Manson has distinguished by appropriate names. Whether they belong to different species or are stages of development in one or two forms is still unsettled, though I am inclined to accept their specific independence. Such embryos have been reported from urine, tears (?), and secretion of the Meibomian glands as well as from the blood in cases of chyluria and elephantiasis, and also in apparently healthy individuals. In the Barbadoes nearly thirteen per cent. of the persons examined were infected, and yet two-thirds of the infected cases manifested no external sign of the disease.

Manson was also the first to establish the periodicity of the embryos, as those of this species appear in the blood toward evening, increase in numbers during the night, and disappear in the morning. Manson views the "filarial periodicity as an adaptation of the habits of the filaria to those of the mosquito, the intermediary host indispensable to the future life of the parasite." But since it has been shown that by reversing the period of sleep the habits of the embryo filariæ may be reversed also, the explanation of von Linstow appears more probable, namely, that the tonus of the capillaries is reduced during sleep; and thus the embryos, which are too large to enter them during the day, find entrance possible owing to the increased size of the vessels. Manson found the embryos massed in large arteries and irregularly scattered through the capillaries in the day time.

The presence of embryos in the blood is evidence of the parasitism of the adult in some part of the lymph system. The duration of life of both adult and larvæ is entirely unknown; for the former, however, it is certainly several years. So far as known the embryos do not bring about pathological changes, though leucocytosis with an increase of eosinophiles is noted in early stages, to disappear later. The adults occlude large lymphatics and produce lymph stasis with resulting dilatation of the lym-

Digitized by Microsoft®

phatics. The clinical manifestations depend upon lymphatic obstructions and give rise to both general symptoms and local, which latter vary widely according to the part involved and to possible modification by infective processes.

An estimate has been made of from forty to fifty millions of embryos in the blood of a single man, and yet the individual suffered no apparent effect. It must be said, however, that the results of the parasite are brought about gradually; they are primarily a varicose condition of the lymphatics, giving rise to various conditions, such as chyluria, varicose inguinal glands, lymph scrotum, chylocele, lymphangitis, elephantiasis (*q. v.*). In the latter it is probable that the obstruction to the flow of the lymph produces mechanically the distention and excessive growth of such parts as arm, leg, scrotum, which is characteristic of the disease.

For examination Manson recommends a thick film of blood drawn at 8 to 9 P.M., when the embryos are most numerous. Fixing is unnecessary and the stain (fuchsin, gentian violet) is made by adding a few drops of an alcoholic solution of the dye to a watch glass of water. Overstaining is reducible by dilute acetic acid.

Prevention.—The protection of drinking-water from contamination by mosquitoes is strongly to be advised, and the case of the Friendly Islands is cited as evidence of the value of this measure. There forty per cent. of the males are affected by filariæ, all the people drinking from open pools; but the chiefs who have closed-water tanks rarely acquire the disease. It may, however, be urged in favor of mosquito inoculation that the chiefs are also least subject to mosquito bites. In any event, the protection of drinking-water and the destruction of useless pools will certainly reduce the number of mosquitoes, and consequently the extent of the disease, whether transmitted through drinking-water or by direct inoculation of a mosquito.

It must be noted that the presence of an infected individual is a distinct menace to the health of a community, since the widespread distribution of mosquitoes capable of acting as the intermediate host insures the possibility, and under some circumstances the certainty, of wider transmission of the disease. There is little doubt that the cases recorded from the Southern United States are primarily traceable to such introduction from the West Indies. The same explanation lies near at hand for those occasional cases which have been recorded in various localities, both here and abroad.

Filaria Magalhaesi R. Blanchard 1895.—(Syn.: *F. Bancrofti* Magalhaes 1892 *nec* Cobbold 1877.)

Body slender, elastic, resistant; cuticula heavy, cross striated. Female, 155 mm. long, 0.33 mm. broad at head, 0.285 mm. at neck, 0.7 mm. in maximum; vulva 2.56 mm. from cephalic extremity. Male, 83 mm. long, 0.407 mm. broad; tail with double spiral, on each side four preanal and four large postanal, papillæ of mulberry form (Fig. 3550); smaller (?) spicule 0.23 mm. long, longer unknown. Eggs 38 by 14 μ; embryos 0.3–0.35 mm. long and 5 μ broad with transversely striated cuticula.

Of this form Magalhaes discovered in Rio Janeiro two adults in the left cardiac ventricle of a man in whose blood embryonic filariæ were also present. It was at first wrongly assigned to *F. Bancrofti*, from which it is easily distinguished by the above characteristics. Like all Nematoda living in the heart the cuticula is tough to resist the powerful blood pressure, the body being like catgut, whereas *F. Bancrofti* is delicate and easily torn. The proportions of embryos and adults also differ materially.

The life history is unknown.

F. perstans Manson 1891.—(Syn.: *F. sanguinis hominis minor* Manson.)

The embryos, which have been known for some time, are found in the blood at all hours. They have no sheath, and measure only 0.18–0.23 mm. long by 4.5 μ broad, being thus much smaller than those previously described. Their continued presence in the capillaries may be due to this fact. The head is armed with a minute, exceedingly delicate filiform spine set on a papilla; this structure may be protruded and retracted rapidly. The embryo not only wriggles actively, but also travels about very rapidly. It is not numerous, but may be found in company with *F. nocturna* and *F. diurna*.

The adult was found by Daniels in a native of British Guiana, in whose blood both blunt- and sharp-tailed (*F. Ozzardi*) embryos were present. A male and a female lay in subperitoneal connective tissue. Manson also found an adult in one case of "sleeping sickness." Among the negroes on the west coast of Africa from one-third to one-half are infected, and most such show the earlier symptoms of this disease in nearly all cases of which *F. perstans* is present. Yet this parasite is found in apparently healthy individuals, so that its etiological relation to the disease mentioned is still a matter of doubt.

F. Ozzardi Manson 1897.—Male, 45 mm. long, 0.06 mm. broad; female, 70–80 mm. long by 0.12 mm. broad. Embryos in blood, without sheath, sharp-tailed, 0.173–0.240 mm. long by 4–5 μ broad.

The embryos were originally reported from the blood of Carib Indians from British Guiana, and were present in about fifty per cent. of the cases examined. At first both sharp- and blunt-tailed embryos were found together and were regarded as developmental stages of one species. Daniels found adults, chiefly females, in the mesentery, and in fat at various points in the peritoneal cavity; and in a later case two sets of adults, the one which is regarded here as belonging to this species, and the other, which was viewed by Manson as *F. perstans*, to which the blunt-tailed embryos are also assigned. The relation of the adults to these embryos is still a matter of considerable doubt.

In addition to the foregoing there are also several species of *Filaria*, known only by the embryonic form which inhabits the blood. While von Linstow regards them all as developmental phases of one species, I cannot concur in a conclusion so widely at variance with their differences in structure, habits, and distribution. They may be briefly noted as follows:

Filaria diurna Manson 1891.—Only free embryos of this species have been observed. They were found in the blood of negroes from the west coast of Africa. They appear in the peripheral circulation about 8 A.M., increase in numbers until noon, and decrease later, to disappear by 9 P.M. The periodicity was maintained for some weeks. As adults of *F. loa* were found in one of the cases, Manson regards it as likely that *F. diurna* is the larval form of that species.

Filaria Demarquayi Manson 1891.—The embryos of this species were found in the blood of apparently healthy natives of St. Vincent, and later also of St. Lucia, West Indies, and of New Guinea. They have also been reported very recently from other localities in the West Indies. They resemble the embryos of *F. Bancrofti* in general appearance; they are, however, only half so large (in dry smears) and they are without a sheath. Their presence in the superficial capillaries is constant day and night.

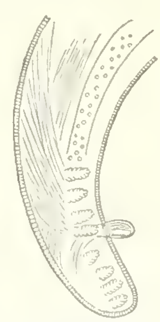

FIG. 3550.—Tail of Male *Filaria Magalhaesi*. Magnified. (After von Linstow.)

For convenient reference the characteristics of the blood filariæ may be given here in tabular form (p. 216) so far as they have been determined.

Filaria romanorum-orientalis Sarcani 1888 is a species observed in the blood of a Roumanian woman. The parasite measured 1 mm. long by 0.03 mm. broad, and had an alimentary canal and well developed sexual organs.

Family of the Trichocephalidæ. Body extremely elongated with two distinct regions, the longer anterior very slender and the shorter posterior more or less enlarged. Œsophagus very long, anus terminal. Males sometimes without a spicule, more often with a single simple one which possesses a sheath. Female with sim-

Body	Central granular mass.	Indistinct central granular mass.	No central granular mass.	Central granular mass.		
"V" spot	Present.	Present	None	Clear spot	Present, 0.052 mm.	

ple ovary; vulva at junction of the two regions of the body; eggs with peculiar translucent plug in the shell at each pole. Development direct and without ecdysis.

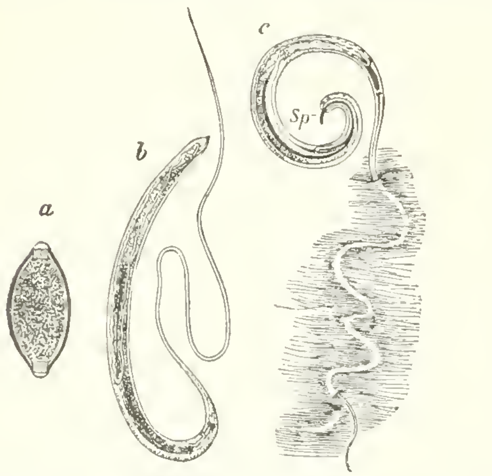

FIG. 3551.—*Trichocephalus trichiurus.* *a*, Egg; *b*, female; *c*, male with anterior end embedded in mucosa; *sp*, spicules. (After Claus.)

Of the half-dozen genera only two are important here, but they include two of the commonest and the most feared of human parasites.

Trichocephalus Goeze 1782.—Anterior region very long and filiform; posterior region, which contains the intestine and reproductive organs, short, sharply set off from anterior and markedly inflated. In the male it is rolled into a spiral; one spiculum with infundibuliform sheath. In the female the posterior regions are lightly bent, but not in a spiral. Parasitic in the large intestine and cæcum of mammals.

Trichocephalus trichiurus (L. 1771).—(Syn.: *Ascaris trichiura* L. 1771; *Trichocephalus* Goeze 1782; *T. hominis* Schrank 1788; *T. dispar* Rud. 1801; *Mastigodes hominis* Zeder, 1803.)

Male, 40–45 mm. long, with strongly attenuated anterior region comprising three-fifths of the total length. Spicule single, 2.5 mm. long, located in a spinous protractile sheath; posterior region in a flattened spiral. Female, 45–50 mm. long, with attenuated anterior region two-thirds of total length. Eggs, 51–53 μ long by 21–23 μ wide, brownish, thick-shelled, with polar knobs, and deposited before cleavage begins (Fig. 3551).

The striking appearance of this genus, a single species alone of which is parasitic in man, is due largely to the regions of the body. The filiform region contains only the œsophagus, leaving the remainder of the alimentary canal and all the reproductive organs for the greatly enlarged posterior region in which the transparency of the body wall permits one to recognize the various structures even in the living worm. The orifice of the vagina lies near the level of the transition from œsophagus to midgut.

Life History.—The eggs are produced in large numbers, four hundred thousand annually by a single female (Leuckart), and undergo no development until they have passed out of the human body. Cleavage takes place in water, but only at the end of some months or even more than a year. The eggs are well protected by the heavy shell from adverse circumstances, so that Davaine has kept embryos living within them for five years. The introduction of these embryos still within the shell is ordinarily brought about through drinking-water, though Blanchard suggests the evident possibility of their introduction on salads and uncooked vegetables. In the human stomach the shell is dissolved and the embryos are set at liberty to reach sexual maturity at the end of a few weeks, as has been definitely established by the experiments of Grassi.

Distribution.—This is one of the commonest parasites of man, being distributed over practically the entire earth, though more abundant in the warmer regions. Local variations in its frequency are noteworthy. Braun cites, as records of autopsies, its presence at Dresden as 2.5 per cent., at Erlangen 11.1 per cent., at Kiel 31.8 per cent., at Munich 9.3 per cent., at St. Petersburg 0.18 per cent., at Göttingen 46.1 per cent., at Basel 23.7 per cent., at Greenwich 68 per cent., at Dublin 89 per cent., at Paris 50 per cent., and in Southern Italy near 100 per cent. This species is growing rarer in Paris according to statistics available, and probably elsewhere also, owing to the disuse of surface water for drinking.

Pathology. — *Trichocephalus trichiurus* inhabits the human cæcum ordinarily, but rarely also the vermiform process and colon, and may be found in persons of all ages, even occurring in infants of a year old.

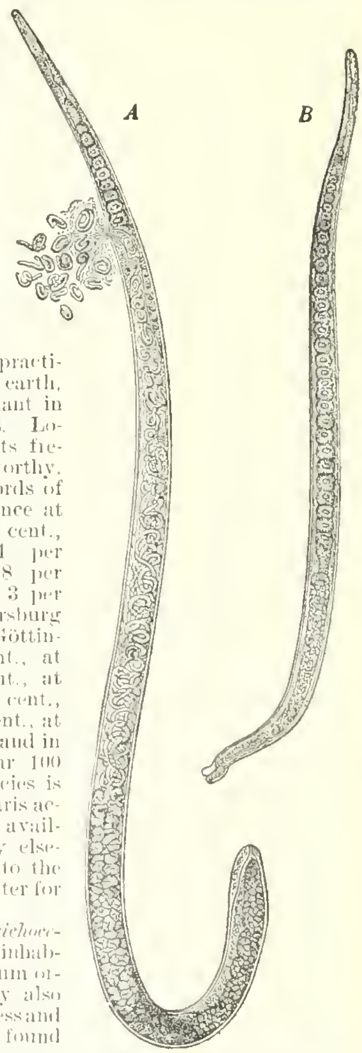

FIG. 3552.—Intestinal Trichina. *A*, Female with embryos; *B*, male, × 80. (After Heller.)

Usually only a few individuals are present in a single host, but in some cases as many as one thousand parasites have been found at

Digitized by Microsoft®

once. Normally they occur with the filiform anterior region embedded in the mucosa, and recent investigation tends to demonstrate that such as are found free in the canal have been driven out by post-mortem changes.

This species has been regarded earlier as playing a pathogenic rôle in typhoid, cholera, and beri-beri, and more recently all pathogenic significance has been denied it. Though the presence of a few does not occasion pathogenic symptoms, yet since Askanazy has shown the occurrence of hæmoglobin in the alimentary canal of these worms, the fact that they nourish themselves on the blood of the host cannot be doubted. In occasional severe cases noteworthy depression, suppression of the urine, with fever, cardiac weakness, and often nervous symptoms, have been noted.

www.fbtool.com.cn

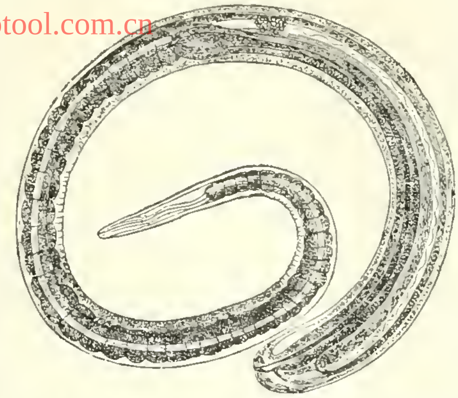

FIG. 3553.—Fully Developed Muscle Trichina with Alimentary Canal and Genital Primordium, Removed from Cyst. Magnified. (After Leuckart.)

Treatment is said to be difficult, and naphthalin, thymol, and pelletierine have been used with only moderate success. A later writer commends santonin as rapid and effective.

Prophylaxis.—Care in obtaining drinking-water and in selecting and cleansing uncooked vegetables will evidently limit the spread of the parasite.

Trichinella Railliet 1896. — (Syn.: *Trichina* Owen 1835.)

Very small, slender, without marked distinction of regions in body. Male without spicule, but with lateral appendages at posterior end, as if a poorly developed bursa were present. Female ovoviviparous; vulva at anterior fifth of body. Only a single species.

Trichinella spiralis Raill. 1896.—(Syn.: *Trichina spiralis* Owen 1835.)

Male (Fig. 3552, *B*), 1.4–1.6 mm. long by 0.04 mm. broad, without spicules, but with a short conical appendage on either side of the cloaca, behind which are two pairs of papillæ. Female (Fig. 3552, *A*), 3–4 mm. long, 0.06 mm. broad; vulva ventral near anterior fifth of body; anus terminal, viviparous. Fully developed larva, 0.8–1 mm. long by 0.04 mm. broad; cyst measures 0.4 by 0.25 mm.

The sexually mature parasite, sometimes called the intestinal trichina, inhabits the small intestine of man and various other mammals. The larval form, known as the muscle trichina, is found encysted in muscular tissue. Easily infected are man, pig, rat, mouse, guinea-pig, rabbit; less easily sheep, calf, horse; with difficulty cat, dog, badger. The intestinal form will develop also in birds, but the embryos are expelled with fæces and do not reach the muscles.

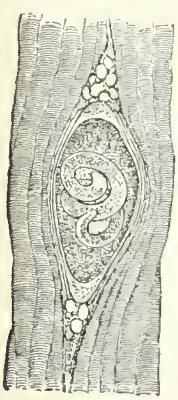

FIG. 3554.—Encapsulated trichina. (After Leuckart.)

History.—Encysted trichinæ were first noted by Peacock in London as early as 1828, but it was 1835 before their character as encapsulated entozoa was recognized by Paget and the parasite described by Richard Owen. The presence of encysted trichinæ in man was confirmed by a multitude of observations from various countries, and Joseph Leidy added a most important fact in the discovery of similar worms in pork. Feeding experiments by Leuckart, Virchow, and Küchenmeister, together with the observations of Zenker on a maid that had died of apparent typhoid, led to the elucidation of the life history and to proper estimation of the pathogenic character of the parasite which had heretofore been regarded as harmless or as the immature form of a *Trichocephalus* or *Strongylus*. Rapid accumulation of isolated cases and of epidemics of trichinosis, almost all from North Germany, placed beyond question the etiological significance and importance of the trichina.

Life History.—If a portion of flesh containing the larval worms is eaten by a suitable host, the larvæ are set free in the stomach and pass into the small intestine. They attain sexual maturity in about two and one-half days, copulate, and the male soon dies. Two opposed views as to the dispersal of the young have long been held. According to one the migration of the embryos is an active one in that they bore their own way out of the canal and through the connective tissues to their ultimate seat. The other view, however, of passive transport by the blood and lymph streams may be regarded as demonstrated by recent work, particularly that of Graham, whose account is followed in the main here. The gravid female bores into the intestinal wall as far as the lymph vessel. There the young are produced, being set free by the female into the lymph stream, which carries them ultimately into striated muscle tissue. At birth they measure 0.09–0.11 mm. in length by 5–6 μ in width, and at the close of this migration but little more, being then 0.12–0.16 mm. long. In eight days these embryos are in the intramuscular connective tissue and only a few days later in the muscle fibres themselves (Fig. 3555). The fibres lose their transverse striation and undergo granular and fatty degeneration. The embryo increases rapidly in size, and rolls into a loose spiral in an expansion of the completely degenerated fibre. By the action of the surrounding connective tissue, in which connective-tissue corpuscles and leucocytes are contained, a cyst of characteristic form is produced (Fig. 3554). It is thickened at the poles and measures about 0.4 mm. by 0.25 mm. in diameter. This process occupies several weeks, during which later broods of embryos are produced, since each female lives five to seven weeks and gives birth to from eight thousand to ten thousand young. Thus in the early stages of an infection one finds in the muscle embryos in various stages of development and encystment, side by side.

FIG. 3555.—Muscle Trichina Fifteen Days After Infection. × 165. (After Leuckart.)

Once encysted the larvæ remain quiescent; it may be for long periods. Thus encysted trichinæ have been found living in human muscle, twenty-five and even thirty-one years after the presumed infection. Not infrequently, though perhaps not always, one finds evidences of further change in the formation of a delicate calcareous layer about the cyst (Fig. 3556). In some cases this encroaches upon the larva so as to produce ultimately a calcareous nodule in which a remnant alone of the worm is contained. It is held by some that calcification does not ensue until after the death of the larva from unknown causes. Fatty degeneration of the encysted trichinæ can also be observed, and is likewise held to be a pathogenic process. Such larvæ as rarely occur in connective tissue are without the characteristic cyst, but appear to be smothered in a mass of proliferating connective tissue.

Digitized by Microsoft®

While it has been determined experimentally that a considerable number of hosts furnish conditions favorable for the development of the trichinæ, the normal host is no doubt the rat, and evidence has been adduced to prove the introduction of this parasite into Europe from

www.libtool.com.cn

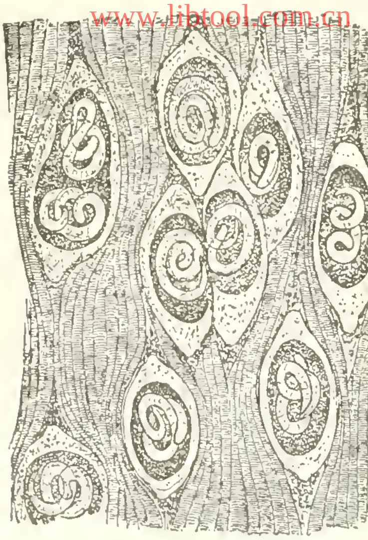

FIG. 3556.—Muscle with Encysted Trichinæ in Process of Calcification. (After Braun.)

the East with the brown or Norway rat. The method of transmission in this species is clear when one recalls that rats are cannibals and universally make way with aged or infirm members of the tribe. The well-known avidity with which pigs catch and eat rats explains the infection of swine, and it is from this source that man is infected.

Nearly all of the epidemics of trichinosis on record are confined to North Germany. In Saxony from 1860–75 there were 39 epidemics affecting 1,267 persons, of whom 19 died; at Hedersleben (1865), a town of about 2,000 inhabitants only, a total of 337 were sick and 101 died; at Emmersleben (1883) fully one-third died among those who ate the infected meat. Stiles has given a statistical review of trichinosis in Germany during recent years, from which is taken the following: 1860–1880—8,491 cases, 513 deaths, 6 per cent. mortality; 1881–1898—6,329 cases, 318 deaths, 5 per cent. mortality.

From the table of separate years it appears that there has been a general decrease in trichinosis in Germany during recent years, due probably to general education of the public on the dangers of eating raw pork as well as to meat inspection. The latter, which removes from consumption 1,500 to 2,000 trichinous hogs annually, is carried out in a most scientific manner by an army of some 30,000 inspectors and microscopists, at an annual cost (estimated) for the German Empire of $3,000,000, while for the city of Berlin alone the cost is $80,000. In spite of this system and expenditure security from trichinosis has not been attained *even for the meat examined*, as the following table shows, according to which more than half the cases of this disease are traceable to inspected meats.

During double the period given there have been recorded in the United States approximately 900 cases.

Of the 18 cases and 3 deaths alleged to have been due to American pork during 1881–83, neither Virchow nor others have accepted the evidence as tenable, and the careful examination made by Stiles renders it clear that the attacks upon American pork found in the German press are not supported by German health statistics. While the inspection doubtless diminishes chances of infection, it certainly gives rise to a false feeling of security

SUMMARY FOR THE GERMAN EMPIRE 1881–98 INCLUSIVE.

	Cases.	Deaths.
Meat inspected and passed as free	2,042	112
Meat condemned but used	142	13
Due to defects in inspection system	1,204	7
Total results of errors	3,388	132
Inspection uncertain	63	0
No inspection of meat used	874	84
Data obscure or wanting	1,968	98
Said to be due to American meats	18	3
Due to uninspected Russian meat	18	1
	6,329	318

For the years 1860–95 Stiles has collected records of about 900 cases from the United States. Undoubtedly during this time cases have been diagnosed as atypical typhoid or rheumatism which were in reality attacks of trichinosis, but in the opinion of various authors there were also unrecorded cases in Germany. Nevertheless it is clear that there is a much less prevalence of the disease here, and it is interesting to note the nationality of these cases so far as recorded.

TABLE OF TWO HUNDRED AND SEVENTY-FOUR AMERICAN CASES.

	Cases.	Per cent.		Cases.	Per cent.
German	208	76.0	American	4	1.5
"Foreign"	37	13.0	French Canadian	3	1.0
Negro	10	3.0	"French descent"	1	.4
Italian	4	1.5	Dane	1	.4
Irish	4	1.5	Swede	1	.4

Statistics as to the prevalence of trichinosis are given by numerous European authorities from examinations made at autopsies. The results vary from nothing in France, according to Blanchard, to about two per cent. in Germany, according to various authors. These figures are based upon macroscopic examinations in large part at least, and Leuckart with others has remarked that greater success would follow more rigid search. In the United States Williams has subjected five hundred and five cadavers to a careful microscopical study, with the result that twenty-seven cases were found to be infected, or five and a third per cent. One-third of them were classed as severe, and only two were evident on examination with the naked eye. The nationality of the cases is given in the following table, which is suggestive, though the number is too small to warrant the drawing of final conclusions:

	Positive.	Negative.	Total.	Per cent. of positive cases in each nationality.
United States, white	6	201	207	2.89
United States, colored	5	65	70	7.14
British and Irish	5	57	62	8.06
Canadian	2	10	12	16.66
German	6	43	49	12.24
Italian		10	12	16.66
Other nationalities	0	27	27	0.00
Unknown	1	65	66	1.51
	27	478	505	5.34

The infection of rats varies so widely in different localities that little dependence can be placed on figures heretofore given from the examination of small numbers of individuals. The examination of pigs shows in Boston 4–5.7 per cent. infected (Billings), in United States army 2.1 per cent. (Müller), in various German districts from 1.5 per cent. to 0.1 per cent. The records of Mark show distinctly that reasonable hygienic conditions reduce the percentage of infection among pigs enormously, even in a few years.

Digitized by Microsoft®

Nematoda.

The trichinæ are found most abundantly in the muscles of the diaphragm, tongue, and neck, and are present at times in incredible numbers, estimated by Leuckart at from thirty to forty millions for a single host (man). Diagnosis of the disease may be positively confirmed by the discovery of embryos in bits of muscle removed from the patient by scalpel or special harpoon.

www.fbtodl.com.cn

The occurrence of other nematodes of somewhat similar size and appearance, the so-called false trichinæ, in the muscles and other organs of hare, rat, mouse, bird, fish, and even man (*cf.* case of Cobbold above, under *Leptodera terricola*) make it imperative that the determination be made with care in suspected cases of trichinosis. Of definite diagnostic value is the so-called "cell body" of the œsophagus, which is prominent in the anterior pointed region of the worm and which, though varying in length, is easily recognizable in all stages of growth and in both sexes (Fig. 3553).

Prophylaxis.—Man acquires the disease by the consumption of pork, in which are found living trichinæ. The chance of infection from all other animals is utterly inconsiderable, though a recent German author calls attention to the necessity of submitting dog meat to inspection on account of its rapidly increasing use as food. It has also been proved that salting, smoking, and other methods of curing ham do not afford a guarantee for the death of trichinæ which may be present. Two preventive methods have been suggested. The first is followed by Germany in her system of meat inspection; as already noted the system is expensive and does not afford absolute protection. Furthermore, unless the number of trichinæ present is enormous so that pathological changes have been induced in the flesh, the destruction of the meat constitutes an unnecessary loss of valuable food material. The second method of preventing the disease is the thorough cooking or curing of the meat so as to destroy the trichinæ. A temperature of 70° C. is sufficient to kill the encysted parasites, but in order that the centre of a piece of meat may reach this temperature cooking must be prolonged. One may determine the sufficiency of the cooking by the uniform clear gray color of a cut surface and the absence of red juice under pressure of the knife. This individual prophylaxis is both most reasonable and most effective; for the consumption of well-cooked pork is free from danger.

The old-fashioned slaughterhouse, at which the refuse was thrown to pigs and fell in part also to the rats infesting the place, was a serious menace to the health of the community, and offered the most admirable conditions for the rapid multiplication of parasites, especially these. On the other hand, the great modern packing establishments, in which all scraps are utilized under methods that destroy the life of any parasites present, are important agents in the limitation of this disease and in the general improvement of public health. Proper methods of slaughtering, curing, and preparing pork, and the abandonment of the unsanitary custom of eating the flesh of the pig uncooked are the true methods for the suppression of the disease.

Family of the Strongylidæ.—Body elongated, cylindrical, rarely filiform; alimentary canal complete; mouth provided with six papillæ, sometimes in the axis of the body, sometimes turned toward the dorsal or ventral surface, and frequently armed by chitinous teeth; œsophagus more or less enlarged at the posterior end, but not provided with a distinct bulb; sexes separate; male with caudal sac or bursa in shape like a saucer, or, if deeper, a bell encircling the end of the body. One or two spicules project from it, and the ribs or rays which mark its surface have characteristic arrangements in different species. The margin of this sac may be notched or deeply cut, so that it appears to consist of two separate parts; near the male orifice a small number of papillæ are often found. Female with one or two ovaries; female sexual opening very variable in position. The eggs when laid have undergone at least part of their development.

Strongylus apri (Gmelin 1789).—(Syn.: *Gordius pulmonalis apri* Ebel 1777; *Ascaris apri* Gmelin 1789; *Str. suis* Rud. 1809; *Str. paradoxus* Mehlis 1831; *Str. elongatus* Duj. 1845; *Str. longevaginatus* Dies. 1851; *Metastrongylus paradoxus* Molin 1860.)

Male, 12–25 mm. long, bursa bilobed, five ribs in each lobe, spicules very long and slender, measuring 2.5–4 mm. in length. Female, 20–50 mm. long, with short fish-hook tail at the base of which lies the anus and just in front of it the vulva on a rounded eminence. Eggs ellipsoid, 0.06–0.1 mm. long by 0.04–0.07 mm. broad; when laid they contain well-developed embryos.

The parasite inhabits commonly the bronchi and bronchioles of pig, sheep, and occasionally also man. Diesing reported it first from a six-year-old boy in Klausenburg; Chatin found some individuals, probably by accident, in the alimentary canal of a patient in France.

The observation of Rainey and Bristowe on nematode embryos from the larynx, which they called *Filaria trachealis*, points to this species even if an exact determination is impossible. Its abundant occurrence in the pig in Europe, and its extreme rarity in man point to some feature in the unknown life history, which renders human infection improbable.

Strongylus subtilis Looss 1895.—Body very slender and delicate, cuticula finely striated, oral papillæ inconspicuous; buccal cavity infundibuliform; œsophagus nearly one-sixth as long as the body. Male with inconspicuous alæ at anterior end, 4–5 mm. long, 90 μ in diameter at anterior end, 70 μ near bursa; two spicules, 0.15 mm. long, with accessory piece 0.05 mm. long (Fig. 3557). Bursa bilobed, with asymmetrical ribs. Female, 5.6–7 mm. long, 0.01 mm. in diameter at head, and 0.09 mm. in posterior third of body. Tail sharply pointed, anus near tip; vulva about one-fifth length from posterior end; uterus bilobed, with a few (three to six, or even eight or nine) eggs in each lobe; eggs oval, 63–70 by 41–36 μ, thin shelled, unsegmented, or partially segmented in uterus; development unknown. Infection by drinking-water.

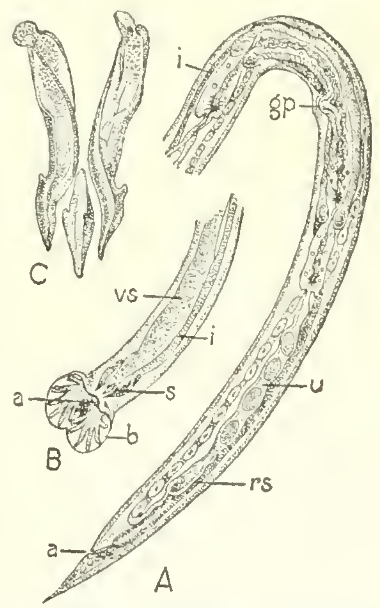

Fig. 3557.—*Strongylus subtilis.* *A*, Tail of female; *a*, anus; *gp*, genital pore; *i*, intestine; *rs*, seminal receptacle; *u*, uterus; *B*, tail of male; *b*, bursa; *s*, spicules; *vs*, seminal vesicle; *C*, spicules and accessory piece. Highly magnified. (After Looss.)

This parasite was described by Looss from specimens found at post-mortems in Egypt. It occurred in the stomach and duodenum of man and the camel. The infection was regularly light, and Looss doubted its pathogenic character on account of this as well as its small size and unarmed buccal cavity. Later Ijima reported a record made by Ogata of the discovery of as many as two hundred small nematodes in fluid taken from the stomach of a woman who died in Japan during the "Miura plague" of 1889. These parasites were identical with Looss' species, and while they were not regarded as the cause of the epidemic, it is clear that the presence of so large a number of parasites creates a presumption against their supposed harmlessness.

In view of its occurrence in such widely separated re-

Digitized by Microsoft®

gions, its discovery in intermedial territory is probable, and its introduction into the United States by travellers from the Orient or by returning American troops is an evident possibility under present circumstances.

Dioctophyme renale (Goeze 1782.)—(Syn.: *Ascaris canis* et *martis* Schrank 1788; *A. visceralis* et *renalis* Gmelin 1789; *Strongylus gigas* Rud. 1802; *Eustrongylus gigas* Diesing 1851; *Strongylus renalis* Moq.-Tand. 1860; *Eu. visceralis* Raill. 1885.)

www.libtool.com.cn

Generally blood red, slightly tapering at both ends, especially the anterior; mouth triangular, bordered by six small papillæ. Male, 13–40 cm. long, 4–6 mm. broad. Caudal extremity obtuse, encircled by membranous pouch without rib lines, but with papillæ on margin. One slender spicule, 5–6 mm. long. Female, 20 cm. to 1 meter long; 5–12 mm. broad; tail obtuse and slightly curved; anus terminal; female sexual opening, 50–70 mm. from anterior end; eggs ovoid, thick-shelled, brown, 64–68 μ by 40–43 μ.

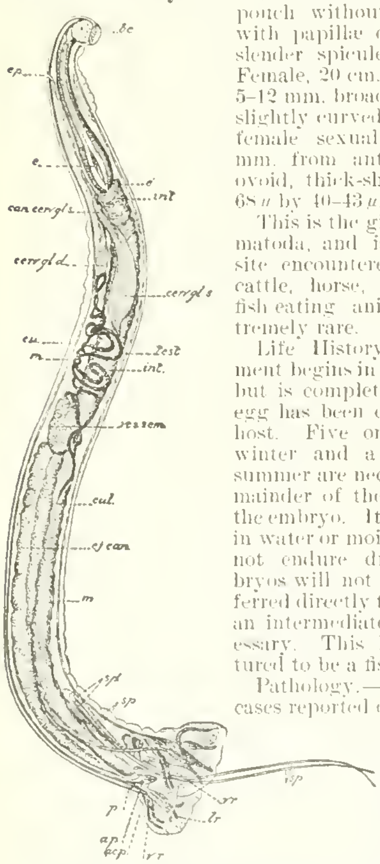

FIG. 3558. Male of *Uncinaria duodenalis*. Magnified. (After Schulthess.)

This is the giant of all the nematoda, and is a kidney parasite encountered in man, dog, cattle, horse, wolf, and many fish eating animals. It is extremely rare.

Life History.—The development begins in the female worm, but is completed only after the egg has been expelled from the host. Five or six months in winter and a shorter time in summer are necessary for the remainder of the development of the embryo. It lives a long time in water or moist earth, but cannot endure drying. The embryos will not develop if transferred directly to the dog, so that an intermediate host seems necessary. This has been conjectured to be a fish.

Pathology.—Of the numerous cases reported of the occurrence of this parasite in man, the majority are assignable to other parasites. Not more than ten are authentic. Trumbull's case (*New York Medical Record*, 1897) has been explained by Stiles as probably a *Filaria*.

Uncinaria Fröhlich 1789.—Anterior end curved dorsad; mouth opening obliquely from chitinous buccal capsule surrounded by transparent border; dorsal portion of capsule shorter than ventral, supported by conical structure sometimes projecting into cavity, at base of capsule two ventral teeth; near inner free border ventral wall bears on each side of the median line chitinous structures or teeth, often recurved like hooks (uncinate); inner dorsal wall also with teeth at times. Oviparous, eggs with thin transparent shell.

Of the species of this genus, which contains dangerous blood sucking intestinal parasites of the higher mammals, two occur in man, one an Old-World species long known and the other recently discovered on this continent. In medical writings the worm is more ordinarily called *Anchylostoma*, and the disease which it produces is spoken of as anchylostomiasis. As the recent important contribution of Stiles, to whom I am also indebted for valuable personal communications, shows clearly, the name of one at least of the species in question here is that given above, and the term uncinariasis or uncinariosis should be adopted as the correct designation of the disease which is known also as brickmakers' and miners' anæmia,

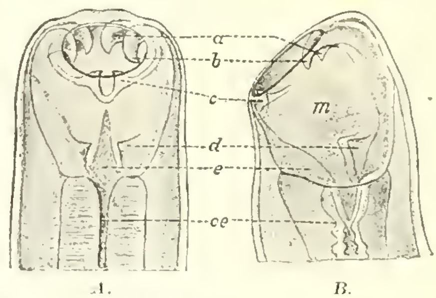

FIG. 3559.—Oral Capsule of *Uncinaria duodenalis* in (*A*) Dorsal and (*B*) Lateral Aspect. *a*, Inner; *b*, outer ventral tooth; *c*, dorsal tooth; *d*, stylet; *e*, dorsal rib; *m*, buccal cavity; *oc*, œsophagus. (After Hertwig.)

Egyptian chlorosis, tunnel disease, etc. Its chief symptoms are anæmia with the circulatory disturbances accompanying the pernicious type, colicky pains in the abdomen, great weakness, alternating constipation and diarrhœa with brownish or bloody stools, nausea, and œdema. Positive diagnosis is made by the discovery of the parasites and eggs in the fæces. In such cases care should be exercised not to confuse this with other species.

As the effects due to the two species are not distinguishable, a general discussion may be given for both together. By means of the powerful armature of the buccal capsule they pierce the intestinal mucosa and with the muscular œsophagus pump out blood. The intestinal epithelium is lost from the area taken into the capsule, and in addition to this the parasites move from spot to spot so that the host loses not only the blood taken by the parasite directly, but that lost through many minute hemorrhages at previous points of attack. The functional vitality of the intestinal wall is evidently reduced, and some are inclined to believe that the parasite also produces a poison which acts upon the host unfavorably.

Thymol and male fern are most frequently used for driving out these parasites, and Stiles quotes the following directions for thymol treatment:

Two grams of thymol at 8 A.M., repeated at 10 A.M., and castor oil or magnesia at noon. Diet of milk and soup. As some cases are obstinate, a re-examination of the fæces in a week is necessary, and the repetition of the treatment if eggs are still to be found. It should be noted that on the whole experiments are very unfavorable to the use of alcohol during the thymol treatment.

Rational prophylaxis must be based on better knowledge of the extent of the disease. When it is suspected microscopical examination of the fæces and treatment of all infected individuals are necessary preliminaries to its eradication. The construction of water-tight latrines in tunnels, brickyards, and other corporation properties where the disease is prevalent, together with the periodic disinfection of their contents by quicklime or by cremation, will largely prevent the spread of the disease. If, in addition, defecation in other places is forbidden and the regulation enforced, while on the other hand fresh pure drinking water is supplied and workmen are impressed with the necessity of personal cleanliness as a preventive for the disease,

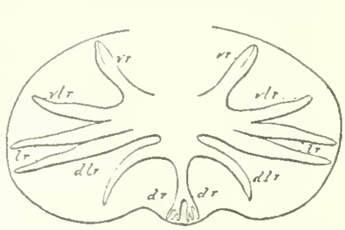

FIG. 3560.—Bursa of Male *Uncinaria duodenalis*. Magnified. (After Railliet.)

