There is always a pendulous abdomen with anteflexed uterus and a tendency to malpresentation, which is usually corrected by the onset of pains. Engagement of the head in the first stage may be delayed. As soon, however, as the head is engaged progress is normal until the outlet is reached. Here the bony obstruction may be such that prolonged moulding or assistance by forceps becomes necessary for the extraction of the head. The narrowing may prevent the forward rotation of an occiput posterior, or even cause an anterior position of the occiput to turn into a posterior. Four per cent. of cases are reported to present by the face. In this deformity the bi-ischiatic measurement is of importance in prognosis. If it is below 8.5 cm. there is probability of serious difficulty.

FIG. 3757.—Side View of Same Showing Pendulous Abdomen.

Oblique deformities of the pelvis of the extreme type are due to failure of growth of one of the sacral alæ. To this deformity the name of Naegele, who first described it, has been given. The oblique measurements vary widely. The short oblique is that of the normal side. The sacrum, which is narrowed, faces from the small side. The pubic arch is asymmetrical. The sacrum is narrowed. Vaginal examination shows the front of the sacrum and promontory facing toward the diseased side. The ischial tuberosity is higher on that side and the corresponding posterior superior spine is higher, lying closer to the sacrum. The subpubic angle is asymmetrical and looks toward the diseased side.

The failure in growth may be due to a congenital developmental defect or to disease. If it is due to a con-

Digitized by Microsoft®

genital defect, the deformity is not evident until after walking has occurred. Pressure then causes the crowding up, in, and back of the innominate bone on the diseased side, and the rest of the asymmetry noted above. If it is due to disease of the sacro-iliac joint, tuberculosis, or some acute arthritis secondary to the general disease, must in early life have been sufficiently extensive to destroy the bony nuclei of the ala of the sacrum on that side. Ankylosis of that joint is the usual accompaniment of the deformity, but is not the absolute rule.

FIG. 3758.—High Dorsal Kyphosis. (Service of Dr. Edwin B. Cragin, Sloane Maternity Hospital.)

www.libtool.com.cn

The diagnosis is easily made by means of the pelvimeter and the vaginal examination. If disease be an etiological factor the presence of a scar or sinus over the affected iliac joint aids in the diagnosis.

The effect produced by this deformity upon labor in the less extreme cases may not be serious. But usually the distortion is so extreme that the natural delivery is impossible. The delivery, if possible, is accomplished by extreme flexion and moulding of the head, as in the generally contracted pelvis. Abnormalities of rotation and flexion are apt to occur in the lower pelvis.

The forceps may be tried, and if these fail craniotomy or the Cæsarean section may be performed. Symphyseotomy is contraindicated on account of the probable ankylosis of the sacro-iliac synchondrosis on the affected side.

Where both sacral alæ have failed of development that rare deformity, the *double obliquely contracted pelvis*, is found. In 1842 this type of pelvis was described by Robert, and has since been known as the Robert type. Very few cases of this type have been reported. From the same causes as in the Naegele pelvis, the sacral alæ are both absent or only partly developed. There results the extreme type of transversely contracted pelvis. The pelvic brim presents the outline of a long narrow ellipse. The conjugate is of normal or only slightly lessened size, the obliques are much shortened, and the transverse diameter excessively narrow. The sacrum is long, narrow, and oblong rather than triangular. Both sacro-iliac joints are usually ankylosed. The posterior superior spines are very close to each other. The pubic arch is narrowed. Unequal development, due to partial growth of one ala, may cause a slight degree of obliquity.

The effect of such extreme contraction must be complete obstruction to the passage of a viable child.

Another rare type of developmental deformity is that in which the pubic rami have not developed sufficiently to meet at the symphysis. This is called the *split pelvis*. It furnishes no obstruction to delivery.

The lesser degrees of obliquity, which rarely have much effect on the mechanism of labor, are due to scoliosis; to injuries or disease of hip, knee, or ankle-joint; to failure in development of one limb from some kind of paralysis, usually poliomyelitis; or to club-foot.

In cases of *scoliosis* extra pressure is transmitted through the lower acetabulum and there is consequent shortening of that oblique. Simple scoliosis is common, but it often accompanies rachitis or vertebral caries. If there is rachitis, there are the other rachitic effects on the pelvis and a greater obliquity. If scoliosis is combined with Pott's disease, there is merely slight obliquity added to the typical kyphotic pelvis. This is the so-called *kyphoscoliotic pelvis*. The slight obliquity caused by such simple scoliosis is of no significance, but the shortening of the spinal column may cause a pendulous abdomen, which will give trouble in the engagement of the head at term.

Any cause which acts so as to limit or do away with the use, in early life, of one of the lower extremities, reacts upon the pelvis by throwing greater pressure upon the well side. Tuberculous disease of the hip, knee, or ankle-joint is the most common disease affecting the lower extremities. Local deformity of the pelvis has been encountered from erosion of the acetabulum and displacement of the head of the femur through into the pelvic cavity. Ankylosis of one or both femora in adduction may cause an obstruction to delivery.

A congenital hip dislocation causes the pelvis to develop with one short oblique from pressure on the healthy side. An anterior displacement of the femur may drive in the anterior wall of the pelvis. The head of the femur may project over the ramus into the pelvic outlet. If both femora are dorsally displaced there is a shallow pelvis with wide outlet.

A rare deformity, but a most serious one from an obstetrical standpoint, is that known as *spondylolisthesis* of the lumbar vertebræ. It was described by Rokitansky in 1859, and later by Neugebauer. The bodies of the vertebræ are dislocated forward. There is some lumbosacral dislocation permitting a slipping of the body of the last lumbar vertebra in front of the sacrum. Here it becomes ankylosed. Then exaggerated lordosis occurs, and possibly there is a descent of the fourth and third lumbar vertebræ, so that they project over the pelvic brim. The sacrum is pushed down and back. In compensation the symphysis rises, lessening the inclination of the brim. There is narrowing of the brim, with antero-posterior limitation, which will prevent the passage of the head.

FIG. 3759.—Low Dorsal Kyphosis. (Service of Dr. Edwin B. Cragin, Sloane Maternity Hospital.)

This deformity may be started by disease, especially lumbar caries, or by injuries, or perhaps it may date from intra-uterine life. For diagnosis we must depend upon the history of the case—the

Digitized by Microsoft®

story of injury from a fall or accident, or of spinal disease; perhaps the fact of carrying heavy weights.

There are extreme shortening and a pendulous abdomen. Examination shows the ribs lying close to the ilia. The shoulders are carried well back, as the patient stands in lordosis. There may be lumbar crepitus, felt while walking. The vulva, owing to the change in pelvic inclination, presents anteriorly as the patient is standing or sitting. By vaginal examination the bodies of the projecting vertebræ may be easily felt and the contracted outlet also noted. The limitation at the pelvic brim precludes any possibility of a normal fœtal head engaging.

Tumors of the pelvis may be of large size and may almost obliterate the pelvic cavity, or they may be merely bony excrescences springing from the region of the pelvic brim. They may grow from the inner surface of the symphysis, from the sacro-iliac joints, or from the ileo-pectineal line. If sharp they form what is known as the pelvis spinosa. The projecting bits of bone may cause dangerous circumscribed pressure on the child's head. The larger tumors may be enchondromata, sarcomata, or carcinomata. They necessitate embryotomy or Cæsarean section. Fractures of the pelvis rarely may cause deformity from the growth of callus.

Ankylosis of the sacro-coccygeal joint, which normally occurs after the menopause, may happen prematurely and furnish some resistance to the passage of the child's head. The uterine contractions are usually of sufficient force to fracture the bone. Sometimes the head is held by this deformity until the bone is artificially fractured or the forceps is applied. With the fracture a snap is sometimes plainly heard and the head thereafter advances readily. The fracture of the bone should be accomplished under chloroform, the thumb and forefinger of the accoucheur grasping the coccyx.

FIG. 3760.—Lumbar Kyphosis. (Service of Dr. Edwin B. Cragin, Sloane Maternity Hospital.)

The consideration of pelvic deformities is incomplete without a word concerning *prophylaxis*. The possibility of the results of rachitis upon the pelvis should make the mother careful about the feeding of the infant, its general hygiene, and especially about its allowance of fresh air. Early attempts at walking should be forbidden, especially if the infant is heavy. The effect of disease or deformity of the skeleton of the female child upon the pelvis is an argument for early consultation with the orthopedic surgeon and the early correction, if possible, of existing deformities.

When the deformity exists in the child-bearing woman the obstetrician must be able to recognize the deformity, and by trained judgment determine its probable effect on labor. The question may arise whether the patient is warranted in entertaining the hope of having children at all, or, if she be in earlier pregnancy, whether the deformity calls for an induction of premature labor. Should the patient be in labor, other conditions must be taken into account. These are: the extent of obstruction presented by the soft parts, the relative size of the child's head and its capacity for moulding, the force of the labor pains, and lastly, the ability of both mother and child to withstand the strain of delivery. The history of previous labors is of value, but it must be remembered that the size of the child tends to increase up to the fifth or sixth pregnancy.

FIG. 3761.—Kyphosis so Extreme as to Necessitate Cæsarean Section. (Service of Dr. Edwin B. Cragin, Sloane Maternity Hospital.)

If the child is small or premature, slight pelvic deformity may have no significance; and yet with a child above normal size this defect may constitute a serious obstruction. Such cases of overgrowth of the child are occasionally met with, and are the result of a large father, overnutrition of the fœtus from the mother, and sometimes of the prolongation of pregnancy one or more weeks beyond normal.

Those cases of slight obstruction, in which delay occurs in the second stage, justify a waiting policy. Nature with time will accomplish sufficient moulding in a safer way than if forceps were used. Good judgment requires that one know how long it is safe to allow this moulding to continue. Too long compression of the head gives danger of intracranial hemorrhage. Too long-continued pains expose the mother to exhaustion and shock, and ultimately to a tonic uterus with possible rupture, or an exhausted uterus with resulting post-partum hemorrhages. On the other hand, early interference before the head has had time to mould will expose both mother and child to needless trauma. Account must be taken of the force and frequency of the pains; the maternal pulse, and evident amount of suffering caused by the pains; the rate and force of the fœtal heart; and the amount of moulding, as shown by the caput and overlapping suture, and by the advance of the child's head.

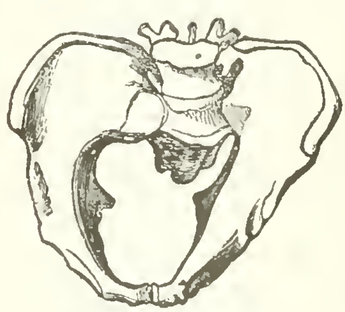

FIG. 3762.—Obliquely Contracted Pelvis. (After Duncan.)

Digitized by Microsoft®

In some cases the severity of the pains or the poor condition of mother or child may necessitate operative delivery before the patient has been in the second stage an hour. In other cases in which the uterine contractions have been of poor quality some good may be accomplished by a delay of several hours. Uterine action may be stimulated meanwhile by tonics, such as strychnine or quinine. The erect posture increases the force of the pains. In cases with a flat pelvis some increase in the conjugate, from 0.5 to 1 cm., may be accomplished by the Walcher position. The patient lies in the dorsal position with the thighs extended over the end of the table, and the feet barely touching the floor. If there is some advance of the head, pressure on the fundus, during the pains, may be tried.

www.libtool.com.cn

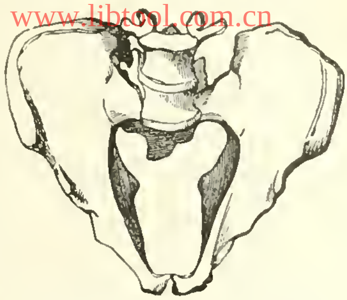

FIG. 3763.—Robert's or Double-Obliquely Contracted Pelvis. (After Duncan.)

For the more extreme degrees of dystocia, due to deformity, there may be used the forceps, podalic version, usually combined with breech extraction, the induction of premature labor, symphyseotomy with forceps, the Cæsarean section, craniotomy, or, in the cases of extreme contraction, craniotomy with evisceration.

The low forceps operation for deformities of the pelvis is usually necessary in those cases of limitation of the pelvic outlet, as in the kyphotic cases or those of the masculine type. In the worst kyphotic cases symphyseotomy may be necessary. The medium forceps operation is more common in the generally contracted pelvis. For the flat and generally contracted pelves high forceps may be needed. In justo-minor pelves, the only possibility of safe delivery by the natural route lies in extreme moulding of a well-flexed vertex.

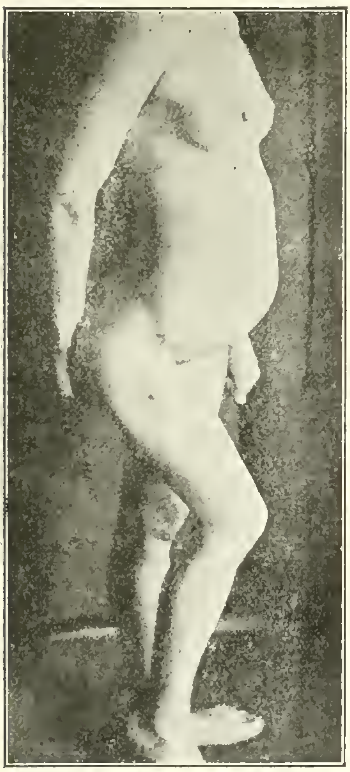

FIG. 3765.—Obliquely Contracted Pelvis, Following Coxitis. (Service of Dr. Edwin B. Cragin, Sloane Maternity Hospital.)

In the flat pelvis the indication for high forceps is not always so plain. The head in these cases coming down in the transverse diameter must often be grasped by the forceps with one blade applied to the occiput and one blade to the face. The effect of traction then is partly to mould the head so that the biparietal diameter tends to widen. As has been described above, the after-coming head in a breech extraction accommodates itself in such a way that the bitemporal diameter engages the narrowed conjugate. For this reason version and breech extraction are frequently resorted to, in cases of flattening, with good result.

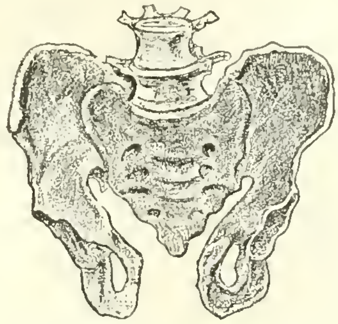

FIG. 3764.—Pelvis in which the Pubic Rami Fail to Meet at the Symphysis. (Schauta.)

If the head, in case of a flat pelvis, is engaging well, forceps may be tried gently. If the head persists in not engaging, version is preferable provided there is a reasonable possibility of bringing the head through. If in the case with the head engaged the forceps fail to accomplish advance, the head may be disengaged and version tried. It must be remembered that the version is of value only in the simple flat pelvis which is ample in other measurements. In a flat justo-minor pelvis version is worse than useless.

Where the conjugate is quite short, the head may be prevented by the deformity from descending far enough to dilate the cervix. In such a case, before any operative delivery is attempted, the cervix should be carried to full dilatation by means of the hydraulic bags or by digital stretching.

FIG. 3766.—Simple Scoliosis. Patient delivered by low forceps. (Service of Dr. Edwin B. Cragin, Sloane Maternity Hospital.)

The *induction of premature labor* in selected cases is

Pelvic Cellulitis.

an operation which has a most important field of usefulness. If the pelvis is small and the head seems to be riding high, or if a woman habitually has larger children than can safely be born, it is proper carefully to watch the patient during the last two months of gestation and to terminate pregnancy at any time when the child's head seems, relatively to the pelvis, a close fit. Once a week the patient should be examined, and by the bimanual method the ratio between the size of the head and the diameter of the pelvis carefully estimated. There will be a certain proportion of disappointments, but what might be otherwise fatal dystocia will be avoided, and in many cases a healthy child secured.

www.lbtool.com.cn

FIG. 3767.—Spondylolisthesis. (Neugebauer.)

As a rule any child of over eight months' gestation will do well with proper care, and sometimes one even younger will thrive. The success depends on the judgment of the physician, who should allow to the infant every week of intra-uterine life that is possible. An error either way is bad. If the operation is delayed too long, the premature infant will resist very poorly the manipulation necessary for an operative delivery. If labor is induced too early, the child is robbed of just so much vitality.

The operation of *symphyseotomy* has lost favor in the last few years because of the risk of infecting the mother, or of leaving her permanently crippled from failure of union of the symphysis, and because of its uncertain results as compared with the good results of a properly performed Cæsarean section. It must be restricted to cases in which the possible separation of the pubic bones of 7.5 cm. will enlarge the pelvic canal sufficiently to allow the head to pass. It is of no value in those cases in which the sacro-iliac synchondroses are ankylosed. The tedious convalescence of the mother is a serious matter.

FIG. 3768.—Enchondroma of the Sacrum of such a size as to Diminish very greatly the Capacity of the Pelvic Cavity. (Behm.)

Compared with the Cæsarean section, it is the more dangerous, more uncertain of the two, and of greatly restricted range of application.

The *Cæsarean section* must be employed in those cases in which there is no other possible method of delivery of the child living or dead (the absolute indication), or it may be employed (the relative indication) in cases in which delivery of a living child is possible only by laparotomy. The indication has been extended, by some, even to those cases in which delivery of a living child is improbable except by laparotomy.

This operation in properly experienced hands seems to promise great usefulness. Every year the indications for this operation are enlarged. Whereas a few years ago, on account of the great mortality of the Cæsarean section, only the absolute indication for the operation was considered valid, now, granted good surgical facilities, the question of a conservative laparotomy in the interest of both mother and child may be decided in the affirmative in cases of obstructed labor. If the deformity is so great that a successful induction of premature labor in a later pregnancy is improbable, the uterus should be removed at the time of operation.

The mutilating operation on the child, commonly known as *craniotomy*, is indicated where the obstruction is absolute and the child dead, or where the condition of the mother, or the lack of facilities for operating, prohibits surgical interference. The crushing followed by traction on the head is usually sufficient to effect delivery without much additional shock. Rarely, if the child is of large size, evisceration or further mutilation of the child must be resorted to. *Franklin A. Dorman.*

PELVIC CELLULITIS.—DEFINITION.—Pelvic cellulitis is an inflammation of the pelvic cellular tissue which may or may not go on to abscess formation. The same condition is also described sometimes as parametritis, perimetritis, pelvic abscess, etc.

ANATOMY.—Before describing pelvic cellulitis, a few words as to the anatomy of the pelvis will be necessary. Rosthorn defines the functions of the pelvic cellular tissue as follows: 1. It serves as a material to fill in empty spaces between the organs. 2. It serves to connect the peritoneum to the underlying organs. 3. It serves as a sheath for the blood and lymphatic vessels. 4. It serves as ligaments, holding the various organs one to the other and to the surrounding bony structures. We can see, therefore, that the connective tissue is freely distributed through the pelvis and forms the loose framework in which lie the organs. The denseness of this tissue varies according to its function and position. In places there is a distinct thickening, forming, if we may call it so, a species of curtain, which divides one portion of the pelvis from another and tends to localize infection to one part of the pelvis, though when an abscess forms it may be easily imagined as breaking through the septa. These septa or curtains are difficult to demonstrate by dissection, and the most striking way of showing their relations is by the injection of material which will harden *in situ*. By this method three main regions are found to occupy each side of the pelvis. (1) The anterior region comprises the cellular tissue around the bladder and that lying anterior to the cervix, there being a connection between these regions on the two sides through the cellular tissue binding the posterior surfaces of the bladder to the anterior portion of the cervix and uterus. (2) The next region is bounded anteriorly by the above-described partition, posteriorly by a second curtain which extends from the uterus outward along the infundibulo-pelvic ligament, giving to this area a rough triangular shape with the base directed toward the pelvic wall and the apex toward the uterus, and including practically all of the connective tissue lying in the fold of the broad ligament and continuous with the cellular tissue filling the iliac fossa. (3) The third, or posterior area, surrounds the rectum and is continuous with the cellular tissue of the retroperitoneal area.

Besides these three main divisions, anatomists describe several less well-marked areas where an infection may be localized.

ETIOLOGY.—Infection of the cellular tissue is always due to the attack of one of the pathogenic bacteria, and, according to whether the bacteria gain entrance directly to the cellular tissue through a wound or by lymphatic infection, or whether the infection follows by direct ex-

Digitized by Microsoft®

tension from inflammation of the tube or other pelvic structures, we divide the cellulitis into the primary and the secondary forms.

In the primary forms the cellular tissue is invaded directly by the disease-producing bacteria, generally through a tear or wound in the cervix or uterus, or by direct lymphatic extension.

www.libtool.com.cn

In the secondary form the seat of infection primarily is the tube, ovary, bladder wall, or rectum, the cellular tissue being invaded by contiguity. The primary cellulitis is the rarer of the two, and for some years its possible occurrence was denied.

Wounds of the cervix are not frequent in any condition save that of childbirth, and this is by far the most frequent etiological factor in primary cellulitis, the bacteria being introduced by the unclean finger and advancing directly into the tissues. In an occasional case the infection also results from a wound of the cervix from careless dilatation, or from the use of the uterine sound or other instrument in such a manner as to cause a puncture through the vaginal wall of the cervix or the uterine wall.

Secondary cellulitis of some part of the pelvic tissue accompanies almost every case of distinct inflammation in any of the pelvic organs. Most frequently the condition follows salpingitis or pyosalpinx, the tube being the most frequent site of inflammation in the female pelvis.

Morbid Anatomy.—The pathological picture presented in this disease varies according to the type and the degree of virulence of the infecting organism. Most of the cases of primary cellulitis are due to invasion of the tissue by the streptococcus, and naturally the picture of a virulent infection is given. If the tissues be examined early enough all that will be noticed is a brawny infiltration of the loose tissue, which on minute examination is found to be due to a rapid proliferation of round cells and to the effusion into the tissues of serum and leucocytes. Later, we find distinct small abscesses scattered through the tissues, the size of the abscesses varying from the point to the head of a pin. Still later, if the infection continues and the patient lives, we find that the numerous small abscesses have become conglomerate, and that a distinct abscess has been formed. Not infrequently, however, an abscess does not form, but, instead, the tissues appear to gain a certain amount of resistance against further breaking down, and in place of the conglomerate abscess a slow absorption of the minute abscesses present and a gradual healing take place. In the secondary infections we are less apt to find abscess formation, especially if the infection is due to a not extremely virulent species of microorganism (the gonococcus, for example). Naturally, when the tubal or ovarian disease is due to infection by the more virulent organisms, we find more frequent abscess formation, generally in the folds of the broad ligament. As already stated, in the primary forms the streptococcus, either alone or in company with one or more of the other organisms, is the cause of infection. In the secondary cellulitis the gonococcus, the staphylococcus pyogenes albus and aureus, the typhoid bacillus (rarely), the proteus and certain other rarer forms, have been isolated from the tube or ovary and evidently would be found in the focus of secondary infection.

Symptomatology.—*Primary Cellulitis.*—In this form the symptoms are usually quite well marked. Generally three or four days after a labor in which careful asepsis has not been observed, or in which there has been much handling, the patient will have a distinct chill, the temperature rising to 102° or 103° F. She will complain of general malaise, violent headache, possibly nausea, and of acute pain in the lower abdomen, generally located in one side or the other. On examining such a patient the lower abdomen will be found somewhat full, and palpation will be impossible from the amount of muscular spasm present. In making a vaginal examination a sense of resistance will be found at the base of one of the broad ligaments, the uterus will also be found to be somewhat more mobile than it should be, and the patient will complain of extreme pain when we attempt to move the uterus or make pressure upon the lateral fornices. After a day or two a distinct induration will be felt through the vagina, and on bimanual palpation a moderately-sized mass will be felt lying in the broad ligament. In some cases this indurated mass can be easily felt above Poupart's ligament as a dense hard tumor.

Secondary Cellulitis.—The symptoms of this form are commonly masked by the primary disease, and it is practically always the primary disease that we are called upon to treat, for, unless an abscess of the cellular tissue be present, the curing or the removal of the primary point of infection will be followed by a slow amelioration or disappearance of the cellular inflammation.

Diagnosis.—The diagnosis of the primary form is based partly on a study of the symptoms, but chiefly on the results of the abdominal, the vaginal, and the bimanual examinations. For if we find on abdominal examination an indurated mass extending up along the anterior abdominal wall; if on vaginal examination the lateral fornix of the same side is found to be hard, dense, and brawny, or possibly depressed toward the outlet; and if on bimanual examination we can outline a distinct mass between our hands, separate from the uterus or enclosing the uterus in its outlines, we may feel reasonably sure that whatever else is present we have an inflammation and probably an abscess in the pelvic cellular tissue.

The diagnosis of the secondary form is not of so much importance if the diagnosis of the primary focus be made, as we may be sure that with pyosalpinx, ovarian abscess, or any collection of pus in the peritoneum, there will be more or less involvement of the contiguous cellular tissue.

Treatment.—*Primary Cellulitis.*—In this affection we must be governed by the inflexible surgical rule that, if pus be present, it must be evacuated by the shortest available route, and it only remains for us to decide which would be the shortest route for its evacuation. In many cases it is difficult to be absolutely certain as to whether pus is present or whether the tissues are merely densely infiltrated, and fortunately this need not greatly bother us, as the best results are gotten by breaking down and draining such an exudation. Hence in every case of primary cellulitis, whether the exudation has broken down and pus has formed, or whether merely a dense indurated mass is present, the indication is clearly to provide effective drainage.

There are two paths by which we may get at such a mass and drain it: first, through a vaginal incision; second, through an abdominal incision. The best drainage is undoubtedly gotten through the vagina, as it is the most dependent part, and this avenue of attack is selected in those cases in which the abscess or the indurated mass is distinctly palpable through the vaginal vault, or in which the abscess is distinctly pointing in this direction. The abdominal route is selected in the cases in which it may be difficult or dangerous to make the vaginal puncture, or when the mass is distinctly pointing above Poupart's ligament. To make the vaginal puncture the patient, after being anæsthetized and after the vagina and surrounding parts have been made surgically clean, is brought to the edge of the table with the buttocks protruding slightly over it and the thighs flexed on the abdomen, where they are held by an assistant or by one of the many leg-holders. A final careful examination is then made to outline again the pelvic mass. A Simon's speculum is introduced into the vagina, the posterior lip of the cervix is grasped with the tenaculum, and the posterior vaginal fornix put on the stretch. Then with the knife or scissors a little incision is made in the vaginal vault through the vaginal mucous membrane just back of the cervix. The speculum then having been withdrawn, the forefinger of the left hand should be introduced into the rectum, and the thumb of the same hand into the vagina, the tip of the thumb resting against the incision made in the vaginal vault. Then a sharp-pointed pair of scissors should be carried into the vagina, and under the guidance of the thumb the pointed end of the closed scissors should be placed in the small incision in the vault and at the proper moment plunged boldly into the pelvic mass. The presence of the forefinger in the rectum serves not only to indicate

Digitized by Microsoft®

the exact position of this organ, but also to guard it against possible damage. If an abscess be punctured by this manœuvre, there will be a gush of pus into the vagina and the scissors can be withdrawn. Then the opening into the abscess may be widened by careful cutting or by tearing with a pair of Goodell dilators, and after this the cavity should be explored with the finger to estimate its size and position, and to make sure that no more unopened abscesses remain behind. If no pus follows the puncture by the scissors this instrument is to be withdrawn and the finger is to be carried into the track of the puncture. By this manœuvre one may oftentimes succeed in finding an abscess which was not opened by the scissors. If no abscess be present the brawny indurated tissues are broken down with the finger so that a moderately large cavity remains where the indurated mass was before. The opening into this cavity must also be widely dilated so as to prevent undue narrowing before complete healing has taken place. Then either the abscess or the artificially made hole in the indurated tissues is to be firmly packed with iodoform or subiodide of bismuth gauze, and this gauze is allowed to remain in place for some days unless untoward symptoms appear. After the lapse of five or six days the gauze is slowly removed, a little bit being taken out each day until the whole shall have been removed. In some cases it may be necessary after this to pack again.

If the path through the abdomen is chosen, the abscess or the mass of indurated tissue must be reached and drained in precisely the same manner as would be adopted in the case of any other collection of pus in the abdominal cavity. The incision is generally made parallel to and just above Poupart's ligament, care being taken to avoid the deep epigastric artery which runs directly under the incision. When the abscess is reached the pus escapes through the opening thus established. Then either a glass or a rubber drainage tube should be carried down to the bottom and gauze packed around it. On the other hand, if simply a mass of indurated tissues is found, then this is to be broken down in the same way as through the vaginal incision.

In some cases it is desirable to combine the two methods of procedure; that is to say, we may establish drainage both through the vagina and through the abdomen. Such double drainage is usually followed by a more rapid healing of the abscess cavity, but it leaves an unsightly scar on the abdominal wall, and the sinus will sometimes remain open for some months before final healing takes place.

The treatment of the *secondary cellulitis* resolves itself into the treatment of the associated primary condition, and needs no special notice.

Prognosis.—The prognosis of pelvic cellulitis will necessarily vary according to the virulence of the infecting organism. In any event, however, the prognosis, in a case of the primary form, must always be very guarded, as the patient may linger along for weeks and finally die of exhaustion even though the abscess has been thoroughly opened and apparently good drainage obtained. At the same time, if the patient survives the formation of an abscess, we may rightly expect that the free incision and the establishment of drainage, in combination with careful general treatment, will be followed by a final recovery.

Otto G. Ramsay.

PELVIC PERITONITIS.—Definition.—Pelvic peritonitis is an inflammation of the visceral or parietal pelvic peritoneum, and either remains confined to this portion or extends upward into the general peritoneal cavity. Pelvic peritonitis should not properly be described as a separate and distinct disease, for it is due to the same causes as those which excite an inflammation of the general peritoneal cavity, and the effects which are produced are also essentially the same. Because, however, of the situation and peculiar anatomical relations, inflammation here is much more commonly localized than is inflammation in other parts of the peritoneum, and for this reason we are justified in describing it separately.

Synonyms.—(Pelveo-peritonitis; parametritis; perisalpingitis, etc.)

Varieties.—There are three varieties of pelvic peritonitis, viz., (1) acute or fresh pelvic peritonitis, (2) chronic exudative peritonitis, and (3) chronic adhesive peritonitis. Except in those cases in which there is tuberculous disease, we rarely see the chronic form except as the outcome of a preceding acute inflammation. The converse is not necessarily true, viz., that the acute form of inflammation is always followed by chronic manifestations; at the same time it is not common to have an acute pelvic peritonitis clear up entirely without leaving some few slight adhesions, or a certain amount of roughening and thickening of the pelvic peritoneum.

Etiology.—Acute pelvic peritonitis is always the result of bacterial infection, and practically always secondary to some acute inflammation elsewhere, as in the tube, the ovary, the uterus, the bladder, or the rectum; or possibly it may develop from an appendicitis.

The most frequent causative micro-organism is undoubtedly the gonococcus, which, so far as danger to life is concerned, may rightly be considered the least malignant. The streptococcus pyogenes is another organism which causes pelvic peritonitis. Owing to its greater malignancy, however, this micro-organism gives rise to an inflammation which rarely remains localized in the lesser cavity, but extends upward to the general peritoneum. Pelvic peritonitis has also sometimes been due to the presence of the staphylococci, of the colon bacilli, or of some of the micro-organisms which in exceptional cases play a part in exciting tubal inflammation. As other possible sources of infection may be mentioned an ovarian abscess, or a focus of infection located in the cellular tissue or in the network of lymphatic vessels.

Morbid Anatomy.—The reaction of the pelvic peritoneum to irritation is exactly the same as that which takes place in any serous membrane. The only features to which, in the limited amount of space at my command, I need to call attention, are the following: There is a decided tendency, in an inflammation of this character, to the throwing out of plastic lymph upon the free peritoneal surface, and, at the points where this occurs, adhesion between the contiguous parts is almost sure to follow. In a few cases, however, the exuded lymph may undergo absorption, and the affected serous surfaces may eventually return to a normal state. In the majority of instances the pelvic peritonitis, after the subsidence of the more acute manifestations, assumes the characteristics of either a chronic exudative or a chronic adhesive peritonitis. The chronic exudative form is characterized by the exudation of serous fluid, which, as a rule, is found in a sort of cul-de-sac that is walled off from the general cavity by a roof of adherent intestines. This sac, in the early stages, contains a clear serous fluid, but sooner or later this fluid becomes purulent in character, by reason of the wandering in of leucocytes. In the chronic adhesive form, instead of a serous exudation, there is thrown out, as already stated, a more plastic lymph which glues together all the pelvic structures. This is the form of the disease which is most frequently observed and in which the adhesions may be so numerous that the tube, ovaries, and uterus are bound together in one indistinguishable mass.

Symptoms.—Acute peritonitis gives rise to well-marked symptoms. The patient complains of acute pain localized in the lower abdomen, and with the pain there is a distinct rigidity of the lower portion of the abdomen and probably some abdominal distention. The temperature is found elevated, sometimes reaching 103° or 104° F.; the pulse is rapid; and there may be nausea with vomiting. On examining such a patient we are almost sure to find that acute tenderness is present over the lower abdominal zone; and a vaginal examination, although it may fail to reveal anything very distinctive, is sure to cause acute pain when pressure is made on the fornices, or when any attempt is made to move the uterus. The patient, it will also be noticed, lies perfectly quiet on her back with the legs drawn up, as any move-

Digitized by Microsoft®

Pelvic Peritonitis.

ment causes greatly increased pain. Generally, after the lapse of three to four days, the symptoms decrease in severity, the abdominal distention and muscle spasm disappear, and the temperature falls. In those cases in which the disease assumes a chronic character it is astonishing to note in how many instances the severity of the symptoms is out of all proportion to the small extent and slight degree of chronic inflammation present. These patients, as a rule, complain of much menstrual distress; backache is very common, and pain is often complained of in one or the other ovarian region. These patients are also apt to complain of headache or of some form of nervous, gastric, or intestinal disorder.

The chronic exudative form of peritonitis is characterized by the presence of an exudate, and with this may be associated the symptoms of a pelvic abscess. In cases of the latter nature acute local pain is present in the earlier stages; there are also decided abdominal tenderness, rapid pulse, and fever, and yet it is to be noted that, in the later stages, fever is not necessarily present. We find on local examination a fluctuating mass which pushes the uterus forward and which is very tender on pressure. It will also be observed that the more dense and indurated the walls of this mass are, the more apt are we to find a collection of pus rather than one of serum.

Diagnosis.—The diagnosis of an acute pelvic peritonitis is not difficult, and is based on the acute pain, the spasm of the muscles, the rise of temperature, and the local findings. In the chronic form which is characterized by adhesive inflammation, the diagnosis rests on the lessened mobility of the organs, on their abnormal positions, and on the fact that we can actually feel the presence of more or less distinct bands of adhesions.

In the chronic form which is characterized by the presence of an exudation, the differential diagnosis may have to be made between it and a pelvic hæmatocele. This, however, is usually an easy matter, as the histories of the two affections are very different, and besides, on examination, we can satisfy ourselves, in the case of the hæmatocele, that we are handling a solid tumor, which often, under the pressure of the finger, yields a crackling sensation, owing to the breaking down of the clot.

Treatment.—In the treatment of acute pelvic peritonitis two very important objects should be kept in view: First, that life may be saved; and second, that the local changes resulting from the disease may be diminished as much as possible both as regards their extent and as regards the seriousness of their character. The therapeutic measures to be adopted must vary according to the nature of the infection. Inasmuch as most of the cases of acute pelvic peritonitis are gonorrhœal in origin, this fact will be one of the first to be thought of when the questions of etiology and prognosis are taken up for consideration. In these cases, as a rule, life is not in extreme danger, because the tendency of gonorrhœal peritonitis is to remain localized in the pelvic cavity.

A patient who is suffering with an attack of this character should be put to bed and advised to remain as quietly as possible on her back. The object of this advice is to prevent any sudden movement which might cause a breaking down of adhesions between the end of the tube and the surrounding structures, and so prevent the outflow of bacteria-containing secretion from the freshly opened end. The inflammation is also to be combated by the free use of salines such as Rochelle salts, or by frequently repeated doses of Carlsbad salts. The pain may be relieved by the use of hot moist applications, or, if the attack is seen in the very early stage, cold applications may give more relief, and may possibly abort the attack. Opiates are dangerous remedies, and are not to be used unless the pain becomes extreme, in which case good results may be obtained by the use of suppositories containing extract of opium and extract of belladonna. Hot vaginal douches are also of value, if they can be given without causing the patient great discomfort. The patient should be put upon an extremely light bland diet, and she should also be allowed the free use of liquids. Such a patient should be kept quietly in bed for at least a week after all acute symptoms have disappeared. This precaution will be found to be a great help in preventing a recurrence of inflammation.