Digitized by Microsoft®

the difficulty will be reduced to a minimum. It must be kept in mind that Looss has demonstrated the probability of infection from water with larvæ coming on to the skin, so that the presence of such larvæ in standing water is a real menace, even if none of it ever reaches the mouth.

The Old-World species has been known for some time, and its effects are clearly traceable back of the historic study of Perroncito, which showed it to be the cause of the severe miners' anæmia, which was associated with the construction of the Saint Gothard tunnel. It is only within the year 1902 that Stiles has called attention to the tremendous economic and hygienic importance of the New-World species in our Southern States, although the records of the presence of some species, probably this one, extend back for many years. In Central America uncinariasis has been for centuries the most important and dangerous general disease, involving twenty-three per cent. of the population; it appears in the old Indian traditions, and with the disease is associated "dirt-eating." The species has not been precisely determined. In Africa the infected negro does not seem to be subject to any resulting anæmia.

www.libtool.com.cn

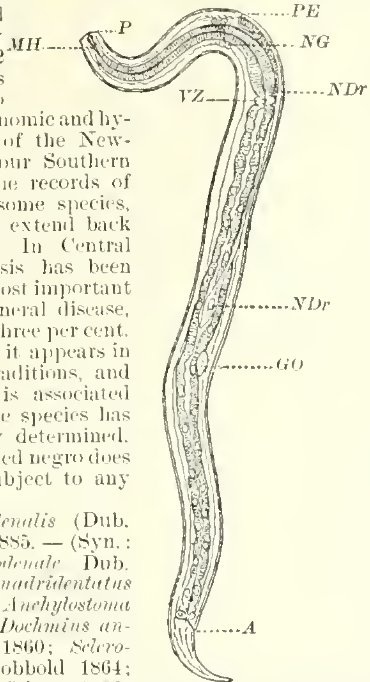

FIG. 3561.—Young *Uncinaria duodenalis* Four Days After Infection. *A*, Anus; *GO*, genital cell, *NDr*, œsophageal glands; *MH*, oral cavity. × 190 (After Looss.)

Uncinaria duodenalis (Dub. 1843) Railliet 1885.—(Syn.: *Agchylostoma duodenale* Dub. 1843; *Strongylus quadridentatus* v. Sieb. 1851; *Anchylostoma duod.* Dub. 1850; *Dochmius anchylostomum* Molin 1860; *Sclerostoma duodenale* Cobbold 1864; *Str. duodenalis* Schn. 1866; *Dochmius duodenalis* Leuck. 1876; *Ankylostoma* and *Ankylostomum duod.* auct.)

Body cylindrical; buccal cavity with two pairs of uncinate ventral teeth, and one pair of dorsal teeth, directed forward; dorsal rib not projecting into capsule. Female, 10–18 mm. long by 0.5–0.6 mm. wide; vulva at or near posterior third of body; eggs 52 by 32 μ, segmenting when deposited with direct development. Male (Fig. 3558), 8–11 mm. long by 0.4–0.5 mm. wide; caudal bursa (Fig. 3560) with dorso-medial lobe, dividing at two-thirds the distance from base, each branch being tridigitate, and with prominent lateral lobes united by a ventral lobe; spicules long, slender.

This species occurs in the upper region of the small intestine of man, and has been reported from Europe, Africa, Asia, the Philippines, and recently also from North America and the West Indies, where some regard it as of very recent introduction. A number of cases, including one fatal one, are on record in the United States within two years.

Structure.—One point in the structure deserves special attention—the so-called pharynx or buccal capsule (Fig. 3559). This is very nearly spherical, and is armed with four strong curved chitinous teeth. At the bottom of the capsule are two triangular lance-like organs, the function of which is the penetration of the tissue of the host. The body is curved dorsad at the anterior end on account of the shortness of the dorsal wall of the buccal capsule, so that the orifice actually points dorsad.

Life History.—The eggs are deposited in the alimentary canal of the host and must pass out of the body in order to undergo development, which will not take place in water, but proceeds rapidly in fæces or in slime, so that the rhabditiform embryo is hatched in twenty-four hours at 27° C. As 1° C. kills the eggs in from twenty-four to forty-eight hours, the climate of a large part of this country is an evident barrier to the spread of the parasite. At hatching the embryo measures 0.3 mm. in length, but grows rapidly, and after moulting once it enters upon a resting stage within the cast-off skin of the second moult. In this, the infecting stage of the parasite, the worms may live for a month or more in water without food, but if subjected to desiccation they perish. This naturally points to water as the probable means of infection, although the presence of such larvæ on moist salads and other vegetables, eaten uncooked, may well be a subsidiary means.

Recently Looss has brought forward the idea that these larvæ may enter the human body by way of the skin, which stands in perfect agreement with his earlier observations, that the larvæ which were fed to various animals in water did not settle down but were discharged per anum unchanged; yet part of them bored into the mucosa of the larynx and œsophagus and were active and growing two weeks later. When taken into the human body the worms undergo radical changes in structure. One may distinguish with Looss a third stage without buccal capsule (Fig. 3561), a fourth with provisional buccal capsule (Fig. 3562), and a fifth in which this organ corresponds to the adult form. From four to six weeks from the time of infection are required for the parasites to mature.

The view of Looss, that infection may take place through the skin, has been confirmed by a number of observations and experiments. Most striking was the infection of a limb about to be amputated and the subsequent discovery of many larvæ, which had forced a way in between hair and follicle and appeared in sections to have penetrated as far as the subdermal tissue. This method of infection, which Looss believes to be the most extensive, explains the susceptibility of Egyptian field laborers, and also epidemics among brickmakers as well as all cases in which the workmen are wont to work in moist earth with bare feet and hands. It explains the infection of children walking on damp ground, and gives, according to Bentley, the key to the "ground itch," or Pani-ghao, an affection of the skin of the lower extremities, endemic in Assam and in the West Indies. Its appearance is coincident with the advent of the rainy season, and is associated by this author with the presence of the larvæ of *Uncinaria duodenalis* in the soil of the infected areas. The typical lesion consists in a primary erythema followed by a vesicular eruption, which frequently becomes pustular, and in severe cases may result in obstinate ulceration or even in gangrene.

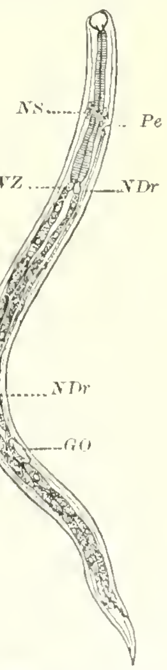

FIG. 3562.—*Uncinaria duodenalis* in Stage II. of Development. × 105 (After Looss.)

Uncinaria americana Stiles 1902.—Ventral recurved uncinate teeth absent from mouth, one pair prominent dorsal semilunar plates, and an inconspicuous ventral pair being present; dorsal median conical tooth projecting prominently into buccal capsule (Fig. 3565). Female, 9–11 mm. long by 0.31–0.35 mm. wide; vulva near middle of body but in front of it; eggs (Fig. 3564) 64–72 μ by 36–40 μ, segmenting or with well-developed embryos when deposited. Male, 7–9 mm. long by 0.29–0.31 mm. wide; dorsal ray of caudal bursa divided to the base, each

Digitized by Microsoft®

branch bipartite to tip (Fig. 3563). Species otherwise similar to *U. duodenalis*.

This form has only just been differentiated by Stiles from the long known European *U. duodenalis*, from which in fact it differs radically. It has been obtained from cases of uncinariasis in man in Texas, Virginia, Florida, Porto Rico, and Cuba, and its wide occurrence goes to show that the parasite, though not recognized hitherto, is endemic in the Southern States, where it causes the most common disease on the farms and among the poor whites. The life history of the parasite is unknown, though the early stages correspond to those of *U. duodenalis*. The cases of the disease have been collected and abstracted by Stiles, who holds with evident right that it is not a recently imported disease, but has existed unrecognized for years. It has been traced from Virginia to Florida, and is most abundant in sandy areas. Guiteras has also an unpublished case from Brazil.

www.libtool.com.cn

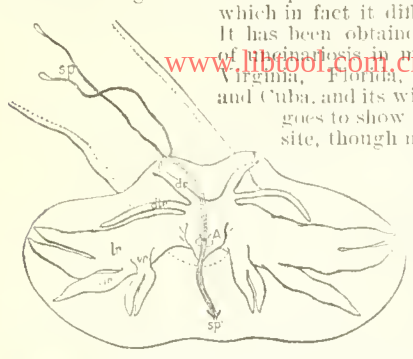

FIG. 3563.—Bursa of *Uncinaria americana*, Showing Ribs (*dr*, *lr*, etc.). *a*, Anus; *sp*, spicules. Magnified. (After Stiles.)

Physaloptera caucasica von Linstow 1902.—Cuticula heavy, non-striated, forming a projecting ring about the head, within which a pair of equilateral lips bear four papillæ in the submedian line and two conical teeth near the mouth opening. Œsophagus one-fifth the entire length; lateral lines strongly developed. Male, 14.22 mm. long by 0.71 mm. broad; bursa broad, rounded, tapering posteriad, with central longitudinal rows of small conical papillæ; spicules two unlike; lateral to the cloacal orifice two pairs of long stalked papillæ, in front one pair, behind two pairs, on the tail three pairs more. Female, 27 mm. long, 1.14 mm. broad, vulva at one-sixth the length from the anterior end; eggs heavy shelled, 57 by 39 μ.

The single account of this species by O. von Linstow is based on specimens, two males and nine females, in the collection of the museum at St. Petersburg, Russia. They are said to have been taken from the alimentary canal of man in the Caucasus. Further details are not given.

FIG. 3564. Eggs of *Uncinaria americana* from Fæces. × 235. (After Stiles.)

Family of the Ascaridæ.—Body relatively thick; mouth surrounded by three lips, one of which is dorsal, the others ventrolateral; œsophagus long, muscular, inflated at the end and often accompanied by an œsophageal bulb; male with one or two spicules; female with double ovary, oviparous; development direct. All are intestinal parasites.

Ascaris L. 1758.—Polymyaria, with very prominent lips; males with two equal spicules and many preanal and postanal papillæ; vulva in advance of centre of body. More than two hundred species are recorded; three have been reported from man.

Ascaris lumbricoides L. 1758.—Body reddish or grayish-yellow when living; spindle-shaped; lips (Fig. 3566) almost similar, approximately semicircular, with fine teeth on the edges, the dorsal possesses two papillæ, and each of the ventral ones only a single papilla. Male, 15–17 or even 25 cm. long and 3 mm. thick, with the posterior end curved toward the ventral face; spicules two, short, 2 mm. long; papillæ fifty-five to sixty preanal and seven pairs postanal. The female, 20–25 or even 40 cm. long and 5–5.5 mm. thick, with straight conical posterior end. The female sexual opening at the limit of the anterior third of the body, and situated in a ring-shaped depression. Fertilized eggs (Fig. 3567) elliptical, shell with transparent mammillated covering, 50–75 μ long by 40–58 μ wide, laid before cleavage begins. Unfertilized eggs, irregular, with scanty albumin covering, coarser granules, and thinner shell, measuring 81 by 45 μ.

This, the common round worm of children, is one of the most abundant and widely distributed of human parasites. It is distributed over the entire world, and though more abundant in the warmer regions, is recorded from Finland and Greenland. It is also more common in the country than in cities, which may be due to the presence of the same species in the pig and sheep. This parasite was well known to the ancients, both the Greeks and the Romans, although the ἀσκαρις of Greek authors is the form now known as *Oxyuris*.

Life History.—The development of the eggs does not begin until long after they have been expelled from the human intestine, and is dependent upon both moisture and warmth. Under mean temperature the embryo is completed in from thirty to forty days, and then lies in a spiral within a thin shell, which it does not seem to leave so long as the egg remains free, though it undergoes a moult here. The embryo may live long within the shell, even up to five years. The further development was believed by Leuckart to require the intervention of another host in which a larval stage is passed, but Davaine was successful in hatching the embryos in the intestine of the rat, and believes that the intervention of a second host is unnecessary. Subsequent experiments by various authors have strongly confirmed this view by raising experimentally adults in the human alimentary canal two months after the ingestion of eggs containing embryos. Accordingly the eggs are probably introduced into the human system with the embryo within by accident or by means of the drinking-water. The embryo is then set at liberty in the alimentary canal, and further development is merely growth. Of course the infection may be brought about by the means of contaminated vegetables, especially salads, which have been imperfectly cleaned.

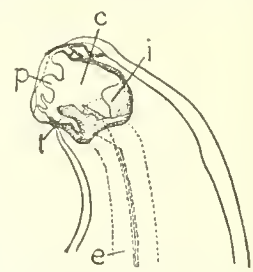

FIG. 3565.—Lateral View of Head of *Uncinaria americana*. *c*, Oral capsule; *e*, œsophagus; *i*, stylet; *p*, papilla; *t*, dorsal median tooth. (After Stiles.)

Pathology.—It has already been mentioned that the worms are most frequently found in children of medium growth, but this is due to the case of infection rather than to conditions for development, since the worm has been obtained from persons of all ages. Ordinarily one finds only a few specimens at once, but in some cases from five hundred to one thousand have been obtained from a single individual. It is noteworthy that hæmoglobin has been detected in the alimentary canal of the

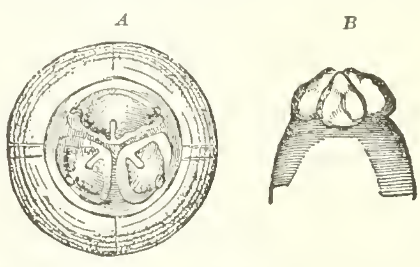

FIG. 3566.—Anterior End of *Ascaris lumbricoides*. *A*, Apical and *B*, Dorsal Aspect.

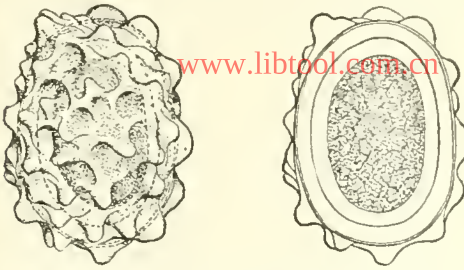
Digitized by Microsoft®

parasite, showing that its food consists in part of human blood. Their normal location is the small intestine, but specimens not infrequently wander into the stomach and are vomited. Rarely they have been known to make



www.libtool.com.cn

A. B.

FIG. 3567.—Egg of *Ascaris lumbricoides* from Fæces. *A*, In surface view and *B* in optical section. (After Stiles.)

their way into the pharynx and choanæ, with the result of causing fatal suffocation both in children and in adults; also into the Eustachian tube or ductus choledochus, and they have even been found in abscesses of the liver.

Recently a number of unimpeachable cases have been brought forward in which the worm has bored its way through the uninjured wall of the intestine and has been found in the peritoneal cavity. Their presence here after having pierced abscesses of the wall is also known, and in some cases even, in which adhesion of the intestinal to the abdominal wall was present, the worm emerged from the body through an abscess at this point. In fevers the Ascaridæ will spontaneously desert the intestine.

It is evident that these wanderings are associated with great danger to the host. The presence also even of a few individuals in the intestine gives rise at times to marked nervous disturbances, hysteria, epileptic attacks, congestion of the brain, aphonia, etc., which are most easily explained on the basis of a poison excreted by the worms. In fact, recent investigators have been able to obtain such a toxic substance from the body of this species, and students in the laboratory handling specimens of *A. megalocephala* from the horse have been distinctly affected by poisonous emanations. The symptoms disappear with the removal of the worms. Moniez, however, is inclined to attribute the troubles in large part to the use of santonin for the expulsion of the worms, as this substance has an unfavorable effect upon the human organism. Guiart has called attention to the important fact that the parasites by their movements produce lesions of the wall so as to afford a point of attack for intestinal fevers, and thus become a source of great danger for the host. Knotted masses of this parasite have also been the cause of fatal intestinal obstruction.

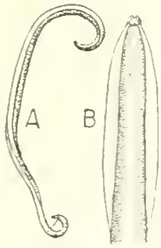


FIG. 3568.—*Ascaris canis*. *A*, Male. (Natural size.) *B*, Head showing papillæ and wings. Magnified. (Original.)

Treatment.—In general opinion santonin is the specific against *Ascaris*, and no one of the many other substances tried has achieved the same results. Moniez advises the use of centigrams equal to the number of years in a child's age, and for an adult 20–25 cgm. The drug kills the parasites, and the administration at the same time of a purgative is advantageous in bringing about their immediate expulsion. Careful watch should be kept for the violent symptoms which sometimes accompany the use of santonin and means taken at once to counteract them.

Ascaris canis Blanchard.—(Syn.: *Lumbricus canis* Werner 1782; *A. teres* Goeze 1782, *A. cati* and *caniculæ* Schrank 1788; *A. canis* and *felis* Gmelin 1789; *A. tricuspidata* and *felis* Bruguière 1791; *A. Werneri* Rud. 1793; *Fusaria mystax* Zeder 1800; *A. marginata* and *A. mystax* Rud. 1802; *A. alata* Bellingham 1839.)

Anterior end ordinarily curved and provided with two wing-like membranes which extend one along each side (Fig. 3568), lips almost equal, three- to six-cornered. Male, 40–90 mm. long, 1 mm. broad, with twenty-one preanal and five postanal papillæ. Female, 120–200 mm. long, vulva in the anterior fourth of the body, eggs almost spherical with thin shell, 0.068–0.072 mm. in diameter.

An abundant parasite in the small intestine of cats and dogs and also reported from various allied wild species, it has been found several times in man in England, Germany, Denmark, and the United States. Grassi doubts the accuracy of these determinations since experimental infection was not successful.

The development is direct and in general like that of the preceding species. The thin shell is highly impervious so that development continues in alcohol, turpentine, etc. It is probable that the embryo does not desert the shell until taken into the stomach of the host.

Ascaris maritima Leuckart 1876.—Known only from a single immature female, which was vomited by a child in North Greenland in 1865. The specimen was 43 mm. long and 1 mm. broad, and is regarded by some authors not as a normal parasite, but as one accidentally ingested with the viscera of some food animal. According to Leuckart it is very near *A. transfuga* of the bears.

Oxyuris Rudolphi 1803.—Three lips poorly developed or wanting; œsophagus long and provided with a distinct bulb. Male with only one spicule and with two pairs of preanal papillæ. Female with greatly elongated, pointed posterior end, two ovaries and vulva in anterior part of the body.

Oxyuris vermicularis Bremser 1819.—(Syn.: *Ascaris vermicularis* L. 1767; *Fusaria vermicularis* Zeder 1803. Œsophagus long and followed by a distinct bulb with teeth; body white, cuticula striated, forming wing-like projections from the dorsal and ventral surfaces near the head and also a low crest along the lateral lines of the body; three small retractile labial papillæ. Male, 3–5 mm. long, with spirally rolled tail; a single spicule and six pairs of papillæ. Female, 9–12 mm. long, 1 mm. broad, tail awl-shaped; vulva a little in front of the limit of the anterior fourth of the body, eggs elliptical, thin-shelled, 50–54 μ long by 20–27 μ wide, containing an embryo when deposited (Fig. 3569).

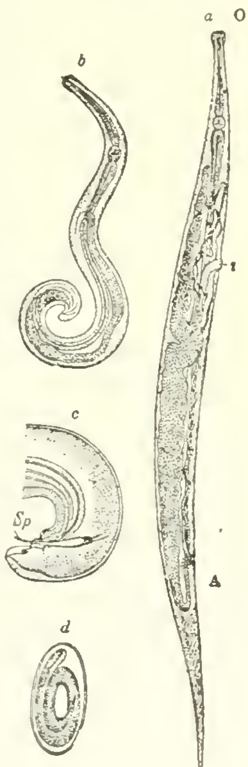

FIG. 3569.—*Oxyuris vermicularis*. *a*, Female; *b*, male; *c*, posterior end of latter; *d*, egg with embryo; *i*, vulva; *sp*, spicule. Magnified. (After Leuckart.)

This species, known from remote antiquity, is a cosmopolitan parasite of the human intestine. It has not been definitely recognized as a parasite of other animals, but Leidey's *O. compar* from the cat is very likely the same form. It is more abundant in cities than in the country, and occurs equally in cold and warm regions. These parasites are most abundant in infants, a fact which accords with the ease of auto-infection as shown by the development.

Life History.—The embryo develops within the egg shell while still contained in the uterus, and it was long thought that the further development could take place

Digitized by Microsoft®

in the canal. In fact, however, the female at the time of oviposition lives in the lower part of the rectum and even attains the vicinity of the anus, although the earlier portion of the adult life history is passed in the small intestine, where the worms acquire sexual maturity and copulate. Evacuated from the body, the embryo undergoes transformation to the so-called embryonic stage while still within the egg shell, and now awaits ingestion by a new host. The primary infection is by drinking-water or contaminated fruit or vegetables, which are eaten uncooked; but self-infection and transference to other individuals are brought about by scratching and rubbing with the fingers to allay the intense itching caused by the daily migration of the females out from the anus on to the perineum and the surrounding parts. Perhaps in the distribution of *Oxyuris* eggs the flies play a part such as Grassi has demonstrated for *Trichocephalus* and eggs of *Tænia*. The direct development is very rapid, as Leuckart obtained experimentally *Oxyurides* 6–7 mm. long within fourteen days after ingestion of the eggs; Grassi and others have confirmed this by further experiments.

www.libtool.com.cn

Pathology.—The females are far more numerous than the males, and by their migrations determine unbearable pruritus, which recurs periodically on retiring. In a number of cases among young girls the worms have migrated into the vagina and have produced onanism, and even the inception of nymphomania. In many cases large numbers in the rectum have excited no untoward symptoms, but in others they have produced reflex nervous activities of all grades up to epileptic attacks, such as have been noted under *Ascaris*. Recent investigations in Egypt have demonstrated the responsibility of this parasite for nodules on the rectal wall, previously attributed to *Schistosoma*, which contain eggs of *Oxyuris vermicularis* in a calculus. *Oxyuris* has also been recorded in tuberculous nodules in the cavum Douglasii of a female, and Vuillemin has recently discovered them in a tumor near the anus of a boy. The latter case shows definitely the wandering of the worms through 2 cm. or more of solid tissue. This habit exhibits a new and evidently dangerous feature in the parasitism of this species through the disturbance of the tissues and the introduction into them of bacteria from the rectum.

Treatment.—It is difficult to remove these worms entirely. Vermifuges and purgatives with enemata, etc., are successful to a degree; but the case of auto-infection is an obstacle to a complete cure. Local application of mercurial ointment will alleviate the pruritus, and manual extraction, if prolonged, will reduce their numbers rapidly. But in any event treatment is prolonged.

The sub-class of the Gordiacea includes forms familiarly known as "hair snakes" or "hair worms." They are greatly elongated, slender worms, somewhat filaria-like in external appearance, but of radically different internal structure. Lateral fields are wanting, and the body musculation is of a different histological type from that of the Eunematoda. The mouth is occluded and the alimentary canal persists in the adult only as a functionless vestigial strand. In both sexes the reproductive organs open to the exterior with the alimentary canal at a terminal or subterminal cloaca. The reproductive system is constructed on a different plan, and the lateral canal system is wanting. The male has no spicules, but the posterior end of the body is forked and functions as grasping organ.

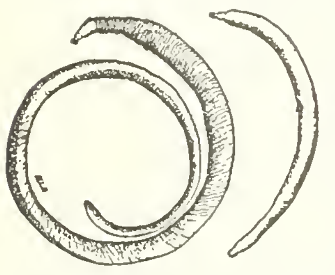

FIG. 3570.—*Gigantorhynchus gigas*. Male at right, female at left. Half natural size. (Original.)

The adult lives free in ponds, swamps, and other bodies of water, and the eggs are deposited on the stems of water plants. The larvæ possess a proboscis armed with hooks and bore into the body cavity of aquicolous insect larvæ, or rarely mollusks, where they encyst. According to Villot the second stage is passed in the intestine and body cavity of fishes. More commonly apparently the worms develop to maturity in the body cavity of insects, from which they emerge into the water for the adult free existence.

Several species have been reported from the human alimentary canal. They are pseudoparasites, having been swallowed, according to one view, in the adult condition with drinking-water; but their occurrence in fruit, especially apples, makes this even a more likely source of infection. Lockwood noted in 1876 the frequent presence, in fruit, of *Mermis*, another genus of Eunematoda, and suggested the probable occurrence of this form as a pseudoparasite of man under conditions; this has not been actually recorded so far as I find. But of Gordius as a pseudoparasite Parona has recently listed eleven cases, the first as early as 1638; of these Kirtland's (Ohio) is the only one from the United States. Two other unpublished cases have recently been communicated to me from Michigan and Maryland. It will be of no particular value to enter here upon a detailed description of the species found.

The Gordiacea are, however, emphasized by Cobbold as important for the medical practitioner, since they have been passed off as the guinea-worm and as having been evacuated with fecal matter by neurasthenic persons under treatment.

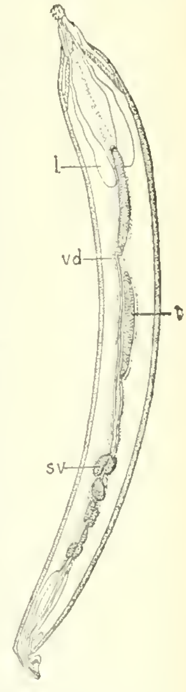

FIG. 3571.—*Gigantorhynchus gigas* Opened to Show Internal Anatomy. *l*, Lemniscus; *sv*, seminal vesicle; *t*, testis; *vd*, vas deferens. Modified. (Original.)

The Acanthocephala may best be discussed as an appendix to the class Nematoda, although they are regarded by many as a cognate class and by others are separated even more widely. The forms included here, though parasites of the most complete type, are not common in man. The group may be characterized as follows: Elongated, cylindrical body, often deeply corrugated, bearing at anterior end a retractile proboscis provided with many minute hooks in rows. No trace of alimentary canal. Reproductive organs open at posterior end; sexes separate. Male with campanulate bursa about the orifice. Mostly small forms, parasitic as adults in vertebrates only. The structure is uniform, and can be learned from the brief account which follows of the largest and commonest species.

Gigantorhynchus gigas Hamann 1892.—(Syn.: *Tænia hirudinacea* Pallas 1781; *Echinorhynchus gigas* Goeze 1782.)

Body milk white, sometimes slightly tinted, with transverse irregular ridges. Posterior end somewhat smaller; proboscis spherical, armed with five or six rows of hooks. The proboscis can be retracted into a neck-like region, which is much slimmer than the following portion of the body. Male, 60–90 mm. long by 3–5 mm. broad, with bell-shaped caudal pouch. Female, 230–350 mm. long by 4–9 mm. broad; tail blunt; eggs almost cylindrical, 0.087–0.1 mm. long with three embryonic envelopes.

The adult worm is found in the small intestine of the pig, ordinarily fixed to the wall by the proboscis, and is widely distributed.

Structure.—The elongated body (Fig. 3570) is largest near the head and tapers gradually toward the posterior end. At the anterior end a sharp constriction separates

Digitized by Microsoft®

the body from the short neck portion, which is not more than one-fourth or one-fifth the diameter of the body close to it. From the apex of this region may be projected the proboscis which is contained within it, like the reversed finger of a glove. As the proboscis rolls out the hooks also turn www.libtool.com.cn the proboscis is completely extruded the shape of the organ is nearly that of a sphere on which are from five to six irregular rows of hooks. Behind these the proboscis is slightly smaller.

If the internal structure be examined, it will be seen that the proboscis is provided with retractor muscles, by means of which it may be withdrawn into the body. At the base of the proboscis is the small mass of nervous matter which represents the brain.

There is no trace of an alimentary canal, hence these forms, like the tapeworm, take nourishment by absorption. Two elongated sac-like organs hang down into the body cavity along the sides of the proboscis. These are the lemnisci (*l*, Fig. 3571); their function is uncertain.

The mass of the body is made up of the organs of the reproductive system. All these worms are diœcious. The male organs (Fig. 3571) consist of two large testes, together with the ducts and accessory glands connected with them. The tail of the male has a hemispherical expansion, something like the caudal bursa of other Nematoda; the male sexual opening in the centre of this sac at the tip of the body is provided with a small copulatory organ. The internal sexual organs of the female are much similar in general appearance; the ovaries lie toward the front of the body cavity, which is largely filled with eggs in various stages of development. These are discharged by the oviduct, which opens at the posterior end of the body.

Life History.—The eggs of *Gigantorynchus* are discharged from the alimentary canal of the host and distributed with fæces. When eaten by some insect they are hatched in its intestine. The embryo, which has a conical form armed at one end with four hooks like tapeworm hooks, and a number of smaller ones, penetrates into the abdominal cavity of the insect and encysts there. In this condition the embryos may even live through the metamorphoses of the insect until the host is eaten by some pig. In the alimentary canal of the pig the embryo is set free, attaches itself and acquires maturity. There is some dispute as to what insect is the intermediate host; the white worm-like larva of the May bug and the larva of the common rose chafer have been found to contain these worms in Europe, and Stiles has experimentally infected the larvæ of the June bug in this country. It is also maintained that various species of snail may function as the larval host. In all probability the larva is not confined to a single host, but may develop in many.

Leuckart accepts some reports of the occurrence of this species in man as trustworthy, and Lindemann says that it is not rare as a human parasite in Southern Russia. Schneider notes the consumption, as food, of the larvæ and adults of *Melolontha*, the May beetle, which acts as the intermediate host, so that infection is evidently possible.

Gigantorhynchus moniliformis (Bremser 1819).—Body attenuated anteriorly. Proboscis, 0.425–0.450 mm. long, 0.175–0.19 mm. broad, with hooks in fifteen transverse and twelve longitudinal rows. Male, 4–4.5 cm. long. Female, 7–8 cm. long, or even up to 27 cm. according to Westrumb. Eggs ellipsoidal, 85 μ long, 45 μ broad.

The normal hosts of this species are field mice, rats, etc., and the intermediate host in Italy has been determined as *Blaps mucronata*. Calandruccio in experimenting on the life history succeeded in infecting himself with the adult. The severe symptoms which manifested themselves were dispelled by the evacuation of the worms. In other cases of the occurrence of this species as a human parasite its identity was less definitely established.

Echinorhynchus hominis Lambl 1859.—Length, 5.6 mm.; width, 0.6 mm.; proboscis almost spherical with twelve transverse rows of eight hooks each. Large hooks, 103 μ long, small hooks, 77 μ.

An uncertain species of which Lambl found a single specimen at Prague in the small intestine of a boy who had died of leukæmia.

Echinorhynchus sp. Welch 1872.—In 1872 Welch described as *Echinorhynchus* a body which he found encysted in the mucosa of the jejunum of a soldier. According to Railliet it was evidently a Linguatulid (see *Arachnida*).

Echinorhynchus sp. Moniez 1896.—Kunstler and Pitres found certain peculiar bodies in the pleural cavity of a patient who had suffered two years from pleurisy, but without fever. They interpreted these structures as coccidia, but Moniez holds with greater probability to their likeness to eggs of *Echinorhynchus*. The case is entirely isolated under either explanation.

NERVES, GENERAL PHYSIOLOGY OF.—HISTOLOGICAL AND GENERAL.—Nerves consist essentially of the long, slender processes of nerve cells. They are hence composed of protoplasm, and they possess the general chemical and physical properties of this substance; but they differ physiologically from other forms of protoplasm, in that they possess to a high degree the properties of conductivity and excitability, while the properties of growth, metabolism, respiration, and contractility are feebly developed or altogether absent. There is in these respects a marked physiological difference even between the nerve and the cell body from which it arises. Many of the reactions of the cells to external conditions are the opposite to the reactions of the nerve. The cell generates nerve impulses; it possesses spontaneity or automatism, absent in the fibre; it is closely dependent on a supply of oxygen, while the nerve is almost independent; it has an active metabolism, which the nerve lacks almost entirely; it respires, while the nerve respires little or not at all; it or some of its dendritic processes may be contractile, the nerve has lost this property altogether. The physiology of the nervous tissue, which includes nerve cells, differs therefore in many respects from that of the nerves proper, which we shall consider here. In short, the nerve cells possess pre-eminently the property of automatism or spontaneity; the nerve fibre, the property of conduction.

Digitized by Microsoft®

This physiological differentiation of the conducting protoplasm of the nerve is accompanied, as might be expected, by an histological differentiation. The protoplasm of the nerve fibre, called the axis cylinder, or axon, differs in physical appearance from that of the rest of the cell body from which it arises in that the fibre is striated longitudinally as if composed of distinct fibrils, and is surrounded by a fatty sheath. These fibrils can be more easily seen in invertebrate than in vertebrate nerves, and particularly in the leeches, where they have been traced by Apathy[1] from one nerve cell into and even through other nerve cells. Some observers even go so far as to maintain that these fibrils are the true conducting portions of the fibre, but of this there is no physiological evidence. Besides this peculiar fibrillar structure of the axis cylinder, nerves are as a rule easily differentiated from other tissues even by the naked eye by their white, glistening, fatty sheaths. Nearly all nerve fibres which take their origin in the brain and spinal cord, and many having origin elsewhere, are surrounded by such a sheath, which is called the medulla, and such nerves are called medullated nerves. The nerves of invertebrates and those of the sympathetic system of vertebrates, on the other hand, often lack these sheaths, and are called non-medullated nerves. The function of this medullated sheath is not definitely ascertained, but it has been suggested that it prevents the spreading of the impulse from one fibre to another. It appears to influence the physiological behavior of the nerve, for medullated nerves are generally more easily excited than non-medullated, and they react differently to an exposure to a constant electrical current. A momentary exposure of a non-medullated nerve to a constant electrical current may block conduction in the region of the anode or positive electrode for several minutes or hours; whereas medullated nerves after such treatment recover their conductivity very quickly.[35] Waller[2] suggested that the medulla was reserve material which was used up by the metabolism of the nerve during conduction, and he explained in this way the indefatigability which medullated nerves possess; but Miss Sowton[3] has recently shown that the non-medullated olfactory nerve of fishes is almost or quite as inexhaustible as are medullated nerves, if we may judge from the undiminished size of the electrical response attending conduction after long stimulation. Nerve fibres differ from other protoplasm also in the quickness with which they stain blue when exposed to a solution of methylene blue. It is thus possible to stain them before the other tissues are colored, and an important method for tracing the course and distribution of nerves has been founded on this peculiarity.

The chemical composition of the axis-cylinder process is not definitely known. Other portions of gray nervous matter which it resembles consist largely of colloidal substances of proteid nature, and differ from most tissues in the unusually large amounts of lecithin and cholesterin present. Nothing can be said positively regarding the inorganic salts present in the axis-cylinder process. Ranke[4] believed its reaction to be slightly acid, but most observers have found the cut surface of the nerve alkaline to litmus; it is possible that like other protoplasm it is neutral to phenolphthalein. The medulla consists chiefly of cerebrin, lecithin, cephalin, cholesterin, and neurokeratin. The latter substance forms a horny supporting framework. Lecithin is a trimethyl cholin-distearyl phosphoric acid glycerin ester. Other fatty acids may be present in place of the stearic acid, and the lecithins from different animals vary in this respect. The kephalin or cephalin, according to Koch and Thudicum, is probably monomethyl cholin lecithin. The constitution of cerebrin is unknown, but in the brain of the sheep it contains the sugar galactose, two or four molecules of stearic or oleic acid containing nitrogen, possibly united to a hexatomic alcohol or to glycerin. The cerebrins obtained from the brains of different animals differ chemically. The high content of all nerve tissues in lecithin and cholesterin is probably of physiological importance, as will be shown farther on, and possibly determines their susceptibility to the anæsthetics.

As the conducting part of a nerve fibre consists of protoplasm, it cannot continue to exist for any length of time if cut off from the rest of the cell, but soon degenerates and disintegrates. Experiments on plant cells and infusoria have shown that portions of the cell cut away from the nucleus die and no longer grow, although they may continue movement and some other functions for some days.[5] The nerve fibre shows the same relationship, demonstrating that its maintenance in a normal condition depends on its connection with a nucleated part of the cell body. If a mammalian nerve is severed, the peripheral portion, whether sensory or motor, loses its power of conduction and excitability in from four to six days.[9] In frogs conduction may persist for from five to eight days, and, in nerves kept cool, even longer. These facts indicate that the nerve fibre, however close its connection with the peripheral cell which it innervates, is not nourished from it and does not enter into organic connection with it; and, further, that it is not nourished by the nuclei of the medullary sheath. No immediate functional reunion of the peripheral and the central ends of a severed nerve can be brought about by suturing, for whether sutured or not degeneration of the peripheral part always occurs. This is accompanied by the division of the nuclei of the medulla and the fragmentation and fatty degeneration of the axis cylinder and medullary sheath. Degeneration does not extend gradually downward from the cut end of the fibre, but takes place with the same rapidity in the whole of the cut-off portion. The restoral of function in the cut nerve is brought about by the growth downward of the central ends of the cut fibres—of those fibres, in other words, still in connection with the nerve cells.[6] These push down in the paths of the degenerating fibres and ultimately become medullated and re-establish union with the peripheral organs, although this may be prevented if the fibres meet in their course any obstacle which turns them aside. There appears to be no choice of termination on the part of the fibre—for example, of a motor fibre for a muscle cell or of a sensory fibre for a sensory end-organ—for if the central end of a sensory nerve is sutured to the peripheral end of a cut motor nerve, the sensory fibres will innervate the muscle fibres formerly supplied by the motor nerve, and vice versa.[7] Also if the vagus and sympathetic be cut and the central end of the vagus cross-sutured with the upper end of the sympathetic in the neck, the vagus fibres growing upward in the paths of the degenerating sympathetic innervate the submaxillary gland and cause secretion on stimulation, and thus take on a secretory function.[8] Similar facts have been established by Langley for the fibres innervating the pupil and those erecting the hairs on the cat's neck, and by Cunningham and other observers in other nerves. The time required for the restoration of the function of the nerve will depend in part on the distance the nerve has to grow to re-establish union, and in part on the nerve which is regenerating. The longer the distance which the regenerating fibre has to grow before reaching its destination, the longer will be the time required for regeneration. On the other hand, nerves differ somewhat in their speed of regeneration or growth, and no doubt constitutional differences of this sort exist among different individuals. The time required is as a rule from two weeks to four or more months. For some reason the nerve fibres within the cord appear in mammals to have little power of regeneration if the cord is severed. The reason for this peculiar reaction is not yet satisfactorily explained. The subject is badly in need of careful investigation, since even the possibility of regeneration in mammals is not definitely disproved.[10]

Excitability.—Nerves are excitable—that is, they will respond to stimulation, at any point in the course of the fibre. No variation in excitability at different points of the nerve has been detected in any one nerve as long as it remains uninjured in the body,[11] but if the nerve is injured by cutting it or its branches, an increase of ex

Digitized by Microsoft®

citability is brought about in the immediate neighborhood of the injury.[12] This increase in irritability is probably due to the electrical disturbance set up in the nerve by the injury and called the current of rest. This apparent variation in excitability, really brought about by injury following the cutting of branches of the nerve, has been described by Grützner and others, and was at first interpreted as showing variations in irritability in the normal nerve. It is easily demonstrated in the frog's sciatic in the neighborhood of the branches given off to the thigh muscles. The region of increased excitability extends about 5-7 mm. along the nerve from the point of injury.[12] While there is no variation in excitability in the same nerve, there is a considerable variation between the different motor nerves of the same animals, those nerves most frequently used appearing as a rule to be the most easily excited. Thus the sciatic nerve of the frog is far more irritable than the brachial nerve to all kinds of stimuli,[13] and sympathetic fibres appear less excitable than motor.