Operative interference, during an acute attack, is indicated only when the symptoms are somewhat urgent. The abdominal cavity should then be opened from above, in the usual manner, and free drainage established, or an opening may be made into the cul-de-sac from below, by way of the vagina.

In chronic exudative pelvic peritonitis, the exudate lies in the cul-de-sac, and can be most easily reached through the posterior vaginal fornix, as it generally points most distinctly in this locality. Before the operation is begun, the vulval area and the vagina should be thoroughly scrubbed and disinfected. The patient's legs being flexed on the abdomen and held in this position by a leg-holder or by assistants, the surgeon should introduce the forefinger of the left hand into the rectum, and the thumb into the vagina, the tip of the latter being kept pressed against the fluctuating swelling in the cul-de-sac. Then the pointed end of a closed pair of sharp-pointed scissors should be plunged into the mass under the guidance of the thumb, the forefinger in the rectum acting both as a guide and as a means of preventing puncture of the rectum. The insertion of the sharp-pointed instrument into the cavity is followed by a gush of clear or purulent fluid. The blades of the scissors are separated and withdrawn from the cavity, and the opening thus established should then be made still larger by stretching and tearing its sides with the Goodell dilator. Finally, the cavity should be washed out and packed with gauze, and the latter should be allowed to remain in for five or six days or even longer unless there be symptoms indicating that it should be removed sooner.

In the treatment of chronic adhesive peritonitis the use of frequent hot douches, in conjunction with the application of the tincture of iodine to the fornices, and with the introduction of cotton or lambs' wool tampons soaked in glycerin, often proves very helpful. Besides these local measures pelvic massage, regular exercise, and a general tonic treatment will sometimes be followed by an apparent cure, though such patients are very apt to have a recurrence of the disease after any imprudence.

The question whether an operation should be advised, or whether better results may not be obtained from the employment of the palliative methods of treatment, is always difficult to answer; the proper answer will depend on circumstances. In the first place, it must be remembered that the operation is always attended with a certain amount of danger, and that this danger must be incurred not for the saving of life, but simply for the relief of symptoms. On the other hand, if the patient has to work for her living, the surgeon cannot rightly refuse to place her under the best possible conditions for successful work. For this reason he is scarcely justified in advising a patient whose family is dependent on her exertions for their support, to undergo the long-continued applications, etc., which are required under the palliative method of treatment. On the other hand, in the case of a woman who can command everything necessary, palliative measures may be followed by splendid results.

On the whole, the results of operations in the pelvic cavity have thus far been very satisfactory.

Prognosis.—The prognosis of acute pelvic peritonitis, so far as life is concerned, is generally good, but caution should always be observed in promising a complete return to normal health.

In the chronic exudative pelvic peritonitis, the prognosis, after the cavity has been opened and drained, is fairly good. In most cases the patient will regain health, and, if the tubes have not been completely destroyed, she may in course of time bear children. In the adhesive form a complete cure must not often be looked for as the result of simple palliative treatment; and even when an operation is resorted to, the degree of completeness of the cure will depend on the condition of the pelvic structures.

PELVIS.—(Latin, derived from the Greek πέλυς, a basin, the same root as Eng., pail; Fr., *bassin*; Ger., *Becken*; It., *bacino*. The appropriateness of the appellation will be evident on placing a human pelvis on a table in a horizontal position, when it will be seen to resemble a somewhat deep wash basin, with the rim broken away in front and behind. In a restricted sense, the bony and ligamentous skeleton of that portion of the trunk to which are attached the abdominal limbs. Topographically the term is used to designate the whole region for which the bony pelvis serves as a framework, comprising, in this sense, the whole of the pudendal, perineal, sacral, subinguinal, coxal, trochanteric, and gluteal regions, and a part of the pubic and inguinal regions.

www.libtool.com.cn

The importance of the skeletal framework is great and twofold. First, because it is through it that the weight of the body is supported, and from it that arise the powerful muscles that move the posterior limbs; second, because it forms a bony canal which contains an important portion of the genito-urinary apparatus, and through which the matured fœtus must pass to reach the outer world. The first of these considerations is architectural, the second obstetrical, while both have important surgical bearings.

Boundaries.—This portion of the trunk is defined on the surface of the body by certain landmarks and furrows. Above, there may be noted, in well-nourished individuals, crossing the median line in front, a shallow depression, concave upward, separating the pubic eminence (mons pubis, mons veneris) from the general superficies of the abdomen. This may be called the pubic furrow and extends from groin to groin. From either end of this the shallow but well-marked inguinal furrow (sulcus or plica inguinalis) may be followed upward and outward to the anterior superior iliac spine. The crest of the ilium may then be easily traced along the flank backward as far as the depression which marks the posterior superior iliac spine. From this a line should be drawn to the spinous process of the fifth lumbar vertebra, which for topographical purposes is usually included in the pelvic region, and is characterized by a well-marked depression. This boundary, drawn on each side, will mark the limits of the pelvis above.

Below, it is best defined behind by the well-marked gluteal fold (sulcus gluteus) that indicates the lower border of the nates or rump. An arbitrary line drawn horizontally outward from the outer end of this fold, around the thigh to the inguinal furrow, will roughly include somewhat more than may properly belong to the pelvis, as it takes in the upper part of the femur with the great trochanter, usually regarded as belonging to the crural region.

Surface Markings.—Within the area thus delimited there is in front the pubic eminence, covered with hair in the adult and resting upon the pubic bone. It is more prominent in the female. On either side of this the inguinal furrow follows the course of Poupart's ligament from the anterior superior spine of the ilium to the spine of the pubis. It is maintained by fibres passing from this ligament to the skin, resembling in this respect the axillary fossa. Shallow and broad when the subject is standing erect, it is deep when the thigh is flexed. Above, it is continuous with the iliac furrow; below, it ends in the genito-femoral furrow. In females and well-nourished persons a second furrow is usually seen, corresponding more nearly to the flexion of the thigh. This terminates before reaching the anterior superior iliac spine at a depression corresponding to the separation between the sartorius and the tensor of the fascia lata. Below, it runs into the inguinal furrow.

In muscular persons, not too fat, the outer edge of the rectus abdominis, well defined upon the abdomen, may be traced down to the inguinal furrow, which it cuts at an acute angle. It is at this point (the inguinal trigone of Henke), immediately above and external to the spine of the pubis, that is found the external or superficial abdominal ring from which the spermatic cord in the male and the round ligament in the female may be easily traced to the scrotum and the labium majus respectively. The internal or deep abdominal ring is a little more than half an inch (15 mm.) above Poupart's ligament, and midway between the anterior superior iliac spine and the symphysis pubis.

The spine of the pubis (tuberculum pubicum) lying, as it does, between the course of an inguinal and that of a femoral hernia, becomes an important point to determine. In fat persons it cannot be felt with ease except by pushing up the skin of the scrotum or labium, but may always be found by tracing up the tendon of the adductor longus muscle, made tense by adducting the thigh. The spine is nearly on a level with the top of the great trochanter, and this enables us to determine its position when it is desired to avoid external manipulation. Between the spine and the symphysis pubis the pubic crest may be made out.

Another important point is the anterior superior iliac spine, always easily felt. It is used as a point of reference in judging of deformities and injuries to the pelvis, and in measuring the relative length of the two limbs. Although situated much farther from the median line than is the spine of the pubis, it will be seen, when the pelvis is viewed laterally in its normal position, to be in the same frontal plane. A line connecting the anterior superior spines of opposite sides passes just above the level of the promontory of the sacrum. In females it is, when the pelvis is normally placed, at the same height as the middle of the third sacral vertebra, and very nearly on a level with the upper edge of the great sciatic notch. In males it is 1 or 2 cm. higher.

Below the pubic eminence appear the external organs of generation, separated from the thigh by a deep groove, the genito-femoral furrow, more fully seen on the perineal aspect. The angle of the pubis, where the two pubic bones unite at the median line, may be obscurely felt from without. In the female it is much more obtuse than in the male, and is easily accessible by vaginal examination. In the normal position of the pelvis its vertex is on a level with the lower bony edge of the obturator foramen and with the middle of the posterior surface of the tuberosity of the ischium.

If the pelvis be looked at from the side, it is seen to be limited above by the crest of the ilium, whose general situation is indicated by a slight superficial depression, the iliac furrow (sulcus coxæ). This does not, however, exactly correspond with the underlying crest, the difference depending on the varying length of the aponeurotic fibres of the external oblique muscle of the abdomen, which is inserted on the outer lip of the crest. The mid-axillary line produced passes through the highest point of the crest (punctum coxale), the most prominent part of the great trochanter and the lower part of the tuberosity of the ischium (punctum ischiadicum), and bisects a line connecting the anterior and posterior iliac spines. When the arm is extended at right angles in front, the scapula is so rotated as to bring its inferior angle into this vertical. The level of the crest of the ilium is usually a little lower than the umbilicus, corresponding to the disc between the fourth and fifth lumbar vertebræ, though it may reach as high as the body of the fourth.

On this aspect the situation of the great trochanter should be noted. Usually a distinct prominence, more in relief than the crest of the ilium, in fat persons, owing to the tendinous insertion of the gluteus maximus, it may be marked by a depression. Its top is on a level with the middle of the acetabulum, and when the thigh is at rest, with the muscles relaxed, it just touches a line drawn from the anterior superior spine of the ilium downward and backward to the tuberosity of the ischium (Nélaton's line). It may rise somewhat above this line when the thigh is fully abducted (Sheild).

The most prominent features of the pelvic region, when viewed from the rear, are the rounded masses forming the buttocks or nates. While the main body of these protuberances is formed by muscles they owe their rounded outlines to a thick layer of fat. For this reason they are

Digitized by Microsoft®

better developed in well-nourished persons, in the young, and in women, than in athletes, and are frequently the seat of lipomatous tumors. In some African tribes the deposit of large quantities of fat in this region seems to be normal, especially among the females, and it forms a large projecting mass (steatopygy). The underlying masses that influence surface form are the gluteus maximus nearest the median line and the gluteus medius laterally. In muscular individuals in good training the separation between these two muscles is usually observable on the surface. They are especially important for keeping the trunk upright; and since man is the only animal that habitually walks erect, the prominence of the nates is peculiar to him.

www.libtool.com.cn

The nates are separated from each other by a well-marked cleft, the intergluteal furrow (crena ani), usually quite deep. At its bottom is found the tip of the coccyx, a little lower than the horizontal line drawn through the top of the symphysis pubis, and about a finger's breadth farther forward is the margin of the anus, hidden from sight except in emaciated persons. Here the furrow ends in the male; in the female it becomes continuous with the beginning of the genital cleft.

Below, the nates are limited by a sharp crease, the gluteal fold (fold of the nates, gluteo-femoral fold, sulcus gluteus), caused by the attachment of the integument to the deep fascia by means of fibrous bands, which prevent the fat of the buttock from sliding down into the thigh when the sitting posture is assumed, thus making of it a veritable cushion. This fold does not correspond to the edge of the gluteus maximus, which runs obliquely downward and outward to its femoral insertion, but is nearly or quite horizontal when the subject is standing erect. When he is resting on one leg only and allowing the gluteus maximus of the free member to become stretched, the fold assumes more nearly the direction of the muscle. Externally each natis is defined by a broad, shallow depression (lateral gluteal furrow), due to change from muscle fibres to aponeurosis of insertion.

The nates are bounded above by the crest of the ilium, which terminates toward the middle line in the posterior superior spine, on a level with the spine of the second sacral vertebra, and at a point corresponding to the middle of the sacro-iliac synchondrosis. Immediately above the spine is a small area of bone quite free from muscle fibres, and therefore marked externally by a depression, especially noticeable in females. Below this the converging masses of nates leave between them a flattened triangular area which extends down as far as the fourth or fifth sacral vertebra. This flattening extends upward as far as a depression just below the spine of the fifth lumbar vertebra, and taken altogether the area constitutes a rhomboidal field (sacral rhomboid, Kreuzraute of Waldeyer) of which the two upper sides are much shorter than the two lower ones. In females the upper angle is 3–4 cm. higher than the line connecting the posterior superior spines. Through the middle of this there extend from above downward on the median line the coalesced spines of the sacral vertebræ (sacral crest, crista sacralis media), the most prominent part of which is the third sacral spine.

The general direction of the gluteus maximus is indicated by a line drawn from the posterior superior iliac spine to the most prominent part of the great trochanter. The juncture of the first and second thirds of this line is at the level of the great sciatic notch, where the gluteal artery emerges from the pelvis.

The tuberosity of the ischium, on which the body rests when sitting, is readily felt beneath the gluteal fold. It is situated in the same frontal plane as the transverse process of the fifth lumbar vertebra, and its middle is nearly the same horizontal distance behind the centre of the acetabulum that the anterior superior spine of the ilium and the spine of the pubis are in front. A line drawn from the posterior superior spine of the ilium to the outer part of the tuberosity of the ischium crosses the posterior inferior spine at 4 cm. and the spine of the ischium at 10 cm. distance, and the sciatic and internal pudic arteries make their exit from the pelvis at the juncture of its middle and lower thirds. The tuberosity is well padded with fat contained in small loculi formed by fibrous bands that pass between it and the skin. Several small bursæ are frequent near it, one, under the tendon of the biceps and semitendinosus, being quite constant.

There is, besides, another aspect of the pelvis almost wholly concealed when the subject is standing erect with the thighs approximated, being then reduced to a mere furrow. This is the inferior or perineal aspect, corresponding to the outlet of the pelvis. To examine it the thighs should be flexed and abducted when there will be displayed a rhomboidal space known as the perineal region, lying between the thighs, having its angles at the angle of the pubis in front, the tip of the coccyx behind, and the ischial tuberosities on either side. Its sides are formed in front by the ischio-pubic rami, behind by the great sciatic ligaments, which may in this position be felt in thin subjects on deep pressure along the edge of the gluteus maximus.

It will be seen that the gluteal fold encircles on each side the inner aspect of the thigh and ends in the genito-femoral furrow. Frequently an accessory furrow is found running parallel to it. From the rounded protuberance of the nates a pointed process extends forward, bounded laterally by the gluteal fold on the outer side, mesially by a furrow (gluteo-perineal furrow) that separates it from the external genitals and ends in front by uniting with the genito-femoral furrow.

In both sexes the external genital organs impinge upon the anterior part of this space, the area occupied by them being known as the pudendal region. The remaining space is usually divided for topographic purposes by a line drawn arbitrarily between the anterior part of the tuberosities of the ischium (interischiadic line). It has been pointed out by Waldeyer and others that a more suitable line, from a morphological point of view, is formed by curving somewhat forward to where the urogenital trigone, or triangular ligament, meets the pelvic diaphragm (line of the perineal septum). This separates a urogenital region through which the urogenital orifices pass, from an anal (ischio-rectal) one through which the alimentary canal discharges.

In this region there may be noted, in the median line, the tip of the coccyx, often marked by a slight depression; the anus, its centre about 3–4 cm. in front of the coccyx in the male and a little farther in the female; then the median raphe of the perineum, extending in the male from the anus to the scrotum, in the female lost almost at once in the genital cleft. The point where the raphe crosses the line of the perineal septum is called the tendinous centre of the perineum (centrum perineale), where the two layers of deep fascia and the triangular ligament meet. It affords a point of origin for several muscles. A slight swelling in front of this marks in the male the underlying bulb of the urethra, situated 1–1.5 cm. from the anterior edge of the anus.

THE OSSEOUS PELVIS.—Of the bones composing the pelvis two, the sacrum and the coccyx, belong to the spinal column; and two others, the so-called ossa innominata, or hip bones, belong to the limbs and constitute the pelvic girdle, which differs remarkably from the thoracic girdle in that it is articulated firmly with the sacrum, thus affording a firm basis of support.

The Sacrum.—This bone is said to owe its name to the use made of it by nations who offered human sacrifices, it being held to be particularly sacred to the gods, because it was used as an offering representing the entire victim, it being evident that the subject must be dead if the sacrum was offered. It is reputed to be found entirely uninjured when other portions of the skeleton have decayed, and a rabbinical tradition holds that it is the essential or sacred part of man, which is to be preserved, and from which the entire body is to sprout at the judgment day. Hyrtl, whose authority on such matters is entitled to weight, considers, however, that these are mere etymological fantasies, and that in the phrase *os sacrum* the adjective is used in the sense of great or im-

Digitized by Microsoft®

portant, because it is the largest bone of the spinal column.

The bone presents the appearance of an irregular pyramid, the axis of which has been curved so that the concavity looks downward and forward, the base presenting upward, jointing with the last lumbar vertebra, the apex downward, jointing with the coccyx. Laterally it articulates with the innominate bones. Even a superficial examination shows it to be composed of coalesced vertebræ, normally five in number, six or four being occasionally found; but this is usually accompanied by a corresponding increase or decrease of the vertebral elements of contiguous regions of the spinal column. Accordingly the main descriptive features of the sacrum depend upon its composite character. There are, on the anterior surface, transverse lines showing the original divisions; on the posterior, vestiges of the spinous and articular processes, and of the laminæ; on both surfaces

www.libtool.com.cn

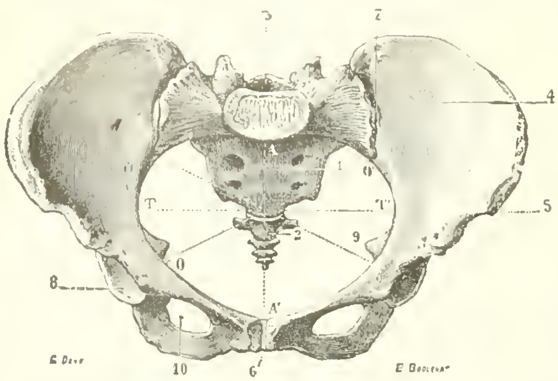

FIG. 3769.—Antero-Superior Aspect of the Pelvis. (From Testut.) 1, Sacrum; 2, coccyx; 3, sacral canal; 4, internal iliac fossa; 5, anterior superior spine of the ilium; 6, symphysis pubis; 7, sacro-iliac articulation; 8, acetabulum; 9, spine of the ischium; 10, obturator foramen.

foramina for the exit of nerves from an axial canal, a continuation of the spinal canal of the lumbar region. Anteriorly, obliquely cut grooves lead from the sacral foramina outward, affording, to the sacral nerves that lie in them, some protection from sliding pressure.

The non-articular vertebræ diminish rapidly in size, their characters are more obliterated, and they curve forward much more than the others. The summit of the curve formed by the sacrum is therefore in the third sacral vertebra, the spine of which projects in the median line. The prominence of the spine is not, however, a good guide to the convexity of the curve, which varies much in different individuals. The depth of the curve from a line subtending the arc averages 18.8 mm., having a maximum of 44 mm. and a minimum of 4 mm. The curve is developed during intra-uterine life, being probably due to an adaptation of the spinal column to the pelvic viscera. Cunningham found it in a fœtus 46 mm. long (about ten weeks). It is also seen in anthropoids.

Meyer calls that part of the sacrum which articulates with the ilium the pelvic portion, the remainder the perineal portion. Broca has pointed out that, in considering the question of the number of bones that form the tail of a vertebrate animal, we should not make the division at the sacro-coccygeal joint, as that is a character which may be considered merely a matter of special arrangement for each animal, but should rather begin to count at the non-articular portion of the sacrum. Viewed in this manner the articulating vertebræ would form a true sacrum, and those which follow would belong to the tail, and be divided into *true caudal*, having a spinal canal, and *false caudal*, reduced to centra only. According to this view, almost all the lower apes have three sacral vertebræ, as has man; and man has a tail formed of from six to eight pieces, resembling in this respect the anthropoid apes, they varying merely in the unimportant circumstance of having a few segments more or less.

The rectum reaches the spinal column at the third sacral vertebra and thence continues along it. Rose therefore designates the portion of the spinal column thus related as the rectal cover (*Mastdarmdeckel*). As it may be necessary to remove some of these vertebræ in operations for tumors, it becomes important to know how high it is safe to go. While the spinal cord terminates far above this, its envelopes continue down within the sacral canal, and the sac containing the cerebro-spinal fluid may reach as low as the third sacral vertebra. It is therefore allowable to remove the fourth and fifth sacral vertebræ; and, since the sac is pointed, to encroach laterally upon the third. In children the sac is lower than in adults. The width of the sacrum at the upper limit of surgical interference (between the second and third sacral vertebræ) is 8–11 cm. ($3\frac{1}{2}$–$4\frac{1}{3}$ in.). In the last two vertebræ the arch becomes deficient behind, leaving the sacral canal covered by membrane. This is, therefore, a weak point, and sloughing bedsores may here invade the canal and induce a meningitis. At the sides of the coalesced vertebræ fused costal elements form strong bars known as the lateral masses of the sacrum.

As compared with other animals the sacrum of man is broad in proportion to its length. The same holds when the sacra of Europeans are compared with those of the lower races of man. In order to express this Sir William Turner has devised the *sacral index*, obtained by multiplying the breadth of the sacrum by 100 and dividing by the length. The following are the average results of many measurements: European, female, 116; European, male, 112; negro, 106; Australian, 99; Andaman Islander, 94; Orang, 87; Gorilla, 72.

Sacra having an index above 106 are termed platyhieric; those between 100 and 106, subplatyhieric; those below 100, dolichohieric. The variations in width appear to depend mainly upon variations in the lateral masses.

The Coccyx.—This is also an assemblage of from four to five coalesced vertebræ, and corresponds to the tail of lower mammals; and in very rare instances it may, like that, be enclosed in a fold of skin. The vertebral characters of its elements are very much reduced, there being but little more than the centra or bodies, with two vestigial articular processes called the cornua, which articulate with the sacrum. It is triangular in form and continues forward the curve of the sacrum, making together with it an almost complete quadrant, so that the apex points directly forward. It may be readily felt in rectal or vaginal examination.

The number of vertebræ in the coccyx is subject to considerable variation; five is considered the normal number in the male, four or five in the female, while six are sometimes found. In vertebrate animals the number of caudal vertebræ varies greatly, from two hundred and seventy in some sharks to two in the gibbon and fruit-bat.

The Innominate Bone.—This is a complex of three originally distinct elements, the ilium, the ischium, and the pubis. When complete it resembles in shape two of the twisted blades of a propeller extending radially on opposite sides of an axial depression, the acetabulum, which receives the head of the femur. The upper expanded and somewhat longer blade is the ilium; the lower one, which has a large fenestration called the obturator or thyroid foramen, is formed by the combined ischium and pubis, the pubis forming the anterior por-

FIG. 3770.—Innominate Bone of Alligator, showing the Rod-like Character of the Separate Elements.

Digitized by Microsoft®

tion, the ischium extending backward and downward to afford support while sitting. The narrowest part of the bone (the isthmus coxæ of Waldeyer) is just above the acetabulum, lying between the greater iliac notch of Henle (from the anterior inferior iliac spine to the symphysis pubis) and the great sciatic notch.

A study of the characters of the bone throughout the vertebrate series shows that its components were originally rod-like in form. This is shown in a striking manner in the alligator (Fig. 3770), and is also indicated by the course of ossification in the human bone, for accessory points form at the crest of the ilium, the symphysis pubis, the tuberosity of the ischium and within the acetabulum, that is to say, exactly where terminal epiphyses would form at the extremities of long bones. Even in the higher mammalia the rod-like character of the bones is still apparent (Fig. 3771). When the upright position begins to be assumed, lateral expansions becomes necessary to support the weight of the viscera. A transition form is seen in the pelvis of the gorilla (Fig. 3772).

www.tibtool.com.cn

The thickness and strength of the different parts of the innominate bone vary according to the weight and strain to which they are subjected. While a person is standing,

FIG. 3771.—Pelvis of the Horse.

the weight of the body is supported by the upper lip of the acetabulum, whence it is transmitted to the symphysis pubis on the one side and the sacro-iliac joint on the other. Hence a strong bar of bone extends from the symphysis along the upper edge of the acetabulum and the ilio-pectineal line to the posterior superior spine of the ilium, where it ends in a protuberance called by Waldeyer the tuber glutæum posterius. This bar may be called the pubic trabeculum. While an individual is sitting, the greater portion of the weight is borne by the tuberosity of the ischium, and is transmitted through the thick strong body of the ischium (superior ramus of many authors) and the posterior edge of the acetabulum, directly upward to a thickened portion of the crest of the ilium (tuber glutæum anterius of Waldeyer). This also is a thickened bar, and may be called the ischial trabeculum. These bars cross each other at about right angles near the axis of motion of the hip-joint.

The upper edge or crest of the ilium is sinuous and thick, and gives attachment in front to the great, sheet-like muscles that form the parietes of the abdomen, and behind to the muscles of the back. Below the crest is a comparatively thin portion caused by the hollowing out of the substance of the bone within, for the attachment of the iliacus muscle, forming the internal iliac fossa, and without, for the attachment of the glutei muscles, forming what is sometimes called the external iliac fossa (ala ossis ilium). The internal iliac fossa supports the weight of the intestines laterally and forms in the articulated pelvis the lateral portion of what is known as the false pelvis, separated from the true pelvis by a ridge (ilio-pectineal line, linea terminalis) passing from the crest of the pubis backward and upward.

The acetabulum or cotyloid cavity appears a little below the middle of the external surface of the innominate bone. It is hemispherical in shape, formed by portions of the ilium, ischium, and pubis, and receives the head of the femur. It may become perforated by suppuration within the cavity, and thus inflammation of the intrapelvic structures may be induced. Below, the edge of the cavity is incomplete, giving passage to vessels that supply the joint. This notch is usually directed downward, and it therefore affords a means for establishing the normal position of the bone.

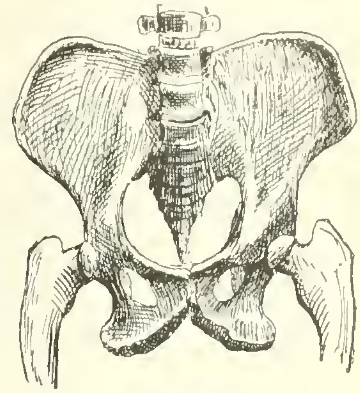

FIG. 3772.—Pelvis of a Gorilla.

The united ischium and pubis constitute the side of the true pelvis. They here form three bony bars that surround the large obturator foramen, closed in, during life, by a thick sheet of fascia called the obturator membrane. This is deficient above, affording, between it and the bone, a passage about an inch long, walled in above by the bone and below by the membrane, the obturator muscles and some masses of fat. This passage, the obturator canal, contains the obturator vessels and nerve. The membrane is reinforced near the canal by independent bands attached to small bony projections on the edge of the foramen. Three of these projections have been distinguished as fairly constant. They are named by Waldeyer according to their situation—the tuberculum obturatorium laterale superius, the tuberculum obturatorium laterale inferius, and the tuberculum obturatorium mediale. The arrangement of the fibrous bands and the shape of the canal have important effects upon obturator hernia.

The two anterior bars enclosing the foramen are known as rami, the upper one being the horizontal ramus of the pubis, the lower one being the descending ramus of the pubis above, the ascending ramus of the ischium below. It may be remarked that these terms apply rather to the artificial position of the pelvis given when it is set upon a table than to its true position in the body during life, as the "horizontal" ramus is far from being horizontal, varying from that by as much as 30° in some subjects. Along these bars are attached the muscles of the perineal

Behind, the ischium expands to a large tuberosity that gives origin to the great hamstring muscles (biceps, semitendinosus, semimembranosus), and affords attachment to the great sciatic ligaments. A pointed process (spine of the ischium) divides the posterior border into two notches, the greater and lesser sciatic.

Articulations.—The pelvic bones are joined together by five joints, all of which are synchondroses (Figs. 3773 and 3774). Two of these are vertebral joints, viz., the

www.libtool.com.cn

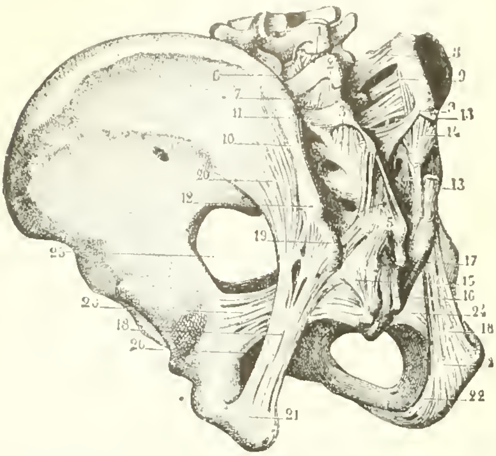

FIG. 3774.—Posterior View of the Ligaments of the Pelvis. 1, 2, 3, 4, 5, Interspinous ligaments; 6, 7, ligamenta subflava; 8, ilio-lumbar ligament; 9, posterior sacro-iliac ligament; 10, its oblique portion, continuous externally with the great sacro-sciatic ligament; 11, posterior superior spine of the ilium; 12, tubercle representing the transverse process of the fourth sacral vertebra; 13, deep layer of the posterior sacro-iliac ligament; 14, insertions of the same; 15, 16, lateral ligaments of the sacro-coccygeal articulation; 17, posterior ligament of the same; 18, great sacro-sciatic ligament; 19, its sacral insertion; 20, its iliac insertion; 21, its ischiatic insertion; 22, reflected portion; 23, lesser sacro-sciatic insertion; 24, its attachment to the sacrum and coccyx; 25, great sciatic notch converted into a foramen by the sacro-sciatic ligaments; 26, lesser sciatic notch, forming with these ligaments a triangular orifice.

lumbo-sacral and the sacro-coccygeal; there is one on either side of the sacrum where it unites with the ilia; and one in front, where the innominate bones join, called the symphysis pubis.

At the lumbo-sacral joint we have the same general features as in other spinal joints, viz., a union by means of fibro-cartilage between the bodies of the last lumbar and the first sacral vertebra, and a pair of arthrodial joints between the articular processes of the two bones. The anterior common ligament of the spine passes downward upon the sacrum in front, and within the spinal canal the posterior common ligament does the same. Besides these the anterior lamina of the lumbar fascia becomes thickened to strong bands, which, springing from the transverse processes of the fourth and fifth lumbar vertebræ, pass to the inner lip of the crest of the ilium (ilio-lumbar ligament) and to the brim of the true pelvis and the base of the sacrum (lumbo-sacral or sacro-lumbar ligament).

The joint is indicated by a well marked angle, the promontory of the sacrum, slightly greater in females than in males, being determined by Cunningham as averaging 137° 40' for females as against 133° 6' for males. This is not usually the most anterior part of the spine, for that must be sought in the forward projection of the lumbar curve, that is to say, in the fourth lumbar vertebra or even as high as the disc between the fourth and the third. Externally it may be felt on deep pressure of the relaxed abdominal wall if the subject is lean. It is one of the landmarks by which a contracted pelvis is known, and cannot, in a properly formed pelvis, be reached by the finger through the vagina, but can easily be felt in a rectal examination.

The joint between the sacrum and the coccyx is very simple, being entirely similar to that between the bodies of the vertebræ. The articulation is usually sufficiently free to permit the apex to be displaced some 2 cm. or more, and there is sometimes a midcoccygeal articulation between the first and second coccygeal vertebræ. Movement usually occurs during defecation and labor, but the bone may be so firmly ankylosed to the sacrum that it offers an obstacle to the delivery of the head of a child. In the male pelvis the joint is frequently obliterated quite early. A number of ligamentous bands have been described, but they appear to have no practical importance beyond that of an investing capsule.

The joint between the sacrum and the iliac bones on either side possesses an incomplete synovial cavity. The ear-shaped articular surfaces may be divided into two parts—an upper which is clothed with cartilage and synovial membrane, and a lower whose surfaces are interconnected by means of an interosseous ligament. The joint is a very strong one, as the entire weight of the trunk is thrown upon the articulation. Owing to the wedge-like shape of the sacrum it is often described as the keystone of the pelvic arch. It should be noted, however, that in the natural standing position the bone is somewhat narrower behind and above than below and in front, so that it would seem that the weight of the body resting upon it from above might tend to displace it. This is prevented, (1) by the sinuous character of the articular surfaces; (2) by the extremely strong sacro-iliac ligaments that bind the sacrum closely between the two iliac bones, so that any displacement forward tightens the joint; (3) by the sciatic ligaments that stretch from the sacrum and the coccyx to the tuberosity and spine of the ischium and counteract any tilting forward of the upper end of the sacrum. The interosseous ligament that closes the joint behind is very thick and strong, while the anterior ligament that closes it in front is thin. Hence it is easy to open the articulation from the abdominal cavity, but difficult to do so from behind. Injury to it is rare, but when it occurs it is of a serious nature, owing to the weight the joint carries in the standing posture.

The articulation usually affects the three upper sacral vertebræ, but variations from this frequently occur. The following are the results of 265 cases observed by Paterson and Waldeyer:

S 1 + 2	21 times.
S 1 + 2 + 3	242 "
S 1 + 2 + 3 + 4	3 "
S – 2 + 3	3 "
S – 2 + 3 + 4	3 "
L 5 + S 1 + 2	1 "
L 5 + S 1 + 2 + 3	4 "
L 6 + S 1 + 2	2 "
L 6 + S 1 + 2 + 3	1 "
Total	280 "

The total amounts to 280 instead of to 265 for the reason that in 15 cases the articulation differed on one side from that on the other. It will be noted that the second sacral vertebra is always involved in the articulation.

As already mentioned, the sacro-sciatic ligaments act as restraining bands to this articulation. (See Figs. 3773 and 3774.) The great or posterior sacro-sciatic ligament (ligamentum sacrotuberosum) appears as if a continuation of the sacro-iliac, passing to the lateral parts of the sacrum and the coccyx and then to the external surface of the tuberosity of the ischium. It is somewhat narrower in the middle than at either extremity, and in its course becomes twisted upon its axis. At its lower insertion it runs as a thin sharp band (falciform process) along the ramus of the ischium and protects the internal pudic artery. Its interlaced fibres are somewhat extensible, so that it offers no considerable resistance to the moderate movement of the coccyx during labor. It is believed to represent a former continuation of the biceps and semitendinosus muscles whose tendons pass directly into it.

The small or anterior sacro-sciatic ligament (ligamentum sacrospinosum) lies in front of the great ligament

Digitized by Microsoft ®

and is partly covered by it. Triangular in form, it passes from the side of the sacrum and coccyx to the spine of the ischium. It blends at its insertion with the coccygeus muscle and is regarded morphologically as a fibrous reduction of it.

These two ligaments convert the sciatic notches of the innominate bone into foramina, through which pass important structures. The greater sciatic foramen, above the spine of the ischium, is nearly filled by the pyri-

The dotted lines indicate the diameters of the inferior strait. *A, A,'* conjugate or coccy-pubic diameter; *T, T'*, transverse or bi-ischiatic diameter; *O, O'*, oblique diameter.

formis muscle, small intervals being left above and below—the suprapyriform and infrapyriform foramina of Waldeyer. Through the former pass the gluteal vessels and the superior gluteal nerve; through the latter the internal pudic vessels and nerve, the sciatic vessels and nerves, the inferior gluteal nerve and the muscular branches of the sacral plexus. Through the lesser sciatic foramen, below the spine of the ischium, pass the obturator internus muscle, and the internal pudic nerve and vessels re-entering the pelvis.

The two pubic bones are united in front by a fibrocartilage that forms a slight eminence on the pelvic aspect of the joint. During pregnancy this swells and relaxes, and there is thus obtained a mobility that may persist for some time after delivery. Traces of a synovial cavity are occasionally found as a small slit lying near the pelvic surface, not lined with synovial membrane and apparently being a simple lymph space. This is found in both males and females, though it is larger and more constant in the latter, and is not dependent upon pregnancy. It is not found in young children. Four peripheral ligaments are described: anterior, posterior, superior, and inferior. The investment is strengthened by fibrous expansions from the recti muscles of the abdomen and the adductors of the thigh. Malgaigne considered that the height of the symphysis increased considerably after the menopause, being 38 mm. at forty-five years, and 45 mm. at seventy and eighty years. The arrangement of the abdominal muscles in their insertion about the joint is such as to draw the ends of the bones together, so that during the bearing-down pains of labor the joint is strengthened.

The Ligamentous Pelvis.—Taking now the pelvis as a whole, we find it to be divided into two well-marked parts by a line, the linea terminalis, made up of the promontory of the sacrum, the rounded angle between the upper and the lower surfaces of the sacrum, the ilio-pectineal line, the pecten or crest of the pubis, and the upper surface of the symphsyis pubis. The part above this line which supports the abdominal contents is termed the *false* pelvis; the part below it, containing the pelvic viscera, the *true* pelvis, forming the bony ring through which the fœtus is expelled.

The superior opening of the true pelvis is termed the inlet or the superior strait (apertura pelvis superior). (See Fig. 3769.) Its shape is reniform in the female, cordiform in the male. Similarly the lower opening, by which the fœtus is expelled, is called the outlet, or the inferior strait (apertura pelvis inferior). (See Fig. 3775). It is bounded by the ischio-pubic rami in front, on the sides by the tuberosities of the ischium, behind by the sciatic ligaments and the coccyx, only about half of its circumference being bony. Its form is elliptical, slightly encroached upon by the coccyx.

That part of the pelvic canal between the inferior and superior straits is called the cavity of the pelvis. It is customary to divide this into four regions, an anterior, a posterior, and two lateral. The anterior comprises the symphysis pubis, the posterior surface of the body of the pubis, and the obturator foramen with its membrane. It is limited by a line passing from the tuberosity of the ischium to the ilio-pectineal eminence. The posterior region is formed by the anterior surfaces of the sacrum and the coccyx; the lateral regions are between the anterior and the posterior. Each is again subdivided into two portions called the anterior and posterior inclined planes. The anterior comprises the internal face of the ischium and the interior surface that corresponds to the acetabulum. Its direction is oblique, downward, and backward. The posterior inclined plane is entirely composed of soft parts, and is directed downward and forward. The planes meet at a line passing through the ischial spines.

Normal Position.—When standing erect the pelvis is tilted forward, so that the anterior superior iliac spines and the spine of the pubis lie in the same vertical plane. The promontory of the sacrum is then 9.5–9.9 cm. ($3\frac{3}{4}$–$3\frac{7}{8}$ in.) above the upper edge of the symphysis pubis and at about the same level as the posterior superior iliac spines and the interspace between the first and second sacral spines. The frontal plane tangent to it cuts the middle

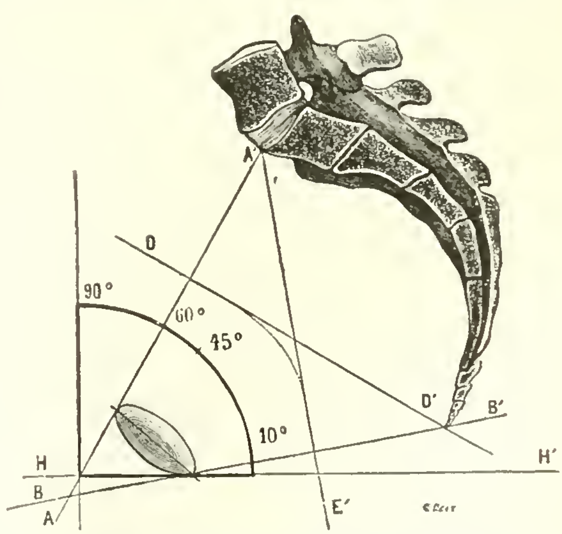

FIG. 3776.—Axes and Inclinations of the Pelvis. (From Testut.) *A, A'*, Plane of the superior strait; *B, B'*, plane of the inferior strait; *D, D'*, axis of the superior strait; *E, E'*, axis of the inferior strait; *H, H'*, the horizontal plane, with which the plane of the superior strait, *A, A'*, makes an angle of from 55° to 60°.

of the acetabulum and passes close behind the angle of the pubis.

In this position the planes of the pelvic inlet * and outlet are inclined to the horizontal plane, the first making

* Strictly speaking the limits of the superior strait do not lie in the same plane, as the promontory never coincides with the plane of the linea terminalis (ilio-pectineal line).

Digitized by Microsoft®

an average angle of about 60° (from 55° to 65°, Naegeli), the second an angle averaging about 12°. (See Fig. 3776).

Meyer proposed to measure the inclination of the pelvis by taking that of a line drawn from the summit of the curve formed by the sacrum (at the body of the third sacral vertebra, see *ante*) to the upper border of the symphysis (normal conjugate). He thought this angle to be more constant than that made by the plane of the inlet, and estimated it as averaging 30°.

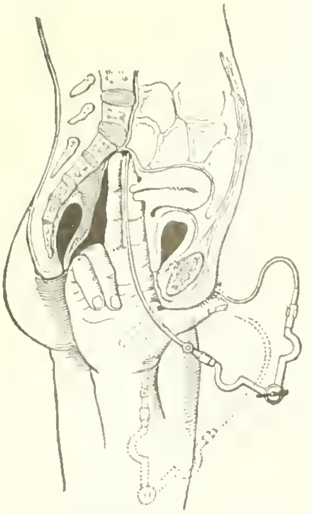

FIG. 3777.—Method of Measuring the Conjugate Diameter of the Superior Strait in the Living.

Measurements.—For obstetrical and surgical purposes it is important that the average dimensions of the pelvis should be accurately known. Of these the diameters of the inlet and the outlet are the most generally useful. The older obstetricians, considering these openings as approximately elliptical, applied to them designations derived from the diameters of an ellipse; so the antero-posterior diameter is often spoken of as the conjugate, the others as the transverse and the oblique diameters.

The conjugate of the inlet might be measured from the middle of the promontory to the top of the symphysis (anatomical conjugate), but for practical purposes the shortest line between the promontory and the symphysis is taken (true conjugate, obstetrical conjugate) which strikes the symphysis below the upper edge, usually about the junction of the upper and middle thirds. The transverse diameter is the longest transverse line that can be drawn between two symmetrical points of the brim. These points are usually situated about the juncture of the posterior and middle thirds of the circumference, immediately behind the acetabula. The oblique diameter is measured from the sacro-iliac articulation to the point on the opposite side where the linea terminalis meets the ilio-pectineal eminence. (See Fig. 3769.)

At the outlet the conjugate is measured from the tip of the coccyx to the angle of the pubis, and is increased by

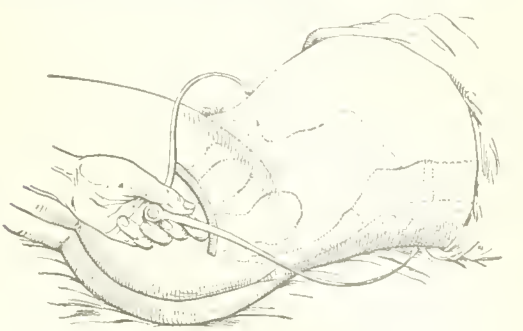

FIG. 3778.—Method of Measuring Baudelocque's Diameter in the Living.

about 2 cm. by moving the coccyx backward. The transverse diameter is measured between the middle points of the posterior borders of the ischial tuberosities. No satisfactory oblique diameter of the outlet can be measured. When stated it is considered to be the shortest distance from either ischiopubic ramus to the great sciatic ligament of the opposite side. (See Fig. 3775.)

The calibre of the cavity of the pelvis varies somewhat from that of the brim. The widest part (amplitudo pelvis) is in a plane passed through the midpoints of the acetabula, the synostosis between the second and third sacral vertebræ and the middle of the symphysis pubis. The narrowest part (angustia pelvis) is between the lower end of the sacrum behind, the summit of the pubic arch in front, and the two ischial spines on either side. The contraction here is caused by a slight elevation (angulus ischiadicus, Waldeyer) that runs on either side from the ischial spine to the lateral tubercle of the obturator foramen, separating a supraspinous from an intraspinous plane.

While these measurements are especially important as relating to normal labor, the following are commonly used for ascertaining pelvic deformities:

The External Conjugate (Baudelocque's diameter). The distance between the upper edge of the symphysis pubis and the tip of the spinous process of the fifth lumbar vertebra. This is readily measured with calipers in the living. (See Fig. 3778.) When less than 19 cm. the pelvis is too narrow for safe delivery.

The Diagonal Conjugate. Distance from the vertex of the pubic angle to the promontory of the sacrum. This may be measured by means of a pelvimeter or closely approximated by measurements made by introducing two fingers into the vagina. (See Fig. 3777.) In a normal pelvis the promontory cannot be reached by introducing a single index finger.

The distance between the anterior superior spines of the ilium.

The greatest distance between the iliac crests.

The greatest distance between the great trochanters.

The external circumference of the pelvis measured from the spine of the fifth lumbar vertebra around to the symphysis pubis on either side, passing between the iliac crest and the great trochanter.

The following table of measurements is from the determinations of Waldeyer, C. Krause, and Schröder:

	Male.	Female.
Inlet.		
True conjugate diameter	10.5 cm.	11.0 cm.
Transverse diameter	12.5	13.5
Oblique diameter	12	12.75
Outlet.		
Conjugate diameter	7.5 (9.5)	9 (11)
Transverse diameter	8	11
Amplitudo.		
Conjugate diameter	11	12.75
Transverse diameter	11	12.5
Angustia.		
Conjugate diameter	9.5	11.5
Transverse diameter	8	10.5
External conjugate	18	20
Diagonal conjugate	......	13
Distance between anterior superior spines	26	26
Distance between iliac crests	26	29
Distance between great trochanters	31.5	31.5
External circumference	.....	89
Dorsal length of sacrum	......	12.5
Ventral length of sacrum	13.5	12
Height of symphysis pubis	5.5	4.5

The *axis* of the superior strait is a line perpendicular to the plane of that strait at its central point. (See Fig. 3776.) It nearly coincides with a line drawn from the tip of the coccyx to the umbilicus. The axis of the inferior strait is similarly obtained, and when produced reaches the promontory of the sacrum. The axis or traction line of the pelvis is one that bisects all possible conjugate diameters. It is practically parallel with the curve of the sacrum and coccyx, and therefore, in the female pelvis, nearly straight above and sharply curved below. It is important to bear in mind its direction when attempting

www.libtool.com.cn
Digitized by Microsoft®

traction upon the fœtus and when introducing instruments.

Indices.—The method of proportional measurements or indices, first devised for the cranium, has also been applied to the pelvis. Two of these are used, first that which Topinard calls the general index of the pelvis, found by comparing the greatest width between the iliac crests with the height taken from the punctum ischiadicum or lowest point of the ischial tuberosity to the punctum coxale or highest point of the crest; second, the index of

www.libtool.com.cn

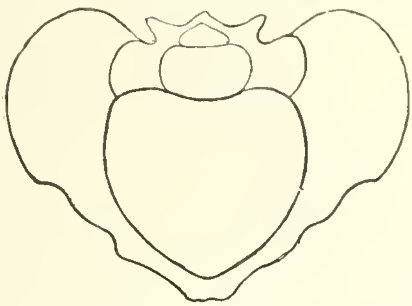

FIG. 3779.—Pelvis of an Andaman Islander. (Garson.)

the superior strait, found by comparing the anatomical conjugate diameter with the transverse diameter of the inlet.

By the first method the height is taken as 100, and the index expresses the proportionate breadth. Topinard obtained the following averages:

46 European males	126.6
17 African negroes, males	121.3
11 Natives of Oceanica, males	122.7
24 European females	136.9
10 African negresses	134.2
10 Natives of Oceanica, females	129.0
20 Anthropoids	105.6
16 Ruminants	77.2
12 Carnivores	68.1
4 Rodents	66.8
4 Kangaroos	63.0
2 Edentates	61.4

These figures appear to show that as we rise in the scale of races the pelvis broadens. It should be remembered, however, that exceedingly heavy animals, like the

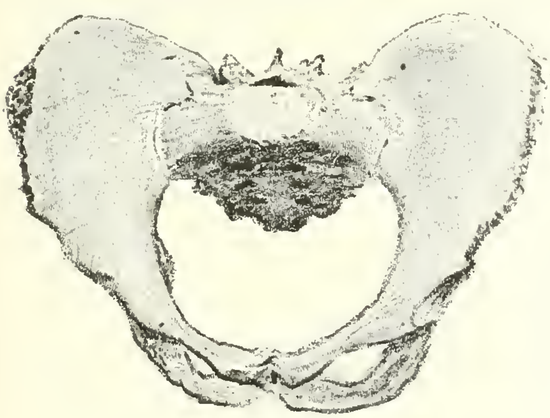

FIG. 3780.—Pelvis of an Aino. (Hennig.)

elephant and rhinoceros, have a proportionately wide pelvis to permit of the insertion of the muscles necessary for sustaining their enormous weights. Some authors use the breadth of the pelvis as the basis of comparison, which changes the figures without altering their serial relation. It will be noted that in all human races the female pelvis is broader in proportion to its height than that of the male.

By the second method the breadth of the superior strait is taken as 100, and the index expresses the proportionate value of the conjugate diameter. Sir William Turner

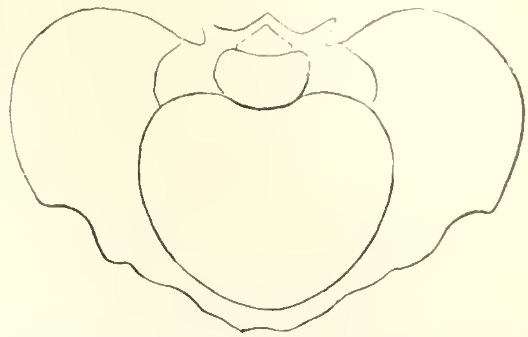

FIG. 3781.—Diagram of European Pelvis, seen from Above. (Garson.)

used this index in his investigation of the bones brought back by the *Challenger*. He devised the terms *dolichopellic* for pelves having an index above 95, *mesatipellic*

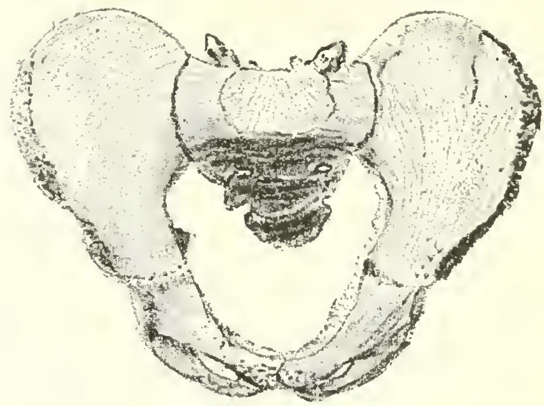

FIG. 3782.—Pelvis of a Young Maori. (Hennig.)

for those from 90 to 96, and *platypellic* for those below 90. The Andaman Islanders appear to have the inlet most nearly circular of any yet examined, Garson finding

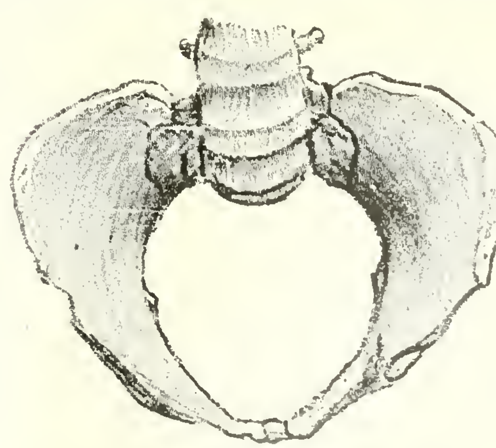

FIG. 3783. Pelvis of a Negress. (Hennig.)

the index 99 in an average of 13 cases. Figs. 3779 and 3781 show a comparison between this pelvis and that of a

Digitized by Microsoft®

European. Other peoples hitherto investigated may be classified as follows:

Dolichopellic.—Australians, Bushmen, Hottentots, Kaffirs, many Polynesians, Malays.

Mesatipellic.—Negroes, Tasmanians, New Caledonians, many Melanesians.

Platypellic.—Europeans, Mongolians, East Indians.

www.libtool.com.cn

This relates to male pelves only, as nowhere do females possess dolichopellic pelves. Anthropoid apes have markedly dolichopellic pelves, much exceeding in this character any human forms. Indeed, as compared with lower animals, the pelvis of man is much broader and of greater capacity. These differences are occasioned by

FIG. 3784.—Pelvis of an Individual Belonging to the Stone Age. (Hennig.)

the erect attitude, which necessitates an effective support of the viscera. In some races of men slight peculiarities appear which may be considered to be transitional forms. (See Figs. 3780, 3782, and 3783.) The Veddahs of Ceylon, for example, have pelves in which the inlet is remarkably contracted in front, so that the inlet appears almost wedge shaped.

Sexual Differences.—From what has been said above it will be seen that the highest and best developed forms of pelvis are not found in the human male but in the female, contrasting markedly with other sexual characters which usually tend toward embryonic or undeveloped forms. This also is a natural result from the erect attitude. In the quadrupedal position comparatively little weight is hung from the pelvic arch, and a marked separation of the bones during parturition does not necessarily impair to any considerable degree the stability of the support of the body. In the erect position, however, so great a weight is thrown upon the arch that no considerable amount of separation is practicable, and there comes to be an antagonism established between the constantly increasing size of the child's head and the diameters of the pelvic straits. The female pelvis therefore becomes comparatively wider, shorter, smoother, and more capacious than that of the male. It has been described as a short segment of a long cone, that of the male being a long segment of a short cone.

The following table, mainly from Waldeyer, gives the principal sexual differences in the articulated pelvis:

Portion.	Male.	Female.
Sacrum	Relatively longer and narrower. Average index 103.5.	Relatively shorter and wider.
Curvature	Generally more marked, uniform.	Usually less; flatter above, more curved below.
Promontory	More prominent	Less prominent.
Coccyx	More frequently has five vertebræ. Co-ossification earlier, projects forward more.	More frequently has four vertebræ. Synchondroses remain later; projects forward less.
Ilium	Higher, narrower; placed more obliquely, inclination of borders to each other = 53°.	Lower, broader, less obliquely placed; inclination averages 50°.
Crests	Thicker, rougher, more sinuous.	Narrower, less rough, less sinuous.
Posterior superior spines	Average distance apart 50 mm.	Average distance apart 40 mm.
Fossæ	Deeper	Shallower.
Ischium	Stronger, thicker	Less massive.
Tuberosities	Nearer together, inflexed	Wide apart, everted.
Ischio-pubic rami.	Margins more everted.	Margins less everted.
Pubis	Arch pointed, more angular (70°–70.95°). *Angulus* pubis.	Arch rounded, arch-like (90°–100°). *Arcus* pubis.
Symphysis	Deeper. At birth its width is narrower than or equal to its height (Fehling).	Shallower. At birth its width is greater than its height (Fehling).
Joint cavity	Rare	Frequent.
Spines	Nearer together	Farther apart.
Crests	Shorter	Longer.
Insertions of graciles muscles.	Nearer together	Farther apart (Cleland).
Obturator foramen.	Higher, more oval, obturator canal narrower.	Lower, almost triangular, obturator canal wider.
Acetabula	Nearer together, show less in front.	Wider apart, show more in front.
Great sciatic notch.	Lower, more oval	Higher, more circular.
Distance from body of ischium to posterior inferior iliac spine.	Averages 40 mm	Averages 50 mm. (Cunningham).
True pelvis	Deeper, narrower, more funnel-shaped, capacity less.	Shallower, wider, not markedly funnel-shaped, capacity greater.
Superior strait	More heart-shaped and dolichopellic, transverse diameter less, plane less inclined.	More elliptical (reniform) and platypellic, transverse diameter greater, plane more inclined.
Inferior strait	Narrower	Wider.
Inclination	Less marked	More marked.

Development.—Each of the three or four upper vertebræ which form the sacrum are developed from eight centres, three of which are primary and like those of other vertebræ, namely, one for the body appearing at the fourth to the eighth month, and two for the neural arch. (See Figs. 3785 and 3786.) From these latter grow out the articular and transverse processes. There are also five secondary centres, two for the epiphyseal plates, that from the tenth to the thirteenth year form along the upper and lower surfaces of the body of each vertebra, one for the spinous process, and two situated laterally and representing costal elements. The lower vertebræ usually lack these. In addition, there are formed in the seventeenth or eighteenth year two marginal epiphyses on each side, the upper ones being connected with the auricular facets. The bone is complete from the nineteenth to the twenty-first year.

tres representing the upper and lower epiphyseal plates, and in the upper vertebra two additional centres for the cornua. (See Fig. 3787.)

The hip bone is formed from three cartilages that originate separately, the one for the ilium appearing latest. (See Fig. 3788.) Ossification occurs by three primary and nine secondary centres, the primary ones being first separated in the acetabulum by a Y-shaped piece, the triradiate cartilage. In rare cases an independent centre, the os acetabuli, may remain in the acetabulum ununited. Marks of the original composition remain on the developed bone: (1) at the ilio-pectineal eminence; (2) on the ischio-pubic rami, at the seat of origin of the corpora cavernosa; (3) as a thickened bar extending from the posterior border of the acetabulum to the great sciatic notch. Ossification occurs in the order shown in the following table:

PEMPHIGUS.—The word pemphigus does not convey to the mind the idea of a clear-cut disease. The pemphigus diseases have been divided into a number of groups whose only common bond of union is the occurrence of bullæ at some time in their course. Any particular group of bullous affections may differ in every other respect from the other groups. Although these bullous diseases differ widely from one another, yet owing principally to the obscurity of their causes, it has been found difficult to segregate them or to remove any particular group from the conglomerate class of pemphigus diseases, and put it under a distinct heading. Duhring and Brocq have done much to simplify the study of pemphigus by removing altogether from this class the group of cases that Duhring has called dermatitis herpetiformis, and Brocq has called dermatitis polymorpha dolorosa. Brocq, under the term dermatitis polymorpha dolorosa, includes rather more cases than Duhring does under the term dermatitis herpetiformis. Some of Brocq's cases are not herpetiform at all.

PEMPHIGUS NEONATORUM.—Pemphigus neonatorum is an instance of what has been before mentioned of groups of cases being removed from the class of pemphigus diseases and classified under a different head. This disease in future will have to be described under the heading impetigo contagiosa, to which class it really belongs. It is described here for two reasons: first, its name is still a familiar one in medical literature, and, secondly, its most striking symptom, sometimes its sole symptom, is a bleb, leading the observer most naturally to look for its description under the heading pemphigus.

Pemphigus neonatorum is an acute contagious disease characterized by the occurrence, during a limited time, of crops of blebs.

Symptoms.—In otherwise apparently healthy infants of from three to eight days old, blebs suddenly arise. They vary from a pea to a hazelnut in size, or they may be even larger. They are at first tensely filled with clear yellow serum, and are scattered anywhere over the cutaneous surface, and spring from an apparently normal or a reddened skin. After a short time the bullæ become flabby and the contents grow turbid. Then shortly the delicate covering of the bleb gives way, exposing a red weeping surface upon which the epidermis has more or less perfectly formed, according to the time, whether early or late, at which it has broken. The blebs arise, become turbid, burst, and heal in a few days. The duration of the disease is from one to two weeks, in which time it produces several crops of bullæ. This constitutes the whole disease, which usually affects only the skin, and seems but rarely to have an influence on the constitution. It may, however, run a severe course, and cause death in a very short time.

Most of the recorded cases are reported as epidemics in foundling asylums. It is probable, however, that even a larger number occur scattered throughout the community, but are left unnoted. The sporadic cases are usually seen only by the obstetrician or midwife, who, seeing that the general health is not affected, adopts some indifferent treatment under which the patients generally recover.

Diagnosis.—In the hereditary bullous syphilide the bullous eruption is particularly marked on the palms and soles, situations that remain free in pemphigus neonatorum. Besides this, in syphilis the base of the bulla is infiltrated and frequently ulcerated, and the eruption is polymorphous, consisting of papules, pustules, and large erythematous infiltrations. In addition, in syphilis, there are snuffles, mucous patches, and condylomata. In varicella the lesions are vesicles rather than bullæ and are rarely large. In Ritter's disease the erythema, usually beginning near the mouth and spreading over large areas or the whole cutaneous surface, is the principal symptom. The bullæ are subsidiary to this. Besides, in Ritter's disease the connection between the horny layer of the skin and the rete Malpighii is loosened as in pemphigus foliaceus, so that the horny layer either comes away spontaneously or can be taken off in large masses or ribbons by a stroke of the finger. It must be mentioned here that Richter, in a recent and careful study, has concluded that Ritter's disease is not an independent affection at all, but an unusually malignant variety of pemphigus neonatorum.

Pathology.—The opinion is gaining ground that pemphigus neonatorum, some cases of pemphigus febrilis, impetigo contagiosa, and possibly Ritter's disease are identical affections. The pronounced contagiousness of pemphigus neonatorum, its confinement to the very surface of the skin, its frequent lack of constitutional symptoms, its self-limitation, and its duration, all correspond

Digitized by Microsoft®

to what we know of impetigo contagiosa. We know also that impetigo contagiosa, even in adults, may be a bullous disease, and that it is particularly apt to be so in

www.libtool.com.cn

FIG. 3789.—Dr. H. M. Sherman's Case of Acute Pemphigus, Probably Infective, in Full Eruption.*

the tropics. In infants, who are always kept very warm and whose skin is delicate, the tendency to form bullæ, even in temperate climates, is marked. It is also urged in favor of this view that if an infant is infected from an adult who has impetigo contagiosa it gets pemphigus neonatorum, and vice versa if an adult is infected from an infant having pemphigus neonatorum he gets impetigo contagiosa (Matzenauer). Luithlen has shown that the bleb in pemphigus neonatorum is caused by separation of the horny layer from the rete Malpighii. This anatomical finding of the superficial situation of the bleb corresponds with what we know of its clinical appearance and behavior, for it will be remembered that the bleb has a thin delicate covering and heals with great rapidity, and it also corresponds with what we know of the very superficial character of the lesions in impetigo contagiosa.

Treatment.—It has been found that pemphigus neonatorum occurs with noticeable frequency in the practice of uncleanly midwives and nurses, and therefore a thorough personal disinfection of these should be required. It is with a view to getting on the track of such disease carriers that the Berlin authorities have ordered all cases of pemphigus neonatorum to be reported to the health office.

If it be true that pemphigus neonatorum and Ritter's disease are simply forms of impetigo contagiosa, then the parturient woman and the infant should be carefully shielded from this very prevalent disease. Attention is here drawn to the facts that many cases of what are commonly called barber's itch in men and impetiginous eczema in children are really impetigo contagiosa, and that impetigo contagiosa is so frequent, particularly in children, that a skin clinic is scarcely ever without examples of it.

As the infants attacked rarely suffer from constitutional symptoms, and the disease is generally short and self-limited, no internal treatment is required. If, however, constitutional symptoms do arise, such as fever and exhaustion, they must be treated on the principles obtaining in such cases, as no specific treatment is known. As the malady is contagious and is scattered over the entire cutaneous surface, a general cutaneous antiseptic treatment is indicated. The antiseptics chosen, however, must be those that will neither injure the infant's delicate skin nor by absorption cause constitutional symptoms. In regard to absorption, it must be remembered that the thin skin of the infant more readily absorbs medicaments than the stronger, thicker skin of later life. As fulfilling these indications, two antiseptics come to mind: alcohol and boracic acid. Boracic acid may be used in the infant's bath in the proportion of about four ounces to the gallon, and a lotion consisting of a saturated solution of boracic acid in dilute alcohol, may also be used as a rub-down. This solution, by the way, is one of the best to use in any case of pyogenic infection of the skin. It may be readily made by the family in the following way: A bottle is half-filled with alcohol, then nearly filled up with water, and then boracic acid is poured in until some of it remains undissolved in the bottom of the bottle after shaking. The supernatant fluid is of course a saturated solution of boracic acid. When an ointment is necessary or desirable, as on the face or in the flexures, a weak ammoniated mercury ointment is the best; it is made by adding five grains of ammoniated mercury to an ounce of vaseline. When crusting takes

* The instance of acute bullous eruption, the subject of these photographs (Figs. 3789 and 3790), occurred in the practice of Dr. H. M. Sherman of San Francisco. The patient was a boy, seven years of age, who had been operated upon for tuberculosis of the right knee-joint. Subsequently to the operation sinuses formed, discharging a bright green pus. The eruption then appeared behind the ears and on the neck, and spread rapidly over the head, trunk, and extremities, even to the fingers and toes. The eruption consisted of blebs only. The contents of these blebs were clear at the start, and remained clear throughout their entire course, and there was no evidence of any inflammatory reaction of the skin. There was no rise of temperature, nor was there any disturbance of the general health; the eruption disappeared at the end of a few days. No bacteriological examination was made. This was probably an instance of an acute infective pemphigus, the exact nature of which is not known.

Digitized by Microsoft ®

place, the crusts must be removed before either lotions or ointments may be expected to be of any use. This is best done by applying boracic acid starch poultices. These are made by adding hot water to ordinary laundry starch while constantly stirring, to make a moderately thick paste. To a large teacupful of the paste a heaping teaspoonful of boracic acid powder is added, and it is then poured into a thin muslin bag and applied.

Acute Febrile Pemphigus.

Acute febrile pemphigus is a very rare disease of which Köbner has formulated the following requirements: After brief prodromes, and after fever has begun to show itself, blebs appear on the previously healthy skin. The fever continues with exacerbations and remissions, and at the same time there are repeated outbreaks of blebs. The blebs are not confined to any particular region of the cutaneous surface, but occur in a scattered manner. After three or four weeks the bullous eruptions subside completely and do not recur. No blebs should appear at a time when no fever is present. It will be observed that the only real point of distinction between pemphigus neonatorum and generalized bullous impetigo of the adult on the one hand and acute febrile pemphigus on the other is a rise of temperature in the latter. Richter, however, has shown that there may be even a severe constitutional disturbance with fever in pemphigus neonatorum, and it is not improbable that in some instances of generalized bullous impetigo there may be fever, so that these three diseases may be identical. There is, however, a still much more severe febrile bullous disease, which has been described by Pernet and Bulloch. Their cases were acute septicæmias; in both instances they occurred in butchers, and followed knife wounds. Probably in the same class are the bullous septicæmias occurring in inflammatory diseases of the umbilical cord, or the bullous septicæmias in the new-born, coincident with septicæmia in the mother. The affection on the skin in such cases may look like an extensive burn with scalding water. These grave bullous diseases seem in many instances to be different from what is understood in speaking of pemphigus neonatorum.

No specific internal treatment has been outlined for pemphigus febrilis. The external treatment would be that advised for pemphigus neonatorum.

Pemphigus Chronicus Vulgaris.

Definition. — Pemphigus chronicus vulgaris is characterized by the appearance of blebs on the skin and also on the mucous membranes. Pemphigus foliaceus and pemphigus vegetans are to be looked upon as varieties of pemphigus chronicus vulgaris. They are worthy, however, on account of their peculiar clinical appearance and course, of a separate description.

Etiology.—The cause of pemphigus is unknown. That it is not merely a local, but a constitutional, disease is shown by the fever that accompanies it, and also by the more or less rapid deterioration in the general health of those afflicted with it. That few blebs on the surface of the body should cause cachexia and death is not to be thought of as a possibility. The blebs are only one symptom of a general constitutional disease. Take, for example, pemphigus vegetans when at times the blebs cease to appear. This temporary cessation of the appearance of the blebs does not seem to retard in the least the general course of the disease.

The occurrence of blebs in diseases of the nervous system, in nerve injuries, and in neural leprosy has led many to think that pemphigus is a disease of the nervous system. These are the only facts, however, that favor this view. That the disease is due to some toxic substance that acts through the nervous system, in some such way as an intoxication with rotten fruit will cause urticaria, is not impossible.

Symptoms.—Pemphigus vulgaris frequently commences with general as well as with cutaneous symptoms. The general symptoms are fever, malaise, gastric disturbance, sleeplessness, and decided nervousness. With these symptoms there appears on the skin a greater or less

Fig. 3789.—Stage of Convalescence from the Attack of Acute Pemphigus. (Same case as that shown in Fig. 3790.)

Digitized by Microsoft®

number of blebs, which may come in crops, each crop being accompanied by an exacerbation of the constitutional symptoms. The course of the disease may present great variations. In the first place the initial crop of blebs and those following may be accompanied by very little rise of temperature or none at all, or there may be much constitutional disturbance, with very little eruption, or the reverse. The outbreak of blebs and the constitutional disturbance may be continuous, reducing the patient's strength very rapidly; or the disease may begin acutely and stormily, gradually linger on for weeks or months, and finally die down altogether, possibly to

www.libtool.com.cn

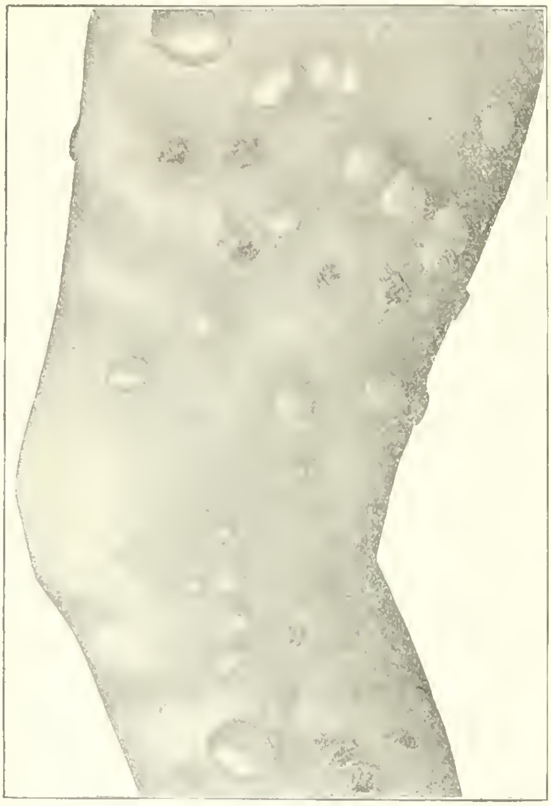

FIG. 3791. Chronic Pemphigus Vulgaris. In the picture the bullæ can be seen with great distinctness to be full, tense, hemispherical and oval, variable in size and springing from a skin, which is, to all appearances, healthy. In some places there are vestiges of old bullæ that have gone through their evolution: some are broken, others are dried down. There are no evidences of scratching. (From a plate in L. Brocq's article on Pemphigus in "La Pratique Dermatologique" par Ernest Besnier, L. Brocq, and L. Jacquet, t. iii., p. 770. This figure is a reproduction of an aquarelle in Cazenave's collection in the Museum of the Hôpital Saint Louis, and had already been published in the "Leçons sur les maladies de la peau" par Alphée Cazenave, 1856.)

start up again at some future time. The blebs arise either from what appears to be a normal surface or from a reddened spot, and are at first filled with a fluid either as clear as water or of a yellow serous appearance, or red or brown or blue from mixture with blood. In any case this fluid quickly becomes turbid then purulent. The blebs may be the size of a pea or a hen's egg, or even larger. After a time the blebs either dry down, forming a scab, under which healing takes place, or they may break spontaneously or be broken, leaving a non-infiltrated eroded surface upon which there forms a flat, yellow, brown, or black scab. In due course this scab falls off, leaving a more or less deeply tinted brown pigmented patch, but rarely a scar. At times, after healing, milium bodies, first described by von Bärensprung, are found in the epithelium.

On the mucous membranes the lesions are rarely seen as blebs, because the delicate and moist epithelial layers soon burst, leaving non-infiltrated erosions, which are either red or covered by a yellowish coating. The circular or polycyclic form of these erosions, together with the tatters of epithelium around their borders, show their origin as blebs. On either the skin or the mucous membranes any individual lesion may stop short of forming a bleb or an erosion as the case may be. On the skin such a lesion would be merely an erythematous spot, while on the mucous membranes it would show itself as a whitish-gray epithelial thickening. In pemphigus there may be no eruption whatever on the mucous membranes, or the outburst on the mucous membranes may precede, be simultaneous with, or follow the eruption of blebs on the cutaneous surface. Mosler and Köbner have seen pemphigus of the mouth exist for four years before there was an outbreak on the skin.

As has been said, it is very rare for scarring to follow pemphigus blebs on the skin. It is also rare, but not so rare, for scarring to occur on the mucous membranes. What is equivalent to scarring occurs on the conjunctiva, constituting what has been called essential shrinking, but this will be considered later on. Sometimes the erosions on the mucous membranes, especially of the mouth, ulcerate. Probably these ulcerations are not an essential part of the disease, but adventitious from the increased vulnerability of the eroded surfaces, and also from infection, usually with staphylococci or streptococci. In the same way pemphigus may be accompanied by lymphangitis and adenitis, the broken mucous membrane being the open door for the entrance of bacteria. It is said that ulceration in the cheek pouches may result in so much cicatricial tissue as to interfere with the action of the lower jaw. Pemphigus of the throat may cause hoarseness, suffocation from swelling of the glottis or of the mucous membrane of the larynx, a feeling as if a fish bone had lodged in the throat, or a disagreeable feeling of rawness. In pemphigus of the mouth or throat the interference with mastication and the difficulty or impossibility of swallowing solid food add to the misery and weakness of the patient.

As in pemphigus of the other mucous membranes blebs on the conjunctiva are very seldom seen. It may be that they very rarely form, or that if they form they quickly burst. The pemphigus lesion as seen on the conjunctiva consists of an irregular-shaped membranous exudation of grayish-white or grayish-yellow color. Pemphigus of the conjunctiva is almost always followed by cicatrization. It is not meant by this that every pemphigus lesion on the conjunctiva is followed by scar formation. In fact almost all the lesions here, as on the skin, heal without leaving a scar. It seems necessary to scar formation that a number of pemphigus lesions should occur successively at one place (Michel), and, as this often happens, scar formation frequently results.