The change in the nerve which gives rise to the nerve impulse, *i.e.*, the excitatory change, may be caused in any one of the following ways: (1) By mechanical shock; (2) by heat of 38° C. or above; (3) by lowering the temperature of the nerve to +3° or −2° C.; (4) by taking water from the nerve; (5) by the action of specific chemical substances; (6) by electrical currents; and (7) by ether vibrations.

Mechanical Stimulation.—Mechanical stimulation, first discovered by Swammerdam[14] about 1650, may be brought about either by suddenly stretching the nerve, by shaking it, or by a sharp blow. Pressure gradually increased does not excite the nerve, though it at first increases its excitability.[15] Mechanical stimulation is seldom used in experimentation, as the nerve is generally crushed or injured by repeated shocks; but special appliances have been developed to avoid this so far as possible. Among these are the tetanomotor of Heidenhain[17] and the apparatus of Uexküll,[16] the former instrument delivering a series of sharp blows; the latter shaking the nerve. The excitability of nerves to mechanical stimulation varies greatly, and may be artificially increased or diminished. Thus the extraction of water from the nerve may render the latter so sensitive to mechanical stimulation that the slightest jar, or the lightest touch of the nerve with a glass rod will cause the discharge of a series of nerve impulses, causing tetanus of the attached muscle. The time relations of the stimulus and the resulting contraction are the same with mechanical and electrical stimulation. After a few blows a nerve may become non-irritable to further stimulation, but if left undisturbed it slowly recovers.[11]

Heat Stimulation.—A moderate degree of warmth (10–25° C.) diminishes nerve excitability. To cause the generation of a nerve impulse by heat the nerve must be heated suddenly to a temperature of 38° C. or higher. Heating a nerve quickly from 3° C. to 20° C. does not generate a nerve impulse. These facts show that it is not a sudden increase in heat or change in temperature of the nerve which stimulates, but the exposure of the nerve to a certain critical temperature; and this suggests that probably heat stimulates by coagulating some of the proteids of the nerve. This conclusion is supported by the fact that if the nerve is kept at 40° C. for a short time it loses its irritability permanently, although if it is exposed for a few moments only, an impulse may be generated and excitability restored if it is again cooled; and by the further fact that the temperature at which a nerve is stimulated by heat is about the temperature of coagulation of a proteid isolated by Halliburton from brain tissues, *i.e.*, 35–40° C. The restoral of irritability on recooling sometimes observed after a short exposure to 40°–45° C., is apparently opposed to the hypothesis that heat stimulation is due to coagulation; but this restoral may be owing to the coagulation having been but partial.

Cold Stimulation.—If the sciatic nerve of the frog is exposed to a temperature of 3° C. or lower, tetanus of the attached gastrocnemius muscle generally follows.[18] Cooling the nerve from 20° to 3° C. increases the excitability of the nerve to all stimuli, but does not as a rule generate nerve impulses sufficiently strong to produce muscular contraction. The cooling tetanus resembles that produced by drying the nerve, and there is thus a similarity between the physiological effects produced by cooling and those produced by the extraction of water, resembling that emphasized by Greeley in connection with the production of spores in infusoria. Below 0° C. or −2° C. the frog's nerve loses its irritability, but may be restored by very cautious warming. Mammalian nerves, according to Howell and others, lose their conductivity at 5° C., or even at a higher temperature, without preliminary stimulation.[19] It has been suggested that the tetanus produced by cold is due to mechanical stimulation by the ice crystals formed; but this is not probable, since the nerve may be stimulated at a temperature above the freezing point of the nerve, and the gradual rise in excitability as temperature is lowered shows that the final stimulation is but a culmination of a process going on as temperature falls. The increase in excitability produced by cold is true also for mammalian nerves (Biedermann). Conductivity, on the other hand, is reduced by cold. Not only does cooling increase the excitability of the nerve fibre, but the whole central nervous system may in the frog be brought by this means into a condition of increased reflex excitability resembling that caused by strychnine.[57] The increase of excitability produced by cooling culminating in stimulation may be compared to the precipitation of moisture from the atmosphere, and, as will be discussed on page 232, may be brought into relation with the change in state of the colloids in the nerve.

Drying Stimulation.—If nerves are allowed to dry in the air they gradually increase in excitability, and finally nerve impulses are generated sufficient, in the case of motor nerves, to cause a prolonged tetanus or series of twitches of the attached muscle. The dried nerve, like the cooled nerve, becomes totally non-irritable and very stiff, but its excitability may be completely restored by placing it in water or physiological salt solution. A similar drying tetanus is produced by placing the nerve in solutions of sugar, urea, glycerin, or other non-electrolytes having an osmotic pressure of thirteen atmospheres or over, that is, in solutions containing something more than a half-gram molecule of the substance to the litre, or by placing it in solutions of neutral salts of the same osmotic strength. Even neutral salts which by their own action annihilate nerve irritability will stimulate if strong enough to extract water rapidly. The stimulating action of solutions of nearly all non-electrolytes and many electrolytes except sodium salts and a few other compounds to be discussed later, is to be explained by the indirect osmotic extraction of water. If the water is extracted very gradually the nerve may be dried without generating impulses strong enough to cause muscle contractions. It has been suggested (Grützner) that this stimulation is really mechanical, due to shock or compression of the nerve substance by the shrinking tissue, but this is probably not the case. A probable explanation of this stimulation will be found on page 232 and may be confidently ascribed to a change in the nerve similar to that produced by cold.

Chemical Stimulation.—The excitation of the nerve by chemicals was first observed by Swammerdam in the seventeenth century. It has been studied by von Humboldt, Eckhard, Kölliker, Kühne, Grützner[20] and many others. The earlier work established the general fact that the application of solutions of many non-electrolytes and electrolytes would stimulate motor and sensory nerves. The strong solutions which were used led to the conclusion that most chemicals stimulated indirectly by the withdrawal of water, a conclusion which was undoubtedly correct. The first careful work comparing solutions containing the same number of molecules in the litre was done by Grützner, who showed that some other factor entered into the stimulation besides the withdrawal of water. He was unable to discover what this was, but

Digitized by Microsoft®

referred it to a specific stimulating action of the salts. Thus sodium fluoride and other sodium salts and some alkalies stimulated in solutions too weak to draw water from the nerve. Grützner found that with certain exceptions a relation existed between molecular weight and stimulating or poisonous action. In salts of the same series those of greater molecular weight stimulated more and poisoned more rapidly. Thus sodium iodide was stronger than the bromide, and this than the chloride. Barium chloride was more baneful than strontium chloride. Grützner believed that sensory nerves were more readily stimulated by potassium salts than by sodium, while motor nerves were not stimulated by potassium salts, but were by sodium. This conclusion is not correct. The author's observations[21] on a large number of salts, acids, and alkalies gave the following results: The frog's sciatic is stimulated by immersion in solutions of any salt, if this be sufficiently concentrated. This stimulation, as already stated, is brought about osmotically. If the solutions have an osmotic pressure no greater than that of the nerve—*i.e.*, approximately six atmospheres—only solutions of electrolytes will stimulate; the non-electrolytes are ineffective. Of these electrolytes all sodium salts of monovalent or bivalent acids, with one or two possible exceptions, will stimulate in isotonic solutions. The similar salts of other metals, such as potassium, lithium, calcium, strontium, magnesium, zinc, silver, mercury, aluminum, iron, and ammonium, will not stimulate, but gradually annihilate irritability. Of the sodium salts the monovalent salts, such as the chloride, bromide, iodide, nitrate, and acetate, are least powerful; the bivalent salts, such as the sulphate, oxalate, tartrate, and borate, are from two to three times as powerful as the monovalent; while the trivalent salts, such as the citrate, ferro- and ferricyanides, and the phosphate, are about six times as powerful as the monovalent salts. This shows that the stimulation is due to the anion and not to the cathions, and further, that it is dependent in part upon the number of electrical charges on the anion. In other words, chemical stimulation is really due to the negative electrical charges of the salt, and chemical stimulation is an electrical stimulation. The positive ions have an effect opposite to that of the anions, and tend to prevent stimulation and lower irritability, and this is due to the positive electrical charges which they bear. Thus potassium, lithium, ammonium, and hydrogen not only will not stimulate the nerve except in strong solutions or when united to still more powerful trivalent anions, but they annihilate nerve irritability very rapidly. All acids destroy nerve irritability rapidly unless applied in very dilute solutions. In some acid salts, however, such as copper sulphate, a nerve may remain highly irritable for several hours. In solutions having a strength of one-fifth normal or higher, acids will often stimulate (osmosis ?), but below this strength they annihilate irritability. Of the alkalies, sodium, potassium, and barium hydrates stimulate in dilutions not greater than one twentieth normal; ammonium hydrate will not stimulate the motor nerve, but destroys its irritability. This is in harmony with the small dissociation of the compound. Of the oxidizing salts the permanganates will stimulate both in the case of potassium and in that of sodium, in one twelfth or one-fourteenth molecular solutions. Of the monovalent sodium salts the fluoride, iodide, bromide, and chloride stimulate in the order named, the fluoride being the strongest. Something besides the number of charges is thus seen to be of importance. The author has suggested that this is the movement of the charges about the atom, but this is as yet hypothetical. The general result of this work is that positive and negative ions act as a rule in an opposite manner, and that chemical stimulation proper, as apart from stimulation by osmosis, is in reality an electrical stimulation and produces the same kind of a change in the nerve as does electrical stimulation.

Electrical Stimulation.—Nerves may be stimulated electrically in several ways, but the end result is a disturbance of the electric equilibrium, if we may so term it, within the nerve and a resulting change in the nerve itself which causes the nerve impulse. One way, as has just been shown, is to introduce the electrical charges into the nerve in the form of ions in solution, but the more usual method of stimulation is to change the distribution of charged particles already in the nerve and thus upset electrical equilibrium. The nerve may be stimulated by induction by bringing near the nerve a highly charged Leyden jar and suddenly discharging the jar, or, as in unipolar stimulation, by connecting the nerve with one pole of an induction coil, when on making and breaking the primary circuit stimulation may ensue.[22] In both these cases, at the moment of making or breaking the current, there is a sudden equalization of the charges which have been accumulated in the nerve by induction. In other words, the electrical equilibrium is upset by induction. Herz waves may stimulate a nerve which is near the induction machine, but the nerve quickly loses its irritability and conductivity under their influence.[23] The exact manner of action of the Herz waves has not been clearly determined. Induced currents from the inductorium and constant currents from the battery are the forms of electrical stimulation most generally used. Both these currents stimulate in the same way, the differences between them being due only to differences in intensity and duration of the current. The most probable explanation of their action, speaking in general terms, is that they alter the distribution of ions in the nerve, the negativity of the nerve being increased in the neighborhood of the cathode owing to the predominance here of negative ions and the positivity in the neighborhood of the anode. In this way a disturbance of electrical equilibrium within the nerve is produced. It appears that to bring about this disturbance of equilibrium with sufficient suddenness to cause a nerve impulse, polarization must take place in the nerve. This polarization is due to the fact that the membranes surrounding the axis-cylinder process do not permit free osmosis of the salt particles in the nerve through them. It thus happens that when a cathode is brought against a nerve, the negative ions which are repelled from it or are diffusing into the nerve from it accumulate against the outside of the membrane lining the axis-cylinder process. This accumulation of negative particles on the outside of the membrane holds bound to it on the inside the positively charged sodium particles or other positive ions in the nerve in that region. This disturbs the electrical equilibrium of that part of the nerve, as it leaves a surplus of unbound negative charges in the nerve at that point. It is this sudden surplus of negative charges which sets up in the nerve that change which causes the nerve impulse. What the nature of that change is we shall shortly discuss, but it may be said here that it consists possibly in a change in the nature of a precipitation taking place in the colloids of the nerve, strictly analogous to the changes produced by cold or by the extraction of water.

A study of the phenomena of electrical stimulation has led to the general law that that form of electrical stimulation is the most effective in which the intensity of current is greatest and reached in the shortest time.[22] In other words, stimulating power is a function of the intensity and of the reciprocal of the time. For this reason sharp shocks of great intensity, such as induction shocks, are more efficient than the galvanic current, and the break-induction shock is more powerful than the make, as in the latter the rise is more gradual owing to self-induction in the primary coil. Too rapidly repeated shocks will not stimulate, and at 15° C. a duration of 0.0015 to 0.02 second is necessary. Shocks more rapid than three thousand per second generally cause but a single initial muscle twitch.

It has been shown that the nerve impulse does not arise throughout that portion of the nerve which is traversed by the current, but only at its point of exit and entry. The point of entry of the current into the fibre is called the physiological anode, and that of exit is called the physiological cathode. The impulse is formed at the cathode on making the current and at the anode on breaking it.

Digitized by Microsoft®
www.libtool.com.cn

This may be easily demonstrated by ligaturing the nerve between the electrodes so as to interrupt the conduction of a nerve impulse at this point, when it will be found that the muscle will contract only at the making of the current when the cathode is on the muscle side of the ligature and at the break of the current when the anode is on the muscle side of the ligature. It is a curious fact that if either electrode is placed on a portion of the nerve which has been rendered non-irritable by ether or in any other way, the impulse which normally is produced by that electrode no longer appears. It looks as if the passage of the current from a non-irritable to an irritable portion of the nerve will not stimulate. The reason for this fact of polar failure is still obscure. Electrical stimulation taking place at the cathode at the make of the current is thus shown to correspond to chemical stimulation. It is always an increase in the number or efficiency of the negative ions or a diminution in the number or efficiency of positive ions which stimulates. The positive electrode, as we shall see, diminishes excitability like the positive ions. It makes no difference whether the charges are applied to the nerve on atoms in the form of ions, or from a battery, the effect on the nerve is the same. Electrical stimulation quickly exhausts the excitability of the nerve at the point stimulated, unless the current is frequently reversed. This exhaustion is frequently attributed to electrolysis; but as it occurs also with non-polarizable electrodes, it is due not to electrolysis but to changes brought about in the condition of the nerve, or, more properly speaking, its colloidal particles, by the changed distribution of ions in the nerve. In using the induction shocks where reversal of the current occurs with every make and break shock, exhaustion is far less apt to happen than when a constant current is used.

www.libtool.com.cn

The action of electrical currents on the nerve does not end with the initial stimulation but continues during their passage, and will be discussed later under the heading of electrotonus. Suffice it to say here that under ordinary circumstances, and unless the excitability of the nerve has been artificially increased by local cooling in the neighborhood of one electrode, or by drying, or by the chemical action of sodium chloride or other substances, the current generates a nerve impulse large enough to cause muscle contraction only at the moment of opening and closing the circuit. If, however, the local excitability of the nerve is increased in the neighborhood of one of the electrodes in any of the above ways, a series of nerve impulses causing tetanus may be produced, lasting throughout the passage of the current or occurring after its close.

Modification of Excitability.—The excitability of a nerve at any point may be artificially increased or diminished. The local application of cold increases excitability down to about +2° C. for the frog's nerve and somewhat higher for the mammalian. Below this point excitability rapidly falls. Local warming diminishes excitability until a temperature of about 35° C. is reached, when excitability again increases. The excitability of the nerve is increased by local injury such as section, or mechanical pressure, or heat action. For about 5 mm. from the cut end of a nerve this increase in excitability is well marked. This increase may be due to the electrical disturbance or current of injury in the neighborhood of the injured part, a condition of catelectrotonus prevailing at this point. In all electrical stimulation the disturbing influence of this nerve current has to be considered. The local application of alcohol, ether, carbon dioxide, or chloroform is said to increase excitability at first (Waller) before anæsthetization takes place. Waller observed an increase in the size of the negative variation when these agents were used. It is not impossible, however, that it is the conductivity which is altered, the general analogy between the effects of these agencies and moderate warmth elsewhere strengthening this supposition. Excitability is enormously increased by drying the nerve, or by taking water from it by osmosis. It is increased further, temporarily at least, by allowing the nerve to lie in one-seventh normal sodium-chloride solution, or by a brief exposure to the sulphate, citrate, or other stimulating sodium salts, and it is diminished by hydrogen, potassium, lithium, ammonium, calcium, and other positive ions. Distilled water at first increases excitability and then diminishes it. Excitability is also powerfully influenced by the passage of a constant current through the nerve, being greatly reduced in the region of the anode and increased in the neighborhood of the cathode while a current of moderate intensity flows through the nerve. Excitability increases in the neighborhood of the anode on breaking the current. The changes in excitability thus produced will be discussed under the heading of Electrotonus.

SUMMARY.—*Excitability.*—The facts concerning excitability just stated are most readily interpreted by assuming that all the agencies which stimulate or increase excitability do so by producing the same sort of a change in the nerve protoplasm. What that change is we are not yet in a position to state definitely; but the many striking resemblances of the process to the reactions shown by colloidal solutions strongly indicate something more than a passing similarity between the two processes. The facts may be conveniently interpreted if we assume the nerve to consist of electropositive colloidal particles and stimulation to consist in the coalescence or gelation of these particles. The action of cold, of mechanical shock, of negative ions, and of the negative electrode in stimulating may on this hypothesis be easily reconciled, all of these agencies acting in the way specified to produce gelation. This matter will be considered at the end of the article more in detail. The various agencies which diminish excitability diminish the tendency of the particles to coalesce.

Conductivity.—The principal function of a nerve is the conduction of a nerve impulse. Conductivity is not something peculiar to the nerve, but is found in all protoplasm. In the sensitive plants, for example, in the absence of nerves an impulse is propagated from place to place through the cells at a fairly rapid speed. This observation allows us to disregard at once such elements as the medullary sheath or longitudinal fibrillæ of the nerve as unessential in the matter of conduction. As protoplasm without these structures still conducts, it is clear that whatever rôle they may play in determining other factors of conduction, for example speed, they are not essential to conduction itself. Conduction takes place in any nerve in either direction with the same ease. Thus if a nerve is stimulated in the middle the impulse passes both downward and upward and may be detected by the negative variation or electrical disturbance which the nerve undergoes. The effect of this impulse passing downward in a motor nerve is apparent in the muscle contraction; what effect the impulse passing upward to the motor cell may have is not yet determined. The rate of conduction varies in different nerves. It is highest in mammalian nerves and in the frog's sciatic, *i.e.*, 25 to 40 metres per second. In the lobster it travels 6 metres per second; in the mollusc, Anodon, only 1 cm. per second; in the mantel of Eledone 1 mm.; and in the electric nerves of the Torpedo at 5° C. 9 metres per second. At a higher temperature Schönlein found a rate of from 12 to 27 metres per second.[34] In the plant Dionæ, conduction, according to Burdon Sanderson, occurs at the rate of about 200 mm. per second at 30°–32° C. No optical changes have been observed in the nerve accompanying the passage of the impulse, but in the insectivorous plant Drosera and in other plants Darwin observed that the passage of the impulse was accompanied by the appearance of a cloudy precipitate in the cell protoplasm, this precipitate shortly dissolving. This precipitation he called aggregation and compared it to the nerve impulse.

Influence of Temperature.—The speed and character of the nerve impulse are influenced by temperature. Bernstein observed an increase in the height of the muscle contraction if the impulse passed through a warmed area. Howell and Budgett secured similar results in the vaso-constrictor mammalian nerves. Waller found that

Digitized by Microsoft®

a temperature of 10° C. abolished the negative variation and conduction. In the frog's sciatic a temperature of 0° C. does not block the action current and the impulse, but at −2° to −7° C. both are blocked. Between 8° and 35° C. little effect of changes in temperature can be seen. Herrick[25] found that between 10° and 35° C. there was no change in the negative variation, but below 10° C. the negative variation diminishes. In general a low temperature slows and prolongs the negative variation, and a high temperature causes an increase in height and a diminution in duration. In mammals a temperature of 2° or 6° C. blocks conductivity, but conduction returns on warming. The fibres going to the abductors of the larynx are blocked by cold before the adductors.

The Electrical Phenomena of Nerves.—The electrical phenomena of nerves were first studied accurately by Du Bois-Reymond in 1843–45. Like all protoplasm a nerve shows a difference of potential between the uninjured and the injured portions. This difference is of such a character that the injured part appears negative to the uninjured. Thus Du Bois-Reymond found that if two electrodes connected with a galvanometer be placed one on the cut end of a nerve, the other at some point on its surface, a current flows in the circuit from the uninjured surface toward the cut end and may be detected by the deflection of the galvanometer. This current is called the current of rest, or of injury, or the demarcation current of the nerve, and it may amount to 0.0035 to 0.02 volt. The amount of this current is about the same in warm- and cold-blooded animals. Besides this current, which is at its maximum between the equator and the cut end of the piece of nerve, there is a difference of potential between the two ends of a nerve, so that if the two cut surfaces of a motor nerve or a sensory nerve be connected with an electrometer there is a small axial current. In a motor nerve this axial current flows in the nerve from the peripheral to the central end, and in the sensory roots in an opposite direction.[26] The amount of this axial current is not great, but the current is constantly present, and is greater in the posterior than in the anterior roots. In the anterior it amounts to about 0.0006 of a Daniel, in the posterior roots to 0.0015 of a Daniel. The electromotive force of the nerve current of injury is said to be greater in a nerve used constantly, like the pneumogastric, than in other motor nerves. In non-medullated nerves the current is greater than in medullated. This current of rest or of injury persists for some time, becoming constantly weaker, but may be still detected several days after section when the excitability is entirely lost. Although the direction of the nerve current is ordinarily in the sense already mentioned, it may be reversed by high temperature and by desiccation. By appropriate means a nerve may be prepared which shows no current of injury. Thus if a frog's sciatic is removed from the body and placed in frog's blood containing a little calcium, the nerve after several hours is said to show no injury current whatever.[27]

It is probable that the current of injury may be increased or diminished in many different ways, but this subject has not yet been sufficiently investigated to allow us to classify the facts in any general group. Ether diminishes the current as do acids; alkalies increase the current.

The cause of the current of injury is, as its name implies, probably to be attributed to chemical or physical changes taking place in the nerve at the point of injury more rapidly than elsewhere. There are several explanations of this change. Du Bois-Reymond, who supposed the nerve to be made up of bipolar electric particles, of which the two ends were negative and the middle positive, believed it to be due to the exposure of the negative ends of the particles by the section. Hermann[28] refers it, as do most authors, to the alterations in the state or composition of the protoplasm at the injured point. The author has suggested that this change consists in the increase in size or the coagulation of the positively charged colloidal particles of the nerve brought about by the injury, thus causing a change of their surface of separation from the fluid leading to the liberation of formerly bound negative charges. It is impossible, however, at the present time to state positively what the real explanation is.

Negative Variation.—Du Bois-Reymond[22] discovered about 1843 that if one electrode from a galvanometer be placed on the cut end of a nerve and the other on its longitudinal surface, on stimulation of the nerve the needle of the galvanometer, which had been deflected by the current of injury, receded momentarily toward zero. This electrical disturbance he called the negative variation or current of action. It has since been shown that this electrical disturbance generally or invariably accompanies the nerve impulse and is a convenient way of detecting the passing of such an impulse. The variation follows mechanical, heat, or chemical stimulation as well as electrical. It occurs in plants and muscles and secreting epithelia as well as in nerves. The variation is of such a nature that the first electrode reached by the impulse becomes negative to the other. The negative variation is biphasic, that is, a positive phase follows the negative. The negative variation travels at the same rate as the nerve impulse, and shows other parallelisms which clearly indicate its close connection with the phenomenon of conduction. Thus exposure of the nerve to carbon dioxide, ether, or chloroform is said to cause a preliminary rise in excitability and an increase in height of the negative variation, both conduction and the negative variation being later abolished;[29] a ligature abolishes both the variation and the conduction; cold lengthens the duration of the negative variation, but diminishes its height, and warmth increases the height and shortens the duration. These facts so clearly establish the parallelism between the negative variation or action current and the nerve impulse that by most physiologists the electrical disturbance is regarded as an invariable concomitant of the nerve impulse. Others hold a different opinion, however. Cases are on record in which the cooled muscle of a frog has contracted, following a stimulus not accompanied by a negative variation; and in other instances the negative variation may be detected without muscle contraction. Steinach found in warmed frogs tetanus produced with the secondary coil 43 cm. from the primary, while the negative variation first appeared when the secondary coil was at a distance of 39 cm. Boruttau believes that in the one case the muscle is a little more sensitive than the electrometer, and in the other the latter is more sensitive than the muscle. The size of the negative variation is proportional, as a rule, to that of the current of injury, and up to a certain point a larger stimulus causes a larger negative variation and a larger muscle contraction. The negative variation is increased by catelectrotonus and diminished by anelectrotonus. A negative variation occurs also in the tetanus due to natural stimulation of the nerves of strychnine frogs. The cause of the negative variation and its relation to conduction will be discussed on page 232.

Electrotonus.—If two electrodes from a battery are placed upon a nerve, a nerve impulse is generated at the cathode or negative electrode when the current is made, and at the anode or positive electrode when the current is broken, provided the current be fairly strong. While the current flows through the nerve no impulses are as a rule generated, but nevertheless a change in irritability is brought about in the nerve. This change of irritability and conductivity in the region of the electrodes has been carefully investigated by Pflüger and is called electrotonus.[30] The irritability of the nerve is increased in the neighborhood of the cathode during the passage of the current and diminished in the neighborhood of the anode; after the current is broken the anodic region undergoes a rise in irritability and the cathodic region a fall. These changes may be demonstrated by stimulating the nerve in the region of the cathode or anode with stimuli just strong enough in the normal nerve to cause muscle contraction, when if applied to the cathodic region an increased muscle contraction is obtained; if ap-

Digitized by Microsoft®

www.libtool.com.cn

plied to the anodic region no response follows. If the current is strong and continued for some time the cathodic region also becomes less irritable. The strength of current necessary to produce electrotonic effects is very small, 0.0001–0.00001 milliampère may suffice. Sensory nerves show the same phenomena of electrotonus as motor, although Zirhelle thought that both the anode and the cathode diminished excitability in the former. Exceptions to the general statement that irritability is increased by the cathode and diminished by the anode have been noted by several observers, *i.e.*, Budge, Schiff, Valentine, and others. Irritability may increase (though very rarely) in anelectrotonus, and Nasse has observed several cases of the total reversal of the law. The cause of these rare exceptions is not yet clear.

Although the constant current only changes excitability but does not ordinarily excite during the passage of the current, yet in some cases a tetanus of the muscle is observed during the passage of the current, or after it is broken.[39] This tetanus, called Ritter's tetanus, arises from the cathode if it occurs during the passage of the current, and from the anode if it occurs after the current is broken. This tetanus may be artificially produced at will if the excitability of the nerve is increased by cooling, by drying, or by the osmotic extraction of water. This tetanus demonstrates the fact that the changes going on in the nerve during the passing of the current are of the same nature as those which produce the impulse. The current really stimulates throughout its passing, only the changes produced after the current is once applied are too gradual to cause a muscle contraction. If, however, the excitability of the nerve is already artificially raised (that is, if the instability of the nerve substance is artificially increased), the change is sufficiently abrupt to generate nerve impulses so that a number of muscle contractions take place during the passage of the current. It is necessary to bear these facts in mind, since the law of electrical excitation is ordinarily stated in the way mentioned—*i.e.*, that excitation occurs only at the make and break of the current.

The explanation of these electrotonic changes of irritability is not difficult on the colloidal hypothesis already sketched. The primary effect of the current is to cause a disturbance in the even distribution of the ions in the nerve. Positive ions predominate in numbers near the anode, negative ions near the cathode. These ions bring about a change in the state of the colloids. Near the anode the positive ions increase the stabililty of the protoplasmic hydrosol, the colloidal particles are here increasing in numbers and increasing their total surface; near the cathode, on the other hand, the colloidal particles, owing to the presence of negative ions, are diminishing in numbers, increasing in size, and diminishing the surface of contact. The stability of the hydrosol is being reduced near the cathode, and, in accordance with the general law stated farther on, excitability varies inversely with the stability of the protoplasmic hydrosol. If this change is abrupt, so great a contraction of surface of the particles takes place that an impulse is generated strong enough to reach the muscle and cause muscle contraction. If the change is gradual, as it is after the first application, the change is not strong enough at any moment to cause an impulse large enough to reach the muscle. Stimulation takes place at the anode on opening, and excitability is increased here owing to the fact that on breaking the current the positive ions accumulated here in excess diffuse into the region formerly occupied by the cathode, and the negative ions from the cathodic region by diffusion reach the anode. There is thus produced in the neighborhood of the anode a diminished positivity or an increased negativity. The equilibrium of the solution is at once upset, the positive colloidal particles suddenly diminish in numbers and surface and increase in size owing to this diminution of positive ions, and this generates, as always, a nerve impulse which may continue, causing tetanus. Thus the rise in irritability near the anode is explained. Similarly in the region of the cathode, on breaking the current there is a sudden diminution of the negativity of this region and an increase in positivity due to the diffusion into this region of the positive ions from the anode. The result is that a sudden increase in number and surface of the particles results and conductivity and irritability are accordingly reduced. In other words, a process of solution is occurring near the anode and of gelation near the cathode during the passing of the current; after breaking the current the reverse of these processes occurs. It may be stated that these changes, although not visible in nerves, may be readily seen in infusoria and other forms of protoplasm, and the change in state of the protoplasm is of an opposite character at the two poles, liquefaction generally occurring on the anodic side.

Besides the changes in irritability of the nerve produced by the current, there are changes in its electrical behavior at the same time. Polarization takes place, so that on breaking the current a reverse current in the opposite direction may be observed. This polarizing current often reverses itself, running first in one direction and then in the other. This reversal is less pronounced in nerve than in muscle and is absent in dead muscle. These facts show that the polarization current is due not only to a physical polarization taking place at the limiting membranes of the nerve, but also to a change in state of the protoplasm. The polarization current may take place in the same direction as the original current, particularly after heavy currents of very brief duration.

While a constant current passes through a nerve electrical disturbances may be seen on both sides of the electrodes. If electrodes connected with a galvanometer are applied on the anodic side, it will be found that each point nearer the electrode is positive to that farther away, and if on the cathodic side negative to that farther away. We thus get physical electrotonic currents. These currents are due in large part, if not altogether, to the polarization taking place at the boundary of the axis-cylinder process, causing a spread of the current along the nerve.[31] They are, however, not altogether explicable on this hypothesis, for they disappear in dead and disintegrating nerves; they are greatly reduced by etherizing the nerve; and they are suppressed if the nerve be ligatured between the polarization current and the galvanometer electrodes. The currents are more powerful near the electrodes and their intensity is greater on the side of the anode than on that of the cathode. The anelectrotonic current may have an electromotive force of 0.5 of a Daniell, while the catalectrotonic current has but 0.05 Daniell. These currents are sufficiently strong to stimulate other nerves in contact with those stimulated. They exist in non-medulated as well as medullated nerves. They may be reproduced on artificial nerve models called core-conductors, consisting of a wire surrounded by a solution of an electrolyte. The suppression of the current by ether may be due to a diminution of polarization owing to an alteration of permeability of the axis-cylinder wall.

Indefatigability of Nerve.—Nerves are not supposed to be fatigued by the act of conduction. Bowditch[32] curarized frogs, thus blocking the nerve impulse and protecting the muscle from fatigue. The nerve was then stimulated by induction shocks continuously for six hours; at the end of that time the curare was excreted and the muscles began to contract. A similar experiment was tried by Maschek, who blocked the impulse by ether, and by Bernstein,[33] who blocked the impulse by the anode and with the same results. These facts indicate that nerve conduction is not accompanied by metabolic changes.

Metabolism of Nerve.—The only evidences of metabolism in nerve are the changes produced in it by cutting it off from its nerve-cell connection and Waller's observations on carbon-dioxide formation. No heat is produced by nerve conduction. Electrothermic contacts sensitive to 0.001° C. show no indication of heat production.[34] Similarly all attempts to show that carbon dioxide or acid are produced have been fruitless. Waller says that after exposures for a brief interval to carbonic anhydride

Digitized by Microsoft®

nerve irritability is increased and the size of negative variation is increased. The same result is obtained if the nerve is tetanized; so Waller concludes that carbonic anhydride is produced during tetanization. As many other factors affect the negative variation in the same way, we cannot conclude from this observation that the conduction of the nerve impulse is accompanied by a metabolic change, leading to carbonic-anhydride formation.

The Action of Anæsthetics.—The anæsthetics, chloroform, ether, carbon dioxide, and alcohol all temporarily annihilate nerve conduction, although some observers state that a preliminary rise in excitability is their first effect. If not exposed too long to the action of the anæsthetic the nerve will recover; but if too large an amount is used, or if the exposure is too long, irritability and conductivity appear to be permanently lost. Chloroform is much more active than ether and the nerve recovers from it with much greater slowness. This may be due to its being less volatile than ether and hence escaping less readily from the nerve or to its having a more powerful action. The most probable explanation of the action of the anæsthetics is that they dissolve the lecithoproteids or colloids of the nerve. Mayer[55] and Overton[56] have pointed out the parallelism of the anæsthetic action to the fat-dissolving powers of the anæsthetics. The nerve is particularly rich in lecithin compounds, and it is not improbable that the anæsthetics act upon them. The dissolving action of these substances may be easily seen in blood corpuscles, the eggs of many marine forms and other organisms, so that it is probable that they act on nerve protoplasm in the same manner. There is, hence, nothing peculiar about the action of the anæsthetics. They produce the same kind of a change in protoplasm as do positive ions, the positive electrode, or warmth. They put the nerve in a condition of anelectrotonus. They are particularly valuable because they are so soluble in protoplasm, so volatile, and effective in such small amounts.

General Summary.—We are now in a position to see how far the foregoing facts enable us to understand the processes in the nerve which are represented in the nerve impulse. There have been several hypotheses thus far proposed to explain these phenomena. One of the earliest was that of Du Bois-Reymond. In this theory the nerve substance is supposed to be composed of bipolar electrical particles negative at each end and positive in the middle. The current of rest is obtained by connecting the middle or positive surface with the cut end or negative surface. As each portion of a magnet shows the polarity of the whole magnet, so each portion of a nerve shows the polarity of the whole nerve. The nerve impulse is simply a turning of these particles on their axes, so that the negative ends turn toward the surface. This will explain the action current.

Hermann believed that these particles did not pre-exist, but that the current of injury was due to catabolic changes taking place at the cut surface. This became negative to the rest in consequence of these chemical changes. A similar change occurred during conduction, and this change in each part of the nerve caused the part just following it to be put in a position of catelectrotonus. On this theory the negative variation stimulated each part of the nerve in turn and was itself regenerated by the change which it brought about.

Becquerel supposed that there were numerous electrocapillary couples in the nerve which gave rise to electric currents, each couple, consisting of two different liquids, being separated by a capillary opening or by an organic membrane. D'Arsonval, who has developed this theory, supposed the electrical phenomena to be due to modification of the surface of separation of the two liquids similar to the electrical phenomena shown by the capillary electrometer.

Loeb has suggested that conduction is due to a change in state of the colloids, but has furnished no evidence in support of this view. The author believes that the facts indicate the truth of this hypothesis and suggests the following more specific theory:

The protoplasm of the nerve is essentially a colloidal solution. The colloidal particles are proteid in nature and in all likelihood are lecithin proteids resembling the sheaths of the red blood corpuscles, as is indicated by the especial richness of the nerves in lecithin. These particles are of different sizes and are electropositive. They continually change their state of aggregation, being easily precipitated or brought into solution and easily coalescing with their neighbors or breaking up into a large number of smaller particles. Through these changes the surface separating each particle from the surrounding fluid augments or diminishes. When two particles coalesce the total surface is reduced; when one particle separates into two the total surface of separation is increased. Around each particle there are induced in the water electrical changes of an opposite sign. It will be seen that any change in the surface of separation must necessarily produce an electrical disturbance exactly in the same manner as do the movements of the capillary electrometer, and in this respect my suggestion harmonizes entirely with that of D'Arsonval.

Stimulation, whatever its character, whether mechanical, chemical, thermal, or electrical, brings about a change in the state of division of these colloidal particles. It produces either one of two effects, *i.e.*, a coalescence of the particles (gelation), or an increase in number of the particles (solution). According as a stimulus produces one or the other of these effects we say that it excites the nerve or anæsthetizes it. It may fairly be questioned which effect is the excitation and which the anæsthetization. This question may be answered, I believe, by the exciting action of drying the nerve and of applying cold. Both of these processes excite or generate nerve impulses. Since they can hardly be supposed to increase the solubility of the colloids, we may confidently assume that they congeal or precipitate the colloids, and hence that excitation is due to a diminution in the number of colloidal particles and a reduction in their total surfaces; and conversely, anæsthetization or inhibition is due to the reverse process. All the exciting agencies may be interpreted in this way. Thus mechanical shock which disturbs the hydrosol brings about such a condition of temporary coagulation or rigidity of the nerve protoplasm throwing the particles together. This interpretation is strengthened by Mrs. Andrews' observations on the effect of shock on the choano-flagellates, where the rigidity of the previously fluid protoplasm can be easily demonstrated, and by my own observations on other forms of protoplasm, notably eggs. Cold, as will be seen, diminishes the stability of the protoplasmic solution or hydrosol, while warmth increases it; negative ions precipitate positive colloidal solutions and they excite the nerve; excitation takes place at the cathode or negative electrode, where positive colloidal particles will be precipitated; the extraction of water acts in the same manner as cold. In fact all the phenomena of excitation are readily understood on this hypothesis. Similarly the action of all anæsthetizing agents becomes clear. Positive colloidal solutions are rendered more permanent by positive ions, and these annihilate nerve excitability; warmth of moderate amount increases the stability of nearly all solutions, and this diminishes excitability; ether and the anæsthetics dissolve the protoplasm of eggs and other cells and destroy irritability; the anode, which holds positive colloids in solution, abolishes excitability. We may sum up our conclusions in the general law that nerve excitability varies inversely with the stability of the protoplasmic hydrosol. The less stable the hydrosol, the more irritable the nerve. Irritability will be lost when the nerve is stable, either in the condition of solution or in that of total gelation. The rise in irritability at the anode on opening the current is due to the fact that, as already explained, by the action of the current the particles are greatly divided; and after the current is broken the diffusion outward of the positive ions reduces the stability of the hydrosol here and it returns back toward the normal. The electrotonic effects are due to the solution being made more stable near the anode and less stable near the cathode.

Digitized by Microsoft®

As readily as the facts of excitation are understood on this hypothesis, so many of the facts of the electrical phenomena of nerves may be explained. The electrical disturbances are the result of the alterations in the surface of separation of particles and liquid. Whenever these particles coalesce, a portion of the negative charges, formerly induced about each particle, are set free. The portion of the nerve where this is occurring becomes temporarily electronegative to the rest of the nerve. Thus the current of injury is due to the coalescence of particles at the injured end. This is always negative to the uninjured part.

www.libtool.com.cn

If this is true, the exposure of the end of the nerve to acids or anæsthetics should diminish the current of injury, whereas alkalies should increase it. Such I have found to be the case. The current of action is the result of the progressive precipitation of the colloids and a progressive setting free of negative charges. It is, however, impossible within the limits of this article to discuss the bearing of this hypothesis on all the numerous electrical phenomena of nerves. It may be stated, however, that a warmed or etherized portion of a nerve is electropositive; a cooled portion electronegative to the normal nerve.