The scars may be localized, or they may involve almost the whole of the conjunctiva. If they are thus generalized, the conjunctiva will be turned into a dirty gray or whitened, thickened, cutis-like membrane, with a dull dry surface. This is the condition that has been called "essential shrinking." With much shrinking the entire conjunctival sac may be obliterated, and one or both lids may be entropioned, or drawn tight down on the edge of the cornea. In such cases the cornea itself is diseased from exposure, and from the eyelashes of the entropioned lids sweeping over it. It is white and opaque, and its surface is dull and dry, and covered with scaling epithelial cells. Michel never has seen a bleb of the cornea itself, but he quotes Seggel as having seen one, and Mueller as having seen an ulcer covered with a membranous exudation on the upper border of the cornea and on the neighboring conjunctiva; Pergens has also seen a broken bleb of the cornea in an infant.

Pemphigus of the conjunctiva may exist alone or with pemphigus of other mucous membranes such as the mouth, pharynx, trachea, or bronchi, or with pemphigus of the skin. It is held that a diagnosis of pemphigus,

Digitized by Microsoft®

when the mucous membranes alone are effected, cannot be made. It seems, however, that the clinical picture is clear enough, and that such lesions are pemphigus is shown by the fact that after existing for a longer or shorter time pemphigus of the skin may supervene. Just as there can be a pemphigus of the skin alone without pemphigus of the mucous membranes, so also can there be a pemphigus of the mucous membranes without pemphigus of the skin (Kaposi).

www.libtool.com.cn

Eosinophilia, either in the blebs or in the blood of the general circulation, seems to have very little value as a symptom.

Diagnosis.—In dermatitis herpetiformis the mucous membranes are not apt to be affected; the lesions on the skin are multiform and consist of erythematous patches, papules, wheals, vesicles, and bullæ; the itching and pain are severe and occur in distinct attacks; and the general health is undisturbed.

In epidermolysis bullosa the disease occurs in families and is hereditary; the bulla occurs when an injury has been received, even a slight pressure, as on the feet and hands, may cause it; and the general health is unimpaired. Colcott Fox has, however, reported a case in which the disease resembled epidermolysis in every particular except that it was not hereditary, and he warns against drawing too fine distinctions between it and pemphigus. In epidermolysis bullosa the nails also frequently grow to be deformed, and the disease is probably something more than a mere over-sensitiveness of the skin to pressure. Another instance showing the intimate relationship between these two diseases is the case reported by Mertens, in which there was pemphigus of the mouth, throat, and conjunctiva. Blebs appeared also on the skin, but only after trauma.

The vesicular and bullous eruptions that sometimes follow trauma and also those that sometimes follow vaccination, and that in either instance may last for years, resemble more closely the type of dermatitis herpetiformis than that of pemphigus. Just where they stand, however, in a classification, has not yet been determined.

Quinine, iodine, bromine, and copaiba may all cause bullous eruptions that have to be differentiated from pemphigus.

The blisters caused by the external application of drugs must also be considered. Sometimes such drugs are applied with the intention of deceiving. The occurrence of the blebs exclusively on the skin in an hysterical person in situations easily reached by the patient may cause suspicion. The wings of the Spanish fly have been found on the blebs.

Hardy mentions the occasional occurrence of blebs on the hands and feet in eczema. I have seen this occur in two separate attacks of eczema in the same patient. Bullæ may also occur in lichen planus (Whitfield). The differentiation would here be made by the presence of the lichen papules and by the itching.

In impetigo contagiosa the eruption, as has been previously mentioned in the section on acute pemphigus, may be bullous even in the adult. This is particularly apt to occur in the tropics. The swift course of the disease, its marked contagiousness, its non-interference with the general health, the very large yellow superficial crusts, and the occurrence of pustules should put one on one's guard.

Prognosis.—Pemphigus is one of the few diseases of the skin in which the life of the patient is threatened.

In such a capricious disease the prognosis is always uncertain. Cases that begin benignly may end malignantly, and vice versa. Nevertheless there are indications that point to a good or bad course of the malady. Luithlen, for instance, divides pemphigus, in regard to prognosis, into two classes of cases. In the first class the blebs appear on erythematous patches, and there is no rise of temperature. In these cases the blebs are situated in the epithelium, and the rete is not raised away from its bed on the papillary layer. The prognosis here is favorable. In the second class of cases the blebs arise on the perfectly sound skin, and their eruption is accompanied by fever and exhaustion. In this class the blebs arise under the rete and lift it completely away from the papillary layer. The prognosis here is always unfavorable.

When the blebs are tense and filled with a clear white or amber-colored fluid this fact is viewed as a favorable sign; while, on the other hand, when the blebs are slackly filled and pus quickly forms, collecting as an hypopyon in the dependent portion of the hanging bag, the outlook is bad.

In pemphigus of the mouth and throat the difficulty or impossibility of swallowing solid food interferes with the patient's nutrition. Independently of this, however, the occurrence of pemphigus of the mucous membranes may be looked upon as an ominous sign. In general, in those cases in which the mucous membranes are affected at the very first or early in the disease, the prognosis is the worst; but no matter at what time in the course of the malady the mucous membranes are affected the symptom is a bad one.

Pemphigus Foliaceus.

That form of pemphigus which is called pemphigus foliaceus has for its chief clinical characteristic the exfoliation of the skin. There may be very few blebs; indeed, when the disease is well under way and the exfoliation is active there may be no blebs at all.

Pemphigus foliaceus may attack either sex, at any age, even in childhood. The disease appears in all countries, and does not seem to depend in any way on climatic influences. It is neither epidemic nor contagious.

It is said that prodromal symptoms are either absent or are not at all well marked, and that when present, they consist in a feeling of general lassitude and a slight rise of temperature. The first symptoms of the disease proper may appear on any part of the skin, or on the mucous membrane of the mouth. The blebs in pemphigus foliaceus, even at first, generally differ from those in ordinary pemphigus. Instead of being large, clear, and bubble-like, they are small, slackly filled, and slushy, with a delicate covering that soon breaks. The blebs often have a reddish tint from the red color of the injected blood-vessels shining through the thin layer of fluid and the very delicate covering of the bleb. The erosion left by the first bleb that appears in a given locality enlarges by undermining of the surrounding epidermis, and, moreover, new blebs form in ever-widening circles about the site of the first, which by this time will probably have healed. But when this healing takes place it does not end the process. It is just at this point that the most prominent characteristic of the disease and the one to which it owes its distinctive title of foliaceus begins. Serous exudation continues to be poured out rather into than under the newly formed, but by no means normally formed, epidermis. This exudate and the epithelial layers into which it is poured form leaflets resembling French pastry; hence Cazenave's epithet foliaceus as applied to this form of pemphigus. The loosening of the attachment between the layers of the epidermis is also a remarkable phenomenon in pemphigus foliaceus, and may be demonstrated by drawing the finger firmly along the apparently sound skin. The top layers of the epidermis will slip off, leaving an excoriation. This slipping of the epidermis is found in other forms of pemphigus, but is particularly well marked in pemphigus foliaceus.

By the spread and coalescence of diseased patches the whole cutaneous surface tends to become involved. This generalization may take place in a few days, or may not be completed before several months have elapsed.

From the above description one can understand that the appearance of the patient will differ widely according to the stage at which the disease is seen. There may be groups of circinate patches of miserably formed bullæ, or there may be circular patches covered with yellow crusts, or the whole skin may be bluish or brownish-red and actively desquamating, with here and there raw patches, but yet with very little weeping. The skin in pemphigus foliaceus is only moderately or not at all thickened.

Digitized by Microsoft®

Gradually other changes occur. The hair falls out. The eyelids become ectropioned and their lashes fall. The nails atrophy.

At first the general health of the patient remains unaffected, but gradually, through the uncomfortable condition of the skin, the occasional fever, the sleeplessness aggravated by severe attacks of itching, the constitution becomes undermined. The patient becomes thin and poorly nourished, then through complications, either in the lungs, or intestines, or kidneys, he is carried off.

www.libtool.com.cn

It is said that pemphigus foliaceus, after existing for a longer or shorter time as such, may turn to the type of pemphigus chronicus vulgaris (Kaposi).

Diagnosis.—The most important disease to differentiate from pemphigus foliaceus is dermatitis herpetiformis in its generalized exfoliative form. The two diseases are at this stage so closely alike that only a very clear history or a continued observation of a patient enables one to come to a definite conclusion. Severe attacks of itching, the occurrence of the vesicles or bullæ in groups, and only slight interference with the general health should lead one to suspect the disease in question to be dermatitis herpetiformis.

Pemphigus Vegetans.

In pemphigus vegetans the denuded areas left by the blebs, instead of healing over, sprout peculiar vegetations. This is one of the chief characteristics of this variety of pemphigus, and the one to which it owes its distinctive title of vegetans. It is, however, not the only point of difference between it and ordinary pemphigus. The individual cutaneous lesion is usually smaller and more flabby, the contents are more turbid, and the covering of the bleb is more delicate than in pemphigus vulgaris. The blebs and the subsequent erosions may, however, resemble those of pemphigus vulgaris in every respect up to the time when the vegetations sprout.

The bullæ appear suddenly on an apparently healthy surface, and are generally delicate and soon break, leaving smooth, deep, red excoriations exuding an abundant, foul-smelling serum. The border of both the bleb and its succeeding excoriation remains sharply limited, and there is no infiltration. The vegetations may be present before the bleb breaks, but more frequently they appear in the erosion, at first as a rounded, prominent, dirty white elevation, in the centre of which the vegetations sprout. This process slowly extends out over the entire excoriation and even beyond it. This growth is surrounded by a zone of dark red erosion, which in turn is bounded by a collar of loosened macerated epithelium. The vegetations are closely bunched, their free surface is necrotic, excoriated, and dirty, and they have in their substance many pinhead-sized pustules, giving them a stippled look.

Many of the vegetations are flattened across the top, and, although larger than the broad condylomata of syphilis, look strikingly like them. By individual increase in size neighboring lesions coalesce with one another, forming large patches with serpiginous boundaries of tattered, ragged epithelium. As a rule the lesions on the tongue and mucous membrane of the mouth and lips resemble those seen in pemphigus vulgaris, but they may also become vegetative, although these vegetations do not reach anything like the size or extent of those seen on the skin.

The disease may begin by the appearance of blebs on any part of the skin or mucous membranes, but it is particularly apt first to show itself in the mouth. Spiegler has recently said that of twenty-eight cases of which he had known, eighteen began with lesions in this situation.

It is only in bad cases that all the lesions on the cutaneous surface become vegetative. In certain regions, as in the naso-labial and labio-mental grooves, in the armpits, groins, and navel, and on the belly, the lesions are particularly apt to sprout vegetations.

The constitutional symptoms, such as sleeplessness, fever, and loss of strength, are present as in pemphigus vulgaris, but are usually more marked.

The *prognosis*, although commonly far worse than in pemphigus vulgaris, is by no means fixed.

In all medicine there is no disease with a more dramatic course than that of pemphigus vegetans. For instance, a man consults a physician in regard to an insignificant erosion in the axilla. A simple treatment is prescribed. He appears shortly again with some vegetations on the erosion. These may be cauterized, and the patient dismissed without any thought of the serious nature of the malady. The lesion, however, does not heal, and new excoriations and blebs appear, especially about the privates, with coincident dirty white patches in the mouth. At the same time the patient gives off a most horrible carrion-like odor. He shortly becomes a miserable, fulsome, horrible object to himself and others; and, to add to his miseries, there is often the moral degradation of being thought to have syphilis. Inanition from refusal of nourishment, fever, exhaustion, marasmus, spinal irritation, and acute œdema of the brain succeed one another rapidly, and in a few weeks or months the patient dies.

Where the lesions first appear is a matter of importance in the prognosis, for in those cases in which the lesions begin on the lips, in the mouth, on the scalp, or on the genitals the prognosis is bad.

Not all the blebs in a case of pemphigus vegetans become vegetative, and when only a few of them sprout vegetations the prognosis approaches more that of pemphigus vulgaris—that is to say, it is serious, but not necessarily fatal. On the other hand, the more blebs there are that become vegetative, the more quickly does the disease terminate in death.

Necrosis of the surface of the vegetations is the rule, and the more marked the necrosis the worse the outlook for the patient. If, however, this necrosis does not take place, and the vegetations tend to become covered with horny epithelium, the patients may recover and live for years (Neumann).

It is not an absolute rule that a pemphigus vegetans should remain as such throughout its entire course. In general, the vegetations cease appearing as a fatal termination approaches, and Kaposi has demonstrated a patient in whom pemphigus vegetans healed, but the disease returned some time afterward as a pemphigus cachecticus.

As above shown, the estimate of the course which a given case should take may be modified by a number of considerations, such as the severity of the constitutional disturbance, the localities where the lesions first appear, and the abundance and the dirty necrotic condition of the vegetations. The beneficial effects of treatment have also helped to modify the unmitigatedly bad opinion previously entertained of the course of pemphigus vegetans. Under drying disinfecting powders the prognosis has improved, and Köbner, Mueller, Kaposi, and Mraçek have reported cases showing at least temporary relief or cure.

The resemblance of pemphigus vegetans to syphilis is striking. The white patches in the mouth resemble absolutely the mucous patches of syphilis, and the vegetations, especially the button-like ones, differ in no respect, except in their larger size, from the broad condylomata that were at one time supposed to be found only in syphilis. These symptoms, together with the situation of the patches, especially those in the groins, in the folds between the thighs and the scrotum, and in the anal fold, all go to form a picture that is in the highest degree deceptive. There are differences, however, which aid in distinguishing the two diseases. For instance, the growths in pemphigus are always surrounded by the tatters of the blebs, while in the confluent condylomata of syphilis the patches are bounded by sharp infiltrated borders. Furthermore, the condylomata in syphilis always occur at an early stage of the disease and are accompanied by other symptoms of syphilis. In syphilis the growths when left to themselves tend to subside, while in pemphigus the longer the disease lasts the more

Digitized by Microsoft®

the growths increase; and while they grow, the general condition of the patient becomes worse and worse. Furthermore, pemphigus vegetans is a disease of adult life, and the presence of blebs is unknown in the course of syphilis of adults.

Post-bullous vegetations are not absolutely pathognomonic of pemphigus vegetans, as in rare instances they occur in several other affections, such as in dermatitis herpetiformis, impetigo contagiosa, and in the iodine (Hallopeau) and bromine (Wallhauser) eruptions. Post-bullous vegetations also occur in impetigo herpetiformis, but impetigo herpetiformis is by many observers now considered a clinical variety of pemphigus vegetans.

Treatment.—The outlook for the cure of any given case of pemphigus, through either internal or external medication, is not good, yet much may be done to alleviate the symptoms and to stay the progress of the disease.

Arsenic.—So many have praised the effect of arsenic in pemphigus that it should be the first drug to receive a trial. The favorite way of giving it is as Fowler's solution, in increasing doses, beginning with six drops, and, as some advise, running up to twenty or thirty drops a day. Very high doses of arsenic are of questionable benefit as they depress. If such high doses are used it is entirely for their specific effect, and as soon as they are found valueless they should be stopped. On the other hand, small doses, on account of their tonic effect, may be continued for a long time.

Strychnine. — Neisser has recommended strychnine. Its only effect seems to be that of a powerful tonic, useful in combating the great exhaustion, which is so frequently a marked feature of the disease.

Quinine.—Mosler has reported an apparent cure after taking 40 gm. of muriate of quinine in five weeks (Jarisch). In most cases, however, it acts simply as a bitter tonic.

Acids.—Dilute sulphuric acid, acetic acid, and citric acid have been recommended, but no specific action can be attributed to them. They probably act as tonics.

Opium.—Opium besides being a soporific is said by Malcolm Morris to be one of the best curative agents we possess.

Chloral hydrate is an excellent drug for the sleeplessness which is a marked symptom in some cases of pemphigus.

Ordinarily the simplest measures may be employed to relieve the local conditions. Frequently a mild antiseptic powder, made, for instance, of equal parts of boracic acid, starch, and oxide of zinc, is all that is required. If the tension of the blebs is uncomfortable they may be opened, and the above powder may be used to soak up the secretions, and to prevent the excoriations sticking to the bedclothes. If there are much heat and inflammation, or if pus is retained under the crusts, mild antiseptic lotions or salves may be the best topical applications. Lotions will be mentioned after speaking of baths. A red oxide of mercury salve is excellent: ℞ Hydrarg. ox. rub., ʒ ss.; lanolini, vaselin. alb., āā ℥ ss. M. S.: Apply on cloths.

Carbonate of lead, employed as a salve, is also good: ℞ Plumbi carbonat., ʒ i.; lanolini, vaselin. alb., āā ℥ ss.

Baths.—The continuous bath, when it can be obtained, is of the greatest comfort in severe cases. It relieves the tension and pain, softens the crusts, mitigates the fever, and induces sleep. With its help a patient may be carried through an eruptive attack that would otherwise have killed him. Hebra's water-bed is excellent for the purpose. (Fig. 3792.) It consists of a box or bath lined with zinc, with a plug and overflow pipe at its foot, and the feed pipe with hot and cold water mixed, entering at the head of the bath near its bottom. The temperature should be maintained at about 36° or 37° C.

The patient rests on a wire netting over which are thrown woollen blankets. This wire netting may be raised and lowered as wished. After the patient is lowered into the water the bath may be covered over with blankets for the purpose of retaining the warmth.

When such a bed is not obtainable, the patient may be put in a bath for several hours a day. Soothing or antiseptic medicaments may be added to the bath, as for instance one or two drachms of permanganate of potassium, or a couple of tumblerfuls of boracic acid powder, or biborate of soda, or bicarbonate of soda, to sixty gallons of water. It must be remembered that there are people to whom baths are debilitating, and on whom, in such an asthenic disease as pemphigus, their use would be particularly disastrous. In such cases we must content ourselves with compresses either wrung out of simple water or wet with medicated lotions. These compresses may be covered in either with oil silk or with rubber tissue. Hutchinson's lotion is an excellent one for allaying inflammation, irritation, and itching. It consists of: ℞ Liq. plumb. subacetatis, ℥ ss.; liq. carbonis detergentis, ℥ iiss. M. S.: A teaspoonful in a pint of water, to be used as a lotion.

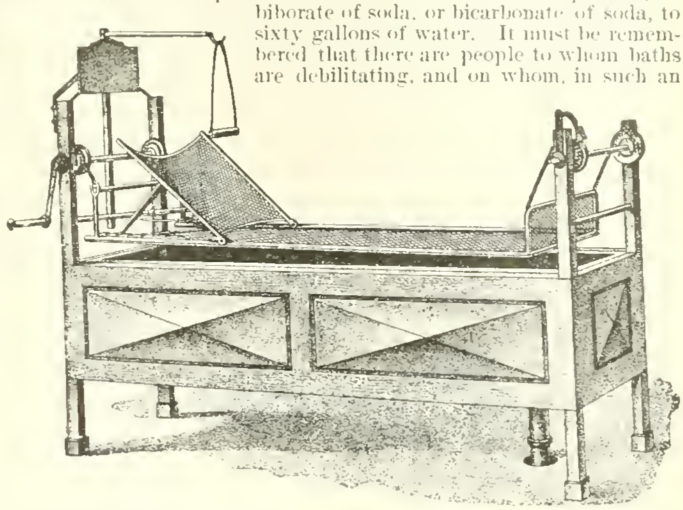

FIG. 3792.—Hebra's Contrivance for Administering a Continuous Bath. (From Jarisch's "Hautkrankheiten," in "Nothnagel's System.")

Other solutions to be used on compresses are those of acetate of aluminum, saturated solution of boracic acid, and liquor plumbi subacetatis. Carron oil, made with equal parts of lime water and olive oil, with the addition of four per cent. of boracic acid, is one of the best applications in pemphigus, and is especially useful in the dry scaly condition in pemphigus foliaceus.

Treatment of Pemphigus Vegetans.—Unna introduced a treatment of pemphigus vegetans which consisted of painting the lesions with tincture of iodine. This treatment is so painful that the patient must be anæsthetized, and on awaking must receive full injections of morphine. Köbner first curetted away the vegetations or burnt them down with the thermo-cautery; then afterward he treated any vegetations that appeared with tincture of iodine.

Jarisch said he saw the lesions in a typical case of pemphigus vegetans clear up with wonderful celerity under a paste consisting of: ℞ Sulphur. præcip., zinc. ox., amyli, āā 10.00; vaselin. flav., 30.00. M. S.: Spread on linen and apply or rub into patches, and dust with some indifferent powder, such as oxide of zinc and starch.

In pemphigus vegetans, however, these measures for controlling the vegetations, no matter how successful locally, have no effect on the course of the disease. The general symptoms of sleeplessness and exhaustion go on unchecked. In fact it is the rule for the vegetations spontaneously to cease appearing as the fatal termination approaches.

Neumann found solutions of salicylic acid applied on

Digitized by Microsoft®

cotton an excellent deodorant for the foul odor present in pemphigus vegetans. A powder made of equal parts of talc and salicylic acid may also be used.

In looking over the literature of the drugs and applications used in pemphigus, one cannot fail to note everywhere a tone of helplessness, with perhaps a slight brightening up when the continuous bath is mentioned. The good effect [illegible] may, in almost all instances, be reduced to their tonic or sedative action, and of the external remedies to their soothing effects, their power to diminish tension and burning, or to control the evil odors and the undue activities of the pyogenic bacteria. The treatment, it is true, is still far from our ideal of what effective treatment should be. Nevertheless, we have grounds for claiming that the actual advance made in the treatment of pemphigus is by no means so small as upon first thought it would seem to be. Thanks to Neumann's discovery of the true nature of pemphigus vegetans we are now able to save many a patient from the mental worry and humiliation of being thought to have a syphilitic disease, and from the physical suffering which he would have to undergo before it could be demonstrated by treatment that this diagnosis was incorrect. *Douglass W. Montgomery.*

PENIS, DISEASES OF. See *Sexual Organs, Male, Diseases and Injuries of.*

PENNYROYAL, AMERICAN OR MOCK.—*Hedeoma.* "The dried leaves and tops of *Hedeoma pulegioides* (L.) Pers. (*Mentha p.* L.; fam. *Labiatæ*)." U. S. P.

This is a slender annual herb very abundant in dry, especially rocky meadows and pastures throughout Eastern and Central North America. The base of the stem is frequently decumbent. The upper portion is usually much branched, the branches are slender, erect or ascending and quadrangular, the leaves opposite, slenderly petioled, blades usually less than 2.5 cm. (1 in.) long, and 1 cm. (½ in.) broad, oblong ovate, narrowed gradually into the petiole, obtuse, distantly and shallowly serrate, pale or grayish-green, thin, with few, strongly ascending secondary veins, and the lower surfaces beset with small, circular, depressed glands, which are usually golden yellow and shining under a strong lens; flowers several in a leaf axil, pedicelled, the calyx tube cylindraceous, somewhat contracted at the mouth, strongly nerved, its tube two lipped and slenderly and sharply five-toothed, corolla tubular, two lipped, pale blue, spotted; stamens four, two of them sterile, odor strong, somewhat mint like; taste aromatic and pungent.

With a little tannin and bitter extractive it contains nearly one per cent. of a volatile oil, official under the title *Oleum Hedeomæ*, which is its active portion.

American pennyroyal possesses the carminative, aromatic, and diffusive stimulant properties of the mints in general, and is similarly employed. There is no official preparation, but an infusion is probably the best form of administration. One of the important properties of this plant and of its oil is that of repelling mosquitoes, to a considerable and useful extent.

Oil of pennyroyal is thus described: A pale yellowish, limpid liquid, having a characteristic pungent, mint-like odor and taste. Specific gravity 0.930–0.940 at 15° C. (59° F.). The oil should form a perfectly clear solution with twice its volume of a mixture of three volumes of alcohol and one volume of water, this solution being neutral or slightly acid to litmus paper. It is also readily soluble in carbon disulphide, or in glacial acetic acid. It consists chiefly of pulegone. The dose is 1–5 minims. The genuine or European pennyroyal is *Mentha Pulegium* L. (*Pulegium vulgare* Mill.) in the same form. It has a similar taste and odor, and contains an almost identical volatile oil. *Henry H. Rusby.*

PENTAL (*Trimethyl-ethylene*), a purified amylene, introduced by Mering as an anæsthetic. It is a colorless liquid with a sharp penetrating odor, but not irritating to the mucous membrane. Specific gravity 0.8; boiling point, 100.4° F. It is insoluble in water, but mixes freely with alcohol, chloroform, and ether.

Pental is administered in the same manner as chloroform. Anæsthesia is produced in three or four minutes and lasts for about four minutes.

Following its introduction pental was employed by many as an anæsthetic, with very satisfactory results, but experimental work upon animals proved that it was a powerful cardiac depressant, and also produced marked renal irritation. Many instances of dangerous depression during its use and several deaths were soon reported, and it rapidly fell into disuse. *Beaumont Small.*

PENTASTOMA. See *Arachnida.*

PENTOSURIA is the term applied to the occurrence of sugars of the five-carbon series (pentoses) in the urine. The pentoses ($C_5H_{10}O_5$) include the carbohydrates arabinose, xylose, and rhamnose ($C_6H_{12}O_5$), the latter being a methyl pentose. The appearance of sugars of this type in the urine was first detected by Salkowski and Jastrowitz in the urine of a morphine habitué. Since then similar observations have been made on various individuals. In some of these instances the pentosuria has been found to persist unchanged for many months and even for several years. The pentose either occurs as the only carbohydrate present in noticeable amount, or it may accompany dextrose, the sugar of ordinary glycosuria.

Various methods of testing for pentoses in the urine have been proposed. Of these the following are most widely used.

Tollens' Reaction with Phloroglucin and HCl.—A small quantity of phloroglucin is dissolved in 7–8 c.c. of HCl (specific gravity, 1.12) with the aid of heat. After cooling, ten drops of the urine are added to one-half of the reagent, and the mixture is immersed in a boiling water-bath. In the presence of pentoses a cherry-red coloration quickly results. An immediate spectroscopic examination reveals a characteristic absorption band between the D and E lines. The remainder of the reagent is used for a control comparison with normal urine. The presence of dextrose may interfere with the reaction. (Salkowski's modification.)

Tollens' Reaction with Orcin and HCl.—The urine is mixed with an equal volume of fuming HCl containing orcin (instead of phloroglucin) and heated. After cooling it is shaken with amyl alcohol, which assumes a greenish tint. In this reaction the characteristic spectral absorption band is between C and D. Salkowski prefers the orcin test to all others.

Reaction with Aniline-acetate Paper.—The urine is treated with an equal volume of fuming HCl and heated to boiling. If a strip of filter paper, moistened with aniline acetate, is now immersed in the fluid, it is quickly colored cherry red by the furfurol formed from the pentoses present.

Liberation of Furfurol by Distillation with HCl.—The method is essentially the same as that used in the estimation of the pentosans in foods. The furfurol may be detected in the distillate by the use of aniline-acetate paper. Normal urine or urines containing dextrose or lactose do not ordinarily give any positive reaction.

Preparation of a Pentosazone.—The osazone is prepared with phenyl hydrazin and acetic acid as in the ordinary tests for sugar. (See *Urine.*) The pentosazone is characterized by: (1) Its greater solubility as compared with glucosazone; and (2) its melting point, 156°–160° C. When large quantities of dextrose are present, they may previously be removed by fermentation with yeast. The pentoses do not ferment, but they reduce alkaline copper solutions.

Preparation of the Benzoyl Ester.—The benzoyl esters are prepared from 500 c.c. of urine, then saponified with sodium ethylate and the mixture is filtered at once. The filtrate will give the orcin reaction for pentoses (see above) and glycuronic acid is said to be excluded. When dextrose is present slight modification of the method is desirable. (Von Alfthan.)

Digitized by Microsoft ®

In considering the possible origin of the pentose found in the urine, the wide distribution of the five carbon carbohydrates in the vegetable kingdom, as shown by Tollens and others, must be recalled. In the form of pentosans they may enter into the diet. Such precursors of the pentoses occur in certain fruits, like cherries and plums for example. In animal tissues precursors of the pentoses are also found, notably in the pancreas, from which the carbohydrate may be obtained, combined as a glyconucleoproteid. Neuberg has shown the pancreas pentose to be *l* xylose. When fed as such, the pentoses are apparently not well assimilated. Regarding their occurrence in the urine, it seems probable from the meagre data at present available that we must look to metabolic processes for an explanation. For there is no evidence that the diet in the cases on record was particularly rich in pentoses, and in one instance at least pentoses were excreted for a long period on an ordinary diet. Furthermore, the urine pentose is the optically inactive racemic arabinose, and is probably a synthetic product. The pentosuria seems comparable to those perversions of metabolism which are seen in severer forms of diabetes in which the sugar excreted is independent of the diet. In accord with this are the observations of Külz and Vogel on diabetic patients and on dogs suffering from experimental diabetes. They were able to detect pentoses in company with the dextrose present in the urine in several cases. Regarding the immediate precursor of the urine pentose in the body nothing definite is known at present.

PENZANCE AND THE SCILLY ISLANDS.—These two localities on the extreme southwestern coast of England, although possessing no great value as health resorts, are taken as representatives of the mild winter marine climate of the south of England. "Penzance appears to be warmer in the winter than any other place on the mainland of England from which we have records" (Dickinson, "Climate and Baths of Great Britain"), and the temperature of the Scilly Islands for the same season is still higher. Mildness and equability of temperature is about all that can be said in favor of such resorts as the above, as well as of others in the same county of Cornwall and in the adjoining one of Devonshire, the most noteworthy of which is Torquay. Such a climate has been resorted to by consumptives and by patients having other inflammatory respiratory affections, notably by those patients with bronchitis who require a moist air.

As will be observed from the climatic chart of Penzance, the temperature range throughout the year is comparatively small. It is neither hot in summer nor cold in winter. Frost and snow are rare. The mean temperature for the three winter months is 43° F., while the mean of the coldest is 40° F. The relative humidity for Penzance is not obtainable, but it probably does not differ much from that at Falmouth, twenty-five miles to the East, which is eighty two per cent. At the same place (Falmouth) the amount of sunshine is said to be greater than at any other place in England except Jersey, and it is therefore a fair inference that Penzance is also similarly favored, although it is said to have more mist than Falmouth. Everywhere in England there is rain enough, and Penzance, it is seen, has its share, the annual rainfall being 42.59 inches. The winds from the north and south are equally common, while those from the west are more prevalent than those from the east. Penzance has a southeastern exposure, and is sheltered from the prevalent west wind by the high country about the Land's End, and "very completely from the north by elevations of from five hundred to seven hundred feet within four miles. It is exposed, however, to the east, although some protection can be obtained by a choice of residence" (Dickinson, *loc. cit.*). With so many unfavorable climatic features—the large amount of rain, the high humidity; the wind and the relatively small number of sunny days, although large for England—such resorts as Penzance cannot compare with many other mild-winter marine ones except as regards equability, such, for example, as those on the Mediterranean coast, or the Pacific coast of Southern California, on the Gulf and Atlantic coasts of Florida, and many insular resorts. For the inhabitant of England, however, who desires for any reason a mild and equable winter climate, it offers an easily accessible retreat.

The situation of Penzance is very picturesque, as indeed are so many of these seaside towns in Cornwall and Devonshire. There are also numerous attractive excursions in the neighborhood and in the adjacent district of Land's End.

The vegetation of Penzance and its neighborhood is very luxuriant and rich and it seems quite extraordinary that in the latitude of 50°, that of Southern Labrador, one should find exotics flourishing in the open air, even in winter; geraniums and fuchsias attaining the dimensions of large shrubs; aloes flourishing, and hollyhocks, mignonettes, magnolias, and roses blooming, sometimes even in January. Potatoes are cultivated extensively, and sent to London and elsewhere during the winter months. A marked difference is noted between the north and south coasts, although only ten miles apart, not only in the vegetation, but also in the character of the climatic effects. On the north coast the vegetation is far less luxuriant and the climate is more bracing and exciting.

The *Scilly Islands*, although but little resorted to by invalids, represent an interesting phase of climate and present many attractions from their picturesque situation, as well as from the fact that the Bishop lighthouse, which marks the group, is the first evidence of land which greets the Transatlantic voyager as he enters the English Channel. The group, consisting of forty islands, some only tiny specks, lies about forty miles southwest of Penzance, from which it is reached in four hours. But five islands are inhabited, and but one, St. Mary's, possesses any satisfactory accommodations. This island, which is the largest of the group, contains sixteen hundred acres, and no part of it is a mile from the sea. The scenery is of a peculiar and weird grandeur; great masses of granite cliffs standing out against the sea and storms. In this country the Isles of Shoals, off the New Hampshire coast, would appear to bear a close resem-

Digitized by Microsoft®

blance to the Scillies both in situation, in the open Atlantic, and in their granitic formation and bold rugged scenery. "The air here (Scilly) is as marine as on the deck of an Atlantic steamer. Every sight and sound tells of the sea, the influence of which is here paramount in every shape" (Dickinson, "The Climate of Cornwall," in "Climates and Baths of Great Britain"). The exposed portion of the island of St. Mary's is treeless and bare; but in the valleys, and wherever artificial protection is afforded, the vegetation is luxuriant and almost tropical. Myrtles, fuchsias, geraniums, and aloes grow in great profusion, and palms and bamboo are abundant. "In the gardens of Tresco, unprotected except by the configuration of the ground, a mass of tropical vegetation presents itself which I suppose has no equal in Europe" (Dickinson, *loc. cit.*). The cultivation of the narcissus for Covent Garden is the chief industry of these islands. The climate is relaxing and soothing, a type of a mild, moist, marine one, with great equability. From the chart the mean yearly temperature is seen to be 52.4°, the highest in England. The mean for the three months, January, February, and March is 45.3°. The relative humidity is high, and the rainfall large. The islands are fully exposed to the east and west winds. The former are especially felt in spring. Whatever value such a climate has must consist in its warmth, equability, and humidity, together with the marine influence. About the only conditions which appear to be favorably influenced by such a climatic combination are inflammatory affections of the respiratory organs other than phthisis, especially bronchitis. Chronic renal disease may also do well in such a climate, although the humidity is not a particularly favorable factor. A very charming description of the scenery of the Scilly Islands will be found in Sir Walter Besant's "Amorel of Lyonnesse."

Several other resorts in Cornwall and Devonshire, possessing somewhat similar climatic features, may be mentioned in this connection. On the south coast are Falmouth, Marazion, Torquay, Sidmouth, and other small resorts. On the north coast are St. Ives, Newquay, Tintagel, and Boscastle in Cornwall, and Ilfracombe, Lynmouth, and Lynton in Devonshire. The resorts on the north coast are frequented only in the spring, summer, and autumn.

Edward O. Otis.

PEPPER, or **BLACK PEPPER.**—*Piper*, U. S. P.; *Piper Nigrum*, Br. P. The dried, nearly ripe fruit of *Piper nigrum* L. (fam. *Piperaceæ*).

The pepper plant is a native of India, but commercial pepper is wholly the product of cultivated plants, and comes chiefly from the East Indies, that of Penang being preferred. The plant is a woody climber, and is trained chiefly to the betel tree. The fruits are produced in aments, somewhat resembling strings of currants. Upon ripening they turn first red, then yellow. After the latter change their properties are largely lost. They are therefore gathered and dried when they begin to change color.

DESCRIPTION.—About 4 mm. (⅙ in.) in diameter, nearly globular, blackish, very strongly reticulate-wrinkled, bearing a low style base at the summit and consisting of a thin fleshy pericarp and a crustaceous, whitish putamen containing a more or less undeveloped seed; odor characteristic, strong; taste strongly aromatic and pungent.

A transverse section of pepper shows a layer of large resin cells near the surface, and beneath this a soft parenchyma (shrivelled in the dry state) containing starch and oil drops. The inner portion of the pericarp contains large oil cells and the seed shows brownish masses of amorphous piperin.

Piper Album, or *White Pepper*, is pepper with most or all of the fleshy portion removed, either before drying or by subsequent grinding. One variety consists of the very young fruit dried entire. Its pungency varies accordingly. If nearly ripe when gathered, it is less pungent than it is when the innermost layers of the sarcocarp have been rubbed or ground away, since these are rich in the active constituent.

COMPOSITION.—The pungency of pepper is due to the presence of ten or twelve per cent. of soft, very sharp-tasting *resin*, which is contained, as indicated above, mostly in the cells just beneath the surface. An *essential oil* of clear white color, having the full fragrance of the spice without its biting taste, exists to the extent of one or more per cent. The third and most peculiar ingredient is the neutral, crystalline, tasteless, and inodorous substance *piperin*, which exists to the extent of from two to eight per cent. It was discovered by Oerstedt in 1819. Piperin is scarcely soluble in water, but dissolves moderately well in chloroform, ether, and alcohol; at 212° F. it melts to a yellow, oily liquid. Besides these, starch, mucilage, and albuminous matters are found, as in other vegetable tissues.

ACTION AND USE.—Applied to the skin, pepper is rubefacient, and finally painfully irritant. It is occasionally sprinkled over the surface of other applications for this effect. In water it is a popular but painful gargle for "sore throat." Taken internally, it is in small doses a stimulant, in large ones an irritant to the stomach—that is, it acts like most other spices. It has been given as a specific in the treatment of hemorrhoids, but is out of use for this purpose. As an antiperiodic it is also obsolete, although piperin is occasionally mentioned in this connection. Whole peppers were formerly swallowed for the cure of some cases of dyspepsia. Dangerous symptoms—"rigors, convulsions, and delirium"—have been said to follow the immoderate use of pepper (Phillips). Although a typical spice, pepper is much less employed in medicine than ginger, cardamon, and cinnamon.

ADMINISTRATION.—For dyspeptics or others needing spices, there is no better way than to eat it on the food, or if a larger quantity is indicated than is agreeable to the taste, 0.5 gm. (gr. vij.) or less may be given in pills or in a bolus, with honey, two or three times a day; or four or five drops of the *oleoresin* (*Oleoresina Piperis*, U. S. P., strength about $\frac{8}{1}$) may be taken if a more compact and stronger dose is needed. Dose of piperin, 0.5 gm. or less.

ALLIED PLANTS.—The genus is a very large one, of six hundred species, of exclusively tropical plants, mostly shrubs, and frequently, like the present one, climbers. Many of them have pungent fruits. *P. officinarum* Cas., D. C., and *P. longum* Linn., are the sources of "long pepper," which comes in compact spikes one or two inches (2–5 cm.) long, and about a sixth (0.5 cm.) in diameter. Its constituents are identical with those of the above, but its flavor and strength are inferior. Long pepper is never sold at retail in this country, yet it is a common article in wholesale houses; it is probably used as an adulterant of black pepper. *P. betle* Linn. is an East Indian vine whose leaves are chewed with areca nuts as a masticatory (or a habit) by many aboriginal tribes of the great Polynesian Islands (see also *Cubeb*, *Matico*, and *Kava*).

PEPPERMINT.—*Mentha Piperita.*—"The dried leaves and tops of *Mentha Piperita* L. (fam. *Labiatæ*)," U. S. P.

Peppermint is a slender, nearly smooth, perennial herb, native of Europe, widely naturalized in temperate regions and cultivated upon a great scale for the herbage, for culinary uses, for flavoring and perfuming, for medicinal employment, and for the distillation of its oil and the preparation of menthol. It spreads by runners, producing frequently dense beds of slender stems about a yard long, ascending from a prostrate rooting base, quadrangular, frequently purplish, and bearing leaves and flowers described below. The stems and leaves are very sparingly and obscurely hairy, the hairs short and stout, usually containing menthol crystals in one or more cells; leaves opposite; exstipulate, petioled, the petioles winged toward the summit, the blades usually less than 5 cm. (2 in.) long and about half as broad, ovate, with the rounded base very abruptly produced into the petiole, acute, sharply serrate, thin, wrinkled, of a bright and usually light green; flower spikes oblong or oval, 1–2 cm. ($\frac{2}{5}$–$\frac{4}{5}$ in.) broad, with rounded summit, dense, or somewhat interrupted at the base; flowers about 6 mm. ($\frac{1}{4}$ in.) long, the calyx tubular, ten-nerved, scarcely two-lipped, five-toothed; corolla light purple, nearly equally four-lobed, or one lobe (consisting of two united) a little larger; stamens four, short, equal; fruit of four ovoid, smooth nutlets; odor strong, but not heavy, characteristic; taste characteristic, pungent, and cooling.

The leaves bear numerous globular oil glands and slender, several-celled hairs which often contain menthol crystals.

The drug contains, with a little tannin, about one per cent. of a volatile oil, which is the active constituent, is official under the title *Oleum Menthæ Piperitæ*, and is described as follows in the Pharmacopœia:

A colorless, yellowish, or greenish-yellow liquid, becoming darker and thicker by age and exposure to the air, having the characteristic, strong odor of peppermint, and a strongly aromatic, pungent taste, followed by a sensation of cold when air is drawn into the mouth.

Specific gravity, 0.900–0.920 at 15° C. (59° F.).

The oil does not fulminate with iodine.

It forms a clear solution with an equal volume of alcohol, becoming turbid when somewhat further diluted, and is soluble, in all proportions, in carbon disulphide, and in glacial acetic acid.

The alcoholic solution of the oil is neutral to litmus paper.

If five drops of the oil be added to 1 c.c. of glacial acetic acid, and the mixture gently warmed, the liquid will assume a blue color, with a red fluorescence.

If 2 c.c. of the oil be mixed with 1 c.c. of glacial acetic acid, and one drop of nitric acid added, the liquid will soon acquire a green, greenish-blue, blue, or violet tint with a copper-red fluorescence.

If 1 c.c. of the oil be dissolved in 5 c.c. of alcohol, 0.5 gm. of sugar and 1 c.c. of hydrochloric acid added, and the mixture gently heated, a deep blue or violet color will gradually be produced.

If to 5 c.c. of nitric acid one drop of the oil be added, and the mixture gently agitated, and allowed to stand for about three hours, it should have a yellowish, but not a bright red, color (absence of *oil of camphor* and of *oil of sassafras*).

If a portion of the oil, contained in a test tube, be placed in a freezing mixture of snow (or pounded ice) and salt for fifteen minutes, it should become cloudy and thick, and after the addition of a few crystals of menthol, being still exposed to cold, it should soon form a crystalline mass (distinction from *dementholized oil*).

When heated on a water-bath, in a flask provided with a well-cooled condenser, the oil should not yield a distillate having the characters of *alcohol*.

This oil contains as its active portion the peculiar substance *menthol*, considered separately under that title. A good article has been found to contain about sixty per cent. of total menthol, about one-fourth of it occurring as ester, the remainder free. However, the percentage and composition of the oil, as produced in different countries, and even in different parts of the same country, varies widely, not only as to the percentages, but even as to the nature, of the compounds.

ACTION AND USE.—Notwithstanding that menthol is the active constituent of peppermint and its oil, yet the action and uses of the latter and of that constituent require separate consideration.

Peppermint and its oil are, from their taste and agreeable action, the most generally liked of all the mints, if

FIG. 3793.—Peppermint Plant. About one-half natural size. (Baillon.)

not of all carminatives. This oil is warming and stimulating to the stomach, very seldom irritating. It is a favorite household remedy for nausea, flatulence, and colic; applied to the skin and evaporation prevented, it is a mild stimulant, useful in neuralgia and rheumatism; applied to the forehead and temples it produces a grateful, cooling feeling, with a little tingling that occasionally relieves slight headaches; this property is mostly due to the menthol it contains. The most common employment of peppermint oil by physicians, however, is as a flavor, vehicle, or adjuvant of other medicines, especially of cathartics, whose griping it undoubtedly diminishes. Like most mints, peppermint is frequently used in hot infusion in colds, etc. It is also a favorite flavor for candies.

The powdered drug is sometimes given in doses of 1–2 gm. (gr. xv.–xxx.). There is, properly speaking, no

Digitized by Microsoft®

official preparation of it, though the official spirit contains one per cent. It is often given in the form of the infusion. The common form of administration is that of the oil (dose 1–5 m.), or of the following preparations of it: The Spirit or Essence (*Spiritus Menthæ Piperitæ*) contains ten per cent. of the oil, and there is three and a half per cent. of it in the popular mixture of rhubarb and soda. The dose of the spirit is 0.3–1 c.c. (♏ v.–xv.). Peppermint water (*Aqua Menthæ Piperitæ*) contains 0.2 per cent. of the oil and is given in doses of 15–60 c.c. (fl ℥ ss.–ij.). The official troches each contain 0.01 c.c. (about ♏ 1/6) of the oil.
Henry H. Rusby.

PEPSIN.—*Pepsinum, U. S. P.* "A proteolytic ferment or enzyme obtained from the glandular layer of fresh stomachs from healthy pigs and capable of digesting not less than three thousand times its own weight of freshly coagulated and disintegrated egg albumen when tested by the process given below."

Our present knowledge and conception of pepsin have been arrived at by the inevitable, slow, intermittent progress in science, marked by brilliant epochs and retarded and clouded by faulty and incomplete observations and erroneous theories. The investigation of ferments and ferment action has necessarily involved the whole field of problem and inquiry in biology. The history of pepsin, therefore, is found in the voluminous recorded labors of a host of workers. In briefest possible mention it begins perhaps with the first perception by Borelli three centuries ago (1608–1679), of the existence of secreting glands in the stomach and of the value of gastric juice, then the studies of the gastric juice of regurgitating birds, which established the independence of digestion of mechanical power (an early theory) and of chemical change produced on food (Réaumur, 1752). In 1772 Hunter's observations established the fact of the post-mortem digestion of the stomach by its own juices. It was in 1783 that the first demonstration *in vitro* with pure animal gastric juice obtained by ingenious devices from living animals (Spallanzani) was made. At about this time also were made the first recorded clinical researches in regard to gastric juice as a surgical solvent and as an internal remedy—researches which were inspired by Spallanzani and made by his colleagues, Jurine, Carminati, Senebier, and others. Many interesting and singularly clear and detailed observations are recorded in relation to the gastric juice of beasts and birds, its properties, behavior with various foods, etc., and its action when used as a topical application; and it was observed to have the power "to remove all disagreeable smell from fetid ulcers, to give them a clean appearance, to change the quantity and quality of suppurative matter, and obtain a speedy cicatrization." It was employed thus successfully for tumors, ulcers, gangrene, old sores, abscesses, etc., and internally with benefit in "weakness of the stomach and all these affections produced by faults in this fluid and particularly by its diminution in point of quantity and energy for the purpose of digestion." Very remarkable effects were particularly noted in a "case of gradual emaciation with continual nausea and vomiting."

In 1824 Prout, Tiedemann and Gmelin discovered hydrochloric acid in the gastric juice. In 1834 Beaumont made his classical observations, and drew the faulty conclusion that gastric juice was the sole digestive fluid and formed gastrites with food. In the same year an impetus was given to the study of gastric juice by Eberle's suggestion and use of infusions from the stomach glands. This led to the brilliant and careful researches of Schwann (1836) upon the active principle of the gastric juice—its behavior, theory of action, method of separation, etc. He gave to this principle the name "pepsin." In 1842 Lehmann published his theories as to the peptic nature and cellular origin of pepsin, and its action in the transformation of albuminoids into absorbable substances. Wasmann also put forward at the same time the theory that pepsin is the granular matter of the cells or the substance from which it is formed. In 185[illegible] Corvisart and Beale suggested the use of pepsin itself in medicine. In 1864 Hoppe-Seyler classified the various forms of proteids according to their solubility and precipitability by various neutral alkali salts, this classification, by reason of the similarity of pepsin in these respects to other proteids, leading to the present methods by which pepsin is produced by these reagents. Scheffer's suggestion and development of sodium chloride as a pepsin precipitant were inspired by his observations of this reaction of proteins.

Pepsin is now produced from the stomach with the same facility as quinine is made from bark, for, in view of its peculiar origin and nature and susceptibilities on the one hand, it is singularly capable of extraction and utilization in a practical way as an article of commerce. During the last half of the twentieth century, with its accurate, scientific methods of research, and especially during the past thirty years in which pepsin has been increasingly utilized, it, as well as the gastric extract and gastric juice itself, has been the subject of elaborate investigation, and we have now exhaustive data concerning pepsin from a pharmaceutical standpoint.

Great therapeutic interest attaches to the very recent methods of Pawlow for obtaining pure gastric juice from the living animal (dog), to his profound studies thereof, and to the free administration, by Fremont and his colleagues, of this juice in cases of disease of the stomach. They gave it in quantities that sometimes amounted to as much as 500 c.c. per day, and the results which they obtained were at times brilliant. They also used gastric juice as a topical application, noting its solvent, healing and sedative action; this latter quality was also attributed to it when administered internally. Fremont considers this animal gastric juice to be especially adapted to all cases of hyposecretion of the stomach, whether resulting from glandular ulceration, from acute or chronic infection, or from disease of the liver, heart, lungs, and nerve centres. Under its influence dyspeptic phenomena have disappeared more or less promptly, and a remarkable gain in weight and strength has taken place. Patients who have suffered acutely from dyspepsia, and who have become extremely emaciated, have also obtained complete and permanent relief under the use of the remedy.

Pawlow especially calls attention to the fact that gastric juice is now pharmaceutically available as a clinical agent. Others have argued that with a corresponding free use of pepsin and acid similar results may be obtained.

Inasmuch as the healthy stomach of recently killed animals affords a resource for gastric juice in a very concentrated form, rendered perfectly pure by simple means of clarification and filtration, sterile, and free from objectionable odor and taste, there is good ground for the presumption that the fullest therapeutic possibilities of the gastric juice may be realized without the elaborate methods resorted to in obtaining the secretion from the living animal. These observations, which represent the last word of modern achievement in this particular field, give great interest and significance to the early discoveries of Spallanzani and his colleagues, and to the fact that they attracted no further attention and were thus barren of result.

Pepsin is found in the gastric cells of all animals, but the gastric juice of the carnivora is much more powerful in proteolytic action. Pepsin itself, however, has no particular degree of energy or peculiarity of action from any particular source; its "strength" is strictly in ratio to its degree of isolation from the associated non-peptic material of the gastric cell or juice, and from the agents used in its separation therefrom. The pepsin obtained from one creature, therefore, is not stronger than that obtained from another. In the gastric juice of the dog, it is to be noted that the pepsin is associated with a peculiarly high percentage of HCl.

Pepsin is normally associated also with another distinct ferment—the milk-curdling enzyme—which is very energetic in the suckling animal. The ultimate composition of pepsin, the method of its elaboration from the cell, the

Digitized by Microsoft®

mode of its action, and its relation to the other constituents of the gastric juice, proteid, hydrochloric acid, and inorganic salts, have been the subject of laborious research and of speculation, and are receiving increased attention in the progress and practical interest of biological study.

www.libtool.com.cn

Pepsin is a soluble, unorganized ferment, an enzyme, having the property of converting native proteids into soluble, highly diffusible, non-coagulable proteids. Its action is exerted only in an acid medium, most freely in the presence of 0.2 per cent. absolute acid, slight variations from this not sensibly influencing its action; if the proportion of acid, however, be materially increased—say, to 0.3 per cent.—the enzyme is much enfeebled.

Pepsin exerts freely its characteristic action in the presence of organic acids in general—lactic, tartaric, citric, etc. Notwithstanding the fact that the ferment is so closely and characteristically related to the HCl, the mineral acids in general are not favorable to its action, phosphoric being the only one which approximates at all to the HCl in its affinity to the enzyme; nitric and nitro-muriatic acids are distinctly unfavorable.

Pepsin exhibits considerable activity at a temperature much below the physiological, converting albumen slowly even at ordinary room temperature (60°–70° F.), and its action is completely arrested only at a temperature of about 40° F., and greatly accelerated at 120°–130° F.

Pepsin does not exist preformed in the gastric cell, but is developed from the mother substance, pepsinogen, and under the influence of the acid simultaneously secreted in the gastric juice. This view has for a long time been entertained, and very recently pepsinogen has by Glaessner been prepared free from pepsin and found to be devoid of proteolytic power. This pepsinogen was found promptly to develop into pepsin under the influence of both mineral and organic acids; while oxygen and neutral salts were without effect, and alcohol, ether, and chloroform proved destructive.

"If it be desired to use a diluent for reducing pepsin of a higher digestive power to that required by the Pharmacopœia, sugar of milk should be employed for this purpose.

"A fine, white, or yellowish-white, amorphous powder, or thin, pale yellow or yellowish, transparent or translucent grains or scales, free from any offensive odor, and having a mildly acidulous or slightly alkaline taste, usually followed by a suggestion of bitterness. It slowly attracts moisture when exposed to the air.

"Soluble, or for the most part soluble, in about one hundred parts of water, with more or less opalescence; more soluble in water acidulated with hydrochloric acid; insoluble in alcohol, ether, or chloroform.

"On heating a solution of pepsin in acidulated water to 100° C. (212° F.) it becomes milky, or yields a light, flocculent precipitate, and loses all proteolytic power. In a dry state it can bear this temperature without injury.

"Pepsin usually has a slightly acid reaction. It may be neutral, but should never be alkaline."

Pepsinum Saccharatum, U. S. P.—"Pepsin triturated with milk sugar in such proportion that the resultant saccharated product shall digest three hundred times its own weight of coagulated egg albumen under the United States Pharmacopœia method of valuation for pepsin."

Pepsin of the British Pharmacopœia is of 1–2,500 strength. The United States Pharmacopœia method of valuation (that of the British Pharmacopœia is similar) in brief is this: 0.003 gm. of pepsin is required completely to digest 10 gm. of hard boiled comminuted egg albumen in 100 c.c. of a 0.2 per cent. solution of absolute HCl in distilled water, the mixture maintained at a temperature of 100°–104° F. for six hours, and the flask shaken gently every fifteen minutes. At most only a few thin, insoluble flakes should be left. Pepsin fluids must be assayed according to the United States Pharmacopœia method, the conditions prescribed being strictly adhered to, but use being made of a corresponding proportion of the fluid to represent the amount of ferment necessary to digest the 10 gm. of albumen.

Pepsin of the United States Pharmacopœia and British Pharmacopœia requirements is obtained by precipitation, with neutral salts, of the alkalies from purified infusions of the fresh, healthy stomach glands, and the precipitate purified by mechanical means—by reprecipitation and dialysis. By this means mucus is wholly, and non-peptic proteids and peptones well, separated. The *rationale* of the process will appear in the consideration of the nature and behavior of the enzyme.

No official method is given in the United States Pharmacopœia or in the British Pharmacopœia; their standards make obsolete the cruder, earlier forms. It is to be regretted that European standards are so greatly inferior, for a uniform, definite, adequate pharmacopœial standard for pepsin of commerce is absolutely essential. In the past pepsin has been too commonly of insignificant value—even inert; and variable and apparently conflicting results and theories are inevitable when pepsin still means in various countries a product of from 1 to 40 to 1 to 3,000 standard; moreover, there are offered in commerce, in the United States, pepsins of even *stated* digestive value below the obligatory pharmacopœial standard.

Both physiological and chemical data almost irresistibly lead to the conclusion that pepsin is a nucleo-proteid and sharply distinguished from all other forms of proteid by its proteolytic action, exhibited under conditions which are in themselves incapable of effecting these chemical changes without the intervention of the enzyme. The degree of isolation of pepsin is necessarily only to be judged by the energy of the product which is obtained by the exclusion of foreign substances capable of separation and identification by chemical processes and dialysis. The enzyme so far isolated exhibits the characteristic behavior of a nucleo-proteid. It is freely soluble in water, is non-dialyzable, readily precipitated by the neutral salts of the alkalies and by strong alcohol in excess, and is coagulated in solution at 160° F. both in neutral and in acid media; it is destroyed in solution at this temperature (160° F.) which, it is interesting to note, is the coagulating point of albumen and destructive to organized ferments; it is destroyed in alkaline solutions at any temperature; its action is strongly influenced by various reagents which do not in themselves effect any known change in the enzymic substance; and, finally, when once destroyed its vitality cannot be restored by any means whatever. A striking example of its physiological relations is found in its behavior with common salt; the presence of sodium chloride in so small a quantity as one per cent. of the digesting mass completely retards digestion *in vitro*, yet we have the fact that pepsin may be precipitated by means of common salt (in saturated solution), and kept in contact with it for a long time without impairment of its activity.

The most perfectly isolated pepsin yet produced is found to be a nitrogenous body with the chemical constitution of a proteid, and this pepsin proteid contains phosphorus and iron like other nuclein bodies. The fact, then, that the chemical composition of pepsin remains yet to be absolutely established is of little significance from a therapeutic standpoint, for it imposes, in the light of all the material and important facts known, no limitations upon the complete utilization of the enzyme.

The physiological test for pepsin is as conclusive and reliable as any chemical test by which we establish the presence or identity of any chemical substance. It is by the physiological test that we readily measure the strength of any specimen of pepsin; and it is by it, furthermore, that we have determined the influence of medicinal and food substances upon pepsin, and have gained accurate data as to the conditions which are favorable and unfavorable to its action or destructive to the life of the enzyme. These data clearly reveal that physiological considerations are as conclusive in relation to the enzymes as are chemical reactions, both in theory and in practice, in relation to the use of other agents of the materia medica.

Pepsin behaves as a true ferment whose peculiar form

Digitized by Microsoft®

of energy is capable of liberating latent energy in complex labile substances—the proteids, breaking them down into simpler, more stabile bodies. We have had the statements that pepsin actually loses its activity in this process, and that it remains unaltered. There can be no doubt, however, that pepsin undergoes no change in exerting its energy, as has been demonstrated.

www.libtool.com.cn

A pepsin having been subjected to the usual digestive test—upon acid albumin mixture—may be made repeatedly to exhibit its action upon the addition of fresh volumes of water and albumin and when the requisite percentage of acid is maintained, thus preventing saturation of the digestive fluid with the soluble products formed. In this way the writer has found pepsin to digest several hundred thousand times its own weight of albumen without exhaustion of energy. Interesting as this may be as to the marvellous power of the enzyme, it seems, however, to be without therapeutic bearing, in view of the fact that the gastric juice is normally discharged into the intestine with the completion of the stomach digestion.

Pepsin in the dry form, if non-hygroscopic, retains its vitality for years at ordinary temperature. In solution it may be readily preserved without serious impairment; alcohol and glycerin combined form the best preservatives, from both the medicinal and the pharmaceutical standpoints; for general use, about fifteen per cent. absolute alcohol and glycerin being the amount required. The anhydrous glycerin does not readily take up the enzyme; when diluted with water, to the extent of about forty per cent., it affords a useful vehicle. Elixirs, essences, and glycerites are commonly and very conveniently made with pepsin. There is no pharmacopœial method or standard for these products; they are variable, and distinctly inferior in therapeutic utility to fluids made directly from the fresh stomach.

Chemical preservatives—salicylic acid, boric acid, etc. —are obviously objectionable. Absolute alcohol precipitates pepsin, and by long contact distinctly weakens it; but the presence of alcohol up to about fifteen per cent. exerts no sensible influence upon the ferment, the enzyme being freely extracted by such hydro-alcoholic menstruum. *In vitro* alcohol, when it constitutes ten per cent. of the medium, sensibly affects the *digestive* action of pepsin; and it checks this digestive action, not by altering the ferment, but simply for the reason that alcohol is not a competent medium for the ferment in any particular. The products of enzymic action are insoluble in alcohol and are of lessened solubility in hydro-alcoholic media in direct ratio to increased percentage of alcohol. This, however, concerns digestion *in vitro* solely, for alcohol as present in any proper peptic fluid becomes in this respect a negligible quantity by dilution with gastric content and its free absorption. The inert or feeble nature of many of the vinous and alcoholic preparations has been due to the insignificant amount of pepsin actually contained in them and not simply to their alcohol content. The intimate relation of pepsin to hydrochloric acid has naturally led to the impression that this and other mineral acids may be freely admixed with the ferment; but this is a serious error. The acid of the gastric juice is bound up in a peculiar manner with the proteids, and thus the enzyme seems to be protected from the acid, whereas pepsin in solution with pure water and the normal content of absolute HCl (0.2 per cent.) rapidly deteriorates at ordinary temperature. This constitutes a striking evidence of the fact that a solution of pepsin and water and HCl is not gastric juice; it represents the proteolytic ferment, and exhibits absolutely the proteolytic action only of the gastric juice. Other mineral acids are distinctly injurious to the ferment in any fluid form. It is not possible to mix a mineral acid in medicinal quantity with pepsin in a fluid mixture of convenient volume of dosage without distinctly injuring the ferment even for extemporaneous use; while combined in a percentage much above that of the gastric juice content, such mixtures are distinctly incompatible with the normal activity of the ferment and unsuited for pharmaceutical products. For instance, if we take five minims as a moderate dose of official dilute HCl, this in two fluidrachms would yield an acidity of 0.42 absolute HCl, which is twice the acidity of normal gastric juice and fatal to the enzyme.

Pepsin fluids should have an acid reaction; but when acids *per se* are indicated medicinally, it is the best practice to exhibit them separately by such vehicle and means as are most desirable in conjunction with the pepsin preparation. If the preparation has an alkaline reaction, this is conclusive evidence of its inertness.

Pepsin is incompatible with bismuth ammonio-citrate in solution. If the mixture has a neutral or an alkaline reaction, the ferment cannot retain its activity; on the other hand, if it is acid, it is impossible to maintain the bismuth in solution. Owing to the unstable and insoluble nature of the salt, its solution is usually effected by the addition of ammonia, which is obviously incompatible with pepsin. The therapeutic value of elixirs of pepsin, bismuth, and strychnine necessarily cannot be attributed in any degree to pepsin; devitalized pepsin cannot in any way add to the value of a medicinal compound.

Pepsin and pancreatin are incompatible in solution, for the reason that if the menstruum be of such acid nature as to preserve the pepsin, the pancreatic enzyme will be in time destroyed; while if it is neutral or feebly alkaline, the pepsin will be destroyed. Acid-pepsin fluids are unsuitable for the admixture of all ferments except the milk-curdling; the pepsin will be the only enzyme of all those originally combined which will retain its activity. Mixtures of the ferments in solution are readily subject to recognized tests for the presence of any one of the ferments. If a fresh and feebly acid infusion of the stomach, or solution of pepsin, be mixed with an aqueous infusion of the pancreas, each one of the ferments contained in this mixture may be immediately made to exert its peculiar action under the proper conditions; the mixture will exhibit the digestive action of pepsin, of trypsin, and of diastase. But upon keeping this mixed ferment solution at ordinary room temperature for a few weeks, it will be found upon systematic assay to have gradually and rapidly deteriorated in respect to one or another of its ferments.

The fact that a number of ferments are mixed in any fluid does not in the least interfere with the method of assay for testing or determining the presence of any one or of each separate ferment in the fluid mixture. When it is desired to combine gastric and pancreatic ferments in solution, they are best directed in extemporaneous mixture of preparations which have been obtained directly from the stomach and the pancreas gland, and thus they will maintain their individual action for such length of time as will ordinarily be required by the patient.

The therapeutic use of pepsin is prejudiced and complicated by the prevalence, in the past, of inefficient products and incompatible combinations, a condition which does not exist concerning any other agent or class of agents of the materia medica, owing to the fact that with the definite and standardized chemicals and galenical products there has been presented no such obstacle in establishing therapeutic action and scientific dosage. The increasing knowledge and application of physiological chemistry in therapeutics, and the accumulation of laboratory and clinical observations with regard to the action of animal gastric juice, have strongly confirmed its rational and obvious utility and promise, and have advanced its repute and use as a therapeutic agent.

Pepsin exhibited in adequate doses aids gastric digestion, with effects apparent in the relief of various dyspeptic symptoms and in the promotion of nutrition; it affords a rational remedy to which the physician may have recourse in cases of feeble and readily disturbed digestion. The beneficial effects of pepsin are not restricted alone to the improvement of gastric disorders; there is abundant evidence that each step in the chain of digestive action is of essential importance, and defective stomach digestion cannot but influence the entire digestive process.

Digitized by Microsoft®

The pancreatic ferments attack with great facility the soft and partially converted proteids and starches in the form in which they normally reach the intestinal tract, breaking them down into their most soluble and diffusible forms, and the development of the latent pancreas enzymes waits upon the influence of constituents of normal gastric juice. Coagulated protein food in masses is but very slightly attacked by pancreas juice in contrast with peptic action, and thus the complete conversion of food is absolutely dependent upon the interaction of both gastric and intestinal digestion. Disorders even of the intestinal tract are frequently benefited by the administration of pepsin. Pepsin in doses so small as to seem a slight factor in the physiological process, and administered either just before or immediately after eating, produces results which can be attributed only to the theory advanced that it imparts an impetus to peptic secretion and action. Pepsin is used to promote the toleration of drugs which impair the appetite and disturb digestion. For all these purposes the gastric juice, extracted directly from the fresh stomach in proper pharmaceutical form, is found most generally useful. This preparation renders available at once all the properties of the gastric juice, both its enzymes (the peptic and milk-curdling) and its acid in proteid combination—the entire organic and inorganic content in natural association. These enzymes are thus less susceptible to unfavorable influence than is the precipitated ferment.

Pepsin is given in scales, powder, tablets, and capsules, ordinarily in doses of from one to five grains; the scales are readily soluble in water—plain or with acid; the glycerite, especially the glycerin extract from the stomach, is useful, and if properly prepared is far more agreeable than the scale itself taken in solution. The essence prepared from the gastric juice is the most efficient and agreeable preparation, and its grateful qualities enhance the effect of the digestive principles contained therein. The desired dose of drug, for instance sodium salicylate or iodide of potassium, is prescribed in the proportion of, say, five grains to each teaspoonful of the essence of pepsin, and this added to two or three tablespoonfuls of warm milk gives instantly a firm curd. The milk may be previously sweetened or flavored if desired, the object being to present the drug in a small bulk for convenience; even this serves well to disguise the medicine.

When pepsin is given simply to promote digestion, it should never be administered in a disagreeable form, and when given to facilitate the exhibition and therapeutic action of disagreeable drugs, the essence is not only valuable as a vehicle, but should be given immediately after the drug if it is desired to obtain its best effect.

The essence of pepsin is much used in combination with savory, soluble, and diffusible food products, the prepared peptonized foods, and it should be mixed in about equal quantities therewith; this combination proves of peculiar value in acute forms of indigestion and intolerance of food; in seasickness, for instance, it is especially useful. Essence of pepsin is also much used in combination with pure phenol, which is thus well masked and well borne, and this mixture, which is both antiseptic and sedative to an irritable gastric mucous membrane, does not in medicinal proportion unfavorably influence the gastric enzymes.

The gastric juice essence is more especially found serviceable as a drug vehicle, and in conjunction with it maximum doses of mercurials, iodides, salicylates, etc., are peculiarly well tolerated. It is also valuable for the production of junket—a jelly-like, diffusible form of pure milk—which is also a carrier of drugs which blend with it and thus lose much of their disagreeable taste and effect. Junket affords an agreeable and wholesome variety of food, and is serviceable in convalescence where liquid foods have become distasteful and are no longer required. It is made as follows:

Junket.—Into a clean saucepan put one-half pint of fresh, cool milk, heat it lukewarm (not over 100 F.); then add one teaspoonful of essence of pepsin, and stir just enough to mix; divide quickly into small cups or glasses and let stand until firmly jellied, when the junket is ready for use, just as it is, or with sugar; it may be placed on ice and taken cold.

Whey.—After preparing the junket by the above method, let it stand until firmly jellied, then beat with a fork until it is finely divided; now strain and the whey (liquid part) is ready for use; keep in a bottle near ice.

Pepsin digestion has long been observed to effect the solution of dead tissue, pus, necrosed bone, etc. The availability of the gastric juice in an active, sterile, and stable extract of great potency, has recently led to its application as a surgical solvent in the bladder, urethra, eye, ear, nose, and throat, and in pus cases in general—sores, abscesses, carbuncles, gangrene, leg ulcers, etc. Gastric juice is thus found to possess peculiar and valuable properties as a solvent, healing, antiseptic, deodorizing, and sedative agent. It is painless in its action and incapable of attacking normal tissue, and has caused a speedy cure in cases which were so aggravated as to have resisted other treatment, thus rendering surgical interference unnecessary. In genito-urinary diseases it promises, from the most conservative estimate of the clinical trial which it has already received, to afford a remedy of great importance.

Benjamin T. Fairchild.

PEPTONURIA. See *Urine, etc.*

PERFORATING ULCER OF THE FOOT.—This is a rare affection, caused by pressure or injury where there is a degenerated nerve supply. It is found in leprosy, locomotor ataxia, lues, and alcoholic and diabetic neuritis. The most common location is where there is great pressure, as over the metatarso-phalangeal articulation of the great or little toe, or over the ball of the toes. Occasionally there are several lesions existing at the same time in one or both feet. A similar condition may also occur on the hands.

The process is very slow. It begins as a thickening of the skin resembling a corn, under which suppuration occurs; and later, when the horny plug is cast off, an ulcer is left. The destructive process extends downward until it reaches the bone, which may also become affected. The condition now is more that of a sinus than of an ulcer. The skin surrounding the opening is usually much thickened, and there may be granulations at the orifice. The diseased parts are generally painless and the neighboring parts are usually anæsthetic. Distortion of the toes, as well as trophic changes in the nails, may occur later; they are usually accompanied by an increased growth of hair, pigmentation, and hyperidrosis. The patients frequently complain of cold feet and neuralgic pains.

The prognosis is unfavorable, even if the lesions should heal, on account of the liability to recurrence, which in turn is due to permanent nerve lesions.

Perforating ulcer has to be differentiated only from a suppurating corn, which latter is painful and is accompanied by abnormal sensitiveness of the surrounding skin. In the case of a suppurating corn the results of surgical treatment are always satisfactory.

Prolonged rest will occasionally lead to healing of the lesion in the early stages, but exercise will cause the sore to recur. Packing the sinus with lint wet with a saturated solution of salicylic acid in glycerin, and the employment of mechanical devices to prevent pressure will frequently produce a temporary cure. Free opening of the sinus or stretching of the nerves which supply the part has been followed by good results in some cases. In the later stages excision of the ulcer is useless and amputation of the foot is necessary. Even then the ulcer may recur in the stump, unless the limb is removed at a point far from the lesion and above the line of anæsthesia.

Howard Morrow.

PERICARDIUM, DISEASES OF THE.—HISTORY.—Anatomical alterations in the pericardium were known long before diseases of the heart proper received careful

Digitized by Microsoft®

study. Galen was familiar with pericardial effusion in animals, and suspected it in men.

The fables about the occurrence of hairy hearts in men of remarkable strength and daring are doubtless based upon the discovery of stringy fibrin deposited upon the heart. Rondelet described pericarditis as having symptoms of fever, dyspnœa, pain under the sternum, and attacks of syncope.

www.libtool.com.cn

In the eighteenth century the authors of works upon diseases of the heart made numerous anatomical observations upon diseases of the pericardium.

Vieussens often met with adhesion of the heart to the pericardium at autopsies, and assigned certain functional disturbances which occur during life to the existence of this condition. In earlier times it was thought to be a congenital defect. Albertini appreciated the difficulties of a symptomatological recognition of pericardial effusion. Morgagni believed that on account of the difficulty of diagnosis, the day was yet remote when we should have recourse to the puncture of the pericardium as suggested by Riolan. Senac realized that it was impossible to make a diagnosis from the indefinite symptomatology, but thought that in hydropericardium he recognized an undulatory movement between the third and the fifth ribs. Corvisart thought that he could feel this. Both were in error. However, Corvisart first distinguished between inflammatory exudations and dropsical effusions, but could not lay down any fixed rules for differential diagnosis. Avenbrugger was the first to state any accurate physical signs; these were bulging of the præcordium and increase in the area of percussion dulness. Laënnec, however, doubted the possibility of diagnosing pericarditis with certainty.

The discovery of the pericardial friction rub by Collins in 1824 made certain the recognition of dry pericarditis. Since this time our knowledge of the physical signs of all varieties of pericarditis have increased remarkably, but none are so pathognomonic or of so much assistance in diagnosis as this peculiar friction rub.

ANATOMY.—Before launching upon a description of the diseases of the pericardium, it will be well to devote a few lines to its normal anatomy. It is a fibro-serous sac, somewhat conical in shape, surrounding the heart and the origin of the great vessels. Its base is directed downward, rests upon the diaphragm, and is firmly attached to its central tendon, and more loosely to its muscular structure by areolar tissue. Its narrower portion is directed upward, and surrounds the great vessels. The fibrous layer is continued for some distance along the coats of the great vessels, in the form of prolongations, which gradually become incorporated in their coats. The inferior vena cava passes through the floor of the pericardium to reach the heart. The serous membrane lines the fibrous sac and is reflected over the surface of the heart, thus constituting its parietal and visceral portions. They are continuous along the great vessels, about an inch to an inch and a half above the base of the heart.

Externally, the pericardium is in contact anteriorly and laterally with the pleuræ covering the lungs, with the exception of a triangular space, behind the lower sternum, which remains uncovered. It is attached by fibrous bands to the manubrium and ensiform cartilage. Behind it are the œsophagus, descending aorta, bifurcation of the trachea and left bronchus, and the other structures which form the root of the left lung. The phrenic nerves pass down, one on each side of the pericardium, on their way to the diaphragm.