The conduction of the nerve impulse may be understood on this hypothesis as follows: Each precipitation of colloidal particles sets free by the accompanying reduction in surface negative charges formerly induced in the water about each particle: these charges at once precipitate the next layer of particles, and so on. Thus the negative variation successively stimulates each following segment of the nerve, as Hermann supposed, and it is regenerated by the change which it itself has produced. The sheath and peculiar structure of the nerve probably, as Boruttau supposes, plays an important part in the electrical phenomena of polarization and stimulation, and possibly in determining the speed of transmission, but the change in the protoplasm itself is the most important factor in conduction. Finally, it should in all fairness be stated that among the difficulties or exceptions to this hypothesis are the statements that the anæsthetics bring about a preliminary rise in irritability, and that conductivity and excitability may vary somewhat independently of each other. Whether these facts can be harmonized with the explanation already offered remains for the present unknown.

NERVES, PATHOLOGICAL CHANGES IN. See *Neurone, etc.*

NERVE TISSUE, HISTOLOGY OF.—According to the fundamental conception of neurology the entire nervous system, central as well as peripheral, has been regarded as composed of morphological units, the neurones, held together by the supporting tissues, the neuroglia. The term neurone was suggested by Waldeyer in 1891, and was accorded almost universally an international acceptance by anatomists, physiologists, pathologists, and clinicians. The term neura, proposed by Rauber, and neurodendron by Kölliker, to designate the same unit, have not met with similar favor. More recent investigations, however (Apàthy, Betha), have thrown some doubt upon the neurone doctrine as formerly held. The neurone consists of a cell body, dendritic processes, and an axis-cylinder process (axone with its terminal ramifications). As the neurone does not consist only of the cell body, but also has processes, some of which are of extreme length, it is impossible to see the entire neurone in the majority of cases. As a matter of convenience, therefore, the description of the neurone may fall under two headings—the nerve cells or nerve-cell bodies, and the nerve fibres.

The Nerve Cell.—The essential part of a neurone originating the nerve impulse is the cell body. Nerve cells or ganglion cells, as they are generally called, occur in groups known as ganglia in the cerebrospinal system, the sympathetic system, and in the organs of special sense. While variable in size, they are among the largest cells in the body, often, as in some of the ganglion cells in the anterior horns of the spinal cord, reaching a size of from 90 to 135 μ, the cells of Betz in the paracentral lobule being especially large. Many nerve cells, however, are much smaller in size, the cells of the granular layer of the cerebellum being only from 4 to 8 μ in diameter.

Study of the morphology of the neurones requires the consideration of their external peculiarities as well as of their internal architecture. The former are best revealed by the methods of Golgi and Ehrlich, and the latter by the methods of Nissl and Held.

Morphology of the Nerve Cells.—Nerve cells vary greatly in shape. Starting originally as spherical cells, some may retain this shape as in the spinal, Gasserian, or other ganglia; others may become ellipsoidal, as in the spinal cord, pyriform as the cells of Purkinje in the cerebellum, pyramidal as the cells in the gray matter of the cerebrum, or stellated as the multipolar ganglion cells of the spinal cord. The most conspicuous peculiarity of the nerve cells is the branching. This may take place only on one side leading to a prolongation of the protoplasm into a single pole, such cells being known as unipolar nerve cells; when the protoplasm is prolonged into two, usually opposite, poles, the cells are appropriately designated as bipolar; when the protoplasm extends in several directions multipolar cells are formed. Each polar prolongation is continued to form a nerve-cell process. Of such processes two kinds are recognized, the branched *protoplasmic processes* and the *axis-cylinder process.*

The branched protoplasmic processes, now usually called the *dendrites*, form prolongations of the protoplasm from the cell body, hence the old name of protoplasmic process. They are always broader and thicker at their origin, becoming gradually narrower as they divide,

Digitized by Microsoft®

Nerve Tissue.

splitting up and subdividing in an antler-like fashion until a rich twig-work or arborization results. The group of terminal end-branches of the dendrites is known as the *telodendrion*. The character of the dendrites, which result from the branching of the protoplasmic processes, varies much in different parts of the central nervous system. In some cells the branching commences a short distance from the origin of the process, while in other cells the process continues for some distance from the cell body before undergoing division, and then suddenly breaks up into a large number of dendritic branches.

www.libtool.com.cn

The cerebellar cells of Purkinje are instances of the former type, the apical dendrites of the pyramidal cells of the cerebral cortex of the latter. The extent and complexity of arborization is also variable, being comparatively simple and with little branching in some cells,

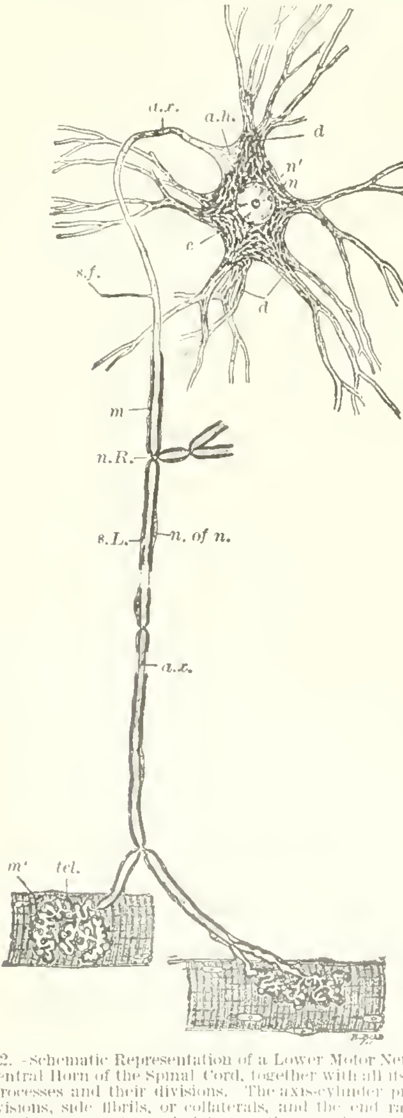

FIG. 3572.—Schematic Representation of a Lower Motor Neurone from the Ventral Horn of the Spinal Cord, together with all its protoplasmic processes and their divisions. The axis-cylinder process with its divisions, side fibrils, or collaterals, and the end ramifications (telodendrions or motor end-plates) in the muscle, represent parts of a single cell or neurone. *a.h.*, Axone hillock devoid of Nissl bodies, and showing a tendency to fibrillation; *a.x.*, axis-cylinder or axone, also indistinctly fibrillated. This process, at a short distance from the cell body, becomes surrounded by a myelin sheath, *m*, and a cellular sheath, the neurilemma, the latter not being an integral part of the neurone; *c*, cytoplasm showing the dark-colored Nissl bodies, separated from one another by the lighter ground substance; *d*, protoplasmic processes (dendrites) containing Nissl bodies; *n*, nucleus; *n'*, nucleolus; *n.R.*, nodes of Ranvier; *s.f.*, side fibril; *n. of n*, nucleus of neurilemma; *tel.*, motor end-plate or telodendrion; *m'*, striped muscle fibre; *s.L.*, segmentation of Schmidt-Lantermann. (From "The Nervous System and Its Constituent Neurones," by Lewellys F. Barker. D. Appleton & Co., New York, 1899.)

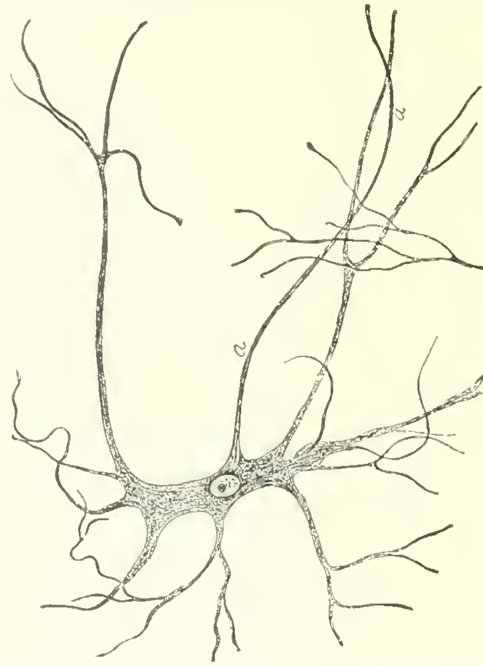

FIG. 3573.—Multipolar Ganglion Cell from the Anterior Horns of the Spinal Cord, Isolated by Maceration and Teasing, showing that the numerous branched protoplasmic processes are somewhat displaced and distorted, owing to manipulation. *a*, Axis-cylinder process; cytoplasm granular; nucleus large, distinct; nucleolus darker than nucleus. (Piersol.)

while in others a complete arborization exists, forming a dense forest which extends over a wide territory. Besides the degree of complexity of arborization the relation of the dendrites to the surface of the cells is of interest, since this branching may arise from only one or two dendritic processes as in the cells of the hippocampus, or it may originate from all sides of the cell like

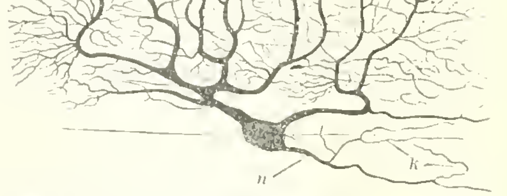

FIG. 3574.—Cell of Purkinje from the Cerebellum of Man. Showing pyriform cell body, large arborescent protoplasmic process with gemmules forming the typical telodendria of the dendrite. *n*, Axis-cylinder process; *k*, collateral fibrils. (Kölliker.)

a radiation as in the ventral horns of the spinal cord. Rarely neurones are characterized by entire absence of dendrites; such *adendritic* elements have been observed in the nervous system of invertebrates and also in the

rite or *axone*, unlike the dendrite, is thin, slender, inconspicuous, straighter in its course and smooth in outline. It was formerly described as an unbranching single process, and was supposed to be always the continuation of the axis cylinder of a nerve fibre. Golgi's investiga-

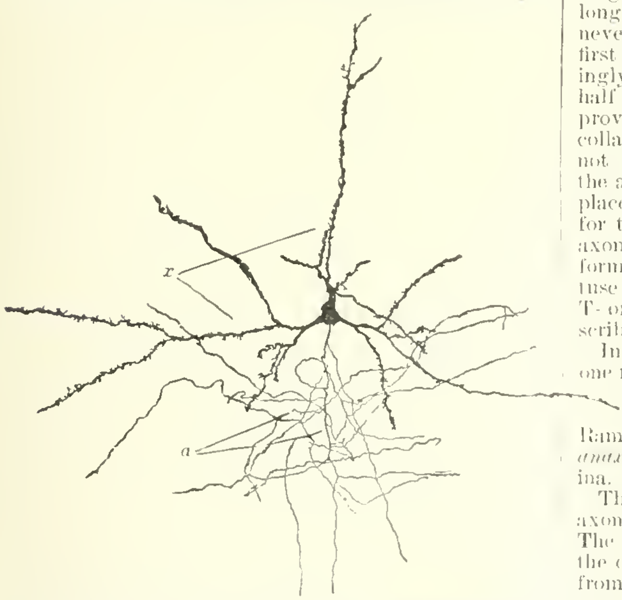

FIG. 3576.—Golgi's Cell of the Second Type from the Cerebrum of a Cat. Showing *x*, the coarse protoplasmic processes easily distinguishable from the more delicate axis-cylinder process *a*, forming the rich telodendrion of the axone. (Kölliker.)

tions have shown, on the contrary, the existence of nerve cells in which the axone is branched and does not become the axis cylinder of a nerve fibre. Hence nerve cells are arranged into two types—cells of the *first type*, in which the single non-branching axone becomes the axis cylinder of a medullated nerve fibre, and those of the *second type* in which the axone does not become the axis-cylinder process of a nerve fibre but undergoes branching, forming a telodendrion of the axone to which the name of

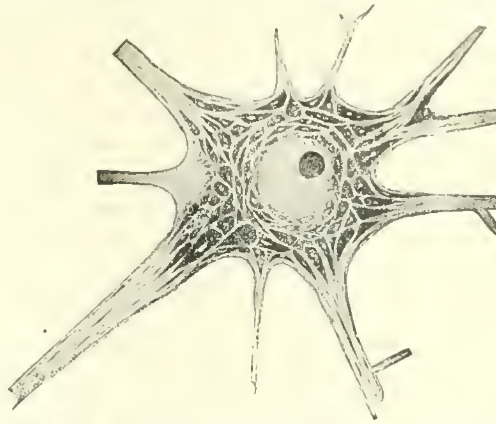

FIG. 3577.—Motor Nerve Cell from Ventral Horn of Gray Matter of Spinal Cord of Rabbit. Of the three lower processes, the middle one represents the axone; all the other processes are dendrites. The margin of the cells and of the masses of stainable substance appear too sharp in the reproduction. At the angle of division of the large dendrite at the left superior angle of the cell is shown one of the wedges of division. The spindle-shaped Nissl bodies are well shown, especially in the dendrites. (From "The Nervous System and Its Constituent Neurones," by Lewellys F. Barker. D. Appleton & Co., New York, 1899.)

dendraxone or neuropodion (Kölliker) is applied. The termination of the dendraxone usually takes place by exhaustion of repeated division. Very rarely and only in exceptional cases the terminal branches are interwoven to form a basket-like meshwork surrounding the cell body of a second neurone. Axones vary greatly in length, being very short, often only a few millimetres long; in nerve cells of the second type the dendraxone never leaves the gray substance. In nerve cells of the first type, on the contrary, the monaxone may be exceedingly long, some extending, as spinal nerve fibres, fully half the length of the body. Monaxones are frequently provided with collateral branches or *paraxones*. These collateral branches should not be mistaken either for the arborization which takes place in the dendraxone or for the true division of the axone into two branches, forming a right or an obtuse angle resulting in the T- or Y-shaped branches described by Ranvier.

In addition to the monaxone neurones, *diaxone* as well as *polyaxone* neurones have been observed. Ramòn y Cajal describes also *anaxone* neurones in the retina.

The mode of origin of the axone also claims attention. The axone may arise from the cell body directly or else from the dendrite; in this case the origin is usually near the cell body, while more rarely it is situated at some distance from the cell body. At its origin the axone is wedge-shaped and hence is called the *implantation cone*. It possesses certain characteristics in its internal structure and will be referred to later. The axone may have protecting coverings or a sheath. When

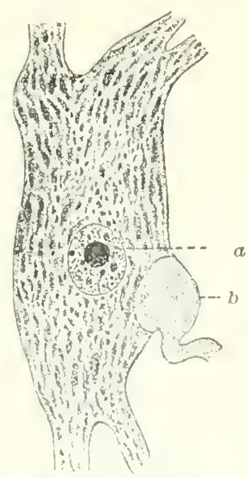

FIG. 3578. Nerve Cell from the Anterior Horn of the Spinal Cord of an Ox. Showing coarse chromatophile flakes, nucleus (*a*), nucleolus, and the implantation cone or axone hillock (*b*), devoid of chromatophile granules. (Böhm-Davidoff.)

no envelope is present it is customary to speak of *naked axones*. The coverings are the *neurilemma* or the *sheath of Schwann*, and the *medullary substance* or the *white substance of Schwann*. One or both may invest the axone for a portion or its entire length. In the case of a nerve cell of the second type, where the dendraxone is limited to the gray substance, no sheath is present. In nerve cells of the second type there are stretches in which the axone is naked, those in which it is enveloped only by the neurilemma, and finally tracts in which both neurilemma and medullary substance are present. In the latter case the medullary substance is the inner sheath, while the neurilemma is the outer one. At times ill-defined fibrous tissue, called Henle's sheath, is present outside of the neurilemma.

www.tibtool.com.cn

FIG. 3579. Portions of Two Medullated Nerve Fibres Stained with Osmic Acid. (From a young rabbit.) × 425 diameters. *R*, *R*, Nodes of Ranvier, with axis cylinder passing through; *a*, primitive sheath of the nerve or neurilemma; *c*, opposite the middle of the segment, indicates the nucleus and protoplasm lying between the neurilemma and the medullary substance. In *A* the nodes are wider and the intersegmented substance is more apparent than in *B*. (Quain.)

Structure of the Nerve Cell.—Nerve cells like all other cells consist of protoplasm, to which the name of *neuroplasm* has been applied by Kölliker. They contain an attraction sphere, within which one or more centrosomes are situated; a nucleus, which is larger than in most other cells of the body; usually a single nucleolus, more rarely several nucleoli; an implantation cone; several nuclear caps, and sometimes several spindles. A variable amount of pigment granules is also present, depending upon the age of the cell. Not every nerve cell, however, contains the above-enumerated parts. In fresh preparations, without the use of reagents, the protoplasm appears more or less homogeneous. With the use of reagents and different methods of fixation the protoplasm varies in appearance, being fibrillar, granular, or vacuolated. The latter two conditions at least may be regarded as probably artefacts, produced by reagents. The granules have a special affinity for certain aniline stains. They appear very distinctly when stained by the Nissl method and are generally known as *Nissl bodies*, *chromatophile* or *tigroid* granules (Fig. 3577). The granules are variable in size, regular or irregular in shape, and are arranged in groups, rows, or irregularly; sometimes simulating rods of variable thickness and constituting the so-called "*stainable substance*" of Nissl. That portion of the protoplasm which has no affinity for stains is known as the "*unstainable substance*" of Nissl.

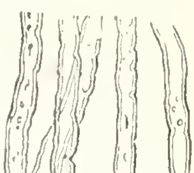

FIG. 3580.—White or Medullated Nerve Fibres (shortly after death), showing the sinuous outlines and double contours. (Quain.)

The granules are more concentrated in the inner portion (or the *entoplasm*) of the cell, while in the outer portion (or the *ectoplasm*) they are more rod-shaped. The rod-shaped elements are present in the dendrite, but are not found in the axone. Nissl suggested an elaborate classification of nerve cells, depending upon the amount, the arrangement, and the proportion of the granular substance to that of the cytoplasm and the relation of the granules to the nucleus. This classification is, however, not generally adopted by neurologists.

The spindles, as their name indicates, are spindle-shaped aggregations of chromatophile granules in the stainable substance of the nerve cells.

The "*unstainable substance*" of the cell body constitutes the ground substance, regarded by Nissl as homogeneous; but the investigations of Held (by a different staining method) have not only shown this substance to become stained of a deep red color in contrast to the blue color of the stainable substance, but also the presence of longitudinal threads not demonstrable by the Nissl method. Within the axone these threads or fibres appear to form a honeycomb network (the *axospongium*), in the meshes of which granules of variable size (the *neurosomes*) are present (Fig. 3578).

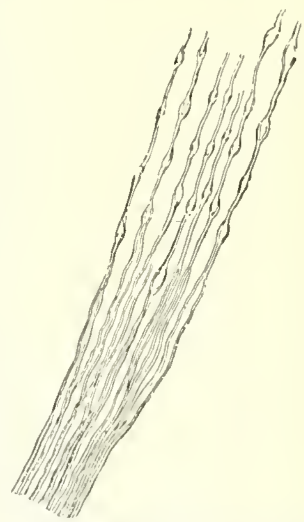

FIG. 3581. — Medullated Nerve Fibres from the Root of a Spinal Nerve near its Termination, showing the varicose appearance of the fibres. (Quain.)

The *implantation cone* or *axone hillock* is free from chromatophile granules, and stands out in marked contrast to the rest of the protoplasm of the cell body on account of the mottled appearance of the latter.

The *nucleus* is relatively large, round, usually centrally situated, surrounded by a delicate nuclear membrane, is single in adult man, and contains numerous granules which have little affinity for stain, whereas the neucleolus, situated in the interior of the nucleus, takes the staining deeply. Lenhossek has described the presence of several nucleoli. The nuclear caps are dense aggregations of chromatophile granules situated outside of the nucleus, but in close contact with it.

NERVE FIBRES.—It is evident from the foregoing consideration that the nerve fibres are the axones of the neurones. The nerve fibres form the chief constituents of all nerve trunks and enter largely into the composition of the cerebrospinal axis, forming not only the whole of the white substance, but constituting also a considerable portion of the gray matter. Depending upon the character of the coverings or sheath surrounding the fibres, the latter are divided into two varieties, the *medullated* and the *non-medullated* fibres. Although this distinction, for purposes of description, is convenient, it must be remembered that the same fibre may be medullated in one part of its course, and later, in a different part, lose its medullary substance before reaching its final termination.

Medullated Nerve Fibres.—A typical medullated nerve fibre consists of the *axis cylinder*, the inner or axial portion of the fibre, the *medullary substance*, or the white substance of Schwann, surrounding the axis cylinder, the *neurilemma* or *sheath of Schwann*, the outer covering surrounding the medullary substance, and the nerve corpuscles or nuclei. The axis cylinder is the most important part of the nerve fibre, conveying as it does the nerve impulse and constituting the only part which is never absent in the nerve fibre. The axis cylinder originates in the cell body of the neurone as its axone and terminates in the tissue to be controlled by that element.

Nerve Tissue.

It appears as a thread, running through the centre of the fibre, but consists of a bundle of very delicate nerve

www.libtool.com.cn

FIG. 3582.—Small Branch of a Muscular Nerve of the Frog, Near its Termination. Showing the well-marked nodes of Ranvier, the axis cylinder, and the division of the fibres at the nodes. (Kölliker.)

fibrillæ, called the ultimate nerve fibrillæ, held together by a homogeneous cement substance and surrounded by a delicate and closely adherent membrane, the *axilemma*.

Surrounding the axilemma is the medullary substance, much thicker than the axilemma, of soft fatty consistency, and acting as a protecting medium to the delicate axis cylinder. In the fresh state the medullary substance does not lie in actual contact with the axilemma, but is separated from it by a lymphatic space. The medullary substance itself is not homogeneous, but consists of a network of neurokeratin, in the meshes of which the soft semifluid substance, the myelin, is held. The myelin is of an albumino-fatty composition, containing protagon, and capable of powerfully refracting light. At regular intervals, along the course of the fibre, symmetrical constrictions of the medullary substance occur, known as the *nodes of Ranvier*. These nodes are constrictions of the neurilemma and complete interruptions of the continuity of the medullary substance, but not affecting the axis cylinder, which at these points is in contact with the neurilemma. That portion of the nerve fibre which is situated between two adjacent nodes is known as the *internode*. In fine nerve fibres the internodes are shorter than in those of greater diameter, and in fibres of the same thickness they are shorter in warm-blooded than in cold-blooded animals. Near the termination of the fibre the internodes are also shorter. At the constrictions the axis cylinder is accessible to various reagents which cannot reach it at other points, as they cannot penetrate the medullary substance. Actual breaks in the medullary substance are artificial markings—the Schmidt-Lantermann segments as they are called,—resulting from the use of reagents. These interruptions may be distinguished from the true nodes by their irregular character, their asymmetry, and by the fact that no constrictions of the neurilemma take place in these locations. Nerve fibres are not uniform in diameter, but vary greatly; according to Kölliker, the finest fibres measure from 2 to 4 μ, those of medium size from 4 to 9 μ, while the largest possess a diameter from 9 to 20 μ. *The neurilemma* or *sheath of Schwann* is the outermost covering of the nerve fibre, and consists of a structureless or hyaline membrane, surrounding the medullary substance. Oval *nerve nuclei*, or nerve corpuscles, lie just beneath the neurilemma in depressions on the outer surface of the medullary substance. Only one such corpuscle is present in each internode and is usually placed in the middle of the internode. The medullated nerve fibres in the central nervous system have *no* neurilemma, nodes of Ranvier, or corpuscles. In the fresh state the medullated nerve fibre has a glistening, homogeneous appearance. After death the fibre appears to have a double contour, but later becomes mottled, as the result of rapid disintegration. Osmic acid stains the medullary substance black.

FIG. 3583.—Portion of the Network of the Fibres of Remak from the Pneumogastric of a Dog. Showing *n*, nucleus; *p*, protoplasm surrounding it and the faint striation caused by the fibrils. (Quain.)

Non-Medullated Nerve Fibres.—The *non-medullated* nerve fibres or the *fibres of Remak* are nothing more than axones or axis-cylinder processes of neurones devoid of medullary substance and neurilemma. The latter, however, is replaced by a delicate sheath, beneath which the small nerve nuclei are located. The nuclei are more numerous in these than they are in

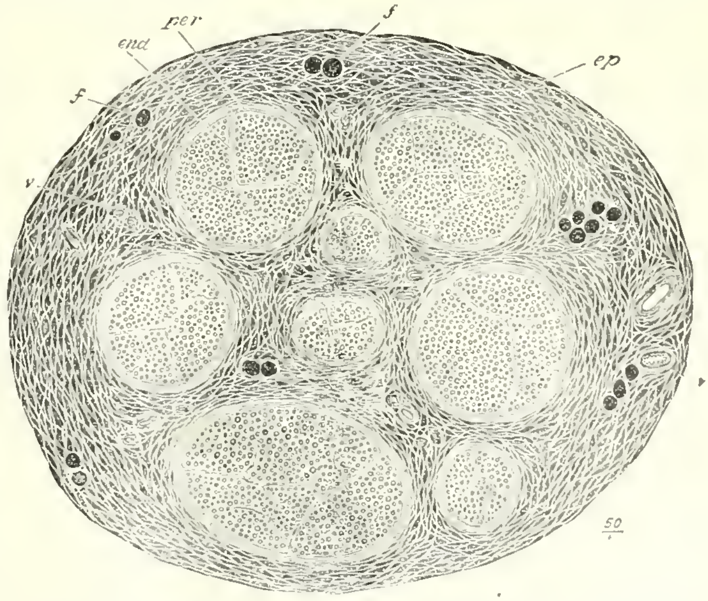

FIG. 3584.—Transverse Section of the Internal Saphenous Nerve of Man, made after being stained in osmic acid and subsequently hardened in alcohol. Drawn as seen under very low magnifying power. The fat cells and the nerve fibres are darkly stained, but the connective tissue of the nerve is only slightly stained. (Quain.)

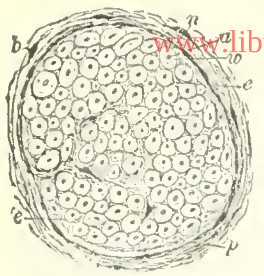
Digitized by Microsoft®

the medullated nerve fibres. Non-medullated nerves often appear varicose and exhibit a marked tendency to branch and form plexuses. Their ultimate fibrillæ are more widely separated than are those of the medullated fibres, protoplasm in the former taking the place of the cement substance in the latter. As independent fibres they occur principally in the sympathetic system, but not infrequently they are associated with medullated fibres in nerve trunks, as in the vagus.



www.libtool.com.cn

FIG. 3585.—A Simple Funiculus More Highly Magnified. The apparent small nucleated cells are sections of the nerve fibres and their axis cylinders. *a*, Axis cylinder; *w*, white substance of Schwann or medullary substance; *n*, neurilemma; *e*, endoneurium; *p*, perineurium; *b*, connective-tissue cells of the same. (Piersol.)

Nerve Trunks.—The nerve fibres are usually collected in bundles or funiculi, several of which constitute the nerve trunk. The individual fibres are held together by a delicate connective tissue, the *endoneurium*. A certain number of the fibres are grouped to form a funiculus, the latter being surrounded by a more dense connective-tissue envelope, the *perineurium*. The funiculi in turn are grouped together to form a nerve trunk, and are surrounded by a larger amount of loosely arranged connective tissue, the *epineurium*. This tissue supports the blood-vessels and the lymphatics, which invariably are present in the interior of the nerve trunk, as well as the adipose tissue often present in the larger nerve trunks.

The Neuroglia.—The supporting substance in the white matter of the brain and cord, as well as a considerable portion of the matrix of the gray substance, is made up of a network of exceedingly delicate fibres, the *neuroglia* fibres, and the neuroglia cells, two varieties of which are distinguished—the *spider cells* and the *mossy cells*. The cell body of the spider cell is smaller, while their processes are long, thin, rigid, with very little branching. They occur chiefly in the white substance of the brain and cord. The mossy cells have a larger cell body, short, richly branched processes, and are principally found in the gray substance, where they are often in intimate relation with the walls of blood-vessels.

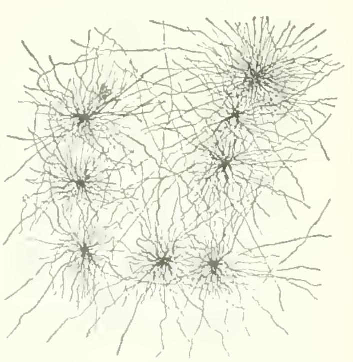


FIG. 3586.—A Group of Spider Cells from the White Substance of the Brain of Man, stained by Golgi's method. Drawn as seen under high magnifying power. (Kölliker.)

Robert Formad.

NERVOUS SYSTEM, TRAUMATIC AFFECTIONS OF.—It is not purposed here to attempt a detailed description of all the affections of the nervous system which are caused by trauma. Within the limits of the present article nothing further can be attempted than a brief analysis of the causal relations in which trauma stands to nervous diseases, with especial consideration of the place which nervous diseases, when caused in this manner, occupy at law. What is to be said, therefore, will be chiefly interesting to the medical man who is brought in contact with injuries to the nervous system and their legal complications. Personal-injury claims form a very important feature of modern life. Not only transportation companies, but private individuals as well, fully expect to pay for injuries which are received through actionable negligence for which they are responsible. Similarly, few receive injuries traceable to the negligence of others without promptly demanding compensation. In our mechanical times the frequency of accidents is enormous. Consequently, the evaluation of injuries received and the compensation to which the injured person is entitled are matters of prime importance. Greater interests are involved than in any other medico-legal question. This becomes plain as soon as we reflect upon the large sums which are annually paid out in such cases. From the report of the Brooklyn Rapid Transit Company for the year 1901 it appears that in that year more than one million dollars was paid for personal injuries and expenses incident thereto. This sum represented nearly ten per cent. of the gross receipts of the company for the year named. Individual verdicts are also often very high. As much as thirty-five thousand dollars has been paid for a personal injury, and for a death claim resulting from the Tunnel accident of the New York Central and Hudson River Railroad of February 8th, 1902, a verdict of $60,000 was returned by the jury. Verdicts varying from $10,000 to $20,000 are not at all unusual, and anything under $1,000 is considered virtually a victory for the defendant. Court calendars are overcrowded with these cases, which form the bulk of jury trials to-day. But the calendar is not a complete index of the degree of activity in this branch of law, as for every case that comes to trial it is safe to estimate that ten are settled by mutual agreement out of court. If the magnitude of the interests at stake are taken into consideration, it is not surprising that trial lawyers should be on the alert, or that there should be great competition for plaintiff's cases. As a result, "runners" or "ambulance chasers," representing legal firms which specialize in accident cases, are constantly stationed about centres of traffic; they rush to the scene of accident, and make their appearance at the hospital door almost simultaneously with the injured person. Thenceforth the claim is prosecuted on the contingent fee plan. The system has doubtless been much abused, and has been made the object of much attack and ridicule. It is made possible solely through the poverty of the plaintiff, who is generally unable himself to carry on the great expense of trial at law, and who consequently is forced to accept professional services which are to be paid for, on a percentage basis, out of the damages awarded. It has many very objectionable features. By such a system the lawyer is made more than an advocate, and the expert medical witness more than a mouthpiece of science. But no practical and better substitute has yet been suggested. The question will probably resolve itself eventually by fewer claims being litigated, and more being settled by mutual agreement. Mr. Herbert W. Page, whose book, "Injuries of the Spine," published in 1882, marked a distinct epoch in the history of this subject, told me a year or two ago that litigation of personal-injury claims in England was becoming more and more infrequent. Erichsen's book, which appeared in 1866, and which furnished the original description of the peculiar symptoms resulting from railway and allied injuries, gave the first effective impetus to litigation of this character. For years afterward personal-injury claims were prominent in the English courts. But now, according to the statement of Mr. Page, they are so infrequent that, in his position as consulting surgeon to the London and Northwestern Railway, he is called upon to go to court only three or four times a year. It has seemed to me that the willingness for compromise is growing in this country also. Among the litigated cases those hardest to compromise are the ones in which injury to the nervous system is alleged. In purely surgical injuries, such as the loss of a limb or of an eye, the cause is definite, and the question quickly resolves itself into one of liability and the appraisal of the value, as far as such an appraisal is possible, of the injured or missing member. But in nervous affections, and especially in the functional af-

Digitized by Microsoft®

Nervous System.

fections, with their obscure causation, their indefinite and often bizarre symptomatology, agreement is much more difficult. The contending parties are often at variance in regard to every particular. Neither is inclined to give in, and the case, if it is a case, goes to the jury.

Nervous diseases are divided into two great classes, organic and functional. A functional, as opposed to an organic disease, is one in which the anatomical integrity of nervous structure remains unimpaired. Functional diseases doubtless have a material pathology. But such a pathology remains inaccessible by any methods of investigation at present at our disposal, and we are therefore obliged to retain this classification, artificial as we know it to be. Of the organic nervous affections caused by trauma, the vast majority are definite surgical injuries to the central or peripheral nervous system. Thus, injuries of all kinds to the head, with injury of the brain; to the back, with injury to the spinal cord; or to the peripheral nerves, are causes. When, in addition to the cause, we can demonstrate certain cardinal abrogations of function of these organs, which we have learned to rely upon as indications of structural alterations in them, the diagnosis of organic injury is justifiable. Thus, after head injuries, paralysis of one or more cranial nerves, or of the extremities, together with other general symptoms, speaks for injury to the brain; paralysis, with anæsthesia in characteristic areas, and loss of control of the sphincters, speaks for injury to the spinal cord; paralysis, with degenerative electrical reactions, speaks for injury to a peripheral nerve. Injuries of this character are ordinarily easy to recognize, and the prognosis in regard to them can usually be formulated with considerable precision. Consequently, in common with other surgical injuries, when they are seen in court, which they rarely are, the questions for the jury to decide concern the legal aspects of the accident rather than its surgical results.

There is a group of chronic organic diseases, with uncertain and indefinite causation, which are not infrequently the subjects of litigation. The most important of these are locomotor ataxia and general paralysis of the insane, or general paresis. Others of this class are ataxic paraplegia, progressive muscular atrophy, paralysis agitans, syringomyelia, multiple sclerosis, etc. These latter are, however, much rarer diseases than the two first mentioned, and consequently of much less importance. Both locomotor ataxia and general paresis are comparatively common (the latter chiefly in cities). As has been said, their causes are obscure and undetermined. It is possible, and indeed probable, that injury can act as a contributing cause in their development. But the weight of scientific evidence is against their ever occurring solely as the result of trauma. Both diseases are often latent for a long time, and both may undergo a sudden outbreak of symptoms as the result of disease or injury. Both diseases, by their symptoms, expose the victims of them to accidents. It is consequently not surprising that both are frequently made the subjects of personal-injury claims. Juries often award verdicts in such cases, in view of the fact that sworn experts, who frequently do not at all understand the condition about which they testify, affirm that the injury was the sole cause of the trouble.

Epilepsy is another disease, which in this connection can be considered organic, and about which legal interest frequently centres. That typical epileptic convulsions follow head injuries, even when there is no discoverable injury to the brain, is an incontestable fact. In order to establish a reasonable support for such a contention in any given case, it is necessary to prove that the patient had not had epilepsy before the accident, and that the accident, in character and severity, was of a nature to produce such a result.

While the three diseases named above not infrequently figure in litigated cases, the chief interest, both legal and scientific, in traumatic affections of the nervous system, centres about the functional disorders known, since the appearance in 1889 of Oppenheim's monograph, as the traumatic neuroses. In the earlier treatises, and especially in Erichsen's, these neuroses were totally misunderstood and were classified with organic injuries. Progress throughout the whole field of neurology has now made it possible, in most cases at least, to distinguish these two great classes. As originally described by Oppenheim, the traumatic neuroses present chiefly the symptoms of neurasthenia and hysteria, but also some which indicate structural lesions. The term was a taking one and has attained a rather different meaning from that which Oppenheim intended. To-day, by a traumatic neurosis is understood a simple neurosis, without known organic basis, plus such characteristics as its traumatic origin has added to it. Thus considered, the traumatic neuroses are composed of symptom groups which can, in nearly all cases, be brought under the rubric of neurasthenia or hysteria. In causation, they have many points in common. They have both attained their prominence through railway accidents. This is partly due to railway accidents so often being due to actionable negligence, and partly to the fact that in such accidents physical injury and mental shock are conspicuously combined. Both mental and physical elements are present in nearly all accidents. In most cases of neurasthenia the bruising and shaking up have been considerable, although severe surgical injuries are usually absent. Hysteria, on the other hand, is a fright neurosis above all else, and the history of injury in its causation is often very inconspicuous. It is well to observe in this connection that in the State of New York there can be no recovery of damages unless there has been a definite physical injury. Injuries resulting from fright alone do not constitute a cause of action.

Much has been written and much said about litigation as a cause of functional nervous diseases following trauma. If one were to be guided by the fluent generalizations of some railway claim agents, one would have to believe that any real injury to the nervous system could not occur on a railway; that all persons who allege such injuries either deceive themselves or wish to defraud the company. Certain experts, on the other hand, who are especially prominent in plaintiff's cases, are not inclined to accord much importance to the financial side of the question. Leaving aside actual simulators and impostors, who are very rare, I may say that my experience has taught me that the question of damages has a great influence on both neurasthenia and hysteria, and that in neither disease is restoration of health probable while litigation is pending. This baneful effect is due to the difficulty of carrying out proper treatment so long as legal questions are pending. Were the treatment for such cases simply medicinal, such a statement would naturally appear absurd. Medicines, however, play a very insignificant rôle in the treatment. They are of some indirect service, but far more important is the psychological direction of the patient. The diversion of the patient's thoughts away from morbid channels, the arousing of his interest in matters not connected with himself or his troubles, the exclusion from his consciousness of suggestions which may magnify or create symptoms,—these are the keys to the successful treatment of the traumatic neuroses. They are rendered powerless by the damage claim. The frequent examinations by experts (in some cases as many as five or six doctors examine a plaintiff), the law's delays, the legal inadvisability of the patient's returning to work, and the thousand and one annoyances inevitable to litigation, render futile any attempt to control the patient psychologically. These factors, in my opinion, are much more responsible for the continuance of symptoms than is any desire which the patient may possess to profit by his misfortune. This is especially true for traumatic hysteria, in which disease, aside from its being an agent in suggestion, the money question has little or no influence. The question of litigation as a cause of the traumatic neuroses must be kept separate from the question of voluntary exaggeration of symptoms actually present, and of simulation or fraud pure and simple. As far as actual simulation is concerned it is very rare, and should not pass undetected by a phy-

Digitized by Microsoft®

www.libtool.com.cn

sician who is skilful and reasonably resourceful in his methods of examination. Voluntary exaggeration of symptoms actually present is more difficult to detect. It is not often encountered in hysteria. But in neurasthenia, the making the most of symptoms is an integral part of the disease and inseparable from it. It is, therefore, not an easy matter to determine when it reaches the point where the patient exaggerates in spite of himself and involuntarily, or when it is intentional, voluntary, and purposeful. There is no rule to guide us in determining how this question may be satisfactorily answered in any given case. Some help may be derived from information obtained from outside sources. But as a general rule the physician's conclusion must be based on his own examination, and the soundness of it is usually directly proportional to his experience and acumen, both professional and worldly.