In health the serous surfaces are kept moist by a secretion normal to serous membranes. The amount is always small, but varies from a few cubic centimetres to an ounce or two. It is common to find at autopsy several ounces of pericardial fluid. In most cases, however, this is a post-mortem transudate. As a result of the presence of this fluid the serous surfaces glide smoothly over each other during the various phases of the heart's action without producing audible or palpable signs.

The pericardium of an adult man with a healthy heart is capable of holding from fourteen to twenty-two ounces of fluid; that of a boy between six and nine years old, about six ounces when the sac is distended to the full by injecting water into it, by means of a syringe, through an opening made into the anterior part of the pericardium (Sibson).

The following are the important diseases of the pericardium:

1. Pericarditis: (*a*) dry or plastic (pericarditis sicca); (*b*) wet pericarditis, or pericarditis with effusion; (*c*) suppurative pericarditis; (*d*) chronic adhesive pericarditis.
2. Hydropericardium.
3. Hæmopericardium.
4. Pneumopericardium.
5. New growths in the pericardium.

MORBID ANATOMY.—I. *Abnormal Conditions of the Pericardium* not of clinical interest, and which do not furnish physical signs.

(*a*) *Absence of the Pericardium.*—This occurs in ectopia cordis. It is usually only partial, there being a slit in the pericardium through which the heart protrudes. Very rarely the heart and the left lung lie in the same serous sac. The heart is covered by the visceral layer of the pericardium; at the origin of the great vessels there are usually found rudimentary portions of the parietal layer in the form of fringe-like reduplications.

(*b*) *Diverticula.*—Hernia-like pouches are rarely found. They are due to the pressure outward of fluid. This occurs in chronic conditions in which the fibrous layer has become weakened, and either yields or separates and allows the serous layer to be pushed through by the exudate.

Such pouches are usually small, but they have been known to contain as much as from three to four ounces. The opening into the pericardium may be wide or narrow. These conditions are not recognized during life.

(*c*) *Milk Spots*, also called soldier's spots and tendinous spots.

By these terms are meant those circumscribed, whitish, slightly thickened spots which are so frequently found upon the pericardium. Some authorities look upon them as evidences of an old pericarditis, and as such they have influenced the statistics of pericarditis.

Most writers now believe them to be areas of chronic hyperplasia of connective tissue. Friedreich believed that they resulted from a continual mechanical irritation of the surface of the heart, and were found most frequently on those parts of the heart which were continually brought into contact with the more resisting portion of the chest wall. These spots are nearly always found on the visceral pericardium and on the anterior surface of the right ventricle along the coronary arteries. They are much more common in advanced age than in youth, and in men than in women. They are of no clinical importance and cannot be recognized during life.

(*d*) *Thinned Pericardium.*—The wall of the sac may be thinned as a result of distention from an enlarged heart or from the pressure of fluid.

(*e*) *Foreign Bodies.*—These have been found lying free in the sac, and have been regarded as polypi detached from the inner surface of the pericardium, or as results of fibrous or calcareous deposits about foreign substances.

(*f*) *Calcareous Deposits.*—In cases of prolonged pericarditis there may be more or less calcareous deposit in the pericardium.

II. *Acute Plastic Pericarditis.*—In this variety both layers of the pericardium are covered with a yellowish, sticky layer of inflammatory lymph of varying thickness. As a result of the constant friction of these two surfaces during the heart's action, this material is thrown into ridges, and at times presents a ragged appearance (so-called bread and butter adhesions of Laënnec), resembling the appearance of two slices of bread and butter, which have been stuck together and then drawn apart. It has also been likened to tripe. The involvement of the pericardium may be universal or only partial. If only partial it is more common at the base of the heart than elsewhere.

The various changes occurring in pericarditis are some-

Digitized by Microsoft®

times described as following a definite order of succession: (1) Increased vascularity; (2) fibrinous exudation; (3) fluid effusion; (4) absorption; (5) adhesion. It is very seldom, however, that these stages can be recognized, as there is likely to be a mixture of two or more—as, for instance, the association of a plastic exudate with fluid effusion, or even the combination of adhesions and fluid.

www.libtool.com.cn

It is possible for absorption to take place, followed by resolution. Very often, however, especially in the pericarditis sicca, the plastic material becomes organized into firm adhesions which pass from parietal to visceral pericardium. In the early stages of an inflammation the adhesions may be very fine and delicate and easily broken with the fingers. Later on, however, they become exceedingly strong, and the pericardium cannot be separated from the heart without tearing the heart substance.

The presence of adhesions may be partial or universal. If universal, there will be entire obliteration of the pericardial cavity. Adhesions may also exist between the pericardium and pleura, or between the pericardium and chest wall, as a result of mediastino-pericarditis (pericarditis externa).

Effusion.—As previously stated, there is present normally in the pericardial sac enough fluid (a few cubic centimetres) to keep the surfaces well lubricated. In diseased conditions this fluid may be enormously increased in quantity and greatly altered in character. Roberts says that the average quantity of fluid in pericarditis is from eight to twelve ounces, but it may range from an ounce or two to two or three pints or more. Balfour says several pints; Broadbent says that any large amount is exceptional.

The statements of different authorities vary much as regards the size of exudates. Sibson states that the effusion is likely to be large in rheumatic pericarditis, while John Broadbent says that it is the exception to find a large effusion in this condition. The truth is, there is no definite rule. Roberts states that the quantity is likely to be small in Bright's disease. However, Dr. Herman Allyn (*American Medicine*, October 18th, 1902) reports a case of pericarditis which occurred as a terminal infection in Bright's disease, and in which he removed by paracentesis, on the day previous to death, forty-four ounces of bloody serum. At autopsy the pericardial sac was found to contain about two hundred and fifty ounces of bloody serous exudate.

It is generally stated that the exudate is large in cases secondary to scurvy. In the Russian epidemic referred to later, the quantity amounted to from four to five pints.

Character of Fluid.—This varies much, depending on the nature of the inflammation. In the typical case of pericarditis it is a clear yellow, in which shreds of fibrin and leucocytes may be present. In rheumatic pericarditis it is usually clear, but may be blood-tinged and may occasionally become purulent. In new growths and tuberculosis the fluid is likely to be blood-tinged, but not necessarily so. In scurvy the exudate is usually bloody; in fact, it may be almost clear blood.

The specific gravity of a pericardial exudate, like that of other serous cavities, is usually above 1.015, though there are rare exceptions to this rule.

Absorption.—The natural tendency in most cases of serous or sero-fibrous effusion is toward absorption sooner or later. This is especially true in rheumatic cases. In fact, after reaching the acme, in a day or so there may be a distinct diminution in amount, and in from four to six days the quantity may fall to normal. In rare cases an ordinary inflammatory exudate does not undergo absorption, but remains as a chronic collection, or may become hemorrhagic or purulent. Many authorities believe that even a fibrinous exudation may be absorbed, up to a certain amount, after undergoing a fatty change.

The fibrous patches left from pericarditis are larger, thicker, and have a more irregular distribution than the so-called milk spots, and as a rule are associated with adhesions.

A consideration of the morbid anatomy of pericarditis would not be complete without reference to the changes which are produced in the heart. Broadbent says: "The heart is usually found to be dilated to a varying degree. In the subacute or chronic cases in which the pericardium has become adherent, the dilatation is often extreme, and the heart muscle soft and flabby, showing evidence, on microscopical examination, of well-marked, inflammatory changes. Dr. Poynton has shown by a series of sections of the heart wall, in cases of rheumatic pericarditis, that the cardiac muscle, as well as the pericardium, is almost invariably attacked by the inflammatory process, and that there are foci of small round-cell infiltration between the muscle fibres throughout the thickness of the heart wall. The myocarditis which accompanies pericarditis is therefore not simply an extension of the inflammation from the pericardium to the myocardium. There is granular and fatty degeneration of the cardiac muscle due to the toxic effects of the rheumatic poison, as well as actual destruction of muscle fibres by inflammatory exudation."

Eichhorst applies the name *Zuckergussherz—frosted heart*—to cases in which the epicardium is thickened by chronic pericarditis, so that it gives the organ the appearance of being covered by a sugar icing, as in the case of a frosted cake.

Calcareous Pericarditis has been referred to above. In chronic cases the heart may be completely invested by a calcareous coat which may in places be 1–1.5 cm. thick (Osler).

ETIOLOGY.—Pericarditis is almost always a secondary infection. Its etiology resembles very closely that of endocarditis. The more careful our examinations and the greater our bacteriological knowledge, the fewer will be the cases of idiopathic pericarditis discovered.

Rheumatism is by far the most common cause of pericarditis. Roberts, in "Allbutt's System," states that pericardial inflammation is to be looked upon not as a mere complication of rheumatism, but as an essential part of the disease.

Sibson noted that in the large majority of cases of rheumatic pericarditis endocarditis was also present. Broadbent states that pericarditis must not be regarded as a separate entity, but as part of a general inflammation of the heart, the myocardium being almost invariably and the endocardium frequently affected.

There is no definite relation, when a large number of cases is considered, between the severity of the joint affection and the severity of the pericarditis. It may develop at any time during the attack, even preceding the joint affection, or late in the disease.

Pneumonia, pleurisy, the various acute infectious diseases, especially scarlet fever—during the stage of desquamation or that of nephritis,—chorea, pyæmia, purpura, scurvy, are all causes of pericarditis. Especially interesting is its association with Bright's disease. Taylor found that pericarditis occurred in about ten per cent. of his cases of Bright's disease. Sibson, in an analysis of 1,691 cases of Bright's disease collected from various sources, found that pericarditis existed in 8.17 per cent. Tuberculosis, carcinoma, extension from contiguous tissues, traumatism, are also causes of pericarditis.

Aneurism of the aorta causes 2.6 per cent. of all cases, a very high figure when one recalls the comparative infrequency of aneurism (Preble).

Scurvy is frequently accompanied by hemorrhagic pericarditis. Seidlitz and Kyber report an epidemic occurring in Russia in 1840, in which 30 out of 60 fatal cases showed hemorrhagic pericarditis. The fluid was dark, and amounted to four or five pints.

Sears, in a study of 100 cases at the Boston City Hospital, assigns rheumatism as a cause in 54 cases, pneumonia or infection with the pneumococcus in 18; in 7 chronic nephritis, and in 5 pleurisy was the primary disease.

It is now generally accepted that the pericarditis of Bright's disease is usually an infection, often a terminal infection. (Banti believes in the uræmic theory.) Chronic disease lessens the resisting power of the tissues and invasion by micro-organisms becomes easier.

Digitized by Microsoft®

Bacteriology.—In acute pericarditis Flexner, in a limited number of cases, found bacteria present in the following order of frequency: M. lanceolatus, 11; streptococcus, 4; staphylococcus, 1; B. pyocyaneus, 1; B. influenzæ, 1; M. lanceolatus and B. coli communis, streptococcus, staphylococcus aureus and B. coli communis, 1; staphylococcus and B. coli communis, 2; unidentified, 1.

www.libtool.com.cn

Infection Atrium.—Pneumonia, 8; bronchitis, 2; erysipelas, 1; leg ulcer, 1; tonsils, 1; peritoneum, 1; cancer of stomach, 1; sloughing myoma, 1; doubtful, 7.

Tubercle bacilli have rarely been found in cases of tuberculous pericarditis.

Symptomatology.—It was early recognized that the symptomatology of this condition was so indefinite, obscure, and inconstant, and resembled so closely that of other cardiac conditions, that a diagnosis could not be based upon it. This is only partly because the disease comes on secondarily to other conditions. The symptoms are often so indefinite that pericarditis is entirely overlooked, and may alter almost not at all the symptomatology of the primary disease. Even in the so-called idiopathic cases the subjective phenomena are very indefinite.

The following important symptoms may be mentioned:

Pain is present in many cases of pericarditis, especially early in their course, when friction sounds are heard, but it is not pathognomonic, and bears no special relation to the severity of the attack. It may be extremely severe in localized pericarditis and entirely absent in large effusions or extensive adhesions. When present it is usually in the precordial region. It varies much in its character, from a dull ache to a stabbing or tearing pain. It usually disappears with the advent of the effusion. There may be pain or tenderness in the epigastric region, especially when upward pressure is made at one or other of the costal angles. This pain usually comes on later than the precordial pain. The patient may complain of only a sensation of distress, a pressure or tightness about the heart, especially if a large effusion is present. There may be dyspnœa and palpitation.

The *pulse* has no special characteristics. The heart action in the early stages is rapid and energetic. Subsequently, as a result of the mechanical embarrassment superimposed by the presence of a large amount of fluid, and the involvement of the myocardium and its nerves, the heart action becomes weak and rapid, possibly irregular. In the early stages it may vary from 90 to 120; later, in rare cases it may reach 160. In some cases there is very little alteration from the normal, and rarely the pulse rate is below normal. Dr. Ewart says that in many cases of effusion the pulse is quick, resembling the Corrigan type. Pulsus paradoxus is said to be more marked in adherent pericardium than in any other known condition.

Friedreich's sign of collapse of the cervical veins during diastole is not considered important.

The respiratory symptoms vary much. Respirations are usually somewhat increased in frequency. If the effusion becomes large, dyspnœa and even orthopnœa may supervene. The patient usually prefers to lie on his back or on the left side. In large effusions there is often a short irritative cough, and in rare cases distressing hiccough due to involvement of the phrenic nerve.

There may be pain or difficulty in swallowing as a result of pressure of an effusion upon the œsophagus, or due to nerve irritation.

Inasmuch as pericarditis is a secondary affection, there is usually present the fever of the primary disease. The pericarditis may cause a slight extra elevation of temperature. It may be practically normal throughout, or only slightly elevated, to 100° or 101°; rarely to 103° F.

It must be remembered that the symptomatology of pericarditis may be altered by the associated primary disease. Thus, a case secondary to Bright's disease would differ from a case secondary to rheumatism.

Enormous effusion, by interfering with the action of the heart and aëration of the blood, may produce the most grave symptoms of dyspnœa, cyanosis, very rapid and weak heart action, which if not relieved may eventuate in death.

The rapid heart action, the pulsus paradoxus, and the asymmetry in the size of the pulse of the radials, the irregular type of temperature, the paralysis of the recurrent laryngeal nerve, the unequal pupils, the disturbed mental state, may all be important signs, if present (Billings).

Physical Signs.—*Acute Plastic or Dry Pericarditis.*—Fortunately the signs of this condition are very distinct; the danger is that they may disappear before the physician's attention is directed to the precordium. In some cases they are very evanescent, disappearing in a few hours; in others they persist for days.

Pericardial Friction Rub.—This is the pathognomonic sign of dry pericarditis. It is a superficial, dry, scraping or rubbing sound, distinctly dependent upon the heart movements. Frequently it is a to-and-fro friction corresponding to systole and diastole. It does not correspond exactly with the first and second sounds of the heart, but may occupy a place between them. At times it is only systolic. It is said to be first heard in most cases over the base of the heart, but may be heard first as a single systolic scratch at the apex. It is usually heard best just to the left of the sternum, between the third and fifth ribs. As the inflammation progresses it may be present over most of the precordium, even to the right of the sternum, in children. It is due to the rubbing of the inflamed pericardial surfaces over each other.

Palpation.—In well-marked cases a friction fremitus can be felt.

Clinical experience has proven that the most common cause of the disappearance of the friction sound is the advent of an effusion which separates the pericardial surfaces. Another fairly common cause is the development of adhesions, uniting the pericardial surfaces. Again, there may be absorption with resolution. The friction sound may reappear after the absorption of the fluid.

Differential Diagnosis.—A pericardial friction rub is usually so characteristic that little difficulty is experienced in its detection. It must be distinguished from organic and functional murmurs and from pleuritic friction sounds. Cardiac murmurs almost never have this superficial scraping, to-and-fro sound; they are likely to be more distinctly systolic or diastolic, and have special lines of transmission. They are not so much altered by changes in the patient's position and are more permanent.

Pleuritic friction sounds are very similar in their character, but are dependent on respiratory movements, and can be eliminated by causing the breath to be held.

Pleuro-pericardial Friction.—A friction sound resembling very closely the true pericardial friction is heard when there is inflammation of that part of the pleura which overlaps the pericardium. With each contraction of the heart the external surface of the pericardium is forced along the under surface of the inflamed pleura, and a friction sound is produced. Forced expiration might tend to eliminate this sound.

Signs of Effusion.—The fact that a friction sound has been heard is of great assistance in diagnosing an effusion. It is fair to suppose that an increased area of cardiac dulness, which develops subsequently to the detection of a pericardial friction rub, is due to an effusion. But one always keeps in mind the fact that a cardiac dilatation must be reckoned with.

Percussion.—It is usually stated that less than 100 c.c. of fluid cannot be recognized by percussion.

In an effusion of moderate degree the outline of dulness is quite characteristic, being of an irregular pear shape, or that of a triangle with rounded angles, whose base faces the diaphragm, and whose apex is above, to the left of the sternum. (Cabot states that he has not been able to make out this characteristically shaped area.)

More important is the fact that the dulness extends much farther to the left, beyond the apex beat, than it does in hypertrophy or dilatation.

Rotch has drawn special attention to the blunting of

Digitized by Microsoft®

the cardio-hepatic angle in the right fifth intercostal space in pericardial effusion. In health this cardio-hepatic angle is approximately a right angle. In pericardial effusion it is more obtuse. Rotch lays great stress upon the presence of absolute dulness in the fifth intercostal space, extending one and one-eighth to one and a half inches to the right of the sternum. However, this is found in dilatation of the right heart; for instance, in a case of advanced mitral insufficiency it is a common experience to obtain dulness in this area, and a consequent blunting of the cardio-hepatic angle. In fact, Broadbent speaks of two cases of dilated heart in which paracentesis was resorted to, because the signs seemed to point conclusively to pericardial effusion.

www.libtool.com.cn

It is also a difficult matter to decide where liver dulness ends and heart dulness begins.

The explanation of the difference of opinion in regard to the value of Rotch's sign in the differential diagnosis between pericardial effusion and dilatation of the heart is due, I think, to the fact that one authority has in mind absolute heart dulness, the other only relative dulness.

With a large effusion, signs of compression of the left lung develop. Above the line of dulness is an area of tympany or hyper-resonance, with increased vesicular or broncho-vesicular breathing. Ewart has called attention to the presence, in large effusions, of a circumscribed patch of dulness or impaired resonance just below the angle of the left scapula, over which there are increased vocal fremitus, bronchophony, and bronchial breathing. Broadbent, I believe, is correct in saying that these signs might also be present in any case of enormously enlarged heart.

Position of the Apex.—It has been held by some of the authorities (Sibson) that the apex is pushed upward and outward by the fluid. Others state that it is tilted upward and inward, that is, is floated by the effusion. Rotch believes from his investigation that this is an erroneous view. It seems impossible for a fluid of a lighter specific gravity than the heart to float it upward.

Ludwig and Bowditch have observed that the impulse of the heart, as seen normally in the fifth left interspace, need not be caused by the heart's apex, but may be caused by a portion of the heart above the apex striking against the chest wall. This fact I have observed many times. It should also be remembered that in children the apex beat is normally in the fourth interspace. The presence of a high pulsation could be accounted for by the tumultuous action of that portion of the right ventricle.

A very important sign is the gradual weakening of the apex beat with the increase of fluid. It may be entirely obliterated. In pericardial effusions the pulse may be strong and the apex beat weak; in heart lesions the apex beat may be heaving and the pulse weak. The effusions may become enormous and thus hinder the heart's action.

The presence of adhesions may prevent a pericardial effusion from assuming the typical shape. Rotch speaks of a case in which dulness failed to appear in the fifth intercostal space (right side), because of the presence of adhesions binding the lung tightly to the right edge of the sternum.

Purulent Pericarditis.—This disease furnishes the same physical signs as the serous effusion. It might be suspected from the etiology, *i.e.*, if secondary to suppuration in the other parts of the body, especially of the lungs or pleura. The leucocyte count would very likely be higher than in the simple serous pericarditis. Paracentesis is the only positive means of determining the nature of the fluid. The temperature curve is of the septic type, resembling that of empyema. The process may come on insidiously. It is usually purulent from the outset, though a serous effusion occasionally becomes purulent.

Adherent Pericardium.—The *symptoms* are not at all characteristic, and cannot be distinguished from those of organic heart lesions.

The *physical signs* in marked cases may be quite distinctive. They depend upon whether the adhesions exist between only the parietal and visceral layers of the pericardium, or whether they include also adhesions between the external pericardium and the chest wall or pleura. The following are the most important: (1) Fixation of the apex beat. Under normal conditions the apex beat moves a considerable distance with change of position of the patient and forced inspiration. (2) Systolic retraction of one or more interspaces. This sign, however, is unreliable, especially if the retraction is present in only one interspace, and at the apex; for it is occasionally seen in greatly hypertrophied hearts, and it may also be due to atmospheric pressure.

If there be distinct dragging in of the costal cartilages at the lower end of the sternum, one can be almost certain of adhesions.

Broadbent's Sign.—"Systolic retraction of the posterior or lateral walls of the thorax may indicate the presence of a universally adherent pericardium. Such retraction may, however, be seen even when the pericardium is not adherent to the heart, but only to a larger extent than normal to the central tendon of the diaphragm, to the muscular substance on either side, and to the chest wall as well. In such cases the heart is usually greatly enlarged and hypertrophied from old valvular disease. The explanation seems to be that the portion of the diaphragm to which the pericardium is adherent is dragged upward at each systole of the heart, so that the points of attachment of the digitations of the diaphragm to the lower ribs and costal cartilages are dragged inward and retracted."

If pericardial adhesions are present between the heart and the diaphragm and the chest wall, the descent of the diaphragm would be much diminished. Fluoroscopic examination would be very useful in demonstrating this point. Litten's phenomenon would be diminished or absent.

Enlargement of the heart is common in adherent pericardium. There are both hypertrophy and dilatation. The hypertrophy results from the obstruction offered to the regular contraction of the heart.

Broadbent states that the heart becomes dilated during the acute pericarditis, and before it regains its original size, becomes anchored in this position by adhesions.

Friedreich's sign of diastolic collapse of the cervical veins is not considered useful by the majority of modern writers.

The pulsus paradoxus has generally been held to be a sign of pericarditis. It is characterized by the disappearance of the radial pulse during inspiration. Kussmaul believes that it is of diagnostic importance in indurated mediastino-pericarditis; it is due to the fibrous cord dragging on the aorta during inspiration.

Most of these signs are dependent upon the presence of adhesions between the pericardium and the chest wall. When such adhesions are absent signs are very indefinite.

Signs and symptoms of incompensation may come on which cannot be distinguished from those of incompensated organic lesions.

An important condition is that of *pseudo-cirrhosis* of the liver due to obliterative pericarditis. In this condition there is an enlarged liver, associated with ascites, but without œdema or enlarged spleen. Autopsies have shown, according to Becker, in all recorded cases, that ascites is due to a passive congestion of the liver, causing a connective-tissue formation with subsequent contraction and obstruction of the portal circulation, the result of obliterative pericarditis.

Differential Diagnosis.—The chief difficulty lies in distinguishing between dilatation of the heart and pericardial effusion, when, as occasionally happens, neither friction sound nor murmur can be heard. This may be better appreciated when it is remembered that on several occasions the right ventricle has been punctured by the paracentesis needle with fatal results, the diagnosis of effusion having been made. In many cases in which the effusion is only of moderate degree it is difficult to be absolutely certain of a diagnosis.

Massive pericardial effusions, amounting to one and a

Digitized by Microsoft®

half or two litres, have been mistaken for pleuritic effusions.

The following excellent table is taken from Rotch's "Pediatrics," p. 761:

DIFFERENTIAL DIAGNOSIS BETWEEN A DILATED HEART AND A PERICARDIAL EFFUSION.

www.libtool.com.cn

Case I.—Endocarditis; dilated heart.	Case II. Pericarditis; effusion.	Case III. Endocarditis; enlarged heart; pericardial effusion.
Girl, eleven years. Attack followed acute articular rheumatism.	Boy, six years. Attack followed acute articular rheumatism.	Girl, eight years, August 3d. Attack followed acute articular rheumatism.
Orthopnœa; precordial pain; heart's impulse feeble, but perceptible a little to left and below left nipple, fifth interspace.	Orthopnœa; precordial pain; heart's impulse feeble but perceptible a little to left and below left nipple, fifth interspace.	Orthopnœa; precordial pain; heart's impulse feeble, but perceptible all over cardiac area, with apex beat a little below and to left of left nipple, fifth interspace.
Vertical absolute dulness not increased.	Vertical absolute dulness not increased.	Vertical absolute dulness not increased.
Absolute dulness under the sternum, and to left of sternum; identical with cases II. and III.	Absolute dulness under the sternum and to left of sternum; identical with cases I. and III	Absolute dulness under the sternum and to left of sternum; identical with cases I. and II.
Absolute dulness did not extend to right of sternum.	Absolute dulness in fifth right interspace 2 or 3 cm. from edge of sternum.	Absolute dulness in fifth right interspace 3 or 4 cm. from edges of sternum.
Systolic murmur at apex.	Pericardial friction rub at base.	Soft systolic murmur at apex, transmitted to axilla; pericardial friction rub at base.
Recovery.	Recovery.	August 6th. Less dulness in fifth right interspace; apex murmur much louder and harsh.
		August 11th. Dulness only to right edge of sternum.
		August 18th. Dulness only to middle of sternum; friction rub ceased.
		December 1st. Physical examination the same as on August 18th, showing enlarged heart and mitral systolic murmur.

The following points, mentioned by Osler, may assist one in differentiating between dilatation of the heart and pericardial effusion:

In dilatation the impulse in thin-chested people is usually visible and undulatory; the shock of the cardiac sound is more distinctly palpable in dilatation; the peculiar area of dulness in effusion, especially if the upper limit shifts with change of position of the patient.

In dilatation the heart sounds are clearer, often sharp, valvular or fœtal in character; gallop rhythm is common, whereas in effusion the sounds are distant and muffled.

Rarely, in dilatation, is the distention sufficient to compress the lung and produce the tympanitic note in the axillary region.

Fluoroscopic examination is extremely useful for differential diagnosis. The opaque area does not pulsate as it does in enlarged heart or aneurism. The upper level can be seen to move with changes of position.

Diseases of the Pericardium in Children.—Only a few special observations need be mentioned under this heading, as the signs of pericardial disease are practically the same at all ages. Rotch states that so far as he could determine by the dissection of sixteen infants of different ages the relation of the infant's pericardium does not differ from that of the adult. The amount of fluid normally present is of variable quantity, but is probably under 5 c.c. When pericardial friction sounds are absent, the diagnosis of pericarditis in a young child is attended with great difficulties. Some writers (Warthin) state that an accentuated pulmonary second sound is characteristic of pericarditis. In infancy, however, the pulmonary second sound is normally much accentuated. Owing to the greater flexibility of its thorax the child is much more likely than the adult to manifest a bulging of the precordium as a result of the pressure of the fluid. It must be kept in mind that on account of the smallness of the child's thorax the heart and pericardium are both brought nearer the surface than in the adult; and as a result the heart's impulse can be felt, and the heart sounds heard, in much larger effusions than would be possible in adults.

Pericarditis sicca is uncommon in childhood. Exudation takes place more frequently than in the adult, and with greater rapidity, and is more likely to be purulent (Rotch). Exudation tinged with blood is not uncommon in early life, and is not so significant of tuberculosis as is a pronounced hemorrhagic exudation.

Holt states that pericarditis is rare in infancy and early childhood, only two cases having been seen in seven hundred and twenty-six consecutive autopsies at the New York Infant Asylum. In later childhood the disease is more frequent. According to Jacobi, Holt, and other authorities diseases of the lung and pleura, especially of the left side, take first rank as etiological factors in infancy and early childhood. After the fourth year rheumatism takes precedence and the pericarditis is then usually associated with endocarditis. Pericarditis may develop in the new-born as a result of infection of the cord. In children pericarditis may develop and become very pronounced, while the articular complaint is mild.

In young children pain seems to be generally absent.

Prognosis.—Pericarditis should always be looked upon as a serious disease, chiefly because of the myocardial degeneration which accompanies it. Death may take place in a few days in the acute cases associated with rheumatism and pneumonia, but this sequel is very uncommon. The immediate prognosis in these cases is generally good. The probability of repeated attacks, the likelihood that adhesions will form, and the presence of myocarditis render the prognosis for a long life unfavorable. When associated with Bright's disease the prognosis is bad.

Patients occasionally die from syncope as a result of embarrassment to the action of the heart from pressure, by very large collections of fluid.

Suppurative pericarditis is nearly always fatal if associated with a general septicæmia; if it is secondary to an empyema or other localized collection of pus, there may occasionally be recovery, with the adoption of early and proper surgical treatment. Of thirty-five cases of suppurative pericarditis treated by incision, fifteen recovered and twenty died (Roberts, *Am. Jour. Med. Sc.*, December, 1897).

In adherent pericardium the prognosis is serious if there are adhesions to the chest wall, or if the heart is enlarged, or especially if these adhesions are associated with valvular lesions. Universal adhesion of the pericardium to the heart, provided the heart is not enlarged, does not necessarily tend to shorten life.

Treatment.—Pericarditis must always be considered a serious disease, even if the symptoms are slight. The patient should be put to bed. The diet should be chiefly liquid, milk forming the major part. The stomach should not be overloaded. In the milder cases soft articles of food may be given. Pain should be relieved chiefly by the application of the ice-bag. In children hot applications may be more satisfactory. Morphine may be required in some cases. Restlessness and sleeplessness should be controlled by suitable doses of bromide or trional. The heart action, pulse, respirations, and color of the patient should be closely watched, and heart tonics, such as strychnine and digitalis and ammonia, given when indicated. The time may come when the heart is overwhelmed by the obstacles presented by the enormous effusion; the pulse becomes extremely weak and rapid, marked dyspnœa and cyanosis develop; then heart tonics are useless, and one must resort to paracentesis to save the patient.

Unless the symptoms are moderately urgent a serous effusion should not be evacuated, because many times the absorption is very rapid. If the effusion is large and has existed for many days, and shows no signs of resorption, it should then be evacuated without hesitation.

Digitized by Microsoft®

Paracentesis Pericardii.—The pericardium is tapped with a Potain aspirating set in the same way as is the pleura. The only difference is in the selection of the points of puncture. An excellent method is first to freeze the part with an ethyl chloride spray, make a very small incision through the skin with a bistoury, then insert the needle at right angles to the chest wall for a distance of from one and a half to two inches. After consulting a large number of authorities upon the correct site for puncture, and finding that each writer advises a different location, I have come to the conclusion that if a fairly large effusion is present it is safe to puncture anywhere from an inch to the right of the sternum to an inch or so beyond the left nipple line, between the fourth and sixth ribs. One is cautioned to avoid wounding the internal mammary artery. Little attention need be paid to the intercostal arteries.

Rotch very strongly recommends the fifth right interspace 4 cm. (1½ in.) outside the right border of the sternum. He states that an effusion of even as little as 100 c.c. can be found at this point, and that there is no danger here of wounding the heart, or the right internal mammary artery, or the pleura. Osler recommends the fourth left interspace, either at the sternal margin or 2.5 cm. (1 in.) from it. He also speaks of the fifth left interspace an inch and a half from the left sternal margin, and close to the costal margin in the left costo-xyphoid angle, as the point where the needle may be thrust upward and backward.

Purulent effusions should be treated like any other abscess, by early free incision and drainage. Irrigation of the sac is not advisable except in selected cases.

The treatment of adherent pericardium is practically that of organic heart lesions (myocardial and valvular). It is necessary to keep up bodily nutrition by proper exercise and diet, and at the same time guard against overtaxing the weak heart. If symptoms of incompensation develop they should be treated by rest, diet, and cardiac medicines, as indicated elsewhere.

Hæmopericardium and Hydropericardium have been considered in detail in Vol. IV.

Pneumopericardium, because of its extreme rarity and hopeless prognosis, is of very little practical importance. By it is meant the presence of gas or air in the pericardial sac. As a matter of fact, gas is never present alone, but is in combination with fluid, usually pus, *i.e.*, pyopneumopericardium. The fluid may be ichorous. It is always secondary to some very serious destructive disease in which a communication is established between the pericardium and a cavity or tube containing air—as, for instance, perforation from the œsophagus, especially in connection with cancer; rupture into the pericardium of a lung cavity, or pneumothorax, or perforation of a gastric ulcer. It may occur as a result of penetrating wounds, such as fractured ribs, concussion or crushing of the chest, or injury from the side of the œsophagus. The gas in pneumopericardium varies in amount and in composition, and is generally offensive. It may be under so great pressure that when the pericardium is punctured the gas escapes with a hissing noise.

Symptoms.—These are very indefinite, and difficult to dissociate from the primary disease. If the gas is present in abundance there will be dyspnœa, cyanosis, attacks of syncope, collapse, a feeble and irregular pulse, and occasionally dysphagia and precordial distress.

Physical Signs.—There may be bulging of the precordial region. The apex beat is weak or absent. The heart movements may produce a very peculiar crackling sensation due to the bursting of bubbles.

Percussion signs are very striking. A metallic tympanitic note is heard over the distended pericardium. Because of the presence of fluid and air a freely movable area of dulness is detected in the dependent part, upon change of position. The quality of the tympanitic note may also vary with the change of position.

Auscultation.—The heart sounds are unusually loud and may have a metallic ring. If murmurs are present they take on the same quality. The cardiac movements and deep breathing agitate the fluid and gas present in such a way as to produce unusual adventitious sounds. They have a metallic ringing quality, and have been likened to the sound of a water wheel.

Treatment is expectant and supportive. It may at times be wise to allow the gas to escape through a fine trocar, or even to incise and treat surgically. Little can be done in a medical way.

New Growths and Parasites.—Under this heading are included tuberculosis, carcinoma, and hydatids. Tuberculosis is much more common than the latter two. It is very unusual to find the tubercles of acute miliary tuberculosis on the pericardium. In most cases tuberculosis of the pericardium is chronic and secondary to tuberculosis in other parts of the body, especially of the lungs and mediastinal lymph glands. In many cases of pulmonary tuberculosis the complicating pericarditis is of the simple serous type. The exudate in tuberculosis and carcinoma of the pericardium is likely to be blood-tinged, and may be purulent or ichorous.

Carcinoma of the pericardium is extremely rare and is always secondary, the sac being involved by extension from neighboring organs.

Hydatids of the pericardium are extremely rare. Clinically we have no means of recognizing the presence of a new growth in the pericardium, except as we infer its presence from the detection of similar disease in neighboring tissues.

James Rae Arneill.

PERINEORRHAPHY. See *Obstetric Operations.*

PERINEUM, SURGICAL ANATOMY OF THE.—I. The Male Perineum.—In the skeleton the perineum corresponds to the outlet of the pelvis. It is a diamond or lozenge-shaped space bounded in front by the pubis and subpubic ligament, behind by the coccyx, and on each side, from before backward, by the rami of the pubis and ischium, the great tuberosity of the ischium, and the great sacro-sciatic ligament.

The whole space measures about three inches and a half from side to side, and four inches antero-posteriorly. At the posterior part it is from two to three inches deep; anteriorly it only reaches the depth of one inch. The perineal space is separated from the pelvic cavity above by the recto-fascia and levatores ani muscles. A line drawn across from one ischial tuberosity to the other, and passing immediately in front of the anus, would divide the space into two parts (see Fig. 3794), the anterior of which is called the *urethral* triangle or true perineum, and the posterior the *anal* or rectal triangle. The anterior triangle contains the bulb and urethra, with the muscles of the perineum proper; the posterior triangle has in it the rectum and the two ischio-rectal fossæ.

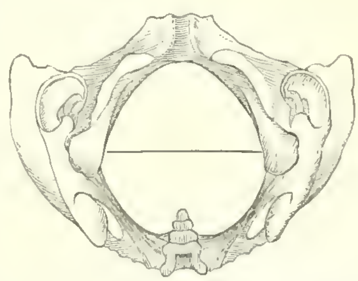

Fig. 3794.—Outlet of the Pelvis. Line dividing outlet into anterior or urethral triangle, and posterior or rectal triangle.