In what has now been said, it has been plainly hinted that the traumatic neuroses are the results of mental impressions, rather than of physical injuries. The different ways in which these impressions act and in which their effects are elaborated constitute the two main symptom groups of neurasthenia and hysteria. Each group has some characteristics in common with the other. But each has also its own individuality, which stamps it as a definite clinical entity. Neurasthenia represents irritability, fatigue, and exhaustion. Such perversion of mental function as exists is in the line of exaggeration of tendencies common to all mankind. Hysteria, on the other hand, is absolute delusion. The premises of the neurasthenic's reasoning may be sound, but the deductions which he draws from them are too general. The hysteric, on the other hand, is wrong in his premises, and the deductions which he draws are insane delusions. The former is within the boundary line of mental alienation, the latter way beyond it. The characteristics of a case of traumatic neurasthenia are usually somewhat as follows:

A man, whose previous life has, according to the evidence, been healthy, is in an accident in which he is considerably shaken up and badly frightened. He is astonished to find that he has escaped without severe physical injury. He is able to walk, and in general accidents he can often render assistance to those more severely injured than he. That night he does not sleep well. He is disturbed by dreams; or thoughts recalling the catastrophe thrust themselves into his consciousness. From then on he finds himself becoming more nervous, more easily fatigued, and more irritable than formerly. His sleep is regularly disturbed, and trifles upset him. He has lost his nerve. In short, he develops the ordinary symptoms of neurasthenia (*q. v.*), with which every practitioner is only too familiar. He differs in some respects from the ordinary neurasthenic. Pain in the back, only occasionally complained of in non-traumatic neurasthenia, is very prominent in the traumatic variety. It may exist as a dull constant pain, or be in the form of lumbago, increased by all movement. The mental state also is dominated by the recurring thoughts of the accident, and by a dread of its repetition. With such slight variations the picture is the same as in ordinary neurasthenia. The mental state varies from that of the irritable, querulous, self-centred, introspective semi-invalid, to that of the pronounced hypochondriac. Depression is a dominant feature, and may entirely do away with working capacity.

Neurasthenic complaints, in addition to those of fatigue, fear, depression, etc., may refer to nearly all parts of the body. Some of them have objective substantiation. There is no true paralysis, but the muscles are quickly fatigued as has been shown by the ergograph. There is often tremor of the face, and with it there is generally associated a fine tremor of the fingers. In addition to subjective pain in the back, there are usually one or more vertebral spines which are extremely sensitive to touch. These spots are often shifting, they are not always in the same places. Headache is another common symptom. It is referred, most frequently, to "the base of the brain." Feelings of numbness and tingling are regularly complained of, but there is never any objective anæsthesia. The vascular disturbances are particularly important. All neurasthenics have unstable sympathetic nervous systems. This condition is shown by the sudden changes in color of the face, by the cold hands and feet, and by the fact that sensations of heat and cold pass over the whole body. The heart is also irritable and often constantly over-active. Attacks of palpitation are common, and are induced by trivial causes. There is also a more or less persistent tachycardia.

Digestive disturbances are almost constant. They, in common with the mental state, are responsible for the poor nutrition of many of these patients. Complaints regarding the genital apparatus are frequent. Women notice disturbances of menstrual function. In men these complaints are chiefly in regard to seminal losses, to prostatorrhœa, etc. In a certain proportion of cases there is loss of sexual desire. The patients worry and reason about this, and fear that they are becoming impotent. As a result they approach the sexual act with timidity and often with great excitement. As a result of their fears there may fail to be an erection, or the excitement under which they labor may cause ejaculation. These failures become more pronounced with succeeding attempts, until finally, in despair, the patient is convinced that his virility is gone permanently. In some litigated cases impotency is the chief item in the complaint. In a recent case a young Swede, a superb specimen physically, brought suit for $25,000 for such a cause. He had fallen with some wooden structure into a river, and in rising to the surface had been struck across the thighs by a wooden beam. He was bruised, but the testicles were not directly injured. Active sexually before, he alleged that after the accident he experienced great loss in sexual power. Experts in his behalf testified that he was sterile and incurable. The jury, however, apparently adopted the view of neurasthenia, for they awarded a verdict of only $2,000, which sum the judge promptly cut in two.

In hysteria, the mental state often has many neurasthenic features, but in its salient characteristics it is totally different. The striking symptoms of hysteria—namely the palsies, the blindness, and the anæsthesias—although they constitute physical manifestations, are of purely psychic origin, dependent upon delusional beliefs or on fixed ideas. That they do not result from structural alterations is proved by their inconstancy and sudden fluctuations. Their occurrence in all peoples and in all times, and their conformity to definite and consistent symptomatic behavior in all classes of people, render absurd the position of those who contend that hysteria is voluntary simulation and not a disease. It seems to me very important that it be more generally recognized that hysteria is a distinct affection of the mind, and that its symptoms, while varied, are none the less characteristic and distinct. Contrary to the popular impression, and to the etymology of the name, it is not rare in men. Traumatic hysteria, in my personal experience, has been more frequent in men than in women. Present conceptions regarding mental diseases lead us to assume that they occur chiefly if not exclusively in persons who are hereditarily predisposed. In most of the cases which I have seen it has been impossible to prove the existence of an hereditary predisposition. I should add, however, that most of these cases were litigated; consequently too great scientific value should not to be given them.

The symptoms of traumatic hysteria are striking and varied. They may appear immediately after the accident, or they may be delayed until the morning after, or even for several days. This interval has been called by Charcot the "period of meditation." During it the patient is reflecting on the accident, is reasoning about it, subconsciously, and then he finally develops the symptoms. These may be referred to every organ and every system of the body. They may very closely resemble symptoms due to organic disease. But in the imitation there is always a flaw. The reproduction is never perfect. Thus, in hysterical paralysis, there are not the

Nervous System.

degenerative electrical reactions which are characteristic of peripheral palsies, or the changes of reflexes, rigidity, etc., which are characteristic of cerebral paralysis. In hysterical anæsthesia, also, the loss of sensibility is too transitory, or its association with other symptoms too contradictory, or its distribution too irregular, to warrant the belief that it rests upon an organic basis. It would be impossible, within the limits of the present article, to go into the symptoms of traumatic hysteria in detail. The reader is referred to the article *Hysteria* in THE HANDBOOK, or to the chapter on Traumatic Hysteria in my work on "Accident and Injury in their Relations to Diseases of the Nervous System." The following brief summary of the more important symptoms may be useful here. Paralysis is usually in the form of hemiplegia, without involvement of the face. In an overwhelming majority of cases it affects the left side. Monoplegia usually affects the arm and is generally the sequence of some slight injury to that member. Paraplegia is rare in traumatic cases. It is not accompanied by involvement of the sphincters. Polyplegia is most unusual. The paralysis of hysteria is of a flaccid type, and usually affects the limb in its entirety. It gets better and worse, according to changes in environment. It is not accompanied by electrical degenerative reactions nor by changes in the deep reflexes. Anæsthesia varies in distribution with the paralysis. Sometimes it affects the whole body. In hemiplegia, there is hemianæsthesia on the paralyzed side; in monoplegia, the sensory loss may affect the whole side, or only the paralyzed member. In paraplegia the genitals retain their sensibility. The anæsthesia of hysteria is profound and affects all forms of cutaneous sensibility. It may change its situation and extent as a result of mental impressions. Sight, hearing, taste, and smell are also commonly affected. The visual disturbances consist in concentric limitations in the visual fields, changes in the color fields, or amblyopia. Spasm of the orbicularis sometimes prevents the patient from opening the eyes. Hysterical deafness is a common symptom. If there is paralysis, at the same time, the deafness is unilateral and on the side of the paralysis. Deaf-mutism is rare; it occurred in one case in my experience. The deafness, which was complicated by hemiplegia, led to mutism, and at last report, one year and a half after the litigation had ceased, this condition still persisted. The hysterical attack is very important in litigated hysteria, as the patient is almost certain to have an attack in court. At a recent trial the plaintiff was in convulsions for two hours and a half in the courtroom. Such demonstrations appeal very strongly to the sympathies of the jury, though in the case referred to the jury disagreed on the first trial, and returned a verdict for the defendant on the second. These attacks are commonly called hystero-epilepsy—clearly a misnomer, as they are not in any way allied to epilepsy. They differ from epileptic attacks in the character of the aura, the quality and duration of the convulsive phenomena, and the absence of biting of the tongue and of the involuntary passage of urine. Epileptic attacks are not precipitated by excitements and crowds. Hysterical attacks have a predilection for dramatic surroundings. The lack of conformity to organic types makes the distinction of hysteria from the diseases which it simulates nearly always possible. Juries, however, fail to recognize this fact and consequently the medico-legal relations of traumatic hysteria are very peculiar. Under existing conditions it is almost impossible for a jury, composed of laymen, to decide justly with regard to traumatic hysteria. The plaintiff is generally brought before them, and he is almost sure to present the acme of all the symptoms which he has had. If some of these symptoms had previously disappeared, they are quite sure to return during the progress of the trial. The psychosis is nourished upon suggestion and introspection, facilities for which are so profusely furnished by the excitement and observation attendant upon court proceedings. It is entirely consistent with the nature of this malady that existing symptoms should become worse or vanished ones return on such occasions. It is not necessary to assume, in explanation, any voluntary exaggeration or simulation on the part of the patient. The effect of this clinical idiosyncrasy on a jury, however, is disastrous to the cause of the defendant. The twelve jurors have heard from the medical experts of the two sides testimony too often directly conflicting. On the one side the opinion has been expressed that the patient's condition is due simply to nervousness aggravated, if not caused by the suit, and that the symptoms will soon subside when the legal proceedings are at an end; on the other side, the belief has been sworn to that the injury is of organic and irreparable character, or, if perchance its functional nature is admitted, that the nervous system has sustained a shock from which it can never recover.

The jurors may be convinced of the honesty of all the views which they have heard expressed, and yet they are unable to determine, from the character of the testimony, which of the opposing opinions is the more likely to be correct. They are, therefore, obliged to rely upon the impression made upon them by the injured person himself. They see before them an individual in an even worse condition, perhaps, than his doctors had depicted. They see an alleged paralyzed limb absolutely motionless; they become witnesses of an emotional outburst more harrowing than any related in the evidence. And they see these things one or two years after the accident has occurred. Their natural inference is that the injuries are permanent. They find it hard to believe that the outlook for a malady which has so long defied the resources of medical skill is anything but hopeless. They are unwilling, if not unable, to believe in the unreality of physical symptoms. They cannot comprehend a part being the seat of paralysis or insensibility, unless there is some grave physical defect behind it; they do not know that a limb which is immobile to-day may be in wonted activity to-morrow. Thrown on their own resources by the contradiction in medical testimony, they render a verdict in accordance with their own impressions as to the plaintiff's injury. These impressions indicate a person severely and probably incurably injured; and the verdict, rendered accordingly, is generally in excess of anything to which the plaintiff is entitled.

The two types, hysteria and neurasthenia, as above sketched out, are in most cases distinct and unmistakable. In some cases the type of mental state is neurasthenic, with enough of the hysterical added to cause a hemianæsthesia or other permanent stigma of hysteria. To this type has been given the name of hystero-neurasthenia. In other cases, coupled with the symptoms of functional disease, are certain signs indicative of material destruction in the nervous system. These latter cases are difficult to classify. It is not to be denied that some of them are the direct outcome of severe traumatic physical injuries. Most of them, however, can better be explained on the assumption that some pre-existing organic disease, such as general arteriosclerosis, syphilis, or alcoholism, has been made worse, or has first been called into prominence, by traumatic agencies.

The prognosis of hysteria and neurasthenia provoked by trauma is a subject on which very diverse views are held. Reliable statistics bearing on the question are few. Certain facts, however, are in our possession. Neither disease is fatal. Some writers maintain that the vascular disturbances of neurasthenia lead to serious degeneration in the heart and arteries and so to premature death. Some few instances also are on record in which death during the convulsive phenomena of hysteria has occurred. Such cases are, however, so rare and so poorly substantiated by reliable evidence that we are safe in asserting that these diseases do not kill. It is not to be denied, however, that some patients have the same symptoms for years and years, and, as far as is known, never get well. On the other hand, there is nothing about either disease which makes recovery impossible. Organic diseases, such as locomotor ataxia or progressive muscular atrophy, are manifestly incurable. But in the neuroses a cure, in the widest sense of that term, is possible.

Digitized by Microsoft®

The vital question concerns working capacity: What are the chances for a return of working capacity, provided that had been lost? To this question the answer is, that under reasonably favorable conditions these chances are very good. They are the best in patients who try to return to work as soon as possible after the accident, who are young, previously healthy, and of good family history.

www.libtool.com.cn

The prognosis which can be given in a case of neurasthenia is not always permissible for a case of hysteria. A person suffering from traumatic neurasthenia can often be brought to a condition in which he can safely return to work soon after the accident. The subjective disturbances, however, of which he complains may persist for months or years afterward. Indeed, it is very difficult to tell when they stop, and the patient may never himself admit that he is the same as he was before the accident. In hysteria, on the other hand, recovery may be longer delayed, but when it comes it is generally more complete. Few if any hysterical persons can undertake any work before the question of litigation is settled. But when that is once out of the way, a period of a few months generally, though not always, is sufficient for a fairly complete return of working capacity.

Pearce Bailey.

NEURALGIA.—Definition and Nature.—The term neuralgia in its strict sense signifies pain along the course of a nerve. The word has been used, however, to indicate conditions in which such pain exists purely as a neurosis, to distinguish it from the cases in which inflammatory and degenerative changes are present in the nerve, to which class the name "neuritis" is applied.

Probably the majority of the neuralgias are due in part only to any primary or essential neurosal disorder of the nervous centres, and indicate, in addition, some irritation of the sensory nerves from without.

This is eminently true of most of the typical neuralgias of the superficial nerves, and as our knowledge of the course and pathology of these diseases advances, many of the conditions formerly classed under the neuralgias are shown to be cases of neuritis. For instance, the gradual onset and decline of certain forms of sciatica and brachial neuralgia, their protracted course, the limitation of the pain to the tract and distribution of single nerves, and the fact that the pain is apt to be remittent rather than intermittent, together with the presence of tenderness along the nerve trunk, persistent alterations in the sensibility of the skin, and even muscular atrophy and trophic changes in the skin, all tend to point to the neuralgia being secondary to a neuritis, while examination of the nerve shows characteristic changes of inflammation and degeneration.

Then there are cases, such as some of the facial neuralgias, in which the character of the pain is that of neuralgia, persistent, intermittent, and frequently in neurotic individuals; and here examination of the nerve, after the affection has existed some time, often shows degenerative changes. The question then arises, Are these changes primary or secondary—*i.e.*, is the case a slow progressive neuritis from the start, or are these changes in the nerve secondary to the long persistent disorder of function which underlies the pain? The recent ion theory of Loeb, that the transmission of nerve stimuli is due to chemical change in the nerve substance, might well account for a permanent change resulting from constant severe pain persisting in the nerve.

Finally, there is the class of neuralgias in which the character, situation, severity, and duration of the pain are wholly determined by processes acting on healthy sensory nerves, and may be called reflex or symptomatic neuralgias. These irritative causes, however, if long continued, may induce a permanent neuralgic habit of the nervous centres.

The group of habit pains might also be classed as neuralgias, and both these and other forms may often be relieved by mental influences.

It is uncertain whether there are special nerves and nerve centres intended for the conveyance and perception of painful impressions, but the results of experimentation and the difference in the behavior in disease of this function—if so it may be called—from the other sensory functions, lead to the belief that such may be the case.

Again, it may be that the nerves of pain are the same with the nerves for the general feelings (*Gemeingefuhle*) of satisfaction or discomfort, which accompany, and yet are distinct from, the special sensations of relation, such as touch, temperature, and the like.

If there are special nerves and nerve centres for pain, it is probable that they are the seat of the disease in neuralgia.

It is common to hear the neuralgias of the superficial nerves spoken of as the only affections really deserving the name, and as belonging in a different category from the visceralgias and the periodical headaches, as well as from the pains of intermittent recurrence, but of ill-defined seat, to which children and feebly nourished persons, and especially neurotic persons, are liable.

In so far, however, as these painful disorders occur under similar conditions with typical neuralgias of the superficial nerves, and are themselves of unknown origin, there is much gained in treating of them both as kindred affections, and contrasting them with each other.

General Etiology and Pathology.—An *inherited neuropathic tendency* is the most important cause of neuralgia, and it is often impossible, in a given case, to measure the degree to which its influence is felt. It is, however, a far more important element in the migraines and the visceralgias than in the superficial neuralgias, and among the latter its effect is most strongly felt in the neuralgias of the fifth pair, and of the intercostal nerves.

The exact pathological state of the nervous centres in neuralgia is not known, any more than it is in the case of the other neuroses. Some of the conditions that give rise to it are, however, better understood.

Chief among these are: *Anæmia*, which acts both by impoverishment of the blood, and by overcharging the blood with carbonic acid; the *presence of abnormal substances in the blood*, as in gout, diabetes, malaria, chronic nephritis, and metallic poisoning; *absorption of the products of imperfect digestion or metabolism*; *the impairment of the vascular tonicity*, as in fatigue; *peripheral irritations*, such as disease of the teeth, eyes, respiratory and digestive tracts, uterus, and ovaries; chronic inflammation of the nerve sheath; *localized anæmia or congestion of nerves or nerve centres.*

Anæmia and states of *nervous debility* or *chronic fatigue* are common underlying causes of neuralgia, even though not the whole cause, and it is almost always best to suspect them and to fortify the patient against them by ample nourishment and tonic treatment. Although anæmic and debilitated patients are more prone than healthy persons to neuralgias of every sort, this is especially true with regard to the superficial neuralgias, the sufferers from migraine and the visceralgias being often in good, even robust, health so far as any anæmic tendency is concerned.

Anæmic neuralgias are, as a rule, protracted, like their cause, but may in the end pass away rapidly under appropriate treatment.

Diabetes sometimes causes intractable and often symmetrical neuralgias, especially sciatica, even though the symptoms of the underlying disease are not marked.

Gout and kindred disorders (lithæmia) may cause neuralgia, partly by alteration of the blood, or by direct irritation of the nervous centres, and partly by inducing neuritis. These neuralgias are sometimes bilateral and fugitive, sometimes lasting, according to their origin. Visceralgias are also common in the gouty, but it is an open question whether this may not be, in part, because of the neuropathic tendency which is intimately connected with gout.

Chronic nephritis, and the vascular and nutritive disorders associated with it, may cause various neuralgias, both superficial and visceral.

Syphilis likewise causes neuralgias both in its early and

Digitized by Microsoft®

in its late stages, and here also the manner of its action may be either direct or indirect. It is also worthy of reflection, in a given case of this kind, whether the cause of the neuralgia may not be the antisyphilitic treatment which has been used, and not the disease itself.

The neuralgias due to *mineral poisoning* are apt to be bilateral, or to attack different parts successively. The arthralgias and visceralgias of lead poisoning belong in this category, but will be treated of with the other symptoms of the same origin.

Peripheral irritations cause neuralgia which is sometimes confined to the region irritated, sometimes located in distant parts, and are always to be carefully sought for and eliminated, since, even when they constitute only partial causes, they may be practically responsible for the seizures. Carious teeth may excite neuralgia in other branches of the fifth pair besides that directly irritated.

Injuries, such as *severe jars*, as in railroad accidents, or *blows*, even when they do not apparently injure any particular nerve, may excite severe neuralgias, and the same is true of *emotional excitement or mental overstrain, acute or chronic*.

The pains due to the pressure of *cancerous growths*, or other *tumors*, and *aneurisms*, though often classed as non-neuralgic, are really not always to be distinguished from neuralgia by any intrinsic characteristic. The diagnosis is often established by other indications of the presence of morbid growths, and, so far as the nervous system is concerned, is rendered probable by unusual persistence and severity of the pain, the occurrence of signs of neuritis, such as marked atrophy, contracture, anæsthesia, etc. A *bilateral distribution* of the pain is also suggestive of such a cause, pointing either to pressure upon symmetrical nerve trunks at their exit from the spinal canal, or, in the case of the brachial nerves, to a symmetrical enlargement of lymphatic glands. Neuralgia of the fifth pair has occasionally been traced to aneurism of the internal carotid.

Cold and damp weather and the atmospheric changes preceding and accompanying storms are fruitful causes of neuralgic attacks, acting no doubt in part by depressing the general nervous tone, and in part by causing congestion or anæmia of the sensitive cutaneous nerve fibres, and even increasing any neuritis that may be present.

It is proper to speak here of the relation to neuralgia of such general influences as *age* and *sex*.

Childhood is usually considered nearly free from neuralgia, but this is only true of the typical, peripheral neuralgias of protracted course. The so-called "growing pains" of childhood may fairly be called neuralgic, and children suffer from visceral neuralgias, and sometimes from typical migraine or periodical headache.

Puberty brings an increased tendency to migraine and headache, which then usually lasts until the age of forty-five or fifty. The neuralgias of acute anæmia and chlorosis occur also largely at this period, though anæmia is probably also a cause of some of the pains of childhood.

All neuralgias are most common in *middle life*, mainly because it is then that the nervous strains incident upon increased cares and exposures of all kinds make themselves most strongly felt, and act both directly and indirectly by increasing neuropathic tendencies.

Neuralgias *rarely begin in old age*, and when they do they are very intractable, perhaps because they depend upon tissue degenerations in the nervous and vascular systems. It is, however, a noticeable fact to which the writers can bear testimony that, in spite of their severity and persistency, the neuralgias of old age sometimes unexpectedly disappear for longer or shorter periods, or even permanently.

The *female sex* shows a relatively great liability to the neuralgias of neuropathic origin; the *male sex* to neuralgias of peripheral origin.

General Symptomatology.—All neuralgias have in common a greater or less tendency to *periodic* and apparently spontaneous *recurrence*, but the degree to which this periodicity is seen varies greatly.

The most regular and spontaneous periodicity is met with in the malarial neuralgias and in those of mainly neurosal origin, especially migraine and the periodic headaches. The visceralgias recur less regularly, but their outbreaks also are frequently, to all appearance, spontaneous, that is, due to cyclic changes within the nervous centres themselves, and not to irritation from without. In both cases this tendency to cyclic outbreaks may be interrupted, and attacks precipitated, by various causes.

Besides these neuralgias of regular recurrence, persons of neuropathic constitution are often liable in some degree to spontaneous attacks of pain, of relatively short duration; but the typical superficial neuralgias of protracted course, as a rule, show but little of this tendency to periodical and spontaneous recurrence, so characteristic of the more distinctly neurosal neuralgias. They may recur, it is true, but this is either from a recurrence of their underlying cause, or because the neuritis, which is usually present as an important complication, if not a cause, does not entirely pass away and excites the neuralgia to fresh outbreak.

Almost all neuralgias have in common a tendency to excite *vaso-motor* and *trophic changes*. The *vaso-motor* phenomena are most marked in cases of the migraines, which are often characterized by a marked pallor or redness, or both in turn, of one side of the head. These vascular changes have, in fact, been widely believed to be the essential feature of migraine, and to be directly responsible for the pain: but this is, in the writers' judgment, a mistaken opinion. Similar symptoms are seen in the other neuralgias, especially those of the neighborhood of the eye, and probably attend, if they do not cause, the changes in the glandular secretions (tears, urine, mucus, gastro-intestinal fluids), which are also very common near the seat of any severe neuralgia, and even at a distance from it. The writers have seen a sharp attack of intercostal neuralgia, for instance, of short duration and due to acute fatigue and exposure, pass entirely away with a copious discharge of limpid urine, such as often attends the close of a migrainoid attack. Finally, migraine is often unattended by any noticeable vascular changes.

The *trophic* phenomena are most marked in the case of the superficial neuralgias, and range from such changes as are obviously due to neuritis (herpes zoster and other cutaneous eruptions, muscular atrophy, and the like), to the more temporary alterations which are partly of vaso-motor origin, or due to irritation of trophic or glandular nerves, and partly of unknown origin (œdema of the skin, changes of color and increased brittleness of the hair, temporary muscular enfeeblement, impairment of the eyesight, possibly even glaucoma, etc.). The cases associated with herpes are occasionally accompanied by palsy of the muscles innervated by the affected or related nerves. The trophic changes in migraine are but slight.

It is often included in the definition of neuralgia, that the pain is confined to the *region of distribution of one or more nerve branches*, but this applies only to the neuralgias of the superficial nerves.

It is common to most neuralgic attacks that the pain is *intermittent or remittent* in severity. When a continuous dull aching is present, it may be suspected that the neuralgia is complicated by a material degree of neuritis.

For further examination of their symptomatology, neuralgias may be divided into:

1. Superficial neuralgias.
2. Migraine and the periodical headaches.
3. Visceralgias.
4. Unclassified neuralgias of irregular distribution.

1. The *superficial neuralgias* are limited to the course and areas of distribution of one or more nerves or parts of nerves supplying the skin and adjacent structures.

The principal varieties are: (1) The neuralgia of the fifth nerve, of which there are several subdivisions; (2) the neuralgia of the occipital nerve; (3) the neuralgia of the cervico-brachial nerves; (4) the neuralgia of the abdominal nerves; (5) the neuralgia of the anterior crural nerves; (6) the neuralgia of the sciatic nerves.

Digitized by Microsoft®

All these neuralgias have the following peculiarities in common: The attacks are sometimes brief, often of relatively long duration.

The *brief attacks* generally occur in persons of neuralgic habit, and under these circumstances are more likely to attack the facial, intercostal, or abdominal nerves than the brachial or the sciatic. They may occur spontaneously, or from some special cause, as fatigue, excitement, or exposure, and may pass away after a night's sleep, like an attack of migraine, the disappearance being sometimes attended with a copious secretion of urine. Gouty persons are also subject to brief neuralgic attacks; and there are other obscure disorders of the nutrition (so-called lithæmia, and the like), of which the same is true, though it is by no means easy to say whether the neuralgia is really secondary to the nutritive disorder, or both are symptoms of an underlying nervous affection. Vaso-motor changes are common in acute attacks of brief duration, leading to pallor or redness of the skin. Such attacks are often attended also by increase, preceded at times by diminution, in the secretion of neighboring glandular organs, and occasionally by œdema of the skin. These phenomena are perhaps of vaso-motor origin. Hyperæsthesia of the skin is often present.

The *attacks of relatively long duration* usually come on gradually and are recovered from gradually. The pain is not felt over the whole area of distribution of the nerve, but has its points of election, and from these points the pain spreads or darts farther. Sometimes, and especially in the case of sciatica, the course of the nerve itself is the painful region, and it is believed that it is the sensitive nervi nervorum ramifying in the main nerve trunk that are mainly or even alone concerned in the neuralgic process in such cases. General tenderness along the nerve points to neuritis, but the localized tenderness which has just been referred to, and which is confined to certain definite spots (*points douloureux* of Valleix), probably do not necessarily have this significance. These spots of tenderness are apt to coincide with the foci of pain, but do not always do so. They are usually found where the nerve emerges from a bony or fibrous canal, or where it begins to ramify in the skin. The pain is often accompanied by subjective and objective *disorders of the sensibility.* The former consist in sensations of prickling and numbness, or of heat or coldness.

These sensations often precede or follow as well as attend an attack. When they overlast the attack a long time, and especially if they are sharply localized, they usually indicate that the nerve has been the seat of the inflammation. The *objective* disorders are of the nature either of hyperæsthesia or of anæsthesia. The former is usually seen at the beginning or at the height of an attack, and the latter usually later. A persistent impairment of sensibility points to destruction of some of the sensitive nerve fibres from neuritis.

Trophic changes in the skin and its appendages, or in the muscles, are common and usually point to neuritis. The muscles near an acutely painful region are sometimes temporarily paralyzed without apparent cause. The hair of the eyebrow and scalp has been known to become blanched during a neuralgic attack of the fifth nerve, recovering its color later. This change of color is probably due to the penetration of air into the hair shafts.

TREATMENT OF SUPERFICIAL NEURALGIAS (*vide* also sections on Neuralgia of the Fifth Pair, Sciatica, etc.).—*Causal Treatment.*—The importance of removing the causes of the neuralgia is evident to every one, but it is not equally recognized that it is necessary to remove partial causes, no matter how many there may be. Such causes are principally: (1) Exposure to alterations of temperature and weather, to be met by suitable clothing, change of occupation, temporary removal to a drier, or, it may be, to a more relaxing climate; (2) peripheral irritations, either near or remote from the seat of pain; (3) neuritis, primary or induced (*vide* below under Electricity and Surgical Operations); (4) dyscrasias, such as gout, syphilis, diabetes; (5) fatigue, anæmia, lack of proper nourishment. It should be remembered in this connection that a state of health sufficient for ordinary purposes may not be sufficient as counteractive of neuralgia. What would seem excessive nourishment (see under Neurasthenia), combined, if necessary, with massage and rest and cod-liver oil, arsenic, and large doses of iron, if well borne, is useful in a large number of cases.

Symptomatic Treatment.—This comprises the means used to relieve pain and to counteract the neuralgic condition and the irritability of the nervous centres. The important remedies of this class are: Quinine, aconitine, (*vide* under Neuralgias of the Fifth Pair), salicylate of sodium, opium, the coal-tar products, croton chloral, electricity, hydriatic treatment, counter-irritation, vibration, and local manipulation in the affected region, and surgical operations. The method of use of these remedies is too familiar to need comment, except that of the last five.

Electricity is mainly useful in the form of galvanism, which is usually applied with one pole of the battery near the nerve centres, and the other near the nerve trunks of the affected part. Its special indications are for the temporary relief of pain and in the treatment of neuritis. It is probably indifferent which pole is used in the painful area, but, on the other hand, it is of great importance, in acute neuralgias, that the current should flow without interruptions and that the strength should not be suddenly increased or diminished. The electrodes should be large and well nourished with warm water. The strength of the current should not be so great as to irritate the skin, and thereby excite, instead of soothe, the patient. Moderate variations of the current strength, as made by sliding the electrodes slowly over the skin, sometimes increase the effect. In chronic cases strong currents are sometimes useful, and it is not necessary to observe the same caution as to interruptions of the circuit.

Static electricity is of value in some cases of neuralgia given either in the form of sparks or in the unipolar method of charging and discharging described by Dr. Morton.

Hydriatic (or *Thermic*) *Applications* (so far as they can be used outside of special institutions) consist in the use of the local and prolonged wet-pack (*vide* under Sciatica); local bathing and showering, or, in chronic cases, the filiform douche; prolonged general warm baths (useful as a general sedative); prolonged application of ice (*vide* under Sciatica); or the application of dry warmth in the form of hot sand or salt bags.

Counter-irritation may be applied in the form of stimulating liniments and ointments, mustard, blisters, the actual cautery, or spray of ether, or of chloride of methyl.

The best liniments are those containing aconite and laudanum combined with alcohol and chloroform, or strong solutions of menthol (ʒ i. to fl. ℥ i.). A strong aconitine ointment (one part to eight) is said to be useful, but must be employed with great caution. These agents act not only by the irritation which they set up, but probably by lessening the sensitiveness of the skin as well. In the same way cocaine, instilled into the eye, will sometimes relieve pain in the globe and in the supra-orbital region.

Prolonged and rhythmical vibration or manipulation over an affected nerve, best done by an instrument designed for that purpose (Granville's hammer), is said to be of service, and similarly some forms of headache can often be relieved by prolonged manipulation or vibrations with the finger tips.

Surgical Operations comprise deep injections of irritants, such as water or chloroform; removal of a portion of the nerve (neurectomy); stretching of the nerve; and extirpation of the nerve roots or of the Gasserian ganglion.

Injections of chloroform have been followed by alarming results, probably by its introduction into a vein, though this is a rare event. The best way to avoid it is first to introduce the needle alone until its point comes

www.libtool.com.cn
Digitized by Microsoft®

near the nerve, and not to inject the chloroform if any blood appears. The dose is from ten to twenty minims.

Nerve-stretching is appropriate for mixed nerves, and has been applied to almost all the superficial nerves of the body, including the intercostals. Its effect is partly to diminish the conducting power of the sensitive fibres, and thereby diminish the irritations reaching the nerve centres, partly to alter the condition of nutrition in the nerve trunks, and partly, no doubt, to exert a so-called inhibitory action with regard to the neuralgic condition of the nerve centres. The operation is not often followed by serious results if done under proper antiseptic precautions, but when large nerves are treated in this way morbid changes are occasionally set up in the spinal cord. This operation has found its greatest sphere of usefulness in sciatica, to which heading (p. 247) the reader is referred.

Neurectomy and *extirpation of ganglia* are considered under facial neuralgia (p. 246).

Special Forms of Superficial Neuralgia.

Trifacial Neuralgia.—The fifth pair is more frequently affected in neuralgia than any other nerves. Conrad's statistics of seven hundred and seventeen cases of neuralgia showed thirty-three per cent. to be trigeminal. This frequency is due, in part, to the exposed position and extensive distribution, many attacks being induced by disease of parts supplied by its different branches, as the teeth, nose, eyes, etc.

The forms of trigeminal neuralgia may be clinically divided into three types:

1. Supraorbital neuralgia.
2. Reflex neuralgia.
3. Tic douloureux.

This division may not in a way be absolute, since many attacks of supra-orbital neuralgia, though implying a neuropathic constitution as a *sine qua non*, may be brought on by peripheral irritations, and thus in a way be reflex.

Furthermore, supra-orbital neuralgia may exist as a type by itself, or the nerve may be involved in either of the other two forms.

1. *Supra-orbital Neuralgia* may be divided into: A. Those manifested by constant pain. B. Those in which the attacks are intermittent. C. The periodic attacks.

A. The pain in supra-orbital neuralgia may be *constant* and persist for several weeks or more. In this case its character is generally described by the sufferer as twisting or boring, and radiates from above the eye to the vertex. During the attack there is generally tenderness over the supra-orbital foramen. Such attacks are frequently found with diseases of the eye, especially iritis and glaucoma, and may be benefited by treatment of these conditions. The supra-orbital neuralgias associated with herpes are apt to be very persistent.

B. The *intermittent* type is generally characterized by making its appearance in the early morning and continuing with great severity till two or three o'clock in the afternoon, when the pain subsides, only to recur on the following day. This type, from its intermittent character, was once thought to be always due to malaria; and the fact that large doses of quinine, given three or four hours before the paroxysm is due, has generally proved beneficial seemed to corroborate this view.

In this locality, at least, it is usually a sequel of a coryza which extends upward, causing a catarrhal inflammation of the frontal sinuses, to which the ophthalmic division sends sensory fibres, and free drainage of these sinuses is essential to recovery. This intermittent type, however, may persist as a neurosis or habit neuralgia long after its original cause has gone.

C. The supra-orbital neuralgias which come *periodically* at more or less regular intervals form a group by themselves, the attacks often being foreshadowed by marked gloom and depression of spirits.

These attacks may be accompanied by eye symptoms and vomiting, and after lasting a definite period of time disappear. This migrainoid type derives its name not only from the character and periodicity of the attacks, but from the fact that it sometimes alternates in the same patient with typical attacks of migraine. Moreover, there are patients who suffer from migraine from childhood till adult life, when the character of the attacks changes and the migrainoid neuralgia takes the place of the old headache.

2. *Reflex Neuralgias.*—The characteristic of the reflex neuralgias is that they stay until the cause is removed. The most common form is that due to diseases of the teeth, especially where cavities have led to exposure or disease of the pulp. They may also be due to changes in the alveolar processes, or to swelling and thickening of the periosteum of the bony canals through which the nerve passes. More rarely they are caused by aural disease.

The pain in this group of neuralgias is usually constant or jumping, though it may be paroxysmal, simulating tic douloureux. It is possible that in some cases true "tic douloureux" begins as a reflex (tooth) neuralgia. Against this, however, is the fact that the teeth have so often been drawn without benefit. Moreover, these reflex neuralgias often occur before the middle period of life.

3. The third type of trifacial neuralgia, *Tic Douloureux*, is to be sharply distinguished from the other forms. It begins in middle or advanced life and runs a characteristic course. The pain is located in the area of distribution of the second, or the second and third divisions of the fifth nerve, more rarely involving the first or all three branches. It generally starts in the upper lip or at the side of the nose, and is described at times as flashing upward along the nerve, at times as radiating outward like a pinwheel. It is paroxysmal in character, the attack being lightning-like in onset, of extreme severity, and lasts about a minute, disappearing as abruptly as it came. During the attack there is flushing of the affected side of the face, with twitching of the muscles, and often there are lachrymation or salivation and a serous discharge from the nose. The lightest touch or draught of air will precipitate an attack, while the patient dare not speak and refuses to eat solid food, so great is his dread of the pain.

These paroxysms come from several to many times a day, for periods of a few weeks or months, after which the patient may be free from them for an interval of several months. It is oftentimes a striking feature in these attacks that the pains occur with great frequency during the day, while the sufferer may go to bed at night and sleep unmolested.

The rule is for these alternations between periods of pain and periods of relief to persist over long intervals of time. It is not uncommon to see patients who have suffered for fifteen or twenty years.

Pathology.—Tic douloureux has been considered due to degenerative changes in the Gasserian ganglion, as described by many investigators. Coenen, however, maintains in a recent article that these changes are secondary to peripheral operations previously done for relief of the pain.

Degenerative changes of varying intensity have been shown to exist in the nerves by many investigators. Whether these are the original cause of the pain, or whether they result from the continued severe paroxysms cannot be decided with certainty.

Some investigations have demonstrated an endarteritis in the vessels supplying the affected nerves, at times resulting in marked diminution in the lumen of the vessel. This may be a factor in many cases by giving rise to nutritional disturbance.

The *treatment* of tic douloureux is medical and surgical, and the former should be given a thorough trial before the latter is undertaken. If the medical treatment is successful, the immediate attack is prematurely terminated, but permanent cure is rarely experienced. This, however, is often all that is accomplished through the peripheral operations, though the results of the latter are more constant.

Besides the so-called "overfeeding," and the observa-

Digitized by Microsoft®

tion of general hygienic rules, the following drugs, out of the large number recommended, give the best results:

Aconitine (the crystallized alkaloid) is best given at first in doses of gr. $\frac{1}{100}$ to gr. $\frac{1}{300}$ every two to three hours, in pill form or solution; then if no unusual susceptibility shows itself, in doses of gr. $\frac{1}{200}$ to gr. $\frac{1}{100}$ or even more, though this amount is rarely reached without the patient's complaining of severe tingling and numbness of the extremities and sometimes of a sense of coldness and faintness. A moderate degree of these symptoms does not contraindicate the continuance of the treatment for some days, or even weeks, if the patient is otherwise in good health and is constantly under observation. Tincture of aconite root can be substituted if necessary, but is less certain in its action.

Gelsemium may be given in any reliable preparation until the signs of physiological action appear, the most characteristic being a drooping of the eyelids.

Castor oil certainly does good in some cases, if given every morning on rising, in half-ounce doses, increased to one ounce as he patient becomes accustomed to the drug. Purgative effects often fail to appear after the first few doses, hough the remedial action persists.

Iodide of potassium has many advocates and certainly does seem to do good in some cases, especially if given in moderately large doses.

Strychnine in massive doses is recommended by Dana, in cases of not over four or five years' standing. He keeps the patient quiet in bed and administers the strychnine subcutaneouly, starting with gr. $\frac{1}{30}$ once a day, and gradually increasing until gr. $\frac{1}{6}$ or gr. $\frac{1}{5}$ is reached. This should be given for four or five days, and then the dose gradually diminished. This should be followed, he says, by an iodide-of-potassium treatment.

Opium given in gradually increasing doses till the pain is controlled is advocated by La Tourette, who claims very satisfactory results from it.