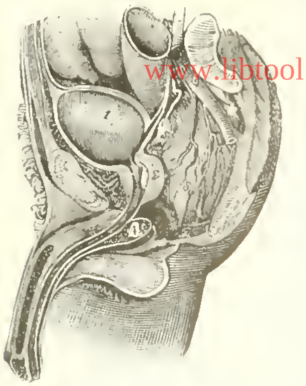
Surface Anatomy.—In the undissected subject the superficial area of the perineum is very limited, especially when the thighs are brought together; it then consists of a narrow space or groove reaching from the coccyx behind to the symphysis pubis in front. In the centre of this groove is an elevation of the skin, called the median raphé, which runs from the front of the anus, over the scrotum, to the under surface of the penis. No vessels cross this line, and in this situation incisions may be made without any fear of hemorrhage. The osseous boundaries of the perineum may be easily made out through the skin; the great sacro-sciatic ligaments, however, being covered by the gluteal muscles, can be felt

Digitized by Microsoft®

only by pressing in a line drawn from the coccyx to the ischial tuberosity. In thin subjects they can be more easily felt. The anus is situated at the midpoint between the tuberosities, and its centre is about one inch and a half from the end of the coccyx. The central point of the perineum is a little more than an inch in front of the anus; this point corresponds to the middle of the free border of the triangular ligament. A knife introduced here, and given a slightly upward direction, would reach the membranous urethra. Immediately in front of the central point may be felt, in all but very fat persons and children, the bulb of the urethra and the corpus spongiosum. Abscesses point, and urethral fistulæ are often seen, in this region.



www.libtool.com.cn

FIG. 3795.—1, Bladder; 2, prostate; 4, bulb; 5-6, seminal vesicles and vas deferens; 7, ureter; 8, rectum; 9, sphincter ani. (Roser.)

The membranous portion of the urethra perforates the triangular ligament one inch below the symphysis pubis, and one inch and a half in front of the anus. The skin of the perineum is thin and covered with hairs; about the anus it is of a brownish color and thrown into radiating wrinkles by the contraction of the external sphincter; these folds are much enlarged when the hemorrhoidal veins are swollen and inflamed. If the skin of the anus be everted, a fine white line is seen which marks the junction of the skin and mucous membrane, and corresponds exactly to the lower margin of the internal sphincter. There are a number of follicles about the margin of the anus, and small subcutaneous abscesses frequently occur in this situation. These must not be confounded with fistulæ. The usual incision in lateral lithotomy passes between the anus and ischial tuberosity, a third nearer the tuberosity than the anus.

If the finger be introduced through the anus into the rectum, many important landmarks may be felt. The finger for the first inch is grasped by the sphincter muscles, principally the internal. Here the internal openings of fistulæ may be felt, these openings are rarely much above the upper border of the sphincter ani. One can easily feel ulcers and fissures in this situation, when they are present. In the front wall of the bowel the membranous portion of the urethra can be made out in the middle line, and when a catheter is introduced into the bladder it can be easily felt as it passes through the membranous portion; with the finger in the rectum a catheter can be guided into the bladder in cases of enlarged prostate, and if the instrument enters a false passage it can be detected and directed into the proper channel. The prostate gland can be felt one inch and a half from the anus, and its condition ascertained if it be enlarged or inflamed. Passing beyond the prostate the finger comes on the trigone of the bladder. When the bladder is distended it may be made out through the rectum as a soft fluctuating tumor. It is more easily felt when the other hand, placed above the pubis, presses the apex downward. The bladder, when distended, may be tapped through the trigone with a curved trocar, without there being any danger of wounding the peritoneum, which generally reaches only to within four inches of the anus. In rare cases the peritoneum passes down between the gut and the trigone. In such cases, of course, in this operation, it would inevitably be wounded.

The vesiculæ seminales can rarely be felt, unless affected by disease.

Stone in the bladder in children can often be diagnosed through the rectum. Above the trigone of the bladder transverse folds of mucous membrane in the rectum can be felt; these are soft and velvety when healthy, but when ulcerated or inflamed they feel thick and cause great pain on defecation. Many diseases are diagnosed by the finger in the rectum, viz., ulcers, polypi, hemorrhoids, stricture of the gut, diseases of the prostate, deep-seated abscess of the ischio-rectal fossa, pelvic tumors, etc.

With the whole hand introduced into the rectum the entire pelvis may be explored, as well as the lower part of the abdomen.

ISCHIO-RECTAL FOSSA.—The ischio-rectal fossa is the space which exists on each side between the rectum and ischial tuberosity. It is of a pyramidal shape, with the apex pointing upward to the pelvic cavity, and is from two to three inches in depth.

Boundaries.—Internally, the levator ani covered by the anal fascia; externally, the obturator internus muscle covered by the parietal layer of pelvic fascia; in front, the triangular ligament and transversus perinei muscle; behind, the lower edge of the gluteus maximus, the great sacro-sciatic ligament, and the coccygeus muscle.

The space is filled with fat, and crossing the fossa obliquely are the inferior hemorrhoidal vessels and nerves. The anterior portion is crossed by the perineal vessels and nerves, and entering the fossa at its posterior part is the perineal branch of the fourth sacral nerve.

The tuberosities of the ischia have also a cushion of fat over them, and when this is removed several bursæ are seen. The apex of the space corresponds to the division of the pelvic fascia into parietal and visceral layers, or rather to the junction of the anal with the obturator fascia. When the anal fascia is removed the levator ani muscle is exposed, and internal to the levator ani is the visceral layer of pelvic fascia.

The lower end of the rectum is placed between the two fossæ, slung, as it were, by the meeting of the two levatores ani muscles, and held in place by the external sphincter and recto-vesical fascia. The fibres of the levatores ani muscles at the lower end of the rectum are separated from one another, and in this situation the anal fascia is also very thin, so that little resistance is offered to the entrance of pus.

Ischio-rectal Abscess and Fistula in Ano.—Abscess in the ischio-rectal fossa is not an uncommon affection, and is often caused by the ulceration of foreign bodies, such as fish-bones, through the bowel into the fossa, and there setting up inflammation. Sitting on cold, damp seats after exercise is another, and perhaps the most common, cause of ischio-rectal abscess.

When pus forms in the fossa it presents at the points of least resistance, viz., the internal wall of the fossa and the skin at the base. When the abscess breaks through the skin it will be found that after a time a sinus remains, which generally communicates with the bowel; this sinus is called a *fistula in ano*. The internal opening of the fistula is usually within half an inch of the margin of the anus, as at this point pus can more easily penetrate the rectum, because of the thinness of the fascia and the scantiness of the muscular fibres. The external opening may be anywhere in the region of the posterior part of the perineum. To prevent the formation of a fistula, the ischio-rectal abscess should be opened early and freely.

PERINEAL FASCIÆ.—The superficial fascia of the perineum consists of two layers, between which, in the rectal triangle, is a large amount of fat; in the urethral triangle there is less, and as the fascia reaches the scrotum the fat is replaced by the muscle or dartous tissue of that structure. The deep layer of fascia (fascia of Colles) is limited to the urethral triangle; it is attached to the base of the triangular ligament, to the anterior lips of the rami of the pubes and ischia laterally, and anteriorly it is continuous with the fascia of the scrotum. By its junction with the triangular ligament posteriorly it forms a pouch, which is divided into two portions by a median septum.

This pouch has an important influence on the direction which urine takes when extravasated, or pus when it

Digitized by Microsoft®

forms, in this region. Owing to the attachment of the superficial fascia to the base of the triangular ligament and to the rami of the pubes and ischia, fluid cannot go back toward the anus or down the thighs, but, as the fascia is continuous anteriorly with the dartos of the scrotum, no resistance is offered to its progress forward and upward over the scrotum to the abdomen.

www.libtool.com.cn

This is the course taken by urine when extravasated in front of the triangular ligament. When an abscess forms in the perineum, owing to the median septum, it is usually confined to one side of this pouch, and the swelling is triangular in shape. The pus, as it passes forward, on account of the deficiency of the septum in front, fills both sides of the pouch.

The anterior perineal pouch contains the superficial perineal muscles, vessels, nerves, and the root of the penis, which latter is made up of the two crura of the cavernous portions and the bulb of the spongy portion.

Muscles.—The muscles of the perineum bound the perineal triangle, in which the knife is entered in the operation of lateral lithotomy. The base of the triangle is formed by the tranversus perinei muscle, the outer side by the ischio-cavernosus (erector penis) muscle, and the inner side by the bulbo-cavernosus (accelerator urinæ); the triangular ligament forms the floor of the triangle.

The point of meeting of the two transverse perineal muscles, the sphincter ani, and bulbo-cavernosus muscles is called the tendinous or central point of the perineum. Along the lower border of the transverse muscles is seen the transverse artery, a branch of the internal pudic.

*Triangular Ligament.**—This ligament divides the perineum into two portions—a deep and a superficial. It has very definite attachments to the subpubic ligament, the rami of the pubis and ischia, and the superficial fascia. It also blends with the central tendinous point

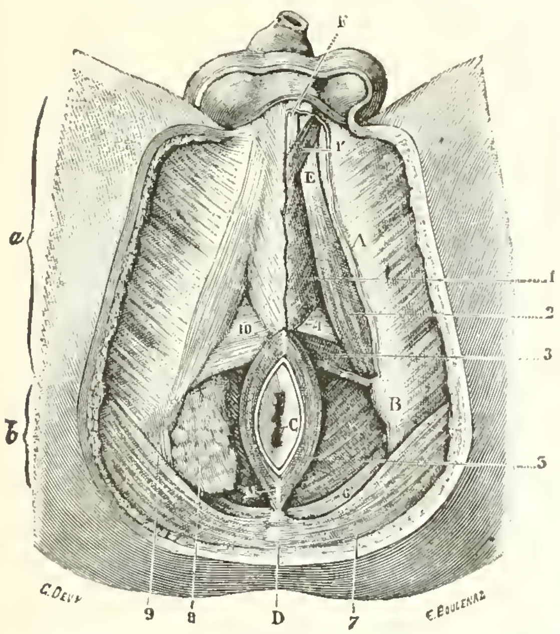


FIG. 3796.—Superficial Dissection of the Muscles of the Perineum. 1, Bulbo-cavernosus muscle; 2, ischio-cavernosus; 3, transversus perinæi; 4, triangular ligament; 5, sphincter ani; 6, coccygeus; 7, great gluteus muscle; 8, cellular fatty tissue of the ischio-rectal fossa; 9, sacro-sciatic ligament; *A*, ischio-pubic ramus; *B*, ischium; *C*, anus; *D*, coccyx; *E*, cavernous body.

of the perineum. As suggested by Prof. D. J. Cunningham, of Dublin, it is better to regard this ligament as a distinct membrane, and to class it in the same category as the obturator membrane; for "it lies in the same morphological plane as the bony and ligamentous wall of the

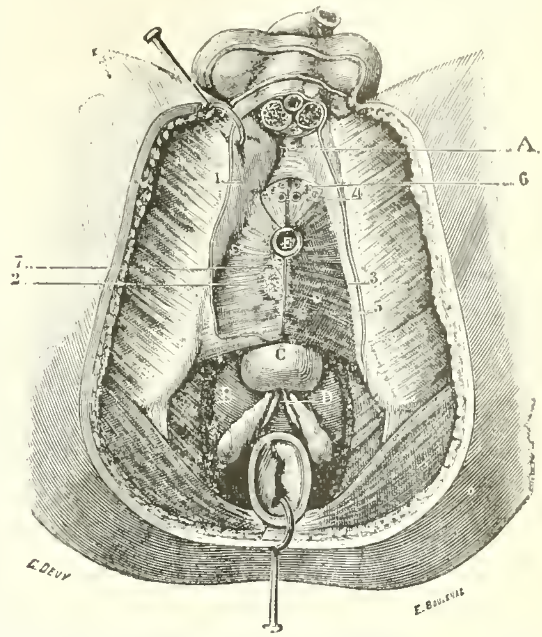

FIG. 3797.—The Muscles of the Perineum, Deep Dissection. *A*, Symphysis pubis; *B*, bladder; *C*, prostate; *D*, seminal vesicle; *E*, urethra cut transversely; 1, triangular ligament; 3, deep transverse perinei muscle; 5, Cowper's glands; 6, subpubic plexus of veins.

pelvis," and it completes the pelvic wall in front in the same manner as the thyroid membrane closes the thyroid foramen.

When the body is erect the lower surface of the triangular ligament looks downward and forward, and the deep surface upward and backward.

Structures in Relation with the Triangular Ligament.—In front are the structures named above as being contained in the perineal pouch.

The ligament is pierced by the urethra, and also by the dorsal vein and nerves of the penis and the internal pudic arteries. The urethra pierces the ligament one inch below the symphysis pubis, in the middle line. The parietal layer of pelvic fascia (posterior layer of the triangular ligament) is above and behind, and is attached to the ligament below, but as it proceeds upward the space between them widens. Between these two structures are the membranous portion of the urethra, the pudic vessels and nerves, with the artery of the bulb, the dorsal vein of the penis, the compressor urethræ muscle, which surrounds the membranous urethra, and Cowper's glands. These latter empty their secretion into the bulbous portion of the urethra; in inflammatory conditions of the urethra they may become inflamed and suppurate; they are the homologues of Bartholin's glands in the female.

The membranous portion is the least dilatable portion of the urethra, and is frequently the seat of *traumatic* strictures; it measures three-fourths of an inch in length.

Behind and above the pelvic fascia (posterior layer of the triangular ligament) is the apex of the prostate gland, covered by the levator ani muscle and by its own capsule. From this description it will be seen that the triangular ligament divides the perineum into two compartments, a superficial and a deep; the superficial contains the perineal muscles and root of the penis; the deep the membranous portion of the urethra, the pudic artery and nerves, the dorsal vein of the penis, the compressor urethræ muscle, and Cowper's glands. The base of the triangular ligament is the meeting-point of three fasciæ,

* This structure is sometimes named the anterior layer of the triangular ligament, the posterior layer being the parietal layer of pelvic fascia. It is also called the deep layer of the deep perineal fascia and the subpubic fascia.

Digitized by Microsoft®

viz.: (1) perineal fascia; (2) triangular ligament; and (3) the parietal layer of the pelvic fascia (posterior layer of the triangular ligament).

The triangular ligament sometimes offers an obstacle to the introduction of a catheter; for if the instrument be

www.libtool.com.cn

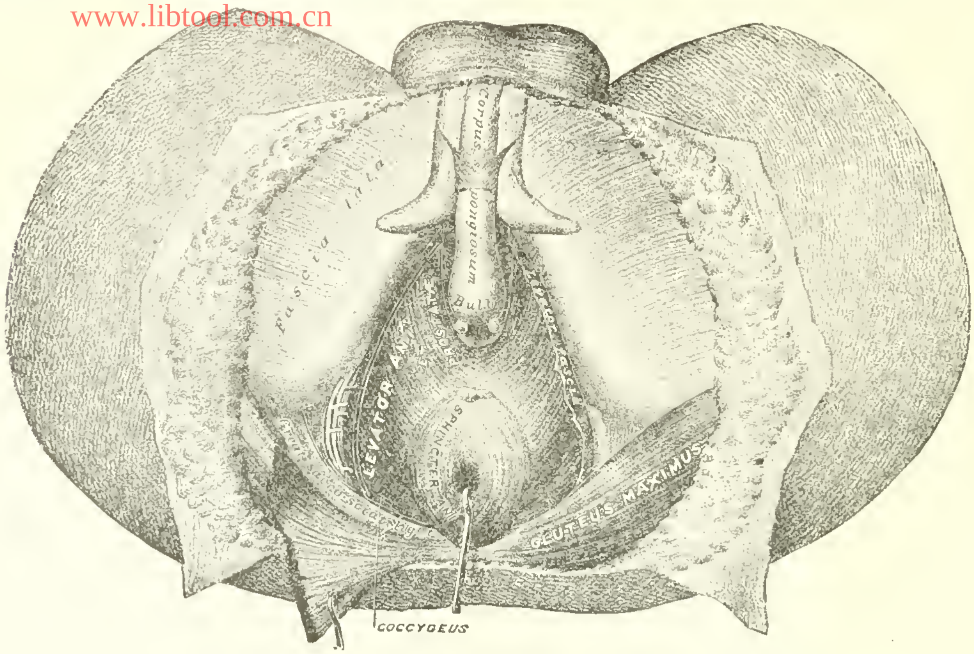

FIG. 3798.

not kept against the upper wall of the urethra, it is apt to sag in the lower wall, which is very distensible, and reach the triangular ligament below the opening of the membranous urethra. After the triangular ligament has been successfully passed, the point of the instrument may be arrested in the membranous urethra by the spasmodic contraction of the compressor urethræ muscle which encircles it; this obstruction may be overcome, without exercising any force, by merely keeping the end of the instrument pressed gently against the obstructing point; after a short time the muscle relaxes and the instrument slips into the bladder.

Kicks in the perineum, or injuries from falling astraddle of anything, may rupture the membranous portion of the urethra, and in these cases blood and urine will be extravasated between the triangular ligament and the parietal layer of the pelvic fascia (posterior layer of the triangular ligament). Should the injury tear the triangular ligament, then the extravasated fluid would take the ordinary course upward over the scrotum and abdomen. When extravasation has occurred, free incisions should be made in the perineum, and if the urethra be completely torn across, the perineum should be opened in the middle line and an instrument introduced into the bladder.

Professor Cunningham, of Dublin, has pointed out, in his "Dissector's Guide," that in removing the various structures from the surface to the prostate gland, alternate layers of fascia and muscle are met with viz.: (1) Superficial fascia; (2) *superficial perineal muscles*; (3) triangular ligament; (4) *compressor urethræ muscle*; (5) parietal layer of pelvic fascia, or posterior layer of the triangular ligament; (6) *levator ani muscle*; (7) capsule of the prostate and pubo prostatic ligament.

Internal Pudic Artery.—The pudic artery is seen in the rectal triangle enclosed within a sheath of pelvic fascia formed by the splitting of the obturator fascia. It lies about one and a half inches above the level of the ischial tuberosity and is accompanied by the pudic nerve and the two pudic veins; proceeding forward, it passes between the triangular ligament and the parietal layer of pelvic fascia (posterior layer of the triangular ligament), and then, running under cover of the rami of the pubis and ischium, pierces the triangular ligament from behind, half an inch below the symphysis and a little to one side of the middle line. It then divides into its two terminal branches, the artery to the corpus cavernosum, and the artery to the dorsum of the penis. The pudic artery, while in the ischio-rectal fossa, gives off the hemorrhoidal, and a little further forward the superficial and transverse perineal, arteries. While passing behind the triangular ligament, it gives off the artery of the bulb, the wounding of which was formerly so much dreaded by surgeons. The pudic artery itself is said to be in danger of being wounded in lateral lithotomy, but this accident could occur only to the most careless operators, when withdrawing the knife and sweeping it outward. It is possible to wound it only after it has left the protection of the pubic arch.

EXPLORATION OF THE BLADDER THROUGH THE PERINEUM.—This operation is little more than a perineal section. According to Sir Henry Thompson, after introducing a grooved staff an incision should be made in the median line, commencing three-fourths of an inch in front of the anus, and the parts should be divided till the staff is reached in the membranous portion of the urethra; the finger is introduced into the bladder through this incision, the prostatic urethra dilating easily; the staff is now removed and the exploration of the bladder is made. Through this median incision tumors and stones of moderate size can be removed. There is little hemorrhage, even should the bulb be wounded, for this latter structure is not very vascular in the median line.

Parts Divided in Lateral Lithotomy.—The incision is commenced one inch and a half in front of the anus, and is carried downward and outward to a point between the anus and great tuberosity, a little nearer the tuberosity than the anus.* In order to reach the staff in the membranous urethra the following structures must be cut:

In the first incision: Skin and superficial fascia; trans-

* The incision employed in lateral lithotomy falls about in a line parallel with the ascending ramus of the pubis and the ischio-cavernosus muscle. (Roser.)

Digitized by Microsoft ®

verse perineal muscle and artery; base of the triangular ligament; the hemorrhoidal vessels and nerves.

Second incision: The knife is now guided by the forefinger, passed up behind the triangular ligament, its point placed in the groove of the staff, and the blade is lateralized and pushed along the groove into the bladder. In this incision the following parts are divided, viz.: Membranous portion of the urethra and compressor urethræ muscle; parietal layer of pelvic fascia (posterior layer of the triangular ligament); anterior fibres of the levator ani and left lobe of the prostate.

Parts to be Avoided.—(1) Artery of the bulb, (2) rectum, (3) pudic artery.

(1) The danger from a wound of the artery of the bulb is not great, and is somewhat traditional; with the modern methods of arresting hemorrhages no one need fear wounding the artery of the bulb. Very frequently it is abnormal in its distribution, and its division cannot be avoided.

(2) The rectum may be cut, especially in children, if the bowel is not emptied previous to operation, or if the incision be carried down too vertically.

(3) The pudic artery need never be wounded in a properly performed operation. It can be cut only by lateralizing the knife too much in withdrawing it. If wounded, it may be secured with the modern artery forceps without great difficulty.

In the withdrawal of the knife a too vertical incision may cut through the prostate, and so divide the visceral layer of pelvic fascia. Should this accident happen, no ill results will follow if the wound be kept sweet and be thoroughly drained. Wounding of the visceral layer of the pelvic fascia is a danger much dwelt on by the older lithotomists, and surgeons of the present day still have a traditional fear of this accident happening. In children, lateral lithotomy can scarcely be performed without cutting through the prostate gland, and at the same time the visceral layer of pelvic fascia; yet no ill results follow; on the contrary, the operation is safer in children than in adults. The real danger in adults is not from wounding the pelvic fascia, but from wounding the prostatic plexus of veins and the ejaculatory ducts. The prostate gland when enlarged can be removed through a perineal incision either transverse or vertical. Also the seminal vesicles can be reached through the same route. When affected with tuberculous disease it is sometimes necessary to remove them. The ureter as it enters the bladder can be reached through the perineum, and stones which have become lodged there successfully extracted.

Testicle in Perineum.—During the descent of the testicle, and after it has passed through the external abdominal ring, it may, instead of entering the scrotum, pass down into the perineum (ectopia perinealis). In these cases it may be felt slightly movable under the skin, about an inch and a half in front of the anus. The scrotum of the side in which the testicle is lodged in the perineum is deficient it the affection be congenital; if the case is of traumatic origin the scrotum of that side is present. The displacement has no evil effect on the testicle, which is always of a good size. The abnormal position of the testicle renders it liable to injury, and patients apply to the surgeon for relief. An operation has been devised for restoring the misplaced testicle to its proper position in the scrotum, but its success has been only moderate. Excision is sometimes demanded to rid the patient of his trouble.

II. The Female Perineum.—The space occupied by the female perineum, owing to the wider pubic arch, is somewhat larger than that of the male. It differs from the male perineum in being perforated in the median line by the vulvo-vaginal opening. This opening occupies the place in the female which in the male is the situation of the bulb. In the female this bulb is, as it were, divided into two halves, as is also the muscle covering it. The space between the divided bulb is the opening of the vagina. The *vagina* extends upward and backward between the bladder and rectum, its upper part being covered by peritoneum, and thus it is in close relation with the peritoneal cavity.

The *triangular ligament* is also divided into two halves, and on this divided ligament rests the divided bulb, the vagina passing between. So we have a bulb which is called the "vestibular bulb" on each side of the vagina, and these bulbs are joined above by a small plexus of

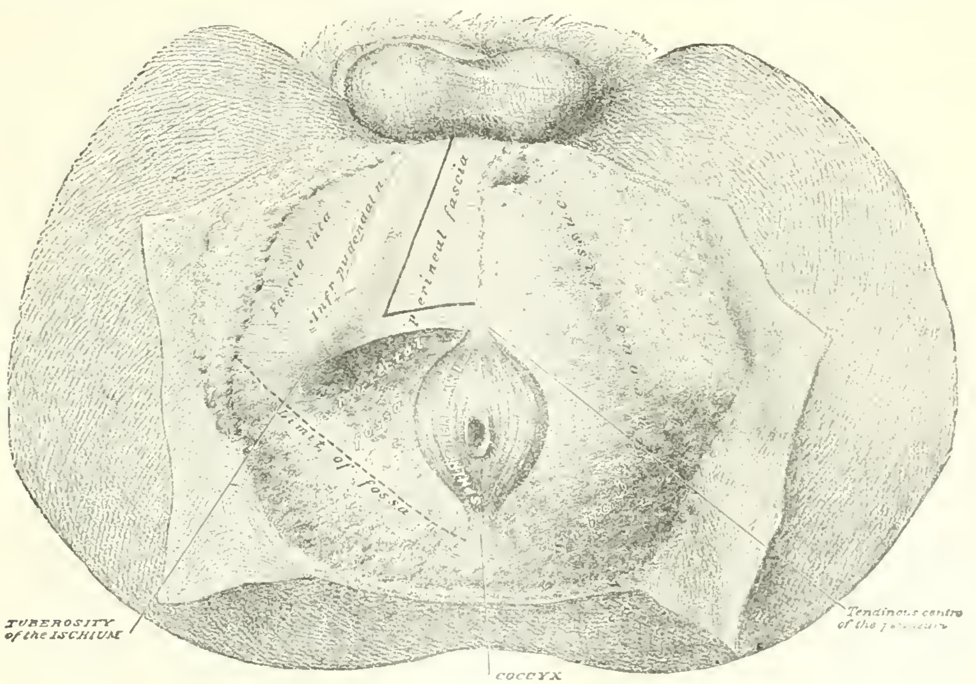

Fig. 3799.

Digitized by Microsoft®

vessels called the "pars intermedia." The bulbs are covered by the sphincter vaginæ muscle (bulbo-cavernosus). This is the homologue of the fused *bulbo-cavernosus* muscle in the male. We also see the anterior fibres of the

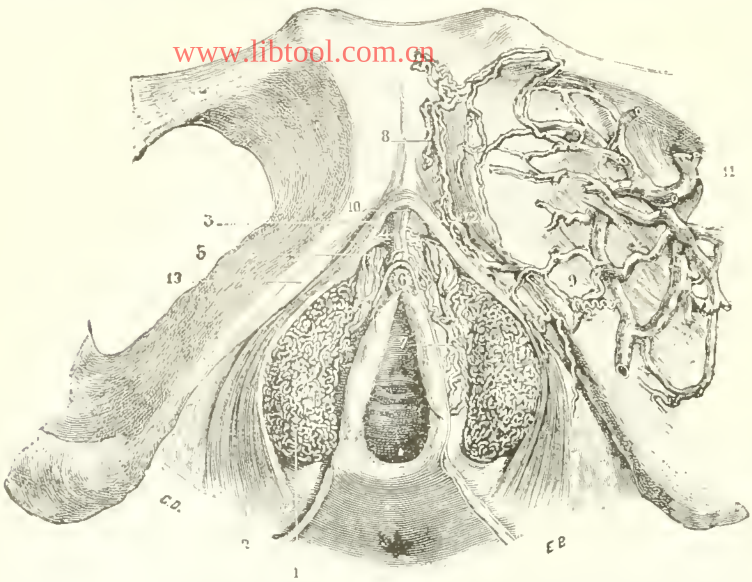

FIG. 3800.—The Bulb of the Vagina with the Venous System of the Clitoris, Viewed from in front. (After Kobelt.) 1, Bulb; 2, constrictor muscle; 6, glans of clitoris; 9, communication with the obturator veins; 13, cavernous body.

levator ani muscle embracing the vagina as they do the prostate gland in the male.

The *superficial fascia* and *Colles' fascia* have the same attachments as in the male, but differ in being perforated by the vagina.

The glands of Bartholin and Duverney are situated on each side of the commencement of the vagina behind the triangular ligament, and correspond to Cowper's glands in the male. Their ducts open on each side between the hymen and labium minus. It is not uncommon to have abscesses connected with these glands, to cure which they have to be dissected out.

The *clitoris* and nymphæ correspond to the penis in the male. The clitoris is composed of two corpora cavernosa and a rudimentary glans. It is much smaller than the penis, and is not perforated by the urethra. The corpora cavernosa are attached to the inner side of the pubic arch in front of the triangular ligament, and, as in the male, are covered by a muscle, the ischio-cavernosus (erector clitoridis). The glans is surrounded by a membranous fold, which is the homologue of the prepuce in the male.

The *vulvar cleft* opens on the surface between the two labia majora; anteriorly opening into this cleft is the urethra, and posteriorly is a recess called the fossa navicularis, and in the centre is the vagina. The space anteriorly between the clitoris and the urethra is called the vestibule, and this is bounded on each side by a labium minus.

The *labia majora* are two thick folds of skin covered with hair and united in front to form the mons veneris. In each labium are blood-vessels and dartous tissue as in the scrotum of the male, of which they are the homologue. The vestibule corresponds to the lower prostatic and membranous portion of the urethra in the male.

On separating the labia majora the nymphæ or labia minora are seen. These are folds of skin which are continuous above with the prepuce of the clitoris and below join the *labia majora* about the centre. As a rule they do not project beyond the labia majora, but in the dark races they are of larger size and project considerably beyond the vulvar cleft. In old age they are also more prominent.

The *hymen* is a thin fold of mucous membrane of various forms, which partially occludes the vaginal orifice; in some cases the vaginal orifice is completely closed, and then we have what is called an *imperforate hymen*. Occasionally the hymen is absent or has been destroyed by inflammatory action in childhood. Its presence is not necessarily a proof of virginity nor is its absence significant of the loss of the same. When the hymen has been ruptured, and in women who have borne children, the remnants are seen as small rounded elevations called "carunculæ myrtiformes."

The vessels and nerves of the female perineum do not differ essentially from those of the male; the pudic artery is smaller, while the superficial perineal artery going to the labia is larger. Owing to the small size of the clitoris as compared with the penis, the nerves and blood-vessels supplying it are much smaller.

The Perineal Body, or the so-called perineum of the obstetrician, fills in the space between the vagina and the rectum; in section it is triangular in shape, with the base of the triangle downward, corresponding to the skin between the posterior part of the vagina and the anterior border of the anus. Anteriorly is the fossa navicularis, and posteriorly is the rectum. The perineal body measures at its base about one and one-quarter inches from before backward, and laterally extends from one tuberosity to the other; in this space is the tendinous point of the perineum, to which are attached several muscles, such as the levator ani, sphincter ani, transversus perinei, and sphincter vaginæ. Laterally we have the ischio-cavernosi muscles. Running across the perineal body we have a transverse septum which, in the female, is very strong and consists of connective tissue, yellow elastic tissue,

Digitized by Microsoft®

and involuntary muscular fibres; it can be felt as a hard body when examined through the posterior commissure of the vagina. The "perineum" is a highly distensible body, as is well seen in childbirth, when it is almost obliterated. Above the perineal body the vaginal and rectal walls are in apposition, loosely connected with areolar tissue. This so-called perineum is frequently torn in first labors, and if the rent be not sewed up immediately so as to enable union by first intention to take place, the vaginal orifice will be much enlarged and the support of the perineal body be lost. Occasionally these rents extend into the rectum, and a very miserable condition results, there being partial or complete incontinence of fæces. Operations undertaken for the repair of this condition are most successful even when of old standing. It is, however, much better to repair the rent as soon as possible after its occurrence.

www.libtool.com.cn

Tearing of the perineum with general relaxation of the pelvic floor and increase in the intra-abdominal pressure predispose to prolapse of the uterus. This condition is rarely seen in the nullipara or in well-to-do multipara. It is the hard-working woman, who gets up to work too soon after childbirth, in whom this condition is most frequently seen. *Francis J. Shepherd.*

PERIOSTEUM, ACTINOMYCOSIS OF.—Actinomycosis is rarely primary in the periosteum; but the periosteum is not infrequently involved by direct extension from actinomycotic processes in neighboring structures. In primary actinomycosis of the mouth the periosteum of the jawbone is first involved, later the bone; in actinomycosis of the lungs the process may extend to the pleura and thence to the periosteum of the ribs and vertebræ. In these cases of secondary extension there occurs first an *actinomycotic periostitis* with formation of granulation tissue. As a result of this a superficial caries is produced and the interior of the bone becomes involved. Here the process develops more rapidly, the bone becomes filled with granulation tissue, and expands into a honeycombed shell. Over this the periosteum may develop irregular masses or spicules of bone or thick layers of fibrous tissue. The microscopical picture is that of a strong reactive inflammation; numerous mast and plasma cells are present. The clinical and diagnostic features are given under the head of *Actinomycosis*.

Aldred Scott Warthin.

PERIOSTEUM, TUBERCULOSIS OF.—Primary tuberculosis of the periosteum is regarded by most writers as a very rare condition; but it probably is of not infrequent occurrence. Though the majority of cases of primary tuberculosis of the bones are of myelogenous origin, there can be little doubt that numerous cases begin as a *tuberculous periostitis* (*periostitis tuberculosa*). The process begins with the formation of a granulation tissue beneath the inner layer of the periosteum. This shows little tendency to caseate, but on the other hand becomes ossified. Small tubercles are found in the early stages, but the process shows a great tendency to self-healing through the formation of bone (ossifying periostitis). As a result of such healing, exostoses or hyperostoses are formed. The writer believes that many of the so-called inflammatory local hyperplasias of bone are tuberculous in origin. In other cases the process may break through the periosteum and a tuberculous sinus or a "cold abscess" may be formed; or in some cases the bone becomes involved, and the clinical picture becomes that of a bone tuberculosis. Superficial caries may follow, either with or without the formation of deep foci. As in the case of gummatous periostitis, pseudo-cysts may be formed by the liquefaction of encapsulated caseous areas. The cyst wall may be bony. Secondary tuberculosis of the periosteum is very common in connection with bone or joint tuberculosis. *Aldred Scott Warthin.*

PERIOSTEUM, TUMORS OF.—The primary tumors of the periosteum belong wholly to the connective-tissue growths. They are both benign and malignant; the former, usually arising from the inner osteogenetic layer of the periosteum, are covered by its outer fibrous layer; the latter break through the fibrous layer and invade the neighboring tissues. Occasionally both benign and malignant forms may arise from the outer layer.

Benign Growths.—The *osteoma* is the most common benign growth of the periosteum, occurring usually as a circumscribed bony growth, termed an exostosis. The periosteal osteomata are classed by some writers under the general term *osteophyte*; but by others the latter term is used to indicate a very small bony growth of the periosteum. Larger, more diffuse periosteal osteomata are known as *hyperostoses*. A *circumscribed hyperostosis* differs from an exostosis in being less circumscribed and more superficial. According to their structure the periosteal osteomata may be classed as: *exostosis eburnea*, composed of hard compact bone without marrow spaces; *exostosis spongiosa*, composed of spongy bone about equally made up of bone tissue and marrow spaces; and *exostosis medullaris*, containing very large marrow spaces. The marrow in the exostoses presents the same general appearance as the bone marrow proper. According to histogenesis the periosteal exostoses may be divided into two classes: those arising from the connective-tissue of the periosteum (*exostosis fibrosa*), and those of cartilaginous origin (*exostosis cartilaginea*). The former may arise either from the inner or from the outer layer of the periosteum; in the first case they are immovable (*immovable periosteal exostosis*), in the latter they are movable (*movable periosteal exostosis*). The cartilaginous exostoses may arise from a proliferation of the periost-perichondrium, usually from the epiphyseal cartilages. They occur most frequently in young children and are usually multiple. In other cases cartilage may first form from the periosteum, and this may later develop into bone. Exostoses are found most frequently on the cranial bones, the bones of the trunk, and the long bones of the lower extremities. Many of them are not neoplasms strictly, but are hyperplasias of inflammatory origin.

Chondroma of the periosteum is of less frequent occurrence. It may develop from the inner layer (*immovable periosteal chondroma*) or from the outer layer (*movable periosteal chondroma*). The cartilage may be formed from pre-existing cartilage (*epiphyseal*), or from connective tissue, or from embryonal inclusions of cartilage *Anlage*. They occur most frequently upon the short bones of the extremities, the shoulder blades, the ribs, and the femur. They are very likely to undergo secondary changes: myxomatous degeneration, calcification, etc. They show a marked tendency toward malignancy. *Osteochondroma* of the periosteum sometimes occurs; and there is also a peculiar growth, the *osteoid chondroma*, which may reach an enormous size. It is found chiefly on the long bones of young individuals and shows a tendency to become malignant. The surface of the growth is usually smooth, the cut surface partly hyaline and transparent, partly lamellated and reticular.

Fibroma of the periosteum is rare. It occurs most frequently in the periosteum of the bones of the mouth and nose (fibroid epulis and fibroid polyps). Through excessive development of blood-vessels the growth may assume the character of a telangiectatic fibroma. It is also very likely to become calcified (*fibroma ossificans*) or to undergo myxomatous change. Malignant changes may develop.

Myxomata arise rarely from the periosteum. They are seldom pure myxomata, but present the appearance of myxochondroma, myxofibroma, myxosarcoma, etc. They form round or oval masses covered on the outside by a dense layer of fibrous tissue.

Lipomata of the periosteum are known as parosteal lipomata. They are very rare, and are nearly always congenital. They usually contain areas of striped muscle fibres. The exact nature of these growths is not yet known. They have been reported as occurring on the anterior surface of the cervical vertebræ, body of the pubis, frontal bone, scapula, etc.

Angiomata of the periosteum are very rare. They

Digitized by Microsoft®

have been observed on the cranium and sternum. An ectatic condition of the blood-vessels is very common in all of the tumors arising from the periosteum.