Surgical treatment consists in the *peripheral operations*, which may be regarded as palliative, and the extirpation of the Gasserian ganglion, which gives permanent relief in most cases.

The peripheral operations generally consist in cutting down on the offending nerve—the customary points being at the dental canal, infra- or supra-orbital foramen, or sphenomaxillary fossa—and in twisting and pulling out as much of the nerve as possible. This procedure usually gives freedom from pain lasting from a few months to two years. Occasionally a patient will be relieved for three or four years, and some cases of cure have been reported. The average relief from forty-three such operations, recently collected by the writers, was ten months. Three or four peripheral operations had often been performed on the same patient. The *Gasserian-ganglion operation*, first done by Rose, ten years ago, is regarded as the only means of affording permanent relief, though it is attended with considerable danger, owing to the location of the ganglion and the liability to hemorrhage. Horsley has performed this difficult operation twenty-one times, with only two deaths. The reports of two hundred and one operations, collected by Türk, show that in seventeen per cent. of the cases the patients died as a direct result of the operation; ninety three per cent. of those who recovered were considered to have been permanently cured. This percentage of cures is, however, open to some criticism, for sufficient time had not elapsed after some of the operations to make it sure that a cure had been effected. On the other hand, the recurrence of pain after some of the earlier operations may have been due to the incompleteness of the operation.

Spiller and Frazier have recently brought forward the question of division of the sensory root of the ganglion as a radical operation. This was tried twelve years ago by Horsley and resulted fatally. It has never been attempted since then until last year, when it was recommended as being a simpler operation, and as attended with less danger of hemorrhage than the extirpation operations. It is an important recommendation of this procedure that it leaves the motor root intact. The only uncertainty is that regeneration of the sensory root may later take place with return of the pain. How great this danger is can be shown only by time.

Occipital neuralgia is generally an affection of the occipitalis major and minor and the great auricular nerves. It approaches the neuralgias of the fifth nerve in severity and in its tendency to assume the epileptiform type, and often superadds itself to them, especially to the supra-orbital variety, by extension. In its typical form it is commonly unilateral, and this, together with its history and the character of the pain, usually serves to distinguish it from the occipital headache met with in neurasthenia, chronic nephritis, intracranial tumor, and eye strain.

In the *treatment* a diligent search should be made for organic disease of the vertebræ and surrounding tissues. This failing, salicylates or coal-tar products or the above-named antineuralgic remedies may be employed for relief of the pain. Galvanism often acts favorably in this form of neuralgia. If, however, the pain proves intractable and relief cannot be obtained from medicine, surgical interference may be resorted to and resection of the nerve may be done. Intradural resection of the posterior root has recently been performed with successful results.

Brachial and Cervico-brachial Neuralgia has the distribution which its name implies, and the characteristics of a typical superficial neuralgia. Like the rest, it is often due to injury or neuritis, the latter sometimes being secondary to affections of the shoulder-joint, but it may occur simply as a sign of debility or a neuropathic diathesis, or from concussion accidents and the like.

The pain usually centres in foci, such as the point of the shoulder blade, the insertions of the deltoid, the neighborhood of the supinator longus muscle, the wrist, and more rarely the fingers, and radiates upward or downward from these points. The hand and even the whole arm are often the seat of sensations of numbness and tingling due perhaps to congestion of the nerve, or to disorders of the circulation of vaso-motor origin, or to neuritis, and these sensations sometimes substitute themselves for the neuralgic pain.

The *pathological diagnosis* should take into account the possible presence of cancerous cervical glands, pachymeningitis cervicalis, spondylitis deformans, and Pott's disease (bilateral pain, muscular atrophy, rigidity of the neck), or of angina pectoris.

Occupations and professions requiring constant use of certain groups of muscles of the arm often give rise to extremely obstinate and troublesome pain, which, however, does not follow the course of any particular nerves, but is generally increased by motions involving the much-used muscles. It is not a muscular affection, but probably comes best under Oppenheim's head of psychalgia brachii.

The chief point in *treatment* of this form is rest of the affected member, but recovery is accelerated by general tonics and static electricity. The treatment of brachial neuralgias in general is that of the other superficial neuralgias. Surgical treatment by nerve-stretching is possible at any point, even as high as the cervical plexus.

Intercostal Neuralgia is one of the commonest neuralgias of debilitated subjects, especially women, and of persons of nervous temperament. The intercostal nerves are surrounded at their origin by large venous plexuses, and are thus liable to suffer from any sluggishness of venous circulation. Neuralgia from this cause is more frequent on the left side, since there is greater obstacle to the emptying of these vessels. It is also met with in connection with brachial neuralgia, or with neuralgia of the thoracic or abdominal viscera. It is often associated with herpes ("shingles"), and then the pain may occur two or three days before the appearance of the rash. It may pass off with the healing of the vesicles or may persist for weeks or months. In many cases of intercostal neuralgia there are tender points at the seat of the pain, which is usually greatest over the side of the chest at the exit of the lateral nerve branches. Often a tender point is also felt at the exit of the dorsal or anterior branches. The path-

Digitized by Microsoft®

ological diagnosis should consider intrathoracic cancer, Pott's disease, aneurism (all of which would be likely, but not certain, to cause bilateral pain), and pleurodynia. In all cases the heart, pleura, stomach, and gall bladder should be carefully examined for disorders. The treatment should be at first directed toward improving the debilitated and anæmic condition so often present. Blisters are often useful in cases not associated with herpes. Iodide of potassium, salicylates, or quinine in large doses may be given with benefit.

www.libtool.com.cn

Ilio-lumbar Neuralgia needs no separate notice except to remark that it is often found in connection with affections of the uterus and ovaries.

Anterior Crural Neuralgia is not very common and needs no separate notice. The pathological diagnosis should consider the possibilities of hip disease, osteo-arthritis of the spine, and pelvic tumor.

Meralgia Paræsthetica.—The symptoms of this condition, as the name implies, consist of paræsthesia and pain, and these are located over the area supplied by the external cutaneous nerve of the thigh. The surface involved usually extends from the crest of the ilium to the knee, on the outer aspect of the thigh, though only part of this may be affected. There is frequently a tender pressure point just below the anterior superior spine of the ilium. This disease may result from trauma, but is commonly seen in people with a rheumatic or lithæmic tendency. The treatment consists in hydrotherapeutic measures, massage, and remedies directed against the constitutional tendencies. The disease is not a very serious one, but often resists treatment almost indefinitely.

SCIATICA is one of the commonest and severest varieties of superficial neuralgia, both on account of the exposed position of the nerve, which renders it liable to injury both within and without the pelvis, and also from causes which are more subtle and less well understood.

The causes of sciatica are: local injuries; primary neuritis, as in herpes zoster; exposure to sudden alterations of heat and cold; intrapelvic diseases, even when they do not directly involve the nerve itself, as uterine disease for example; gout, diabetes, and the various constitutional affections which impair the quality of the blood or the general nutrition. Cancerous disease within the pelvis may, by pressure, give rise to pain which is hardly to be distinguished at first from sciatica, and this cause should be suspected if the symptoms are bilateral, unusually persistent, or attended with marked signs of neuritis, such as anæsthesia, localized numbness, and pricking, muscular wasting, and especially if other nerves are involved at the same time. Chronic inflammation of the tissues around the hip may also give rise to pains which could be readily mistaken for sciatica. It is very important, and usually perfectly easy to distinguish the pains of locomotor ataxia from those of sciatica. The former are bilateral, not confined to the distribution of the sciatic nerve, momentary in duration, and usually affect, by preference, small spots in the fleshy parts of the limb, the knee, or the heel, or dart down the leg and disappear again.

Osteo-arthritis of the spine is commonly mistaken for sciatica, the pain in this affection being caused by involvement of the nerve roots in the inflammatory exudation along the vertebræ. This gives rise to pain which is often distributed in patches, along the areas of distribution of these roots, over the front and side of the thighs and legs. Many of the curvatures described as sciatic scoliosis by many authors are really signs of osteo-arthritis, and are due to muscular spasm on the unaffected side of the spine, in attempts to relieve the involved nerve roots from pressure. This condition is recognized by the marked muscular rigidity on the unaffected side of the spine. The motion of the vertebral joints is quite free when the patient bends toward that side, while the lumbar spine remains perfectly rigid on any attempt to bend forward or toward the affected side.

Symptoms.—The distribution of the pain in sciatica may be coextensive with the distribution of the whole nerve, but oftener it centres in certain regions which may vary as the attack goes on. Such are the sacral region, the neighborhood of the sciatic notch, the back of the thigh, the popliteal space, the calf, the outer side of the leg, or the outer side and dorsum of the foot. Sometimes the course of the nerve itself is marked out by darts of pain. "Tender points" are found at the sacro-iliac synchondrosis, the sciatic notch, the popliteal space behind the head of the fibula, behind the outer malleolus, and often at other places as well. Some cases of sciatica are of short duration and seem to be of purely functional origin, while in others neuritis plays a large part in the production of the symptoms, causing persistent pain, loss of sensibility, cutaneous eruptions, coldness, and wasting, and increased pain on motion, voluntary or passive. Even where these symptoms are absent, and where the pain is fully intermittent, the absence of neuritis cannot be confidently asserted in cases of long standing.

The *prognosis* of sciatica depends upon its cause. Except when it is dependent upon some temporary irritation, however, it lasts usually for weeks or months, or even longer, and is liable to relapses and recurrences. The sciatica of diabetes is said to be peculiarly obstinate, even if the usual symptoms of the disease are not severe.

The *treatment* of sciatica varies with its causation and its stage (*vide* also under General Treatment). The removal of diathetic taints, absolute rest, superficial blistering, counter-irritation by a spray, of ether or of chloride of methyl, the local wet-pack followed by vigorous rubbing with cold water and by warm applications. If access is obtainable to a hydrotherapeutic institution, the Scotch douche may be used with benefit. Galvanism with long-continued mild currents, cutaneous faradization, are always in place, and turpentine, quinine, iodide of potassium, or salicylate of sodium in full doses, may be given in fresh cases for limited periods with some hope of relief.

In chronic cases the remedies may be proportionately vigorous. The galvanic applications may be as strong as the patient can bear, and special pains taken to localize the current on the nerve, at the sciatic notch, and in the popliteal space, by pressing the electrode inward, and seeking to excite referred sensations at the periphery. It probably makes no difference whether the anode or the cathode is employed over the nerve, or whether the current is occasionally interrupted. Indeed, a series of sudden reversals of the current are often of service. Static electricity in the forms previously mentioned (*vide* General Treatment) is of value in these cases. Deep massage along the nerve, even if painful at the time, may be of great value, probably by removing inflammatory exudations. Ice-bags may be applied continuously along the course of the nerve, and deep injections (*vide* under General Treatment) are serviceable, though not without danger. When other means fail, "nerve-stretching" may be used, and, indeed, under proper antiseptic precautions, it is not a dangerous operation in itself. It has, however, been shown that the effects of the traction are felt in the spinal canal, and myelitis has in a few instances been excited. A substitute operation is the so-called "bloodless stretching," in which, the patient being under ether, the thigh is forcibly flexed on the pelvis and the leg extended at the knee, and this position maintained for some minutes. That the nerve can be stretched in this way is beyond question; but it may be doubted whether the method is really safer as regards its secondary effects than that of the exposure of the nerve by a single incision, and the use of a measured amount of direct traction, upward and downward in turn.

Coccygodynia.—This is a severe neuralgic pain in the region of the coccyx, occurring almost exclusively in women. The pain is marked on sitting or during defecation and micturition, and the end of the coccyx is exquisitely tender to moderate pressure. The condition occurs almost always in neurotic individuals, but may be brought on by trauma or difficult labor. It frequently runs an obstinate course and is best treated by tonics, counter-irritation, hydrotherapy, or galvanism. Excis-

Digitized by Microsoft®

ion of the coccyx may be performed, but often fails to give relief.

It might be well to speak here of the importance of examining the feet in all cases of vague and obscure pains in the legs, knees, thighs, and hips, for the greatest variety of sensations, from constant dull aching or burning to sharp neuralgic twinges, may have their origin in weak or broken-down arches, and immediate relief may be obtained from proper treatment. Metatarsalgia is but one instance of this sequence.

Migraine—*vide* the article on *Headache*.

VISCERAL NEURALGIAS.—The visceral neuralgias are of great importance, both on account of the suffering which they cause, and because of their constitutional significance. They occur, like the other neuralgias, partly from general nervous causes, such as fatigue, gout, and other constitutional diseases of the nutrition, and especially the neuropathic tendency, and partly as a result of functional and organic disorders of the viscera. To what extent actual neuritis occurs as a cause is not yet known, but it is certain that chronic inflammation of the nerves is often set up by organic affections of the organs, such as the heart, to the neighborhood of which the pain is referred.

The pain of the visceral neuralgias is usually deep-seated, vaguely located, and dull, but at the same time intense and prostrating, and sometimes attended with faintness, nausea, sweating, and often disorders of the circulation and secretions. Though not sharply localized visceral neuralgias take their name from the organ in the neighborhood of which they seem to be situated, as the pharynx, the œsophagus, the heart, stomach, liver, bowels, ovaries, uterus, rectum, testis, etc.

Angina Pectoris (see Vol. I., p. 227), though a true visceral neuralgia, is so often a symptom of heart disease that it is usually described in that connection. It may, however, be mentioned here that it occurs not infrequently, though hardly in its severest forms, entirely independently of organic disease. In a case known to the writers, for instance, it occurred during a considerable period on the slightest exertion, such as rapid walking, in a lady suffering from temporary debility from overwork, and was each time attended with breathlessness, and with pain and numbness in the left arm, yet eventually passed entirely away. Various other such cases are on record.

Dull pain felt during the intervals of the attacks is looked upon as perhaps indicating neuritis of the cardiac nerves, but in such cases cardiac disease probably exists as well.

It is an interesting question whether nitrite of amyl, which acts so well in angina pectoris of organic origin, would be beneficial also in the functional cases.

The *treatment* should be, in the first instance, tonic, and in the attacks itself diffusible stimulants and analgesics would be in place. Besides the outspoken diseases of the heart, increased vascular tension should be sought for, and signs of Bright's disease, as well as functional irritability of the nervous cardiac apparatus, such as result from physical overstrain and from abuse of tobacco and other cardiac stimulants. Under these circumstances digitalis or other heart tonics might be indicated.

When the attacks are of frequent occurrence electricity, either by the superficial use of the wire brush and faradic current or in the form of galvanism, is said to be of service, as is also counter irritation over the chest.

Gastralgia (gastrodynia, cardialgia, gastric colic) is perhaps the most common form of visceral neuralgia, and in its widest sense covers a variety of sensory symptoms, ranging from sensitiveness and pain accompanying the act of digestion, and perhaps accompanied with signs of delayed or imperfect digestion, yet not due to gastritis or ulcer, to severe paroxysms of pain entirely unconnected with the digestive process.

The *etiology* is similar to that of the other visceral neuralgias, but it is met with in young children oftener than the rest. It is especially common in gouty subjects and in persons of nervous, mobile temperament, and the writers have several times seen slight symptoms of this general character at the time of the menopause.

The pain in gastralgia is felt primarily at the epigastrium, and radiates thence upward in the direction of the œsophagus, and through toward the back, besides laterally through the abdomen. Allbutt ("Visceral Neuroses") says that it may be associated with anginiform attacks, and it may be attended likewise with superficial neuralgia of the abdominal walls and other parts of the body, as the face.

The relation of gastralgia, as well as of the other sensory visceralgias, to the functional affections of the viscera is very important and calls for further study. There is no question that many digestive disorders which attend gastritis, or even cancer, may also occur as pure neuroses, and it is likewise evident that there is a whole range of nervous disorders, sensory and motor, of which these purely painful affections form only one division.

Treatment (*vide* also under General Treatment).—The vices of nutrition and assimilation should be corrected, such as are seen in gout, and evinced also by a variety of nervous symptoms often described under the head of lithæmia, and sometimes attended with the presence of free uric acid or oxalate of lime in the urine. Constipation should be corrected and the diet regulated, but not necesarily reduced to a very small amount, even if digestion is attended with pain. Sometimes it will be found that one kind of food will agree better than another without apparent reason, and, when the gastralgia is associated with serious disorders of the digestion, it may be that a patient who does very badly at home will get on very well if removed from home and placed under the care of a nurse. Indeed, the most significant fact to bear in mind is that, as a rule, it is a general nervous condition which needs treatment, rather than the special symptoms.

Belladonna and the antispasmodics, such as asafœtida and valerian, besides the gastric stimulants, are of more service in gastralgia and the other visceral neuralgias than their anæsthetizing influence would suggest. Morphine must be resorted to if necessary. Deep pressure sometimes gives temporary relief.

It is not necessary to review in detail the neuralgias of the other abdominal viscera and of the genital organs. Attention has already been called to the fact that affections of the *uterus and ovaries* may give rise to neuralgiform affections in distant parts of the body, or in the distribution of the lumbo-abdominal nerves; but besides this the uterine and ovarian nerves themselves are sometimes the seat of neuralgia, not to speak of the pain of dysmenorrhœa, which is, doubtless, in part, of that character.

Neuralgia of the liver is said to be sometimes attended by swelling of the liver and by jaundice; but here, as frequently in the case of the abdominal neuralgias, it is difficult to guard carefully enough against mistaking an organic disease for one of the concomitants of a neuralgic attack.

Neuralgia of the anus and rectum is a well-marked and painful affection, and the tendency to it may be hereditary. The seizures may come on spontaneously, especially after fatigue, or may be excited by slight irritations, such as the passage of hardened fæces, or may follow sexual intercourse or seminal emissions. The pain may be accompanied by clonic spasms of the perineal muscles. The rapid injection of hot water into the rectum, or hard and deep pressure with some smooth object will often stop the attack, which otherwise is liable to last for one or two hours.

Besides the more or less typical neuralgias there are a number of other painful affections, of spontaneous origin or provoked by trifling irritations, and of unknown pathology, which occur usually in persons of neuralgic or neuropathic tendency, and are therefore fairly to be classed as neuralgic, although they do not follow the distribution of a special nerve. Such are pains referred to the skin, the muscles, or the joints, not attended by signs

Digitized by Microsoft®

of local inflammation or by any appearance of local congestion or anæmia, and capable of coming and going with greater or less rapidity. The "growing pains" of anæmic children are of this order, together with a similar affection sometimes met with in adults; also the "general neuralgia" of anæmic patients, and those dermatalgias which are not due to the organic irritation of sensitive nerve fibres, such as occur in locomotor ataxia and neuritis. The arthralgic pains of false (hysterical) joint disease might perhaps be included.

The therapeutic indications are, primarily, to improve the constitutional and nutritive condition, and to relieve the pain by local or general baths or liniments, or by anodynes.

James J. Putnam.
George A. Waterman.

NEURASTHENIA.—The term *neurasthenia* ("*nervousness*," or *nervous weakness or prostration*) has come into general use to indicate certain states of the nervous system of which the anatomical basis is unknown, but which are characterized, on the one hand, by a lack of vigor, efficiency, and enduran , affecting usually a large number of the nervous functions, and, on the other hand, by signs of active derangement, which in part seem to occur as positive symptoms, and in part are due to a failure of the mutual support and control which the different parts of the nervous system aff rd each other in health.

In its widest sense the term neurasthenia is used as covering the groups of symptoms usually indicated by such names as *nervous prostration, spinal irritation, neuropathic or neurotic diathesis.* Even abnormal mental states, such as mild degrees of melancholia and "morbid fears," are often classed as neurasthenia, but their relation to a more serious malady should not be forgotten.

Sometimes neurasthenic symptoms are secondary to localized pathological affections in one or another part of the body, and this fact has led some observers to recognize in neurasthenia only a symptom of errors of refraction, lithæmia, uterine disease, organic disease of the brain or cord, and the like. It would, however, be easy to push this attempt too far, and the writers certainly believe that neurasthenia is a useful term to indicate states of nervous weakness which are often primary, and which even when secondary usually imply a pre-existing basis of functional disease.

Since a sense of fatigue is generally one of the chief symptoms in the neurasthenic individual, it is possible that an actual pathological change in the nervous system is the cause of this condition. Hodge has shown that fatigued animals show degenerative changes in the protoplasm and nuclei of their ganglion cells, and some such process may be the underlying cause of certain types of neurasthenia. On the other hand, the tired feeling may be a purely psychological symptom or the result of an inharmonious working of a brain of which the several parts may be structurally normal.

It has been said with some truth that hysterical and hypochondriacal persons are always neurasthenic, but that neurasthenic persons are not always hysterical or hypochondriacal; and hysteria has also been spoken of as "nervousness" crystallized into the form of a definite disease. Although typical cases of neurasthenia and of hysteria differ widely, yet the two affections run into each other, and the same patient may, at the same moment or at different periods, show symptoms of both diseases.

While it is true that neurasthenia should be looked upon—relatively to hysteria and insanity—less as a distinct disease than as a departure from health, and as an expression of the mode in which degeneration of the nervous powers first shows itself, still it must not be forgotten that neurasthenics present certain symptoms which are almost as characteristic as those of any other of the neuroses.

SYMPTOMATOLOGY.—The symptoms called neurasthenic are conveniently divided into those which arise as a sign that the patient is unequal to the ordinary tasks of a fairly healthy person, and those which are manifestations of a morbid action on the part of the nervous system over and above the indications of simple inefficiency. These can be called, for convenience' sake, *negative* and *positive* symptoms, respectively. Thus, the *negative* symptoms are those of fatigue or pain arising without sufficient cause, but still due to effort, and, within certain limits, proportionate to the effort made; while the *positive* symptoms are nervous outbreaks or signs of excessive weakness of special kinds, occurring almost independently of effort, and at least out of proportion to it. The negative and positive symptoms may run into each other, as, for example, when, in the place of an oversensitiveness or self-distrust, we find an ever-present sense of anxiety or "morbid fear"; or, when a simple incapacity of the eyes to bear a prolonged strain passes into a high degree of photophobia or asthenopia; or when instead of a simple feebleness of the digestion we have an active nervous dyspepsia, and so on through the whole range of nervous functions. Usually the symptoms of special nervous derangement appear on a background of general nervous weakness. It sometimes happens, however, that some one symptom is so prominent that it seems to stand almost alone. In like manner some cases present almost exclusively mental symptoms, and cannot bear a slight emotional strain without great suffering and yet may show more than ordinary physical strength and endurance; while with others by far the most prominent symptoms affect the muscular and vegetative functions.

The late Dr. George M. Beard, to whom we owe many valuable observations on this subject, attempted to base upon this fact a division of neurasthenic symptoms into cerebral and spinal, but this is premature and is not based upon sufficiently well-grounded reasoning.

Individual cases of neurasthenia vary so greatly in the grouping of their symptoms that it will be better to study the symptoms themselves one by one rather than to attempt to describe different types of the disease. It is, however, worth while to bear in mind that the term "irritable weakness" aptly indicates the character of many of the conditions met with.

Special Symptomatology.—The *temperament* of neurasthenics is essentially mobile. They are usually quick, versatile, and sensitive, and may be talented and intellectual, though they rarely have the robustness and endurance necessary for great success. Often a sense of nervous weakness and effort is present, which gives rise to self-consciousness and self-distrust, and finally to a suspiciousness toward others, and to a vague feeling of isolation and dread.

A healthy organism should respond to calls upon it with an elasticity like that with which the cushion of a billiard-table responds to the blow of the ball.

With neurasthenic patients this is usually not the case. A trifling impression arouses an exaggerated *inward reaction* in the form of egotistic or self-distrustful ideas, while the *outward reaction* is correspondingly feeble or unduly delayed. Slight obstacles seem mountains, and some patients can hardly persuade themselves into a decision or an exertion, although under the influence of some slight excitement they may act with energy and intelligence. A similar undue inward reaction is shown in other departments of nervous energy besides the strictly mental. Thus, even with patients who seem well-balanced and of good self-control, trifling causes may excite or maintain neuralgia or dyspepsia, disorders of the sleep, collapse of strength and the like, with provoking and inexplicable readiness.

Instead of the vague sense of anxiety and dread, special "morbid fears" are often present. The variety of these fears is endless. Among the most common is the fear of large open spaces, fear of crowds, of walking alone, or riding in railway trains, fear of contamination from touch, fear of taking food and the like, fear of becoming insane.

In many cases, of course, these symptoms mean something more serious than neurasthenia; but often, on the other hand, they represent the natural or "reasonable"

Digitized by Microsoft®

fears of healthy persons acting upon a morbidly sensitive temperament. Such persons begin by being vaguely timorous and distrustful and end by having special "fears."

Sometimes the neurasthenic temperament approaches the hysterical temperament, in exhibiting gross selfishness and fondness for making a display and attracting attention; but, as a rule, neurasthenic patients are docile, patient, self-sacrificing, and intelligent, or if they are selfish, it is because of a life of semi-invalidism, or of habits of painful introspection, and is not due to a lack of moral sense, which is rather characteristic of the hysterical temperament.

On the other hand, it is not uncommon to see neurasthenic patients exhibiting some of the special disorders which are usually considered as peculiar to hysteria, such as hemiplegic disorders of sensation or motion, alteration of the deep reflexes, photophobia, etc.

The *digestive disorders* of neurasthenia may vary from simple feebleness of the digestion, or digestion perhaps sufficiently well performed but attended with pain, to disturbances almost or quite indistinguishable from true catarrhal affections. Such patients are also very subject to visceral neuralgias, which, when they affect the nerves of the digestive tract, are often attended with marked signs of functional disorder of the corresponding organs.

Other symptoms are likewise met with, which are hardly to be called digestive, though affecting the digestive organs. Such are attacks of nausea, not due to the taking of food; attacks of diarrhœa, or, more strictly, discharges of watery fluid, coming on suddenly as a result of slight nervous fatigue or excitement, and passing away as quickly, or perhaps permanently yielding to an improvement in the patient's general condition; or discharges of large quantities of mucus, in masses or strips, with or without fæces.

These nervous disorders of the digestion are of so much practical importance and interest that they have of late years attracted much attention.

Often the only conclusive diagnostic sign to distinguish them from organic affections is the fact that they do not improve under the usual treatment of gastro-intestinal catarrh, chronic ulcer, etc., which they simulate, while they are greatly influenced by improvement in the patient's general condition and surroundings. Thus, a removal of the patient from home, or his subjection to the "rest cure" (see under Treatment), may effect what the most careful dietetic and medicinal treatment had failed in years to accomplish.

Finally, it is not to be forgotten that in any given case the symptoms may be in part of organic, in part only of functional origin.

In some cases the neurotic dyspepsias are so severe that, what with the nausea and vomiting and general distress and pain, the patient's strength is greatly reduced, and his life may even be threatened. In two cases under the care of one of us these symptoms were attended with symptoms of insanity of the melancholic type, and with suicidal tendency.

Sensory Disorders.—The most important type and instance of the disorders of special sense is simple *asthenopia*, which is often so severe that some patients, who may have otherwise no more serious trouble than a certain delicacy of health, are, for years together, almost totally unable to use their eyes for any fine work. This may be due in part, or wholly, to weakness of the muscles of convergence and accommodation, and is sometimes remarkably relieved by a systematic method of exercise, combined, if necessary, with suitable glasses. Other patients are much annoyed by sparks of light floating in the field of vision, or by glimmering sensations similar to those which often precede sick headache. Tinnitus aurium is sometimes found, but this is less likely to be a prominent symptom in simple neurasthenia than to occur as a sign of irritation of the nervous centres, such as may imply toxic conditions of some sorts.

Neurasthenic patients are subject to *neuralgia*, or to neuralgiform attacks, both superficial and visceral, and usually shifting and fugitive in character (see under Neuralgia), and to periodical headaches.

Backache, sometimes with excessive sensitiveness to light pressure over the spine, is very common, and may be associated with some slight uterine disorder, though it may also occur alone. It is usually increased by exercise, and especially by using the arms above the height of the shoulders, and by anything which causes general fatigue.

The pain of the neurasthenic backache may be along the vertebral column, or farther outward, especially about the sacral and iliac attachment of the large muscles of the back. It is often provokingly obstinate under local treatment, and disappears the soonest under such treatment as best agrees with the patient's general condition. Sometimes, in the class of cases to which the name of "spinal irritation" was formerly given, the sensitiveness of the back to slight pressure, combined with the local pain, is the most prominent symptom present. In such cases, besides the local sensitiveness, the pressure gives rise to special peripheral sensations, thoracic, pulmonary, abdominal, etc., according to the level at which it is made.

Pain in the muscles and joints is not uncommon, without it being possible to discover any sign of typical rheumatism, gout, or neuralgia, and this symptom, like so many others, is capable of attaining a prominence out of proportion to the rest. Thus, in the case of a gentleman of whom one of us has had the care, intense muscular pain in the legs, beginning after an interval of quiescence of half an hour and rising steadily in severity, is brought on so easily by the least exertion that the patient has been obliged for many years to give up walking almost altogether.

Another very common variety of pain, not precisely neuralgic, is a distressing *sense of pressure at the vertex or occiput*, often combined with tenderness and stiffness of the muscles of the neck. This is usually a sign of some special fatigue or strain, but some patients suffer from it almost continuously, and find in it a source of serious distress.

Paræsthesia ("prickling and numbness") in the extremities, or assuming the hemiplegic distribution, is likewise often complained of, but it is to be remembered that the same symptom is met with in debilitated women who are not especially neurasthenic, in cases of chronic lead poisoning and in other conditions.

Palpitation and *cardiac irregularity* are not uncommon, and we have seen one or two patients with peculiar *disorders of the respiratory rhythm*. One of these was cured by systematic exercises of the respiratory muscles.

The writers have noticed that *cardio-respiratory murmurs* occur with great frequency in young male neurasthenics of the thin, poorly nourished type. Sometimes this murmur is very transitory.

Nervous cough is sometimes a marked and obstinate symptom, and may last for months, without any (local) cause whatever, and then pass quickly away. These coughs, like many other of the neurasthenic symptoms, are associated at times with slight irritation in the nose, or pharynx, or ears, or in the genital tract. Sometimes, instead of the cough, we find a veritable *asthmatic seizure*, and in this connection the semineurotic origin of hay-cold is to be remembered.

It is not uncommon to see in patients who cannot be called other than neurasthenic an almost *periodical recurrence of symptoms*, such as migrainoid headaches, attacks of exhaustion, sleeplessness, and the like. Usually some slight overexertion or fatigue seems to act as the immediate cause of these outbreaks, but the cause and the effect are out of proportion to each other.

Neurasthenic patients are, as a rule, very easily affected by *stimulants* of every kind, and at the same time they often feel rather a desire for them. In spite of this, they are by no means always inclined to be immoderate in indulgence, and need not necessarily be advised to abstain altogether from their use.

Digitized by Microsoft®

Insomnia, in one or another form, is almost always present at one time or another, and forms one of the most important symptoms of neurasthenia, on account of its indirect effects as well as for the suffering that it occasions. The early morning period of wakefulness is a time when the depression of spirits, from which neurasthenics often suffer, makes itself most prominently felt.

www.libtool.com.cn

It is also true, however, that such patients usually sleep more than they themselves believe, and that they do not suffer from an amount of real fatigue at all in proportion to their sensations in the morning after a night of restlessness and unpleasant dreams. Excessive *drowsiness* is a less common symptom than insomnia, and, though annoying, less serious in its results.

Vaso-motor Symptoms.—Besides the fact that nervous patients are prone to blush easily, a fact which usually indicates only a general emotional excitability, they often show symptoms which are fairly attributable to a morbid action of the vaso-motor nervous system. Such are the vascular spasms of *digiti mortui*, chilliness, and urticaria, and the vascular dilatation which causes erythematous patches, burning, and swelling of the hands and feet, and even chilblains.

The general sensation of heat, which leads certain patients to go about with light clothing in the coldest weather, is probably not really of vaso-motor origin, nor have we a right to attribute to this cause the attacks of profuse sweating on the slightest exertion from which neurasthenics occasionally suffer, or the watery discharges from the bowels already alluded to. It is more probable that these are neuroses of the glandular nerves themselves.

The "hot flashes," which are often such a serious annoyance, are sometimes attended with visible flushing of the face, hands, etc., and with distressing sensations of fulness and pulsation in the head—symptoms which are probably vaso-motor in character; but sometimes they are unattended by any such phenomena, and, so far as we know, are neuroses of sensation only, and analogous to the many other morbid feelings with which such patients are liable to be attacked.

The *sexual functions* are apt to be disordered in various ways. Impotence, premature ejaculation, sense of prostration after sexual intercourse, and similar symptoms, are much oftener met with among neurasthenic than among healthy persons; and it is with persons of this class, both male and female, that irritations in the genital tract produce, indirectly, their most serious results. The sexual instincts in neurasthenics are usually active and practically normal, the grave perversion of desire belonging rather to the category of insanity.

The *general nutritive condition* of neurasthenic patients may be good and their muscular strength quite up to the normal. They are, however, usually spare in flesh, and if, as often happens, their appetite, digestion, and power of assimilation are disturbed, they may become greatly reduced in health. On the other hand, many of these patients, and some of the worst cases, are over-fat, and often at the same time anæmic.

The *metabolic functions* are apt to be at fault, and indeed, strictly speaking, it is often impossible to say whether the nervous or the nutritive disorder comes first. Free uric acid, urates, or oxalate of lime are often found in the urine; the phosphates are liable to be increased, and the quantity of the urine may be increased or diminished, or both in turn.

Where such conditions as these are traceable to functional diseases of the liver, or to a gouty inheritance, or to the absorption of products of imperfect digestion, the nervous symptoms which occur may fairly be considered to be secondary.

On the other hand, there is little or no doubt that the nervous weakness may be the primary affection, and, even in many cases of gouty parentage, it is probable that the impaired nervous system is often a direct inheritance.

The *pupils* are apt to be unusually large in moderate light, and very mobile.

The *voice* sometimes shows signs of the universal tendency to irritability and weakness, and lacks the normal firm, sonorous quality.

The *hair, teeth*, and *skin* of neurasthenics are said by Beard to suffer from premature denutrition; but this is difficult to prove with certainty, though it may be admitted as possible that a lack of nervous vigor should show itself in this direction as well as in so many others.

The following sketch by Dr. Clifford Allbutt may be quoted as giving an excellent picture of one variety of neurasthenic patients.

After speaking of the contrast between the neurotic and the hysteric types, and the absence in the former of the exaggerated selfishness and feebleness of purpose, which are characteristics of the latter, he says: "He enters your room with a brisk step and a quick, observant eye. You see a slightly built, meagre man, of sallow complexion, or, if colored, with the color painted high upon the cheek-bone. The cheeks and temples are hollow, and the temporal arteries are visible under the lean skin, which often shows tanned markings, deepened during attacks of pain; the hair is straight, fine, and sparse upon the scalp; the features are sharp, often prominent; the lips thin, and the skin dry; and some remnants of eczema may be seen about the chin or ears. The bodily frame is lightly and often finely built, the bony fingers and wrists and the visible sinews and radials betraying the absence of fat. Here and there, in later life, a knotty knuckle may tell of gouty parentage. The pulse, when most tranquil, usually ranges between 70 and 80, and accelerates on the least excitement. The clavicles and ribs in like manner are prominent, and the heart's apex may be seen to beat sharply before the eye; its systole to the ear is likewise short and sharp, and the second sound very audible over a wide area. The limbs are small, but often very sinewy; such persons are as active as birds, and the absence of fat in their muscles often gives to these, in states of health, the quality of hardness under the hand. Their conversation, again, is lively and voluble, often keen and brilliant, but impressionable rather than imaginative; you may generally notice in them, too, some little blinking, twitching, or tattooing trick which quickens as thoughts and cords come faster. His companions will tell you that he is subject to great fluctuations of the animal spirits; gay even fascinating, in society; brisk, orderly, and thorough in business; but at home dejected or fretful. He is a small eater, a light sleeper, and a worn worker. These persons are the heirs of every true neurosis, from insanity to toothache; and, on the whole, when we consider the infinite perturbations of intermarriage, it is surprising how true they run, or how clearly you may detect the neurotic strain in mixed descendants. Of their visceral neuroses I shall have to speak hereafter, and would only say now that in both sexes of them migraine, stomachache, and windy colic are frequent and eminent, and receive the name of dyspepsia; and in the women are added to these uterine and ovarian neuralgias and hyperæsthesias. To call these suffering women of the neurotic type hysterical is to confuse all due acceptance of names, and, what is worse still, is to confuse the real relations of things. The neurotic woman is sensitive, zealous, managing, self-forgetful, wearing herself for others; the hysteric, whether languid or impusive, is purposeless, introspective, and selfish. In the one is the defect of endurance, but in the other defect of the higher gifts and dominion of mind."

Besides this, which might be called the intellectual type of neurasthenia, there is another, in which the element of feebleness, mental and physical, is the predominating characteristic. Many of the "fat anæmics" belong to this class, and in them, in lieu of excitability and misdirected force, the nervous symptoms suggest those of hysteria, of a mild type, in their exaggerated response to slight irritations.

Influence of Age and Sex.—Neurasthenia, unlike hysteria, is almost as common among men as among women. In its full development it is a disease of pu-

Digitized by Microsoft®

berty and middle life, but signs of the neurasthenic tendency are to be found in early youth, consisting in a general mobility of temperament, oversensitiveness, and precociousness, and the occurrence of special nervous symptoms, such as insomnia, somnambulism, chorea, night-terrors, etc.

www.libtool.com.cn

Still later, especially in young women from sixteen to twenty years of age, various other signs of nervous weakness may make their appearance, such as headache, backache, extreme and causeless lassitude; and these years constitute in fact a critical period, during which many persons are nervous invalids, who may later reacquire good health. Very often these periods of prostration are attributed to special causes, such as falls, overexertion, and the like, but these events are rarely more than exciting causes, and are not necessary to the result. Such attacks are often diagnosticated as anæmia, or chlorosis, or as "spinal concussion," but their failure to respond to ordinary tonic or local treatment, and the fact that they are often relieved by means addressed to the general nervous condition, point to their true origin. Of course, true anæmia may complicate this condition of nervous prostration, or even act as its cause, and may require its own special treatment; but the important point is that the nervous element in the case is not to be overlooked.

Course and Prognosis.—Neurasthenia is not likely to shorten life to any marked degree, unless it causes severe disorders of the nutrition. It does, however, occasionally happen that a patient dies from no other apparent cause than a prostration of the nervous functions.

On the other hand, neurasthenia is not, as a rule, an acquired disease, but an inherited weakness of the nervous system, and in this sense is not, strictly speaking, curable. It is, however, often possible to remove the patient from the circumstances which call out the manifestations of this weakness and thus practically to effect a cure. Sometimes even with the best of treatment partial improvement and frequent relapses are the rule. Constant watchfulness and good judgment rarely fail to bring some amelioration. Acquired neurasthenia may pass away with the cessation of its cause, or may overlast this for many years, as in some cases of railway accidents, or similar injuries, and in the case of neurasthenia of the menopause.

Neurasthenic symptoms sometimes constitute the first stage of outspoken mental disease, but, on the other hand, patients may be severely neurasthenic all their lives long without suffering from more serious mental trouble.

The relation of neurasthenia to organic disease is obscure, but very important.

The fact that neurasthenia is so often associated with disordered metabolism, and with impaired nutritive vitality of many tissues of the body, and that its course is often marked by the frequent occurrence of functional disturbance of the heart and vaso-motor system, makes the inference natural that the nervous disorder must sometimes pave the way, or, more strictly perhaps, mark the commencement of more or less serious organic affections.

Our opinion in the matter, as regards chronic neurasthenia, is at present limited to this inference. We do, however, know that *acute* mental strain may be the starting-point of such affections as chronic nephritis, diabetes, and probably many other disorders.

Diagnosis.—This has been sufficiently covered by the foregoing sections. It cannot, however, be amiss to recall again that the presence of neurasthenic symptoms only shows that the efficiency of the nervous system has received a blow of some kind, and leaves still before us the task of seeking the real source of mischief. It is especially important to recognize that some organic diseases, such as disseminated sclerosis or cerebral tumor, may cause neurasthenic or hysterical symptoms, and perhaps for a time no others.

Etiology.—Neurasthenia must be distinctly counted as belonging to the great family of neuroses, and is inheritable from parents suffering from any one of this group of affections. It stands also in a similar relationship to various constitutional diseases, such as gout, phthisis, anæmia, and other less well-marked disorders of the nutrition (lithæmia), as well as to all of the many influences which impair the vigor of the nervous system, including even organic disease of the nervous centres.

Chief among the causes that tend to develop and maintain the neurasthenic tendency may be mentioned an irregular, unhealthy, and overstimulating life, especially at the time of childhood and puberty, when the emotional nature is so active; and, at a later time, exposure to responsibility and worry greater than the patient is fitted to bear.

Some patients are, in fact, neurasthenic only in relation to their surroundings, and appear healthy when under conditions more suited to their powers and character.

One-sided, or unsystematic education in youth, or in early professional life, which makes success in later years possible only at the cost of undue strain, is a fruitful source of mischief.

It has been said that neurasthenia is more common in America than elsewhere, and that the cause of this consists partly in the peculiarities of the climate, partly in the fact that we have been brought rather rapidly under the influence of an overstimulating state of civilization. These statements and arguments are suggestive, but cannot be asserted positively without further proof.

Among the special causes of neurasthenia may be mentioned disease of the uterus and ovaries in women, and of the prostate gland in men; also concussion accidents, fright, grief, or mental strain. A condition of nervous exhaustion, which may be called acute neurasthenia, may be due to excessive overwork, as has been already alluded to.

Some of the more local neurasthenic symptoms may also be excited by irritations in the sensitive mucous tract, especially of the nose, and by errors of refraction in the eye.

Treatment.—The first indication for treatment is, of course, to remove special causes of the neurasthenic state, such as disorders of metabolism, anæmia, errors of refraction, disease of the uterus and prostate, chronic fatigue, etc. It is often found, however, that this attempt is less successful than had been anticipated, because the true relation between the symptoms and their causes had not been made out.

It is also noticeable that the neurasthenic condition can be largely relieved by appropriate general treatment, even while the irritation that caused or maintains it still persists.

The treatment of uterine disorders especially may, on this ground, often be postponed to advantage until the general health has been partially restored by other means, or at least until the confidence of the patient has been fully gained; for, except under these conditions, the local treatment may do more harm than good.

It is certain that benefit often follows gynæcological operations on neurasthenic subjects, but it is often difficult to say why this happens, and equally difficult to obtain reliable statistics for estimating the relative number of good and of poor results.

One powerful factor with some patients is the sense that now, at last, the real cause of the long illness has been found. This cause can be counted on the most in cases in which many other treatments have been tried in vain.

It would, however, be unreasonable to deny that pelvic disorders, even when painless, may act as foci of morbid excitation, so that where operations are not likely to do harm they may be advised. The fact should never be forgotten, however, that no surgeon should operate in this class of cases without the advice of a judicious physician or without having made a careful study of neurasthenia.

It should be noted that the statement made above as to the effect of operations as the starting-point of new encouragement, or hope, applies equally to operations

Digitized by Microsoft®

www.libtool.com.cn

on other organs, as the nose, or eyes, or to the overcoming of morbid mental habits and analogous influences. It is a dangerous practice, however, to undertake operations with encouragement as the sole excuse.

The next indication is to secure that perfection of nutrition for the nervous system which will enable it to work at its best; and to place the patient in surroundings suited to his individual powers and needs. Where this is distinctly impossible, the aim should be to enable him to bear the strain imposed upon him with as little cost as possible.

As has been said, many persons are neurasthenic only in relation to their surroundings, and enjoy good health when leading a simple life, or while in the country, though they cannot stand the excitements and responsibilities of the town. Many persons break down under the strain of emulation and competition, who can do good and active work if freed from these influences. They must learn to estimate their endurance justly, and not to be misled by their excitable temperament into attempting too much.

When the needed change cannot be secured, the time of labor should be shortened by an hour of recreation and rest in the middle of the day, or by early bed hours. Patients who do not sleep well should not work later than the early evening hours.

If exercise can be taken freely, this furnishes an immense resource, where rightly used, and even when vigorous exercise is not well borne, as is very often the case, especially if the patient is at the same time exposed to other sources of fatigue, neurasthenics almost always gain by being a great deal in the open air. The subject of exercise is so important that it must be worked out in detail for each case. Where horseback-riding, rowing, tennis, etc., are to be had, the problem is relatively simple; but for ladies, and in winter, recourse must be had to such amusements as battledore, some thorough system of calisthenics, frequent short walks, and the like, and to rubbing with a wire or hair flesh-brush, either dry or moistened with water, or salt and water.

Neurasthenic patients are, from the want of confidence in their strength, apt to fall into unsystematic habits of life, or to be without a regular occupation, and both these wants should be carefully met. Frequent short intervals of recreation, and frequent change of scene are useful, unless incompatible with proper regularity of life. Almost any change is apt to work well at first.

The strict observance of regular hours of work, rest, and exercise often saves much wear and tear, and makes the difference between an efficient and a useless person. Even a very feeble person can have some real interest, and take some real part in the work of life.

Patients with feeble nervous systems are usually better when taking as much food as their digestions allow, and that is commonly more than their appetites would suggest.

In spite of "delicate stomachs," if the nervous strength is withdrawn from other directions and turned to the service of the digestion, such persons can usually greatly increase their food without much difficulty. As a rule, the most suitable kind of food is that which agrees best with the digestion, but in certain cases great benefit is obtained from special diets. (See article on *Gout.*) In some cases of sick headache I have found a distinct advantage in alternating between the albuminous and the vegetable diets.

Thoroughly cooked and strained oatmeal, or Mellin's food, with warm milk, can be taken as a matter of routine, in the forenoon and afternoon (not always well borne at this latter time) and at bedtime, or one or two eggs, boiled or raw, or scraped meat mixed with bread-crumbs and slightly broiled, may be substituted.

The *medicinal* treatment of neurasthenia is mainly useful in correcting the disorders of nutrition with which the nervous symptoms are associated. Of the drugs that are thought to improve, directly or indirectly, the vigor of the nervous system, only arsenic, cod-liver oil, nux vomica, and perhaps the glycerophosphates, are of much value.

The temptation is strong to exaggerate the anæmic element in neurasthenia and to give iron largely, but this is not advisable, unless distinctly indicated.

Neurasthenia may be the indirect result of conditions which are susceptible of benefit through the so-called *organotherapy*, and the range of this mode of treatment is still *sub judice*. Here, too, in many cases, the physician who believes in the specific treatment cures through the encouragement which his conviction carries.

Electricity, in the form of galvanization of the head, general faradization, the static breeze, and electric baths are sometimes of distinct service. The simplest method of using electricity is to pass the faradic current from the neck to the feet and hands alternately, for fifteen minutes or half an hour, daily.

For the more complicated methods, the special text-books must be consulted.

A judicious *hydrotherapeutic treatment* is after all the very best method of exciting the vaso-motor activity of the nervous system and thus setting better nutritive processes on foot. Its success depends upon the choice of methods by which a good "reaction" will be brought on and maintained. Usually some warm application (blankets, hot cabinet, hot bath) is used to warm the skin and then the stimulus of cooler water follows. At this stage friction, or some other form of mechanical stimulation, is very useful.

A "powerful reaction" is a good thing, but it is a very easy matter to fatigue a very delicate patient, and so one must often be content with a moderate reaction. A good system of graduated baths might embrace:

1. The blanket pack followed by hard friction with cool or cold water.
2. Hot baths followed by quick, strong affusions.
3. The dripping sheet, preceded or not by the wet pack.

For some cases of neurasthenia, where the patient is able to go about and take part in active duties, the above treatment is sufficient; for others, further means are needed to meet special symptoms, or to overcome an amount of prostration such as confines the patient to the bed or house, or totally unfits him for any active employment.

In order to treat successfully the *mental symptoms* of neurasthenia, the physician must thoroughly win the confidence of his patient by attention, kindness, and by showing self-confidence and authority, and must provide suitable employment for his thoughts, as a basis for special advice.

The *nervous indigestion* is in most cases best treated by a careful attention to the general condition, including, if necessary, removal from home, etc.

The food should be simple and digestible, but it is striking how little these cases, in spite of the violence of the symptoms, are benefited by attention to the digestive functions, such as is required in true catarrhal gastritis.

A similar statement may be made with regard to the other special symptoms of neurasthenia. They may all be helped somewhat by such symptomatic treatment as would naturally suggest itself, but as a rule they are to be taken as a sign of general nervous weakness, and require general treatment.

It has been said, with truth, that neurasthenic patients are cured, not by physic, but by the physician.

Nervous indigestion is often benefited by electricity (faradic or galvanic current, or both combined in one circuit) used as a general tonic, or applied directly to the epigastrium, with one pole at the back of the neck.

Such patients should also abstain from active exercise after eating.

The cases of pronounced invalidism require a special consideration. Although they need to be treated on the lines which have been already laid down, it is for them that the so-called "rest-cure," elaborated and practically invented by Dr. S. Weir Mitchell, is so pre-eminently useful. For patients who are so reduced in strength,

Digitized by Microsoft®

and nervous vigor and self-confidence that they become more deeply implicated the more they struggle to free themselves, the rejuvenation often secured through this means is remarkable. For some of them, it is the moral element in the "cure" which is the most important, for others the opportunity for nutritive improvement.

www.libtool.com.cn

The "rest-cure" consists of several parts—seclusion, generally with removal from home and complete rest in bed, during six or eight weeks; forced feeding, massage, and electricity. This system may be modified or simplified to suit special needs, but in severe cases there is no part of it that can be safely omitted. The complete removal from responsibility and care, from unhealthy and familiar surroundings, the anxiety of friends, and most of all, from a vague sense of responsibility as regards themselves, which the enforced rest involves, gives a feeling of mental repose, like that afforded by a long sea voyage to a person simply fatigued by overwork.

The *food* consists at first of skimmed milk,* given in small quantities every two hours, and rapidly increased until the patient takes two quarts daily. Solid meals are then gradually added, so that soon the patient is taking a very large quantity of nourishment, and in the absence of all other calls upon his nervous strength, digests it perfectly well.

Massage† is given once, or even twice, daily, taking the place of voluntary exercise. The latter is absolutely forbidden, even to the extent of feeding one's self, with the result that the patient, having no excuse for feeling tired, soon loses even the apprehension of fatigue. After a time muscular exercises are added to the massage, and eventually substituted for it, and the patient is gradually allowed to walk.

As the patient is obliged to lie constantly in bed, it is important that her time should be sufficiently occupied, and this is not difficult, especially if she has a private nurse of the proper temperament and experience.

The following was the daily schedule of a patient of the writer's, and may be taken as a typical specimen: 7 A.M., small cup of black coffee; patient allowed to brush her teeth. 7:45—Hands and face washed, fire made by nurse. 8—Breakfast, which at this time consisted mainly of a pint of gruel (taken slowly, and kept warm when desired, by table-lamp). 8:30—Sponge bath; bed made. 9:30—Windows open for half an hour (the weather being cold the patient was warmly covered except for the face. 10—Breathing exercises; food. 10:30—Hands and feet exercise, following by reading aloud for fifteen minutes. 11:30—Temperature of body taken, and patient rolled in blankets. 12—Food. 12:30 Bath given. 1 P.M.—Massage and rest. 3—Hair brushed, reading aloud. 4—Food; breathing exercises. 7—Hands and feet exercise; patient arranged for the night. 8—Food. 10—Food.

In some cases we have given patients breathing exercises to carry out every hour or two; and, as a commencement of more vigorous exertion, have had them roll over from one side of the bed to the other a certain number of times. These hints from personal experience are offered, not as constituting material modifications of the treatment as laid down by Dr. Mitchell, but as likely to prove useful where the full treatment cannot be carried out, which so often happens.

The cases which are the most benefited by the rest-cure are those in which the nervous symptoms are caused or maintained mainly by simple anæmia or impaired nutrition. Even in the purely "nervous" cases, however, an occasional treatment of this kind often gives a chance to start fresh once more, which is invaluable.

Some cases are not helped at all in this way. This may often be suspected beforehand, but sometimes a fortnight's trial must be given them (Playfair), and if this is explained to them in advance, they are usually stimulated to do their best.

Perhaps the most indispensable condition for success is that the physician should gain and keep the fullest confidence of his patient. How he will best accomplish this must depend, in the end, upon his own character and temperament. If he never allows himself to be discouraged, and insists on the systematic brushing aside of morbid thoughts on the part of his patients, he will often be agreeably surprised at the results which he initiates.

James J. Putnam.
George A. Waterman.

NEURINE.—Neurine is a ptomaïn which is frequently found in meat and other articles of food which have undergone a certain amount of decomposition. Chemically, it is a derivative of ammonium hydroxide; is, in fact, trimethyl-vinyl-ammonium hydroxide, $N(CH_3)_3CHCH_2OH$. It is often confused with choline; the latter, however, is trimethyl-oxyethyl-ammonium hydroxide, $N(CH_3)_3C_2H_4OHOH$. Neurine was first prepared synthetically in 1858 by Hoffmann by treating trimethylamine and ethylene bromide with silver oxide or potassium hydroxide. The name neurine is due to Liebreich,[1] who is usually credited with having obtained the substance by boiling protagon for twenty-four hours with concentrated barium hydroxide. According to later investigators, however, it seems very probable that Liebreich was dealing not with the vinyl base (neurine) but with an impure preparation of the oxyethyl base (choline).[2] More recently neurine has been obtained by Brieger[3] from putrefying horse, beef, and human flesh. Brieger also obtained it from human brains by boiling with barium hydroxide; it appears probable, however, that neurine occurs in the brain only as a result of putrefactive changes, for Gulewitsch could find no trace of it in perfectly fresh ox brains.[4] It has also been obtained from decomposing mushrooms; such mushrooms are very poisonous.

The genesis of neurine in the above cases is very obscure; it may be that it is formed from the cholin which is a part of the lecithin and protagon molecule (see articles on *Cholin* and *Lecithin*). Bayer showed that choline chloride could be transformed into neurine by chemical processes; this was done by heating the choline chloride with concentrated hydriodic acid and red phosphorus and then treating the iodine compound so formed with silver oxide. On the other hand, neurine may be converted into choline by first making the iodine compound and then heating this with silver nitrate.[5] Schmidt and Weiss,[6] moreover, found that choline and its salts could be converted into neurine by the action of micro-organisms. It is a significant fact that neurine is almost always accompanied by choline; hence it is probable that the latter is, as a rule, derived from the former by the loss of a molecule of water.[7]

Neurine is a colorless syrup soluble in water and alcohol; it has a strongly alkaline reaction and forms easily soluble salts. When heated, either dry or in concentrated solution, it decomposes with the formation of trimethylamine ($N[CH_3]_3$). With platinum chloride neurine forms a double compound $(C_5H_{12}NCl)_2.PtCl_4$, which is insoluble in alcohol; this compound is soluble with difficulty in hot water, from which it crystallizes in small octahedra. These crystals melt, with decomposition, at 195.5–198° C. and contain 33.6 per cent. platinum. A similar double salt is formed with gold chloride. A substance isomeric with muscarine may be obtained by treating neurine with hypochlorous acid and then decomposing the resulting compound with silver oxide.

Neurine may be isolated from organic liquids containing it by the method of Brieger. The method is essentially as follows: To an alcoholic extract of the material is added a saturated solution of mercuric chloride in alcohol. The precipitate (which contains most of the neurine) is washed with alcohol and water and then decomposed by hydrogen sulphide; the mercury sulphide is filtered off and the filtrate concentrated and taken up in alcohol

* Milk mixed with half its bulk of oatmeal jelly answers an admirable purpose.

† The writer has found the application of the wet pack or blanket-pack for an hour or less, as recommended by Dr. Mary Putnam-Jacobi ("Massage and the Wet Pack in the Treatment of Anæmia"), a useful adjunct to the massage.

Digitized by Microsoft®

The neurine is precipitated by an alcoholic solution of platinum chloride; the precipitate is washed on the filter with a little cold water (which dissolves the choline salt of platinum chloride) and the neurine salt is recrystallized several times from hot water.

www.libtool.com.cn

Neurine is a very poisonous substance. 40 mgm. (injected subcutaneously) per kilogram body weight is fatal to rabbits. The symptoms are very similar to those caused by muscarine. A few milligrams of the hydrochloride injected into a frog causes within a short time complete paralysis of the extremities with, a little later, a diminution of reflex excitability. The heart is greatly slowed and finally stops in diastole, as in muscarine poisoning; atropine will cause the heart to begin beating again. As small a quantity as two milligrams is fatal for most frogs. After the administration of neurine to mammals there are profuse salivation, dyspnœa, diarrhœa (due to increased peristalsis), great slowing of the heart and a fall of blood pressure, and finally convulsions and death from failure of the respiration. Before the depression of the heart and respiration there is often a brief period of stimulation, due probably to the sensation of nausea. Cats seem to be much more sensitive to neurine than are rabbits or guinea-pigs; when a cat is poisoned with this substance there is, in addition to the symptoms noted above, a marked secretion of alkaline sweat from the ball of the foot. Many of the symptoms of neurine poisoning are antagonized by atropine, but even after the administration of this drug there remains a condition of general paralysis. The fatal dose for animals is ten times as great when the poison is given by the mouth as when injected subcutaneously.

Under the name of "neurine" a weak solution of choline was formerly occasionally used as a solvent for diphtheritic membranes. *Reid Hunt.*

NEURITIS.—Neuritis is inflammation of a nerve trunk or its branches. As a localized affection involving a single nerve it generally attacks certain nerves, such as the branches of the brachial plexus in the upper extremities, or of the lumbar or sacral plexus in the lower extremities. The cranial nerves may also be attacked by neuritis. When only one nerve trunk is affected, the condition is usually spoken of as "isolated," "localized," or "mononeuritis." When many of the peripheral nerves are involved at the same time, it is characterized as multiple neuritis, or polyneuritis, a condition meriting special description, and which will be discussed later. Neuritis may be either acute or chronic, or the symptoms of acute neuritis may persist for a long time and then become chronic.

The causes of neuritis are numerous. It may be due to traumatism such as direct wounding or contusion of the nerve, or to compression of the nerve by sudden and forcible muscular contraction; to dislocation of joints; to injury to the nerve from fragments of bone resulting from fracture; to compression of the nerve from the formation of callus; to pressure of growths; or, finally, to pressure upon the nerve trunks in the axilla during the use of crutches. Neuritis may also be caused by chemical agents such as ether, osmic acid, or alcohol, coming in direct contact with the nerve through subcutaneous injection. It may also develop from refrigeration through exposure to cold, and as a complication or sequel of various infectious diseases. It may also arise by extension from adjacent inflammation.

Patients who are addicted to the excessive use of alcohol, or those suffering from chronic toxic disorders such as gout, rheumatism, diabetes, chronic nephritis, or syphilis, are more predisposed to the development of localized neuritis after slight traumatism or exposure to cold. Arteritis obliterans and arteriosclerosis may also be considered to be predisposing causes.

Pathologically, there are various types and degrees of neuritis. We thus have: 1. Perineuritis, in which the inflammation originates in the perineurium to which it may be limited. 2. Interstitial neuritis, in which the inflammatory process is located principally in the interstitial structure of the nerve. 3. Parenchymatous neuritis, in which the nerve fibres undergo inflammation and degeneration. The first two forms represent a true inflammatory process. In the third form, the same changes often occur which usually arise as a consequence of complete division of the nerve. As these different processes vary in degree and are frequently found in combination, their clinical differentiation cannot always be accomplished.

Isolated neuritis is generally a perineuritis or interstitial neuritis. There are redness and swelling of the connective tissue enveloping the nerve, the blood-vessels of the nerve sheath are distended with blood, and there may be minute hemorrhages. Sero-fibrinous exudation and migration of leucocytes follow the hyperæmia. These changes may be limited to the sheath (perineuritis), or may extend into the substance of the nerve (interstitial neuritis). When the process is severe or of long standing, the nerve fibres may also become involved. In the parenchymatous form the inflammation begins in the nerve fibres, resulting in their degeneration and atrophy.

Symptoms.—Pain in the course and distribution of the nerve is the principal symptom. Its degree varies with the extent and intensity of the inflammatory process. The nerve trunk is sometimes swollen and extremely sensitive to pressure, the pain often radiating to the ultimate distribution of the nerve. The pain sometimes affects the entire extremity, which may become extremely hyperæsthetic. It is variously described by patients as darting, boring, burning, and occasionally shooting through the course of the nerve. It is increased by movement and is usually worse at night. Numbness and tingling may also be present. This may be attended by some constitutional disturbance as increased pulse rate and rise of temperature. Should the nerve fibres become involved, objective sensory disturbances may arise, such as varying degrees of anæsthesia in the area of the distribution of the affected nerve, with weakness or muscular paralysis. Herpetic eruption or glossy skin may also be present. In severe cases anæsthesia, paralysis, and atrophy usually take place. The faradic irritability of the nerve and muscles is at first increased, but gradually it diminishes, and is finally lost when the nerve fibres undergo degeneration.

The neuritis may ascend a nerve ("ascending neuritis"), reaching the plexus from which the nerve arises, and thus extend to several or all of the nerves of the limb. The inflammation has also been known in rare instances to extend to the spinal cord, causing subacute or chronic myelitis.

Prognosis.—Acute neuritis may disappear in a few weeks if the cause can be successfully removed. The most favorable cases are those due to slight traumatism. More commonly the affection persists in a chronic stage for many weeks or even months. The most protracted forms arise in patients with gout or rheumatism, or in such toxic cases in which the toxin cannot be removed at once. When the axis-cylinder processes are involved, as in degenerative neuritis, the condition may last for many months, paralysis and atrophy becoming permanent if the nerve fibres do not undergo regeneration. An opinion as to the prognosis often depends upon the changes in the electrical irritability of the nerves and muscles.

Treatment.—When a nerve is divided by a wound, the separated edges should at once be approximated and sutured. In compression or injuries of nerves from luxation, fracture, callus, tumors, inflammation of soft parts, abscesses, etc., it is the first duty of the physician to insist upon immediate surgical measures to free the injured nerve if possible.

Digitized by Microsoft®

A cure is not always accomplished by this method alone, inasmuch as any accompanying muscular paralysis calls for subsequent treatment. Under such circumstances surgical intervention must be the first step, otherwise all other treatment will prove futile. The general constitutional condition of the patient must not be overlooked. In acute cases absolute rest of the affected limb is essential, either by keeping the patient in bed, or by immobilization of the limb by a suitable supporting bandage. The relief of pain is an important feature. In acute traumatic cases a Chapman's ice bag applied along the course of the nerve, or cold compresses often prove valuable. The application of hot-water cloths ameliorates the pain in many cases. When anaesthetic areas are present, extreme care should be observed when hot-water cloths are applied, in order to avoid burning the skin. Blistering or superficial linear cauterization over the affected nerve trunk often effectually relieves the pain.

At times it is necessary to administer some of the coal-tar derivatives such as phenacetin, acetanilid, or salipyrin. When the pain is persistent and severe, and is not relieved by other means, we must resort to the use of opium, morphine, or codeine. Local injection of a solution of cocaine at the seat of the greatest pain often gives relief. The continuous galvanic current is also of great value in diminishing the pain. The anode should be placed over the affected nerve, the current strength being from six to eight milliampères, the application lasting five or six minutes daily. For the paralysis accompanying degenerative neuritis after the acute symptoms have subsided, the application of the labile or interrupted galvanic current to the affected muscles seems to hasten the recovery of motility by improving the nutrition of the muscles and accelerating the regeneration of the nerve. Massage is generally contraindicated during the early period of the inflammation, but it can be favorably utilized later. Small doses of mercury have been recommended by Gowers for the purpose of influencing the neuritic process.

Multiple Neuritis or Polyneuritis.—This is a disease in which many nerves are inflamed simultaneously or in rapid succession. It usually affects symmetrically the nerve trunks in the extremities, particularly in their peripheral distribution. In this form of neuritis the pathological process originates in the nerve fibres, the adventitial structures generally being involved secondarily. In mononeuritis the nerve sheaths and the connective tissue, as a rule, are primarily affected. As early as 1828 Graves described the condition as "a form of generalized paralysis probably depending upon disease of the peripheral nerves." The first authentic case with post mortem verification was published by Dumesnil, of Rouen, in 1864, but it was not until further observations were reported by Lancereaux in 1871, Eichhorst in 1875, Joffroy in 1879, Leyden in 1880, and Grainger Stewart in 1881 that the doctrine of multiple neuritis was placed upon a sound pathological basis. During the last twenty years many observations and monographs relating to this subject have been published, the literature now being quite abundant.

Etiology.—Multiple neuritis is invariably the result of some toxic substance circulating in the blood. A very large number of different causes are active in its production.

(*a*) *Poisonous substances introduced into the system* (these being mentioned in the order of their importance): Alcohol, lead, arsenic, copper, silver, phosphorus, mercury, carbonic oxide gas, bisulphide of carbon, and nitrobenzol.

(*b*) *Poisons originating within the body* (autotoxic): Dyscrasic conditions such as gout, diabetes, tuberculosis, carcinomatosis, syphilis.

(*c*) *As a sequel or complication of various infectious diseases:* Diphtheria, influenza, typhoid fever, smallpox, scarlet fever, measles, pneumonia, whooping cough, epidemic cerebrospinal meningitis, erysipelas, gonorrhœa, malarial toxæmia, acute articular rheumatism, leprosy, and all forms of septicæmia.

The majority of cases of multiple neuritis are traceable to alcoholic excesses. It is hardly necessary to mention that the vulnerability of the peripheral nerves to the effect of alcohol varies in different individuals. One person may indulge in large quantities daily for years without developing neuritis, while many others who probably possess less resistance in the peripheral neurons are attacked by the disease after the continued daily use of a comparatively small amount of alcohol. The writer has seen several cases resulting from the daily use of about two ounces of whiskey continued for three or four months. Multiple neuritis as a sequel of acute alcoholic intoxication is almost unknown.

According to the preponderance of one set of symptoms over another, multiple neuritis has been classified into various clinical types, such as:

1. *A motor or paralytic type* (alcohol, arsenic, diphtheria, Landry's paralysis).

2. *A sensory type*, an ataxic form which is often described as "pseudotabes" or "neurotabes peripherica," and is most commonly due to arsenic or alcohol.

3. *A vaso-motor type* (erythromelalgia, Raynaud's disease).

4. *An endemic form* (beri-beri or kakki, particularly prevalent in Japan and the Dutch East Indies).

Multiple neuritis occurs most frequently, however, in transitional forms, and may then be characterized as a common or mixed type in which motor, sensory, and vaso-motor phenomena arise in various combinations.

Polyneuritis usually occurs between the ages of twenty-five and fifty years. Aside from the form due to diphtheria, it is rare in children, although it has been occasionally observed between two and six years of age. A number of cases of multiple neuritis in children as a result of alcoholic poisoning are now on record. In one of the writer's cases the child, who was five years old, had been given whiskey and beer daily for several months by its ignorant mother, for the purpose of strengthening it after an attack of diarrhœa. The disease rarely occurs after the sixtieth year.

Symptoms.—It is now well established that in multiple neuritis no set of symptoms is exclusively related to a single cause. A description of the symptomatology of the alcoholic form will convey a knowledge of the general features of the affection.

Multiple neuritis may be either acute or subacute in its onset, and may follow or accompany an attack of delirium tremens. The temperature may be slightly elevated in the beginning, and some fever may continue throughout the acute period of the disease. Normal temperature is not unusual. At first there is often tingling, or a sensation of "pins and needles" or numbness in the extremities, with vague sharp pains or aches, which gradually become more acute. The paræsthesiæ and pain are soon followed by muscular weakness, or paralysis, or inco-ordination. Either the upper or lower limbs or both may be involved, first and chiefly the hands or the feet. The feet are affected more frequently than the hands; motor symptoms may exist in the legs, and only sensory symptoms in the hands. This is accompanied by tenderness along the nerve trunks and in the muscles, the muscular tenderness usually increasing to an extreme degree. The co-ordinating power may be affected at the same time. Tremor is often conspicuous. Most frequently the knee jerks are absent, this depending directly on the involvement of the anterior crural nerves. The knee jerk is present or even exaggerated in some cases of slight degree, and this invariably indicates that the anterior crural nerves are intact.

In the lower extremities the nerves most commonly affected are the peronei and the posterior tibial and their branches. Occasionally the anterior crural nerves are also involved. Thus, the paralysis usually affects symmetrically the corresponding tibial group of muscles producing "foot drop." In severe cases nearly all of the nerves of the extremities may gradually become involved, and a more or less complete paraplegia develops.

The upper extremities may escape entirely, or the

Digitized by Microsoft®

paralysis is almost always of lesser degree and extent than in the lower extremities. The musculospiral nerve and its branches are most commonly affected, thus producing paralysis of the extensors of the wrist and hand and "wrist-drop." It often happens that other nerves are also involved. A peculiar feature in these cases is the implication of the nerves in their peripheral distribution, the paralysis usually being more pronounced in the distal portions of the extremity. This is also indicated by the fact that at times when the supinators and the long abductor of the thumb in the upper extremity and the tibialis anticus in the lower extremity remain intact, there may be paralysis of the other muscles which receive their supply through the same nerve trunks. Sometimes the muscles above the knees and elbows are also affected. In the more severe cases the diaphragm and the muscles of the abdomen also become involved. In rare instances several of the cranial nerves may be implicated, the facial muscles, those of the tongue, or the ocular muscles thus becoming affected. The paretic or paralyzed muscles soon become flaccid and undergo atrophy and present the reaction of degeneration. Sensory disturbances are often associated with the loss of motor power. They may be altogether absent or exist alone. In addition to the subjective sensations already mentioned, extreme hyperæsthesia may exist over the affected parts, or tactile, pain, or muscular senses may be affected in various degrees. In the ataxic form inco-ordination is the chief symptom. It is usually accompanied by muscular tenderness, and exists with or without the affection of cutaneous sensibility just described. The inco-ordination in these cases resembles closely that of tabes, hence the form in which this symptom is predominant has been called "pseudo-tabes." Its most frequent cause is alcohol, but it has also resulted from arsenical poisoning and from infectious processes.

Trophic changes occur in prolonged cases in the nails, skin, and hairs, and are similar to those of ordinary neuritis. In uncomplicated cases the sphincters of the bladder and rectum are not involved.

In some severe cases in which the neuritis is widely distributed, the pneumogastric nerve or some of its branches may become affected, causing interference with the action of the heart, the muscles of respiration, and the vocal cords.

All of the symptoms vary according to the acuteness and intensity of the disease, and they also differ according to the cause. In lead poisoning the paralysis is usually confined to the upper extremities. In alcoholism all four extremities are often affected, the arms escaping more often than the legs.

Mental Symptoms.—A somewhat characteristic disturbance of memory often takes place. In general, it may be described as a peculiar form of forgetfulness with delusions of recollection. The memory for recent events is generally confused but not always entirely lost. Occurrences of some days, weeks, or months previously are misinterpreted by the patient as of quite recent occurrence, or as having just taken place. Although he may be confined to bed and unable to move, he may assert that he has just returned from a long journey, or has been out for a ride, or has just visited friends, etc. In some cases there are insomnia, delirium, talkativeness, or incoherence, or other more pronounced manifestations of acute alcoholic insanity or confusional insanity. All of these mental symptoms are essentially due to toxæmia, and bear no direct relation to the degree or form of the neuritis. Although more commonly observed in alcoholic subjects, they are known to occur in the course of multiple neuritis due to other poisons and also from infection.

Diagnosis.—In acute cases, when all of the characteristic symptoms are present, and the patient is unable to move from the bed, the diagnosis is very simple. It is the subacute forms that often present some difficulty in their diagnosis. On account of the presence of inco-ordination, pains in the legs, and loss of knee jerks, and some objective disturbances of sensibility, it has sometimes been mistaken for tabes. It is easily differentiated from tabes, however, on account of the presence (in multiple neuritis) of tenderness of the muscles and nerves, the neural character of the pains, the symmetrical diminution or loss of muscular power, the absence of bladder symptoms, and the presence of the pupillary light reflex.

Multiple neuritis has also at times been confounded with atypical cases of poliomyelitis, but poliomyelitis is most frequent in children; its onset is abrupt, the paralysis is rarely symmetrical in its distribution, and there is generally an absence of all sensory symptoms.

The history of some form of toxæmia known to cause polyneuritis is a potent element in the differential diagnosis.

The Diagnosis of the Toxic Cause, and the Differentiation of the Various Types.—It is not always easy to determine from the clinical symptoms alone whether a certain case of multiple neuritis is caused by alcohol, arsenic, lead, or some infectious process. However, there are certain elements in the history, a peculiarity in the distribution of the paralysis, and well-defined indications associated with some special forms of toxæmia or infection, which often conclusively prove the cause of the neuritis.

For instance, the somatic and psychical symptoms may present a classical picture of chronic alcoholism. Thus, in addition to the polyneuritis, there may be tremor in the lips, tongue, and hands, toxic amblyopia, chronic morning vomiting, cirrhotic liver, albuminuria, delirium tremens, or alcoholic dementia. *Arsenical neuritis* is often accompanied by vomiting, a general brown pigmentation of the skin, and the presence of arsenic in the urine. In some cases the ataxia is more pronounced than are the motor symptoms. The arsenic has usually entered the system as a result of acute poisoning after an ineffectual attempt at suicide. Occasionally the neuritis is produced by the prolonged administration of medicinal doses of Fowler's solution as used in the treatment of chorea in children, or from the inhalation of arsenical dust given off from wall paper and other articles containing arsenic. Recently a large number of cases of arsenical polyneuritis occurred in England from the use of beer in which arsenical glucose had been used in its manufacture.*

Multiple neuritis from lead poisoning is most frequently found among those whose occupation requires frequent or continuous contact with lead. The accidental causes are numerous, such as the contamination of drinking-water by leaden pipes, the cooking of food in vessels containing lead in their manufacture, the use of various cosmetics, hair dyes, etc. It has also been traced to snuff, which was found to contain lead. As a rule, the lead enters the system through the alimentary canal as a result of uncleanliness, and the pollution of food by hands that have been in contact with lead. It may also enter the system through inhalation, and by absorption through the skin. As in other forms of toxæmia individual susceptibility to the effects of lead has much to do with the development of neuritis. People in general ill health, and those addicted to alcoholics, are more predisposed to the toxic action of lead. The upper extremities are more commonly affected, a blue line is often seen on the gums, and lead may be found in the urine (see article on *Lead Palsy*).

Polyneuritis from *diphtheria* may be attended with wasting and anæsthesia; but the weakness in the limbs usually succeeds paralysis of the palate and ciliary muscle, which are never seen in other forms of polyneuritis.

Course and Prognosis.—Multiple neuritis usually takes an acute or subacute course and reaches its height in a few weeks or a few months. It then remains stationary for about the same period, and gradually recovery takes place. Some cases are very severe and are accompanied by high fever, and may terminate fatally in a week or two from paralysis of the heart or diaphragm, or from

* Glucose is made by the action of sulphuric acid on various kinds of starch. The origin of the arsenic was found in the sulphuric acid which is commonly made from arsenical pyrites.

pulmonary œdema. It sometimes assumes a course similar to that of Landry's paralysis. The condition is always serious when the patient's general health is poor in consequence of a recent infectious disease, or in severe types of chronic alcoholism, etc. When the vagus or phrenic nerves become involved, the life of the patient may be in constant danger, but recovery has occurred even under such circumstances. When the paralysis is confined to the distal portions of the extremities, the prognosis is more favorable. In exceptional instances the course may become chronic and progressive. In the majority of cases, however, in the absence of complications the disease terminates in complete recovery. Even in favorable cases the affection may last from several months to two years or more, depending upon the underlying cause, the extent and intensity of the nerve degeneration, and the recuperative powers of the patient. The prognosis is always materially influenced by the course and virulence of the toxæmia. When the sphincter of the bladder is involved, it is usually indicative of extension of the inflammatory process to the spinal cord, thus rendering the prognosis as to recovery more doubtful.

Treatment.—The treatment of polyneuritis is essentially symptomatic. Aside from the cause of the toxæmia the various forms receive practically the same treatment. It is essential to discover, if possible, the cause of the neuritis, and to remove it or discontinue its further action. This should be the first consideration, particularly in cases due to alcohol. The sudden withdrawal of the customary stimulant is not always advisable, particularly when cardiac weakness is present. This can usually be successfully accomplished, however, by the administration of suitable heart tonics. Rest in bed, with general supporting treatment, is desirable or absolutely necessary in the majority of cases. A local or general warm wet pack for the purpose of producing diaphoresis, if the patient's strength admits, is often followed by excellent results in the early stage, or, if the patient is strong enough to bear the necessary procedures, a warm bath for fifteen or twenty minutes daily often proves beneficial. General constitutional treatment applicable to the special condition constituting the toxæmic process should never be forgotten. In order to prevent deformities, faulty positions of the extremities should be corrected by giving the necessary support to paralyzed muscles. Thus when there is "foot-drop" the feet should be kept at right angles with the leg by means of sand-bags, pillows, etc. For the purpose of relieving the pain anodynes should be administered when necessary in the same manner as mentioned in the description of the treatment of mononeuritis. When the diaphragm becomes paretic or paralyzed, artificial respiration and the hypodermatic injection of strychnine must be resorted to. Indications of heart failure are to be met by absolute rest and the administration of cardiac stimulants. When deglutition is interfered with, the patient should be fed through the œsophageal tube in order to prevent the entrance of food into the larynx or bronchi.

Fortunately such emergencies arise only in exceptionally severe cases. After all of the acute symptoms have subsided, massage and electricity will prove useful.

William M. Leszynsky.

NEURODIN, acetyl-p-oxy-phenyl-urethane, C_6H_4.$OCOCH_3.NH.COOC_2H_5$, is prepared by acetylation of the compound formed by the interaction of chlorocarbonic ether and amidophenol. It is a colorless, odorless, crystalline substance, soluble in 1,400 parts of cold water and readily in boiling water. It is antipyretic and antineuralgic in dose of 0.5–1.5 gm. (gr. viij.–xxiv.).

W. A. Bastedo.

NEUROEPITHELIOMA.—The name of neuroepithelioma was first given by Simon Flexner in 1891 to a peculiar tumor of the retina in which were found collections of cells resembling the rods and cones of the external nuclear layer. Flexner believes this tumor to have had its origin not in the supporting cells, but in the neuro-epithelial cells of the external nuclear layer, and to be therefore not a glioma but a neuroepithelioma. In this tissue he found the tubular or alveolar arrangement of the cells, so common in glioma of the retina; and among the cells of the tubules he found tiny rosettes composed of long cylindrical cells, the pointed extremities of which were turned toward the lumen of the rosette and formed there a membranous ring. These cells he considered rudimentary rods and cones. He answers the objection of Iwanoff to the formation of tumors from any cells except supporting cells by quoting Klebs' opinion that all the elements of the nervous system are capable of proliferation.

Three years later, Wintersteiner reported a case of so-called neuroepithelioma of the retina in which rosettes similar to those described by Flexner were found. Wintersteiner mentions Flexner's work, but claims to have made his discovery quite independently of the latter, and does not give him credit for the name "neuroepithelioma." He found transitions between the rods and cones and the tumor cells, and considers the membrane formed by the processes of the cells to be analogous to the membrana limitans externa. In a later monograph Wintersteiner discusses eleven tumors with epithelial rosettes which he found among thirty-two gliomata, and in two cases of microphthalmos. He regards these tumors as originating in misplaced cells of the rod-and-cone layer. Several other authors have reported similar tumors, but without giving them the same interpretation. Thus Becker describes rosettes of cylindrical cells in a tumor with a marked alveolar structure which he called "tubular angiosarcoma." Bochert, Eisenlohr, Jung, Thieme, and Van Duyse probably were also dealing with the same kind of tumor under the name of glioma or gliosarcoma, or angiosarcoma. Two observers, Greef and Hertel, working with the Golgi method, were able to demonstrate the presence of true ganglion cells among the ordinary spider cells which formed the mass of the tumor in both cases. They did not, however, apply the term neuroepithelioma to these tumors, but preferred to use the name neuroglioma ganglionare, after similar tumors in the central nervous system.

The best criticism of the views of Flexner and Wintersteiner is given by Ginsberg, who examined two tumors from a case of microphthalmos, and found in them the same rosettes of epithelial cells described by the two former. Ginsberg, however, regards these as cylindrical cells from the pars ciliaris retinæ, not rods and cones. These cylindrical cells are undifferentiated cells of the original Anlage of the retina, formed before the neuroblasts and spongioblasts. As these primitive cells are of epithelial origin he suggests the name "carcinoma retinæ," instead of neuroepithelioma. He bases his theory not only on the appearance of the cells composing the rosettes, but also on the fact that these primitive, undifferentiated cells are capable of proliferation, while in the case of highly specialized cells, such as the rods and cones, there is great doubt as to the possibility of their proliferation. The tumors which Wintersteiner has called neuroepithelioma Ginsberg regards as probably formed from primitive epithelial elements, and not from the highly specialized neural epithelium.

NEUROFIBROMA. See *Fibroma.*

NEUROMA. See *Fibroma.*

NEUROMA OF THE SKIN, PAINFUL.—This is an exceedingly rare affection, but two cases in which the skin was primarily affected being on record. Duhring's "Case of Painful Neuroma of the Skin," *American Journal of the Medical Sciences*, October, 1873, was the first noted and was followed by Kosinski's case in the *Centralblatt fur Chirurgie*, No. 16, 1874. Both cases occurred in men, aged seventy and thirty years respectively. In Duhring's case the tumors had been developing for ten years and in Kosinski's for fourteen.

Digitized by Microsoft®

The tumors, varying in size from a pinhead to a filbert, confluent and disseminated, were thickly studded over the areas affected. In the first case they extended from the left scapula over the shoulder down the arm to the elbow, occupying principally the area of distribution of the circumflex nerve, and in the second case over the buttocks and upper part of the thigh, corresponding to the area supplied by the small sciatic and external cutaneous nerves. The lesions were arranged irregularly, not corresponding exactly to the course of the nerves mentioned, and formed firm, flat, or oval, elastic nodules, fixed in and extending below the skin, and movable only with it. The integument between the nodules was normal, they being purplish or pink in color. In Duhring's case the skin over the nodule was slightly scaly. At the outset pain was variable, but later it became excruciating and occurred in violent paroxysms, lasting an hour or more.

Since they are never malignant these neuromata are best not interfered with unless great distress is caused by the pain. In both the above cases resort was had to a removal of portions of the nerve supply with resulting quick relief from pain and gradual and almost complete subsidence of the nodules.

The new growth is composed of firm connective tissue and non-medullated nerve fibres.

NEURONE, GENERAL PATHOLOGY OF THE.—Introduction.—Notwithstanding the liberal number of papers which have been published in recent years upon the pathology of nerve cells, we have still, in an essay to construct a general pathology of the neurone, only fragmentary data at our disposal. The neuropathologist, like all other special pathologists, meets with insuperable difficulties, due to the fact that a well-developed pathology of the cell in general is still lacking. Investigators are coming more and more to the opinion that in order to build up a satisfactory pathology of the cell, research ought not to be limited to the cells met with in the special tissues of highly differentiated animals, but should be extended to unicellular forms, in which the conditions of life are simpler and with which the possibilities of experiment are more manifold, and the experiments themselves are more easily subject to control. Indeed, at the present time, part of the pathology of each of the special types of cells of the vertebrate animal is based directly upon inferences drawn from work done upon one-celled species. Thanks to the very extraordinary distribution of the protoplasm of the nerve cell in space, however, it has been possible, in nerve cells or neurones, better than in any other specialized type, to study the results of injury to a part of the cell; indeed, this kind of injury can perhaps be better studied in them than in any of the simplest organisms. It is owing to this circumstance, doubtless, that such a goodly portion of that pathology of the neurone which has thus far been evolved has to deal with degenerative and regenerative processes following upon damage to some one of its parts, particularly its axone.

In view of the variety of hypotheses still advanced concerning the ultimate structure of the protoplasm of the normal nerve cell (see this Handbook, Vol. II., article, *Brain, Histology of*), it is by no means surprising that there is lack of unanimity of opinion regarding the fundamental nature of the changes which are met with in the neurone when it is diseased.

The studies of the botanist Fischer, of Leipsic, have shaken microscopical histology at its foundations. Now that we know the varying results which can be obtained, not only by the use of fixing reagents of different chemical constitution, but by the employment of the same reagent in different degrees of concentration, we must needs be chary of the conclusions we arrive at from the examination of fixation pictures in nerve cells, not only in health, but also and perhaps more particularly in disease.

The scepticism excited by these recent observations has, in some quarters, probably become excessive. Realizing that the stainable substance of Nissl can be precipitated in granules of different size by alcoholic solutions of varying strengths, that by treating nerve cells by one series of vigorous reagents, the so-called neurofibrils of Apáthy or of Bethe may be demonstrated, while by treating the same nerve cells by a different series of powerfully modifying solutions the honeycomb structure of Bütschli or the neurosome rows of Held may be put in evidence; and bearing in mind, further, that microscopic appearances similar to karyokinetic figures, centrosomes, and cytoplasmic radiations may be produced by the action of fixing reagents upon albuminous solutions injected into the empty cellular spaces of cork, there are those who would go so far as to say that the microscope and microscopical histological methods have been and can be of very little help to us in unravelling the structure and deciding upon the functions of cells. Such pessimists, however, forget the wonderful advances in neurological knowledge, anatomical and pathological, which are directly attributable to the use of the microscope. It would be as illogical for the student of the nervous system to give up the study of fixation pictures as it would be for the chemist to abandon the method of precipitation as a means of acquiring knowledge concerning the composition of solutions. It may be that the protoplasm of the nerve cell, as well as protoplasm in general, consists chiefly of colloidal particles held in suspension by virtue of the electric charges which they possess; if so, we may expect that some day new and desirable information will be derived from a study of artificially prepared colloidal solutions. Such a line of investigation, attractive and promising as it is, will unquestionably be that along which many can profitably work; but it is to be hoped that there will be others who will continue and extend those studies by histological methods which have done so much for us in the past, and which, many of us are convinced, are capable of supplying us with still more valuable information in the future.

In the brief sketch of the general pathological morphology of the nerve cell to be made here, the changes due to functional activity will first be referred to; next a description of the processes of necrosis and necrobiosis as they affect the neurone will be given, followed by a brief discussion, (1) of the various degenerations which involve the whole neurone or parts of it; (2) of regenerative phenomena; and (3) of the changes consequent upon various forms of intoxication.

Changes due to Functional Activity in the Neurone.

In this connection the studies of Hodge upon the histology of fatigue are by far the most important hitherto undertaken. His researches were made upon the nerve cells of various animals, including sparrows, swallows, pigeons, and honeybees. A comparison of the cells of such animals captured in the morning with cells of animals of the same species killed after a long day's exercise

Digitized by Microsoft®

showed alterations both in the protoplasm and in the nuclei of the fatigued cells. The nuclei were smaller than normal in the tired cells, had irregular margins, and stained with unusual intensity. An examination of the protoplasm revealed a shrunken appearance, and it stained more feebly than normal. The changes in the cells of the occipital cortex in the dog, as depicted by Hodge, are very convincing. Hodge's earlier reports did not contain satisfactory data with regard to the behavior of the stainable substance of Nissl, as he used osmic acid fixation for some of the cells and sublimate fixation with Gaule's stains for others.

www.libtool.com.cn

Later on Mann, working with other methods, compared the pyramidal cells of the cerebral cortex and the motor cells of the ventral horn of the spinal cord of a dog at rest with those of another dog after a long period of muscular activity. In a further series of experiments he bandaged one eye of dogs leaving the other exposed, killed the animals after twelve hours, and compared the retinal neurones, those of the corpora quadrigemina, of the lateral geniculate body, and of the occipital cortex of the one side with those of the other. He concludes that the stainable substance of Nissl increases in amount in nerve cells which are resting; it diminishes during functional activity, owing to direct utilization by the cell protoplasm. In addition, Mann describes an increase in the size of the cell bodies and of the nucleus and of the nucleolus in the early stages of functional activity; if the activities be prolonged to fatigue, there are shrinking of the protoplasm and contraction of the nucleus, the borders of the latter becoming irregular. Similar investigations have been made by De Moor and Pergens.

The studies just described refer to the changes which occur in nerve cells as the result of that normal excitation of cells which accompanies muscular activity or normal retinal illumination. Opportunities for studying other forms of normal functional activity might well be taken advantage of. It is desirable, too, that methods should be devised for testing the effect of alterations of temperature, light, moisture, and non-poisonous chemical stimuli upon different groups of neurones.

The effects of electrical stimulation have been investigated to a certain extent. For example, Hodge stimulated the peripheral sensory nerves of cats and afterward made sections of the spinal ganglia. In the ganglion cells on the side of excitation he found a decrease in the size of the nucleus and a change in its shape. The cell body, also, gradually diminished in size. Vas, on the other hand, stimulating the sympathetic for fifteen minutes, found a distinct increase in the size of the cell body, and a disappearance of the stainable substance of Nissl in the region of the perikaryon immediately adjacent to the nucleus. The nucleus itself, Vas states, becomes swollen and tends to be displaced toward the periphery, sometimes even causing a bulging at the periphery of the cell. The somewhat conflicting statements of Hodge and Vas have been reconciled by the experiments of Lugaro, who demonstrated during the early period of excitation a state of turgescence in the protoplasm of the cell body, while later on, when the stimulation had been continued long enough to cause fatigue in the cell, progressive diminution in the size of the cell body was met with. According to Lugaro the tigroid substance slowly increases in amount during the earlier period of stimulation; after the cell has become fatigued, it is decreased in amount and tends to be more diffusely distributed throughout the cell body.

Necrosis and Necrobiosis of the Neurone.

By the term necrosis of the neurone is meant that condition or set of conditions in which the cell is relatively suddenly killed; by necrobiosis of the neurone is indicated the process which leads, through a series of pathological changes, gradually to the death of the cell.

Necrosis of nerve cells is met with in trauma, in infectious processes directly involving the nerve tissues, in sudden cutting off of the oxygen supply (*anæmic necrosis*) and possibly under other conditions.

The classification of direct necrosis introduced by Klebs is perhaps the most satisfactory one we possess. If the noxious agent which kills the cell affects it equally in all its parts, one gets a microscopic picture not unlike that met with in the artificial killing brought about when we fix the nerve tissues in the fixing reagents of the laboratory; the structure of the protoplasm and nucleus is relatively well preserved. The nucleus is, however, in some cases, first attacked by the noxa, in which event it may either be dissolved (*karyolysis*) or become fragmented (*karyorrhexis*); in such instances the alterations in the cell body may at first be slight, consisting perhaps merely of cloudy swelling. In forms of cell death, on the other hand, in which the protoplasm appears to be first attacked, a primary vacuolar degeneration of the cell body (*plasmarrhexis*) may be encountered.

A cell is doomed to death if its nucleus be destroyed or injured beyond a certain degree. The studies of Condorelli upon the effect of mechanical injury to cells have shown us that rupture of the nucleus not infrequently occurs as a result of trauma. Schmaus has suggested that we may here have an explanation of the direct necroses of ganglion cells which may be assumed to take place in commotio cerebralis and commotio spinalis. Tissues under these conditions should be studied in the early stages and with the aid of modern methods. A beginning has been made in this direction (*cf.* Barbacci, *loc. cit.*, p. 819).

We know but little of the effect of powerful electric currents acting directly upon the neurones. A few cases of electrocution have been examined post mortem without, it must be confessed, adding much to our knowledge. There is here room for fruitful experimentation in the light of the results which were obtained by Eschle upon artificial necrosis due to electrical influences (see also work of Corrado, cited by Barbacci).

In diseases associated with peripheral neuritis (diphtheria, lead poisoning, etc.) we have exquisite examples of partial nerve-cell necroses, the poison killing the axones of the neurones through a distance of from a fraction of 1 mm. to several millimetres. The effect on the whole neurone is the same as that which follows upon artificial section of the axone (*vide infra*).

Careful studies of karyolysis and karyorrhexis in nerve cells have still to be made. There are only fragmentary remarks upon the subject in the bibliography. The difficulty of the study is aggravated by the unusual distribution of the chromatin in the normal nuclei of nerve cells.

The so-called condition of pyknosis in which there is a condensation of the nucleus and cell body is worthy of mention. Schmaus assumes that the so-called "sclerosis" described by Friedmann in acute myelitis is closely allied with pyknosis. This author found in cells otherwise nearly intact glistening masses which stained intensely with nuclear dyes; such masses appeared at first in the periphery or in the interior of the cells, as though they had resulted from fusion of the spindles and granules of

Digitized by Microsoft®

the stainable substance of Nissl. Later, the cells diminished in size, though the glistening staining increased. The nucleus was often well preserved for a long time. It may be that some of the "chromophile" cells of Nissl belong in this category, though in most instances it would seem that they are to be regarded as artefacts due to the fixing reagent. www.libtool.com.cn

A series of necrobiotic changes have been described by Pándi in nicotine, bromide, and cocaine poisoning. In chronic poisoning with nicotine, the nucleus of the cell becomes shrunken, the cell body is diminished in size, and the paraplasm and the nucleus stain of a dark color. In cocaine and bromide poisoning the nuclei show enlarged nucleoli; the chromatic threads in the protoplasm lie closely pressed together, sometimes becoming merged with the deeply stained ground substance of the nerve-cell body.

The experimental work of Klemm upon plant cells has shown the way for a series of experiments upon nerve cells, which, it is hoped, some one in the near future may be induced to undertake. According to Klemm, when a cell is suddenly killed there is never any contraction of it, nor any considerable alteration in configuration. These are the signs of a much slower dying process. The visible alterations in the protoplasm of plant cells on sudden killing are, according to Klemm, of three kinds: (1) Precipitates: usually granular structures giving an increased granular appearance to the cell. Such granules may be united in the form of chains, networks, and dendritic structures. Instead of granular precipitates a fibrillary appearance may be produced. (2) Phenomena of solution: vacuole formation, foam formation, and the like. (3) A mixture of granulation (coagulation) in the plasma with formations of fewer and smaller vacuoles.

Where death is not so sudden and yet very intense effects are suddenly produced, the most marked alterations in configuration are met with. In the still slower "physiological" death the terminal phenomenon is usually coagulation of the protoplasm, and there is a tendency to various forms of degeneration—granular degeneration, vacuolar degeneration, etc. Dying protoplasm has the tendency to break up into small clump-like masses which assume a more or less spherical shape.

Atrophy of Neurones.

Hodge, of Clark University, has made us familiar with some of the changes which take place in neurones in senile atrophy. In a man ninety-two years old, dead of marasmus, the ganglion cells as a rule looked fairly normal, though he describes a diminution in the number of the Purkinje cells in the cerebellum and slight shrinking of those which were present. His study of the spinal ganglion cells demonstrated that the nucleus nearly always had an irregular contour, was more or less shrunken, and often devoid of nucleolus. The cell protoplasm was rich in fat and pigment, which were absent in the fœtus. Hodge's description of fat and pigment in a forty-seven-year-old man is accompanied by the suggestion that the man suffered from premature senescence due to alcoholism. I am of the opinion that the pigment which he describes is visible in the nerve cells of nearly all human beings and probably at all ages, except in the fœtus and in early childhood. I have been struck with the comparatively large number of times the so-called lipochrome of normal nerve cells has been described as a pathological product. Some of those who have studied the Gasserian ganglion in *tic douloureux* have fallen into this error.

Hodge studied the changes due to age in bees, as well as in human beings, and described shrinking of the nuclei, vacuole formation in the protoplasm, as well as diminution of the total number of cells.

Studies of a similar nature have been undertaken by Vas. This investigator made use of the method of Nissl in examining the nerve cells of old people. He describes various alterations in the stainable substance of Nissl, and states that in the last stage the cell body is transformed into a strongly staining, formless mass, which may be broken up into clumps. It does not seem impossible that Vas may have had to deal with artefacts, perhaps the "chromophile" cells of Nissl. They can be obtained occasionally in nerve tissues from individuals of any age. I have pictured one in a former publication (see Fig. 73, "The Nervous System," p. 124).

According to Babes, the processes in the anterior horn cells of the spinal cord are reduced in number in old age. In a group of intact nerve cells one sometimes finds in old people shrunken, colloid, or very pale elements without nucleus or nucleolus, or with a strikingly pale nucleus. The tigroid masses are pale and few in number, or they may be entirely absent in the periphery of some of the cells. In other old people the nerve cells appear to be nearly normal, which proves, Babes thinks, that the capacity for resistance varies greatly in different individuals.

The pigment (lipochrome) is certainly more abundant in older people, a fact repeatedly confirmed by Marinesco, Rosin, myself, and others.

The more one studies the descriptions of atrophy of the nerve cells in old age, the less he feels satisfied with the studies which have thus far been made. The subject should be taken up again now that we have better methods and are more familiar than formerly with changes in the neurones due to causes other than senility.

One of the later studies is that of Marinesco, according to whom the senescence of the nerve cells is due to a defect of metabolism. The anatomical changes include a decrease in the size and number of the tigroid masses; sometimes the Nissl bodies are transformed into granules of variable size (senile chromatolysis), especially around the nucleus, but often throughout the whole cell. Marinesco believes that the "pigment" really represents a product of the involution of the cell, and that when it is increased in amount it reduces the nutritive and respiratory capacity of the cell. The number of dendrites diminishes and their branches disappear. Finally the volume of the perikaryon itself decreases. He denies neuronophagocytosis due to senility. Instead of an increase in the glia cells, these cells disappear *pari passu* with the vanishing of the nerve cells.

Of the atrophy which may take place in a neurone when its axone is injured, or when impulses which normally come to it are cut off, mention will be made in connection with secondary and tertiary degenerations of the neurone.

Degenerations of the Neurone.

Under this heading will be considered (*a*) Primary Degenerations of the Neurone, including (1) cloudy swelling, (2) fatty degeneration, (3) vacuolar degeneration, (4) pigmentary degeneration, (5) albuminous degeneration; and (*b*) Secondary Degenerations of the Neurone.

(*a*) Primary Degenerations of the Neurone.—(1) *Cloudy Swelling.*—In view of the fact that parenchymatous degeneration or cloudy swelling has been described in connection with the acute infections and intoxications in most of the organs of the body, it is rather surprising that we find so few references in the bibliography to this form of degeneration in the nerve cells. The changes which accompany infection and intoxication are so characteristic and constant in the various secreting cells that it seems probable that a similar degeneration has been frequently met with in the nervous system, but has been described under a different name. Doubtless the presence of the peculiar tigroid masses in the protoplasm of nerve cells has been responsible for the difficulty in studying this change. If one reads Benario's careful review of the whole subject of cloudy swelling and then examines the articles by Ewing, Marinesco, and others on the pathological changes in the nerve cells in acute infections, he cannot but feel that the preliminary swelling of the nucleus and protoplasm and swelling of the tigroid masses followed by their breaking up into fine granules, described by these writers, correspond more or less closely to the cloudy swelling which affects gland cells. The alterations described by Franca in the nerve cells in plague, and by Camia in the nerve cells in influenza, are very suggestive in this connection.

(2) *Fatty Degeneration.*—Fat droplets of smaller or larger size are frequently met with in nerve cells in the most different pathological processes, but especially in infections and intoxications. These are usually met with in the protoplasm of the perikaryon and are visible as yellow, glistening droplets in frozen sections, or as black spherules in Marchi preparations. I have often seen black droplets in the nuclei of nerve cells in Marchi specimens; in some instances they appear to be coincident with the nucleolus.

(3) *Vacuolar Degeneration.*—The study of vacuolar degeneration of the nerve cell has had an interesting history. In the older publications, where the studies were nearly all made upon Müller's fluid preparations, nothing was more common than to read of extensive vacuolar degenerations in the cells of the brain and spinal cord. We know now that the majority at least of these were nothing more nor less than artefacts due to the action of the hardening reagent (work of Kreyssig and of Trzebinski). In some of the more recent studies, however, true vacuolization of both protoplasm and nucleus of the nerve cells has been described. Nerlich has investigated the origin of vacuoles in a case of cerebral tetanus in which the nucleus nervi hypoglossi, the nucleus nervi facialis, and the nucleus motorius nervi trigemini contained vacuolated ganglion cells. He found occasionally as many as twenty vacuoles in a single cell. The cell body was swollen, though often surrounded by a large pericellular space. The nuclei were not altered, though they were sometimes displaced from the normal position by the vacuoles.

Besides in tetanus, vacuolization of the nerve cells has been described in various infectious diseases, in acute poisoning with mineral acids (ganglion cells of the heart), and in fasting. Sometimes the nucleus, as well as the cell protoplasm, is vacuolar (Kazowsky).

The study of vacuole formation in cells generally has been approached recently from the experimental side. Two kinds of vacuoles may be distinguished according to their origin: (1) solution vacuoles, which increase in size with the diffusion and endosmosis of the agent producing them; (2) expulsion vacuoles which are formed suddenly as a result of coagulation and do not usually increase in size.

(4) *Pigmentary Degeneration.*—In frozen sections and in Nissl preparations of adult nerve cells in various parts, a yellowish pigment can be made out. This is said to be entirely absent in the newly born. According to Pilcz, Obersteiner, and others it appears at different periods of life in different nerve cells, at the sixth year in the spinal ganglia; at the eighth year in the anterior horn cells. The amount of pigment increases as age advances (*vide supra*, Atrophy).

This pigment is not identical with that of the locus cœruleus, substantia nigra, or substantia ferruginea. It may be improper to speak of it as pigment at all. It stains black with osmic acid, and thus is easily visible in Marchi preparations. It seems to be related to the fats (Rosin). Ramón y Cajal regards it as a metabolic product of the cell, which the latter cannot rid itself of. Whether it arises from the stainable or from the unstainable substance of Nissl is not known. Obreja and Tatuses believe that this pigment is of a fatty or myelinic nature, probably related to lecithin. They therefore look upon it as a store of nutrient substance in the cell; according to their findings it is diminished in amount in the anterior horn cells in strychnine poisoning and in tetanus, while after prolonged rest it is increased. Against this view van Gehuchten urges that the substance is absent from the nerve cells in early life, and further that in a case of tetanus which he examined there was no diminution in the amount of pigment. The whole matter requires further investigation.

Digitized by Microsoft®

derstood those disturbances of nutrition in which insoluble albuminous bodies are deposited in the tissues. In the nervous system we have to deal with two such albuminous deposits: (*a*) the so-called Russell's fuchsin bodies, and (*b*) the corpora amylacea.

Ad (*a*). Russell's fuchsin bodies described in cancer, in 1890, have since been proven non-specific as far as these tumors are concerned. They occur under normal conditions in various tissues of the body, including the nervous system, but are greatly increased in numbers under pathological conditions. They are usually extracellular in situation but may occur also inside of cells. As a rule, several of them exist together. They are small, round, homogeneous bodies, varying from 0.5 to 20 μ in diameter. Under the microscope they appear as glistening masses looking not unlike fat droplets, when examined in water. They stain intensely by Gram's method and in acid fuchsin. In Ehrlich's triacid stain they are tinged sometimes with the acid fuchsin, sometimes with the orange. In Heidenhain's iron hæmatoxylin they stain black. Lubarsch found them in large numbers in atrophic conditions of the brain. The probability is that they are products of the cell protoplasm, rather than of the nucleus. Some of them may be swollen and altered cell granules. It is not impossible that fine granules in the cell protoplasm undergo chemical change and fuse to form the fuchsin bodies. Again it has been suggested that they may have their origin from lecithin. Lubarsch found that pure lecithin yields the same staining reactions as do the fuchsin bodies; on the other hand, pure lecithin is easily soluble in alcohol, while the fuchsin bodies are not.

Ad (*b*). Corpora amylacea have long been known in the central nervous system. Their origin and significance have been much disputed, but there can be no doubt that they are very numerous in atrophic and degenerated portions of the brain and spinal cord. Under normal conditions they appear in the third decade of life and are never absent in people over forty. In the cerebrum they are found in the lining of the ventricles and in the tractus olfactorius; they are less frequently found in the cerebellum. Redlich supposed that they had their origin in the nuclei of neuroglia cells. According to a widespread opinion they arise from the coagulation of myelin. It is not unlikely that some of them at least have their origin through the union with normal tissue juices of altered cell protoplasm exuded from the cell. Spiller believes that at least a portion of the corpora amylacea have been derived from altered blood-vessels. The colloid bodies described by Bevan Lewis and also by Spiller would seem to be closely related either to Russell's fuchsin bodies or to the corpora amylacea.

Recent studies make it seem certain that greater differentiation among these structures than that ordinarily made is necessary. Thus Siegert has divided them into corpora versicolorata (including the "corpora amylacea" of th central nervous system) and corpora flava (including the "corpora arenacea" of the central nervous system). The corpora versicolorata, so-called because they take a variegated tint in iodine or bromine, yield the "amyloid reaction" with aniline dyes, and are further characterized by their brittleness and their morphology. They may be, (*a*) spherical, ovate, or polygonal with rounded angles; (*b*) concentrically lamellated, and (*c*) sometimes radially striated. They never arise through direct transformation of cells, nor do they become calcified. The corpora flava, on the other hand, behave differently in solutions of the halogens (chlorine, bromine, iodine), staining of a yellow color only in Lugol's solution; they do not yield the amyloid reaction with the aniline dyes. They are waxy rather than brittle; they vary greatly in their morphology, being sometimes smoothly spherical, sometimes very irregularly shaped. Concentric lamellation may not be visible in them and they are never radially striated. Unlike the corpora versicolorata the corpora flava are said to arise directly from the transformation of cells and to show a decided tendency to become calcified.

(*b*) SECONDARY DEGENERATION, AND MODIFICATIONS IN THE NEURONE FOLLOWING UPON INJURY TO THE AXONE.—The nutritive centre of a neurone is in the perikaryon. The trophic influence emanates from the nucleus. If any part of a neurone be severed from its connections with the nucleus, the separated part dies. In case it is a medullated axone, which suffers solution of continuity, not only does the whole axone, distal from the lesion, undergo disintegration, but the myelin sheath degenerates in the same area and the nucleated sheath of Schwann or neurilemma undergoes important modifications. These phenomena taken in their totality are usually designated as secondary or Wallerian degeneration.

In the early part of the last century it was known that interruptions of the connection of peripheral nerves with the central system could lead to their degeneration (Nasse, Valantin, Stannius). The first careful study of the subject, with establishment of a law, was that undertaken by Waller, and from him the process has derived its name. He described it in detail—the coagulative breaking up of the myelin sheath and the dissolution of the axis cylinder. If a motor nerve is cut, all the fibres in the peripheral end degenerate completely as far as the muscles which they supply, the central end either remaining entirely intact or perhaps, as a result of the trauma, degenerating as far as the first node of Ranvier. If a sensory nerve be cut distalward from the spinal ganglion, all the sensory fibres of that nerve degenerate to the very periphery, though the portion of the nerve still in connection with the ganglion, as well as the central intramedullary continuation of the nerve, remain undegenerated. On the other hand, if a dorsal root of a spinal nerve is severed between the ganglion and the spinal cord, the portion of the nerve attached to the ganglion does not undergo degeneration, but that connected with the cord degenerates typically, not only in the portion outside the cord, but also throughout its whole intramedullary extent. This is the proof which has been brought for the view that the cell bodies in the spinal ganglia are the trophic centres for the peripheral sensory neurones. Following upon Waller's investigations came the observations of Türck, which demonstrated that the same law holds within the confines of the central nervous system—for example, for the pyramidal tract. Since Türck's studies a host of observations have established the general validity of the law for all groups of neurones. When an axone degenerates, the retrogressive process involves not only the main axone but also its terminals, together with the collaterals belonging to it with their terminals.

The study of secondary degenerations has been much facilitated by the introduction of Weigert's myelin sheath stain and the osmic-bichromate method of Marchi and Alghieri.

The finer histology of secondary degeneration has been studied by Homén, Howell and Huber, Tooth, von Notthaft, Ceni, and others. Von Notthaft subdivides the changes which occur in the nerve after section into two stages, the first including the alterations which take place during the first three days (fragmentation of myelin and of axone for a distance of one or two internodes on each side of lesion), probably due to trauma. The second stage, beginning on the second or third day and confining itself to that part of the fibre cellulifugal from the lesion, represents the true Wallerian secondary degeneration; it is not the direct result of the trauma, but is due to the severance of that part of the neurone from the trophic influence of the nucleus. In this second stage the axone swells up and undergoes fragmentation, and

www.libtool.com.cn
Digitized by Microsoft®

the myelin disintegrates into droplets cellulifugally from the lesion, as far as the peripheral termination. By the fourth day a multiplication of the nuclei of the neurilemma can be made out. Liquefaction of the myelin begins by the sixth or seventh day and continues until the sixtieth or eightieth day, when all of it is dissolved and most of it has been absorbed. The absorption is complete by the end of three or four months. If the degeneration affect medullated nerve fibres inside the central nervous system, neuroglia cells can be seen undergoing proliferation after some forty five or fifty days (Ceni). This proliferation ceases at the end of three months and sclerosis follows.

Marchi's method demonstrates the existence of degenerating fibres as early as eight or ten days after the lesion, and will continue to demonstrate their presence until all the myelin of the degenerating fibres has been absorbed, that is, until some three months have elapsed after the injury. At a later period we have to resort to Weigert's method; the areas which have degenerated show, of course, an absence of black fibres. Marchi's method is far more delicate than Weigert's; the former will reveal single degenerated fibres; the latter can be relied upon only when there is a considerable area of lightening in the region otherwise uniformly filled with black fibres. Anatomists have applied these methods most extensively in experimental work for the determination of the course followed by the medullated axones of the various groups of neurones of which the nervous system is made up. Pathologists utilize them to study the secondary degenerations which accompany various diseases of the nervous system in human beings.

For many years it was believed that the cellulifugal alteration, described by Waller, was the only one which occurred after axone lesion, but the introduction of more delicate methods still has revealed the fact that surprising changes occur in the neurones cellulipetal from the lesion, and particularly in the cell body or perikaryon itself. Nissl by the application of his methylene-blue-and-soap method has demonstrated definite alterations in the cell body as early as a few hours after axone lesion. The changes are most marked, however, when animals are killed from eight to fifteen days after the operation in which the axones have been cut. Nissl refers to this method of study as "the method of primary irritation." His results have been confirmed by Flatau, Marinesco, Lugaro, Van Gehuchten, Erlanger and myself, and many others.

The change which takes place in the cell bodies of the nucleus nervi facialis, for example, after section of the nerve trunk near the pes anserina, consist chiefly in alterations in the tigroid masses, in a moderate swelling of the perikaryon, and in a displacement of the nucleus toward the axone hillock. The change seems to affect the tigroid masses first. The spindles lose their typical stichochrome arrangement, break up into minute particles, become scattered diffusely throughout the cell, and finally undergo solution, the solvent process affecting the tigroid masses in the interior of the cell first, and extending gradually toward the periphery. This disintegration and solution of the tigroid has been variously designated. Marinesco calls it *chromatolysis*; van Gehuchten, *chromolysis*; Retterer, *chromophilysis*; Kohnstamm gives it the name *tigrolysis*, and the latter term is the one which I prefer.

Marinesco has described two distinct stages of the process, (1) A stage of *reaction*, in which the tigroid undergoes the changes above described; and (2) a phase of *repair*, during which the tigroid elements are restored to a more or less normal appearance. The first stage begins soon after section, and reaches its maximum in from fifteen to twenty days. The second stage lasts longer. It is essentially a phase of regeneration, and as in many cases of regeneration the elements regenerated are produced in excess; the individual tigroid masses are larger and more numerous than in the normal cell. During the first stage (that of reaction) the cell is swollen; during the second (that of repair) it gradually returns to its normal size. The nucleus, markedly displaced toward the axone hillock during the first stage, slowly reassumes its former position in the centre of the cell during the stage of repair. A few cells in motor nuclei, after section, fail to undergo this repair, and van Gehuchten assumes that in them the turgescence of the cell has taken place so suddenly during the first stage and the propulsion of the nucleus has been so violent that the latter has been completely expelled from the cell body. Such cells, deprived of their nuclei, necessarily undergo total degeneration. It was thought by Marinesco that the stage of repair was conditional upon regeneration of the distal end of the axone, but Nissl, van Gehuchten, and Foà have shown that this is an error, and that the altered cells return to their normal state entirely independently of the phenomena of regeneration at the point of section. At least this seems true of experiments upon animals, though there are some observations upon the spinal cord of human beings following upon amputation, which indicate that cells still tigrolytic may be observed in the cord for from three to seven months after the operation.

There would appear to be an intimate relation between the degree of injury to the axone and the changes which take place in the perikaryon, for when nerves are torn out, the effects are very different from those which follow simple section of a nerve. Thus Ballet and Marinesco showed that if a nerve be torn out, a large number of the cells undergo complete destruction and are absorbed. This may explain the cellulipetal secondary degenerations obtained by von Gudden's method (*vide infra*).

One of the more recent developments of the study by Nissl's method indicates that tigrolysis occurs constantly after section of a cerebral nerve, but may or may not occur after section of a spinal nerve, though it inevitably follows the tearing out of the same spinal nerve (Van Gehuchten and de Neeff). The inference has been drawn that the lower motor neurones in the spinal cord of the rabbit and dog possess a greater resistance to experimental injury than do the lower motor neurones of the medulla, pons, and midbrain.

The method introduced by Nissl is of very great importance to anatomy, since by means of it the exact cell bodies which give off the motor axones to individual muscles can be easily localized in the central system.

It is now much easier to understand the early investigations bearing upon atrophy of the motor roots and gray matter of the spinal cord after amputation. The younger the individual at the time of amputation, and the longer the time elapsing between the operation and death, the more marked are the alterations. It would appear that if an amputation be done early in life, many of the neurones concerned in innervating the amputated limb undergo complete degeneration and disappear totally, that is to say, in addition to the Wallerian cellulifugal degeneration, which of course occurs in the amputated stump, there takes place in young individuals a slow atrophy or slow cellulipetal secondary degeneration of the whole neurone, notwithstanding the fact that the perikaryon with its nucleus is left in the mutilated neurone. This vulnerability of neurones in young animals is especially well illustrated by the long series of experiments which were made by von Gudden. The distinguished Bavarian investigator showed that after removal of an eye in a young rabbit, in the course of some months not only did a total degeneration of the optic nerve of the same side and partial degeneration of the optic tract of the other side take place, but also extensive degeneration occurred in the superior colliculus of the corpora quadrigemina and lateral geniculate body of the opposite side. This general observation showed immediately what regions of the gray matter are intimately related with the optic nerve. The study of the microscopic changes in these primary optic centres proved that this method permits one to draw also important conclusions concerning the finer histological connections of the axones of the optic nerve with their centres of origin and of termination. Thus while in the superior colliculus after the operation above mentioned entire rows of nerve cells had

Digitized by Microsoft®

disappeared from the superficial layer of gray matter, in the lateral geniculate body the ganglion cells were but very little altered; but between them, and especially in the gelatinous substance lying in the lateral part of this nucleus, there had been a very great loss by absorption of fine nerve fibres, the terminals of the optic nerve. It was easy to interpret these observations. Where as a result of the lesion there had occurred cellulifugal degeneration of the ground substance in direct continuation with cellulifugal degeneration of nerve fibres in the optic tract and optic nerve, we have to deal with the nucleus of termination of the axones of neurones, the cell bodies of which are situated in the retina. On the other hand, in the part of the colliculus superior where there had been a cellulipetal disappearance of ganglion cells, as a result of the removal of the eye, it was evident that we have to deal with a nucleus of origin of centrifugal axones which run out through the optic tract and optic nerve to the eye. That this conclusion is correct, the application of the methods of Golgi and of Flechsig to the problem have left no doubt.

www.libtool.com.cn

Von Gudden and his pupils utilized this cellulipetal secondary degeneration in young animals in extending widely our knowledge of the anatomy of the brain. By it the nuclear origin of the various cerebral nerves were very exactly defined, and later, the connections of the lemniscus, the brachium conjunctivum, the cerebrocortical pontal paths, and various other tracts were determined and their centres of origin and of termination accurately established.

A study of a large series of pathological cases in human beings following upon hemorrhage, softening, or pressure from various causes in the brain has proven that in human beings also the cellulipetal degeneration (corresponding to the experiments of von Gudden) occurs as well as the typical cellulifugal secondary degeneration of Waller. What is more, a study of human cases reveals the fact that if a neurone of a high order fails to receive its normal impulses from a set of neurones of the next lower order, owing to degeneration of the latter, the former undergoes a slow diminution in size throughout its whole extent (diminution in size of lemniscus accompanying sclerosis of posterior funiculi of cord). Again, if a set of neurones in a neurone chain is unable, through degeneration of the next higher group of neurones in the chain, to pass on its impulses to the latter, it undergoes a slow atrophy, all the neurones of the set gradually diminishing in size. This is well shown when, for example, the somæsthetic area of the cortex is destroyed and secondary degeneration of the thalamocortical neurone system results; the lesion is followed in the course of years by marked diminution in the volume of the lemniscus medialis, of the stratum interolivare lemnisci, and of the nucleus funiculi gracilis and nucleus funiculi cuneati of the opposite side, the cell bodies of which give rise to the axones of the lemniscus.

Bethe also studied the degenerative changes in the axis cylinder after section of the nerve. He states that the first change is the disappearance from the fibrillæ of a substance which is primarily colored by basic dyes, and that with the disappearance of the primary colorability of the nerve there disappears its excitability. There follows a breaking up of the primitive fibrillæ into large and later into fine granules; at the same time a breaking up of the medullary sheath with ellipsoid formation. Degeneration is always apparent in the primitive fibrillæ before such is seen in the medullary sheath. This degeneration does not occur in the whole nerve at the same time, but is first apparent near the seat of the lesion from which it can be traced at later periods toward the periphery. Corresponding changes are found in the central stump, though here the degeneration is limited in extent, though certain fibres may be seen degenerating far toward the cord. He denies that in the central stump degeneration ends at the first nerve of Ranvier nearest to the point of lesion (traumatic degeneration). From his investigations he confirms the opinion that sensory fibres degenerate more quickly than motor, and he further states that thicker fibres, both motor and sensory, earlier show signs of degeneration than finer fibres.