Pseudo-cysts may be formed beneath the periosteum as the result of the liquefaction of the contents of subperiosteal hæmatomata or of subperiosteal tubercles or gummata.

Sarcoma is the www.libtool.com.cn primary growths of the periosteum, and—next to the periosteal exostosis—of most frequent occurrence. It may occur at any age, but is more frequent in the young. The periosteal sarcomata may occur in any part of the skeleton, but are more frequently seen near the ends of the long bones, particularly of the lower extremities. They may be divided into the *hard* and the *soft* forms. The soft growths show a variegated surface, and usually contain areas of softening and extravasation; the firmer whitish portions of the growth may be homogeneous or fibrous. The harder growths are usually whitish, and present a more or less fibrous, radiating surface. As a rule, the growths are more or less nodular. Originating in the majority of cases from the inner layer of the periosteum, the growth assumes a more or less spindle shape and tends to surround the bone. Later, it breaks through the periosteum and invades the soft tissues adjacent.

Microscopically, the periosteal sarcomata represent nearly every form of sarcoma: round cell, spindle cell, polymorphous cell, giant cell, alveolar forms, fibro-sarcoma, osteosarcoma, osteoid sarcoma, chondrosarcoma, osteochondro sarcoma, myxosarcoma, angiosarcoma, and numerous combination forms. The most common variety is the spindle-cell form containing bone or osteoid tissue. The most cellular, and consequently the softest forms, are the most malignant. The malignancy of the different varieties varies somewhat with the location. The giant-cell epulis of the jaw is of relatively slight malignancy, but a growth of the same structure on the long bones is much more malignant. The hard fibrosarcoma, and the osteo-, chondro-, and osteoid sarcoma, often show relatively slow growth and but little tendency to set up metastases; but under certain conditions any one of these forms may take on an increased malignancy. Metastases of periosteal sarcomata usually appear first in the lungs, later in the lymph glands, and finally in any part of the body. The metastases are frequently of a softer and more cellular nature than the primary, but may develop bone or osteoid tissue or even cartilage.

As the result of the growth of the periosteal tumor the bone may become infiltrated and rarefied, and in some cases undergo spontaneous fracture; or in other cases there is set up, in the neighborhood of the tumor, an ossifying osteomyelitis which leads to the most marked sclerosis of the bone. New bone is very frequently formed in the sarcoma, particularly next to the old bone upon which the tumor rests, so that the latter seems to spring from an osseous base. In other cases trabeculæ or delicate spicules of bone may be formed in a radiating manner through the tumor mass, or irregular bony masses or spicules may be scattered through it (ossifying sarcoma or osteosarcoma). The degeneration of portions of the growth, as is commonly seen in the softer varieties, may lead to cyst formation, or to ulceration, abscess formation, or gangrene, as the result of secondary infection. Large hæmatomata may result from hemorrhage into the tumor. With the exception of the epulis and the hardest forms, sarcoma of the periosteum usually runs a malignant course. The growths show a great tendency to recur after operation, and as a rule they give rise to metastases.

Secondary tumors of the periosteum are not infrequent; both sarcoma and carcinoma may invade the periosteum from primary growths of neighboring structures. Secondary carcinoma is the more frequent. Caries and secondary involvement of the bone may result. An ossifying periostitis is almost always set up, so that the secondary tumors come to be more or less surrounded by newly formed bone, or contain irregular bony masses or spicules.

PERISTALSIS. See *Intestinal Movements.*

PERITONEUM. (ANATOMICAL.) See *Abdomen.*

PERITONEUM, NEW GROWTHS OF.—Primary tumors of the peritoneum are relatively rare; secondary involvement by malignant tumors, which are primary in some one of the abdominal or pelvic organs, is on the other hand of very frequent occurrence. Further, tumors which are primary in the retroperitoneal tissues are to be placed in a separate class from those which are primary in the tissues of the peritoneum proper, that is, which develop either from the endothelium or from its basement membrane.

Primary Peritoneal Growths.—The most important of the primary growths of the peritoneum is the *endothelioma,* often called *endothelioma carcinomatosum* or *endothelial cancer.* By some writers it is spoken of as *primary carcinoma* of the peritoneum, but the latter usage is confusing and should be avoided. The designation primary carcinoma of the peritoneum should be applied only to those rare carcinomata of the peritoneum which arise from the columnar epithelial cells of embryonal inclusions of intestinal *Anlage.* The primary *endothelioma* of the peritoneum forms multiple flat plaques or flattened nodules, which are more or less confluent or bound together by flattened cords or strands. Rarely the nodules may be larger and more elevated. About the larger plaques there are often seen numerous minute flattened nodules, solitary or becoming confluent into little groups. The color is usually white and the consistency soft; in some cases it is hard and firm (endothelioma fibrosum). The peritoneum about the plaques is more or less thickened. In many of the nodules a yellowish caseous centre is present, the appearances closely resembling small caseating tubercles. A serous or sero-fibrinous exudate, usually hemorrhagic, is often present in the early stages; in the advanced stages it is invariably so. Microscopically the flattened tumors are found to consist of a firm connective-tissue stroma enclosing cords and strands of cells, which are often low columnar, and arranged upon a basement membrane after the manner of gland cells; so that the tumor possesses a distinctly *tubular* character. In many of the tubule-like cords an apparent lumen may be seen. The surface endothelium is usually absent over the larger plaques and nodules, but over the small ones it may be greatly thickened, forming a layer consisting of many strata of cells. Simple necrosis and caseous necrosis are found throughout the larger growths, and occasionally there is a mucoid change. The vascular supply is usually rich. The cells of the tumor appear to rise both from the surface endothelium and from the endothelium of the lymph spaces and vessels (*endothelioma lymphangiomatosum*). The anastomosing cords and strands follow the lymphatics. Metastasis into the solid organs is rare; secondaries when found occur in the pleura, dura mater, or other serous membranes. The pleura may be involved by direct extension. The growth is identical in structure with the flat tubular endothelioma of the other serous membranes; and it should be borne in mind that the peritoneal growths may be the result of direct extension from the pleura or they may be metastatic. The writer has seen one case in which the peritoneum, pleura, and dura seemed equally involved; and the only apparent reason for assigning the primary origin to the peritoneum was the greater area involved in the case of this membrane.

Primary angiosarcoma of the peritoneum occurs very rarely. It may develop as a plexiform angiosarcoma, consisting of newly formed blood-vessels, whose walls proliferate and form cylindrical masses of cells. Myxomatous change is not infrequent in these growths (*myxoangiosarcoma*), and under such conditions the tumor may be mistaken for a colloid carcinoma. In other cases the sarcoma may show the structure of a *perithelioma.* Kaufmann describes a case in which the entire perito-

Digitized by Microsoft®

neum was covered with small warty or flattened nodules of grayish-red color and very vascular. Ascites was present, and the surface of the growths was covered with a thick fibrinous exudate.

Primary carcinoma of the peritoneum is of very rare occurrence. The cases observed have been of a cylindrical-cell variety, with mucoid change (colloid carcinoma), and the growth was diffused over the peritoneum. According to Birch-Hirschfeld the origin of these growths is from the epithelium of embryonal "rests" of intestinal *Anlage*.

Primary benign tumors of the peritoneum are rare. *Lipoma, fibroma, myxoma*, and *chylangioma* have been observed. The lipomata arise chiefly as tumor-like hyperplasias of the epiploic appendices or from the omentum. The cases of fibromata and myxomata reported as arising in the peritoneum are of somewhat doubtful nature. Inflammatory hyperplasias of connective tissue may have been mistaken for neoplasms. The majority of the benign growths undoubtedly arise in the retroperitoneal tissues. Polypoid lipomata of the peritoneum may become freed through tearing of their pedicles; as free bodies they are likely to become calcified.

Mesenterial cysts (*chyle cysts, cystic lymphangiomata*) are of rare occurrence. They have been observed in children. They form bladder-like, thin-walled cysts, which often reach a large size, holding several litres of fluid. The intestines may be adherent to the anterior surface of the cyst, and thus give rise to percussion signs of an area of tympanitic dulness passing over an area of absolute dulness.

Decidua-like proliferations of the peritoneum occur during pregnancy. They are usually confined to the pelvis, but may spread over a larger part of the peritoneum. After delivery they undergo resolution and become calcified.

Secondary Growths.—Secondary carcinoma of the peritoneum is of very frequent occurrence. The primary is most often located in the stomach, pancreas, gall-bladder, intestine, testis, ovary, or uterus. The peritoneum may be involved *by contiguity, by continuity*, or *by metastasis*. In the latter case a *dissemination* or *implantation metastasis* may occur over the entire peritoneum; the deeper parts, the pelvis, flanks, and root of mesentery, showing the most extensive growth. The dissemination of the growth is aided by the accompanying ascites, which is often very great. This may be secondary to the development of the carcinoma, or it may occur before the latter. It is usually hemorrhagic in character. In some cases the development of the peritoneal secondaries is very rapid, partaking of the nature of an inflammatory process, and giving the clinical picture of a peritonitis (*peritonitis carcinomatosa*); or in other cases the secondaries may form scattered or confluent nodules (*carcinosis peritonei*). In the latter case ascites may or may not be present; in the former it is always present to a greater or less extent. The nodular and the diffuse forms pass into each other without sharply defining lines.

The general characteristics of secondary carcinoma of the peritoneum depend upon the nature of the primary growth. *Adenocarcinoma* forms usually nodular peritoneal metastases; they are chiefly located on the under surface of the diaphragm, in the flanks, pelvis, and omentum. The nodules are white, soft, often showing mucoid change. The arrangement along the lymphatics is often very striking. Confluence of the nodules gives rise to flattened warty masses. *Medullary* carcinoma forms soft nodules of large size, showing necrosis, umbilication, hemorrhage, etc. The metastases of this variety into the peritoneum are less common than are those of the other forms. *Scirrhous* carcinoma forms a diffuse fibroid thickening of the entire peritoneum, accompanied by peritonitis which often covers up the appearances belonging to the new growth. The small intestines may be contracted into a hard mass not larger than the fist. The appearances are those of a chronic fibroid peritonitis rather than of a new growth, and the condition is often mistaken for the same. On section the thickened serosa is hyaline, hard, and tendon-like. In all cases in which such fibroid change of the peritoneum is found, the lymph glands should be carefully examined for metastases, secondary scirrhus being more easily recognized in the lymph glands than in other structures. The pylorus, gall-bladder, and prostate should be thoroughly examined for the primary, which may be of insignificant size. The diffuse *mucoid* or *colloid carcinoma*, which is usually primary in the stomach, gall-bladder, or testis, produces very marked and characteristic appearances in the peritoneal cavity—particularly in the omentum and in the neighborhood of the stomach. The entire peritoneum may be infiltrated. The serosa, in particular of the omentum, is greatly thickened, covered with glassy, translucent, yellowish or yellowish-red masses containing mucin. The omentum may be changed into a thick, homogeneous mass, through which run strands and fibres of connective tissue enclosing the colloid substance (honeycomb appearance). The smaller, younger nodules may be white, opaque, and firmer. The *cystocarcinoma* of the ovary or testis may give rise to extensive peritoneal metastases, the entire surface of the membrane being sometimes composed of cysts filled with a mucoid substance. The peritoneal cavity may become entirely filled with a colloid-like mass. Psammocarcinoma of the ovary may give rise to peritoneal metastases, containing calcareous masses.

Secondary Sarcoma of the peritoneum is more rare; melanotic sarcoma, myxosarcoma, lymphosarcoma, osteosarcoma, chondrosarcoma, spindle-cell sarcoma, and angiosarcoma have been reported.

Primary cystadenoma of the ovary may give rise to implantation metastases or may involve the peritoneum by continuity, spreading first over the broad ligament and then over the peritoneum. In the case of the papilliferous cystadenoma or surface papilloma of the ovary, portions of papillæ may be broken off and transported by gravity, peristalsis, or movement of ascitic fluid, and may develop over the peritoneum, wherever they may lodge. Rupture of an ovarian cystadenoma may lead to the covering of the peritoneum with mucoid or colloid material, which, becoming partially organized, gives rise to the condition known as *pseudomyxoma peritonei*. This is not of the nature of a neoplasm, but represents a reaction on the part of the peritoneum, tending to organize the foreign substance spread over its surface. If in the colloid or mucoid substance living epithelium or portions of papillæ are transported, these may grow and form benign growths which later may become malignant. As a rule, such transported epithelium usually dies or forms small cysts which remain stationary after reaching a certain size.

Transplantation Metastasis.—In puncture for the relief of ascites or in operations for the removal of malignant tumors, abdominal metastases may be set up in the puncture or in the seat of surgical wounds (*inoculation metastases*).

Dermoid cysts and *teratomata* occur in the peritoneum of the pelvis, in the mesentery, and in the omentum. In the latter case a primary tumor of the ovary may become adherent to the omentum and later lose its connection with the former organ.

Pseudo-cysts arise from collections of exudate between peritoneal adhesions.

Primary retroperitoneal tumors are much more frequent than those primary in the peritoneum. *Lipomata* of large size (sixty-three pounds) have been reported. They may be mistaken for ovarian cysts. It is important to note that the retroperitoneal lipoma forms an elastic, fluctuating tumor, from which on aspiration no fluid can be drawn (pseudo-fluctuation). *Myxolipoma, fibroma, myxoma, fibrosarcoma, myxosarcoma*, and *angiosarcoma* of the retroperitoneal region have been described. The writer has seen a round-cell sarcoma, apparently primary in the retroperitoneal tissue, weighing eighty pounds. The retroperitoneal organs were not directly involved and showed only changes due to pressure. Secondary ma-

Digitized by Microsoft®

lignant tumors in the retroperitoneal lymph glands are of frequent occurrence in carcinoma of the uterus, etc. (See also *Omentum.*) *Aldred Scott Warthin.*

PERITONEUM, SURGICAL AFFECTIONS OF.—The anatomy and physiology of the peritoneum are discussed under the heading *Abdomen* (*Anatomical*). The pathology of acute and tuberculous inflammation will be found in the article on *Peritonitis, Septic and Tuberculous*, in THE APPENDIX. Under the heading *Diaphragm* will be found a description of subphrenic abscess and its treatment, while additional information in regard to the peritoneum may be found in the articles entitled *Abdomen* (*Surgical*); *Abdominal Tumors*; *Appendicitis*; and in the article immediately preceding this. In the present article the surgical treatment of lesions of the peritoneum is briefly given.

Acute traumatism of the peritoneum is of little significance apart from traumatism of the organ which the peritoneum covers. The effect of direct injury to the peritoneum is often the formation of adhesions between opposed peritoneal surfaces. A familiar illustration of this is seen in umbilical and inguinal herniæ. Such adhesions will produce slight or serious symptoms, according to their situation and extent. If the attachments are between unimportant organs (for instance, between the omentum and the parietal peritoneum), occasional discomfort may be the only result. If more sensitive organs are involved (for example, the stomach or the intestine) the pain suffered may be very great and the function of the affected organ may be seriously interfered with. Furthermore, such adhesions in the form of bands are a not infrequent cause of intestinal obstruction.

Adhesions due to a single traumatism or to an acute attack of inflammation tend to atrophy, and in the course of time they may completely disappear. Thus the scar of a laparotomy may for a time be attached to visceral peritoneum, while at a second laparotomy performed some months afterward it may be found entirely free. Adhesions are due to a loss of peritoneum resulting from traumatism or inflammation. If, therefore, raw surfaces can be avoided at operation, resulting adhesions will be reduced to a minimum. This can be accomplished in several ways. The peritoneum can be sutured over the pedicles of tumors and over fresh wounds. Or, if the peritoneum in the vicinity is not sufficient for the purpose, the omentum may be used to cover the raw surface by stitching it in place; or grafts may be cut from the omentum and stitched over the raw surface; or, finally, sterile peritoneum from the ox may be stitched over the raw surface. This method has been recently advocated by Morris, who has given the name "cargile membrane" to artificial peritoneum of this sort.

For clinical and therapeutic purposes acute inflammation of the peritoneum is best divided into circumscribed and diffused, or general peritonitis. If the circumscribed peritonitis is not purulent, it may be treated by rest, external cold, etc., unless the organ from which it springs requires more radical treatment—for example, circumscribed peritonitis due to threatened perforation of the appendix. If the circumscribed peritonitis is purulent, such symptomatic treatment is dangerous, since no one can say how soon the inflammation may break through the fibrinous adhesions which circumscribe it and spread to other parts of the peritoneum. Therefore it should be relieved by incision and drainage.

The prognosis and treatment of diffuse or general peritonitis are in a most unsatisfactory state, partly on account of the difference of opinion as to what constitutes a diffuse peritonitis, and partly because of the difficulty of determining, even when the abdomen is open, how extensively the peritoneum is inflamed. Some surgeons would limit the term general peritonitis to those cases in which every portion of the peritoneal cavity is involved in the inflammation. Such a widespread inflammation rarely occurs, and is perhaps never recovered from. It seems better, therefore, to use the term diffuse or general peritonitis as indicating inflammation, not limited by well-marked adhesions, having a tendency to extend and sufficiently widespread to make the general symptoms much more prominent than the local ones. Such general symptoms usually become prominent when the inflammation extends to the peritoneum covering the small intestine. Thus peritonitis may exist for a long time in the pelvis, or in the lesser peritoneal cavity without giving rise to the well-known symptoms of general peritonitis. There are also many cases of appendicitis in which, if operation is performed early, the appendix is found not shut away from the general peritoneal cavity. To describe such a case as one of general peritonitis, merely because the surrounding coils of intestine are more or less covered with a fibrinous exudate which has not had time to mat them firmly together, is entirely misleading, and yet this is frequently done by writers who have reported cures of general peritonitis. It is therefore impossible to state the prognosis in a given case or a hundred cases of true diffuse peritonitis other than to say that the prognosis is bad. But it is by no means hopeless.

Unfortunately, the ideas of treatment of diffuse peritonitis are widely at variance, so that one can do no more than to state the different methods by which responsible surgeons believe that they have saved their patients. If diffuse peritonitis is threatened, though not well established, the action of the intestine can be stimulated by the use of cathartics or stopped by opiates, while the rectum and perhaps the colon can be emptied by injections of water, salt solution, soap-suds, oil, etc. Some surgeons employ opiates to decrease peristaltic action, on the ground that peristalsis tends to spread the inflammation; while others claim that the salvation of the patient depends upon increased peristalsis, which will increase the resorptive power of the peritoneum. To decide between these two plans of action is particularly difficult, because no one can say whether a threatened diffuse peritonitis would or would not have spread and killed the patient had the treatment been of a different character. When the inflammation has extended to the peritoneum covering the small intestine, the intestine is paralyzed, and cathartics have no effect, and there is certainly no indication for the use of opium.

In considering the operative treatment of diffuse peritonitis it will be well to take up the steps in the operation one at a time, since there is no general agreement in regard to any one of them. Some surgeons advocate a single incision and some multiple incisions, the latter in the hope of obtaining a more thorough drainage. At any rate, the incision or incisions should permit the surgeon to inspect and cleanse so much of the peritoneal cavity as may be involved in the inflammation.

The second step in the operation is the cleansing of the affected peritoneum from pus, fibrin, and foreign materials, fæces, etc., if such be present. This may be done by irrigation with sterile hot one-per-cent. salt solution or by wiping the peritoneum with gauze compresses wrung out of such solution, or with dry compresses. If irrigation is employed, it should be abundant, so that the abdominal cavity may be quickly flushed. Some surgeons bring the small intestine out of the abdominal wound and others omit this step, which is spoken of as evisceration. The object of cleansing is to remove in the shortest possible time and with the least possible loss of heat the greater portion of the infectious exudate. How best to accomplish this with the least injury to the peritoneum is a question to be settled by the individual surgeon. Probably moist gauze is less irritating to the peritoneum than dry gauze.

If irrigation is employed the fluid which remains after cleansing may be sponged out, or it may be left in place. Some surgeons fill the abdomen with salt solution and close the abdominal wound, claiming that the dilution of the infectious material and the increased resorption from the peritoneum thereby produced are of the greatest benefit to the patient.

If the intestine is greatly distended with gas, some

Digitized by Microsoft®

surgeons empty it by puncture or by one or more short incisions. Such openings are forthwith closed by Lembert sutures. Others take advantage of the operation to inject into the lumen of the small intestine an ounce or more of saturated solution of sulphate of magnesia, believing that the strong peristaltic action which often follows will markedly benefit the patient.

Those who leave fluid in the abdominal cavity suture the wound without drainage. The patient is then placed in bed with the hips elevated so that the diaphragmatic portion of the peritoneum in which the lymphatic circulation is the most active shall be the most dependent portion. Others pass gauze or glass or rubber drains in various directions, either through the chief abdominal wound or through other wounds made especially for drainage in the lumbar and iliac regions, or into the vagina, or even into the rectum in case of pelvic suppuration. Mikulicz's handkerchief drain may also be used. [See *Abdomen. (Surgical).*] Rehn recommends that a tube be passed through the mesentery of the small intestine and allowed to emerge in either loin, so that irrigation may frequently be made through it.

After-treatment consists in the application of heat externally and within the rectum, the subcutaneous injection of cardiac stimulants if necessary, and the subcutaneous or intravenous injection of salt solution; the object of all of these procedures being to combat shock. If the patient is troubled with vomiting, the stomach should be washed out. No opium should be given, and only so much morphine subcutaneously as is absolutely necessary to control pain.

Tuberculosis of the peritoneum may be accompanied by an abundant serous exudate or it may give rise to a fibrinous exudate with adhesions and contractions, or it may assume an ulcerative form.

The prognosis is in general an unfavorable one, although many cures have been reported as the result of both internal and surgical treatment. Recovery is more likely to follow operation when the disease is present in the serous form; but even in such cases one should be careful not to mistake a temporary improvement after operation for a permanent cure. As far as is known Spencer Wells was the first to open the abdomen of a patient having tuberculosis. He did so through a mistake in diagnosis. The patient recovered. Since then many surgeons have operated intentionally, and the good results have been variously attributed to the entrance of light or air, to the mechanical irritation of the peritoneum, or to a simple escape of the serous exudate. A more careful examination of the results of operation makes it doubtful whether such an exploratory laparotomy has any great therapeutic effect. It seems more probable that most of the patients who have recovered after such a laparotomy would have recovered without it, while operation has often a distinctly bad effect upon a patient whose tuberculous peritonitis is associated with fever. The abdomen is usually opened by a three- or four-inch incision in the median line. The fluid which is present is allowed to escape and is carefully sponged out and the various peritoneal pouches may or may not be dusted with powdered iodoform. The abdominal wound is closed by suture, or a drain may be left in its lower angle for a week or more. The shock of such an operation is naturally slight and most patients rapidly recover. A certain amount of fluid quickly appears, but may be resorbed. If it is not, a second operation may be performed. Such a quick recovery from operation may be looked for in the serous and fibrinous forms of the disease, while operation performed upon a patient suffering from purulent or suppurative tuberculous peritonitis will very likely be followed by intestinal fistula and death. Of course, if a focus for the disease is found in some organ which can be safely sacrificed it should be removed. An accompanying disseminated serous tuberculosis will probably be cured if its original focus is removed. But, as stated above, many patients who appear cured at first afterward suffer from a recurrence of the disease or die from tuberculosis in some other organ. However, as the risk of operation is so slight, it seems justifiable in these cases even if it is a mere aid to the natural forces of the body in their effort to overcome the disease.

Benign tumors of the peritoneum, or, strictly speaking, of the subserous tissue, are fibroma, lipoma, and myxoma. Such tumors usually develop in the root of the mesentery, in the mesocolon, or in the omentum, and are described under the headings *Omentum* and *Retroperitoneal Tumors.* In the mesentery are also found serous, chylous, and hemorrhagic cysts as well as congenital dermoid and teratoid cysts. Echinococcus cysts are found in the peritoneal cavity, where they develop after the rupture of some primary cyst of the liver or other organ. Actinomycosis, starting usually from the cæcum, may produce in the peritoneum inflammatory swellings, some of which will contain the characteristic pus of this disease.

The treatment for benign tumors is their radical removal. This also applies to echinococcus cysts when they are so situated as to make removal feasible. If they are not removable, they should be drained externally. Actinomycosis should be treated by removal, if possible, but, if this is not practicable, by curetting, cauterization and drainage, and by the internal administration of iodide of potassium.

Malignant tumors of the peritoneum are secondary to malignant disease of some abdominal organ. Under such circumstances hundreds of metastatic nodules may be scattered over the peritoneum. There is generally a sero-hemorrhagic exudate. Such a condition is of course inoperable and the abdomen should be closed at once. A metastatic nodule in the peritoneum may be excised for microscopical diagnosis and the wound closed by one or two stitches. Thus one avoids the risk of troublesome hemorrhage which may follow excision of a portion of the primary growth.

Plastic operations upon the peritoneum for the sake of covering raw surfaces have been spoken of above and are also described under the heading *Omentum,* for it is the omental peritoneum which is usually employed for grafting.

Edward Milton Foote.

PERITONITIS, SEPTIC AND TUBERCULOUS. See THE APPENDIX.

PERITYPHLITIS. See *Appendicitis.*

PERONINE—benzyl-morphine hydrochloride, C_6H_5-$CH_2.O.OH.C_{17}H_{17}NO\ HCl$—is an odorless, bitter, white powder, composed of prismatic crystals and having the nature of an alkaloid. It is soluble less than one per cent. in cold water and in ten parts of boiling water, and is nearly insoluble in alcohol and chloroform. It is closely related to codeine, dionine, heroin, and morphine.

For the treatment of the cough of tuberculosis, Schroeder, who was the first to study this drug, considered it intermediate in value between codeine and morphine. His report, however, covers only twelve cases, in two of which it produced sweating and difficult expectoration, and in two others of which it failed to influence the cough. Nowak, in eighteen cases, found the cough less frequent and intense, but dry, and expectoration more difficult. At times there were burning in the bronchi and copious perspiration. Munk reports good effects on cough even after morphine and codeine had proved inefficient. He also found peronine calmative to an epileptic who suffered from frequent attacks of frenzy. All the writers agree that there is no habit formation. Mayor found it to be three times as toxic to rabbits and guinea-pigs as is codeine, and believes its cardio-depressant effects too pronounced to permit its use in medicine. Other writers, however, report no unpleasant effect on cardiac, respiratory, or digestive functions.

Besides its antitussive action, peronine is slightly analgesic and hypnotic. It is employed in tuberculosis, whooping-cough, emphysema, bronchitis, and similar affections in doses of 0.02–0.05 gm (gr. $\frac{1}{3}$–$\frac{5}{6}$). Schroeder

Digitized by Microsoft®

had no untoward effect from 0.08 gm. (gr. 1¼), though nausea and constipation followed larger doses.

W. A. Bastedo.

PERRY SPRINGS.—Pike County, Illinois. Two hotels, capacity 350.

ACCESS.—Viâ Wabash Railroad to Griggsville or Perry station, thence by hack nine and six miles, respectively; also from St. Louis viâ Illinois River to Naples, seven miles distant, where steamers land daily.

www.libtool.com.cn

This attractive health and pleasure resort is located among some hills on the west bank of the Illinois River. The surrounding country is covered by luxuriant forests and intersected by numerous deep ravines, narrow valleys, and clear, winding streams. The extreme temperature ranges are 100° F. in summer to −20° F. in winter. The climate is moderately dry and clear most of the time. The springs are three in number, and are located about two hundred yards from one another. The temperature of the water ranges from 50° F. in summer to 48° F. in winter. The water from the iron spring is supplied, hot or cold, to fourteen bath-rooms. The following table contains the analyses of the three springs, as furnished by Dr. Engleman, No. 1 being the iron, No. 2 the magnesia, and No. 3 the sulphur springs:

ONE UNITED STATES GALLON CONTAINS:

Solids.	No. 1. Grains.	No. 2. Grains.	No. 3. Grains.
Calcium bicarbonate	15.89	19.75	19.66
Magnesium bicarbonate	17.01	14.81	10.49
Iron bicarbonate	.55	.40	.27
Aluminum silicate	......	......	.27
Potassium and sodium silicate	2.64	2.28	3.45
Sodium silicate (salt)	0.12	.38	.58
Sodium sulphate	.44	1.10	1.49
Potassium carbonate	1.59	1.45	1.46
Total	38.24	40.17	37.67

No organic matter.

The waters are said to be of considerable efficacy in stomach, liver, and kidney troubles.

James K. Crook.

PERSIMMON.—*Diospyros.* Under the name persimmon, both the bark and the unripe fruit (chiefly the latter) of *Diospyros Virginiana* L. (fam. *Ebenaceæ*) are considerably employed as astringents, particularly in the southern United States. The bark looks not unlike oak bark with the corky layer still upon it. The fruit in the unripe condition is green, drying dark brown, of globose form, and nearly an inch in diameter. It contains several flattened oval or ovoid seeds. Before maturity the persimmon is one of the most astringent of substances, but after thoroughly maturing, and especially after being attacked by frost, this astringency is mostly lost and it becomes sweet and edible. The only important constituent of both drugs is the tannin, and their uses are purely astringent, similar to those of geranium, sumac, etc. The common method of employment in the household is in the form of an infusion or decoction; only the fluid extract is employed by the medical profession. The dose of either the bark or the fruit should amount to 2, 4, or even 8 gm. (ʒ ss. to ʒ i. or ij.).

Henry H. Rusby.

PERSODINE. See *Persulphates.*

PERSPIRATION. See *Skin, Functions of.*

PERSULPHATES.—The alkaline persulphates have recently come into notice because of their excessive content of oxygen and the ease with which this is liberated. Their action may be likened to that of hydrogen dioxide. A five per cent. solution of *sodium persulphate* kills most bacteria, and a half-per-cent. solution will check their development. The fatal dose for a rabbit (*Bull. gén. de Thérap.*) is 0.4 gm. per kilogram of body weight, and for a dog 0.75–1.0 gm. per kilogram.

In three- to five-per-cent. solution it constitutes a good wet dressing for lupus and ulcers (Kionka). Internally, it acts as an antipyretic in fever, and is said to improve the appetite and digestion in tuberculosis, anæmia, neurasthenia, etc. The dose of sodium persulphate is 0.1 gm. (gr. iss.), or from one to two teaspoonfuls of *persodine*, which is a 12 to 1,000 aqueous solution of the sodium salt.

Ammonium persulphate is useful as a test for albumin or indican in urine. In the presence of albumin a ten-per-cent. aqueous solution forms a turbid, grayish zone at the line of contact.

In testing for indican a crystal of ammonium persulphate is added to a mixture of equal parts of hydrochloric acid and urine. On shaking this with chloroform, the latter on settling forms a blue layer if indican is present.

W. A. Bastedo.

PERUSCABIN, benzoic acid benzyl ester, is an artificial product representing the active constituents of balsam of Peru. It is odorless, non-staining, and non-irritating, and is highly recommended by R. Sachs for the treatment of scabies. Diluted with three parts of castor oil, it is applied over the whole surface every twelve hours. The cure is absolute, and no irritation whatever is produced, even in an area affected with eczema or dermatitis.

W. A. Bastedo.

PES GIGAS.—Pes gigas, or macropodia, is the name given to a condition of congenital hypertrophy affecting

FIG. 3802.—Pes Gigas. (From *Journal of Tropical Medicine*, 1903.)

either the foot alone (whence the name) or the leg and the foot. It may be unilateral or bilateral, the former being the more common; the left side is more often affected than the right. Pes gigas is found in two forms:

Digitized by Microsoft®

(1) a form in which the hypertrophy is *true* or *symmetrical;* here the whole foot, or leg and foot, suffer a general hypertrophy, the symmetry and contour of the part being observed, and the only abnormality being the enormous size. (2) The *false* or *asymmetrical form*, in which only certain parts are affected; this is the more common variety, and generally shows itself in enormous development of one or two toes, or in large fatty excrescences, or in hypertrophy of some of the muscles of the calf of the leg. (See Fig. 3802.) The cause of pes gigas is unknown.

www.libtool.com.cn

The skin is always involved, and, in addition to the hypertrophic condition, the cutaneous sensibility may be absent or diminished; it is never increased. In hypertrophy of the toes the nails generally enlarge *pari passu* with the other parts. The subcutaneous fat is increased in amount and is apt to be irregularly disposed in lumps. When the toes are affected the metatarsal and phalangeal bones are always enlarged; but this enlargement is general, and the only deformity noted is an outgrowth at the extremity of the bone, at the junction with the articular cartilage. The condition of the joints involved is variable; sometimes the motion is normal, sometimes it is limited, and sometimes there is complete ankylosis. Passive mobility may or may not be elicited; the ligaments are thickened.

The *treatment* is not satisfactory. (1) *Pressure* in various forms has been recommended; but, besides being tedious in its application, uncertain in its effects, and decidedly painful, it is not free from danger; and hemorrhage, ulceration, and erysipelas have ensued from this method of treatment. (2) *Ligature of the main artery* has also been suggested; but this method, too, has not been characterized by brilliant results. (3) *Amputation of colossal toes* and judicious trimming of superfluous tissue will give a presentable and serviceable extremity. This is probably the best procedure. *R. J. E. Scott.*

Anderson: St. Thomas' Hosp. Rep., N. S., 1882, vol. xi.
Jacobson: Article "Pes Gigas," in Heath's Dict. of Practical Surgery.

PETECHIÆ.—These are small, round, blue-red or purple spots or points in the skin, or in the serous or mucous membranes, that cannot be made to disappear by pressure. They are usually not elevated above the surface. They are caused by minute extravasations of blood into the subepithelial or subserous tissue. They arise for the greater part through diapedesis, and occur chiefly, though not exclusively, on the dependent portions of the body, particularly over the legs. They are often localized in the hair follicles. In the serous membranes they are found most often in the posterior wall of the pleural cavity, and on the posterior portion of the epicardium and pericardium. In the mucous membranes they occur most frequently in the conjunctivæ and mouth, but may be found in any part of the body. According to their etiology petechiæ may be classed as *traumatic, infectious, toxic,* and *neuropathic.*

Petechiæ may be produced by the bites of fleas (*purpura pulicosa*). These may be mistaken for purpura or other hemorrhagic diseases. They may be distinguished from the latter by the fact that the puncture caused by the flea shows as a darker point in the centre of the spot, and by their greater abundance over the trunk. Localized petechiæ may occur also as the direct result of certain forms of trauma, and may be of medico-legal importance in the establishment of the occurrence of trauma.

Petechiæ occur also in the course of many of the acute infections: *scarlet fever, variola, diphtheria, endocarditis, plague, yellow fever, cholera, anthrax, septicæmia, measles, typhus fever, rheumatism, typhoid, acute yellow atrophy, etc.* The cases in which such hemorrhages occur are usually more severe than the non-hemorrhagic ones. The different forms of the primary purpuras are also characterized by the occurrence of petechiæ in the skin and mucous membranes: *purpura simplex, purpura rheumatica, morbus maculosus Werlhofii,* and *Barlow's disease.* In the last-named, innumerable minute hemorrhages may occur throughout all of the internal organs. In *scurvy* petechiæ occur in the skin, in the mucous membranes, and in the pleura, pericardium, endocardium, and peritoneum. It is very probable that the purpuras are infectious diseases, in part caused by the streptococcus, in part by bacteria not yet recognized.

Petechiæ may result also from a lowered nutrition of the vessel walls, as in *starvation, pernicious anæmia, leukæmia, cachexia of malignancy,* etc. It is very probable that in these conditions there is an intoxication which is the chief factor in causing the changes in the capillary walls. Petechiæ occur also in *icterus, nephritis,* poisoning with *bromine, iodine, phosphorus, arsenic, snake-venom,* etc. Petechiæ have also been observed to follow the use of *quinine.*

In chronic passive congestion of marked degree petechiæ may be formed in the body surfaces and also in the internal organs.

Petechiæ may arise as the result of excessive emotion, or during the hysterical or hypnotic state (stigmatization).

As diagnostic and prognostic aids petechiæ are of great significance. The size, location, conditions of occurrence, etc., are all very important factors.

Aldred Scott Warthin.

PETRIFACTION.—The deposition, in the tissues, of solid, crystalline, amorphous, or granular salts of lime, magnesium, or uric acid is known as *petrifaction* or *petrifying infiltration.* When the deposit consists of lime salts or of a combination of salts of lime and magnesium, the process is usually spoken of as *calcification* or *calcareous infiltration.* A physiological calcification takes place during the process of ossification of the skeleton; in this case the deposit of lime in osteoid tissue is an essential step in the development of a new tissue. All other deposits of lime salts within the body tissues must be regarded as being of a pathological nature.

With the exception of the new formation of bone in the repair of fractures and in tumors, calcification is essentially a retrograde change, the precipitation of the phosphates and carbonates of lime and magnesium occurring only in degenerating, dying, or dead tissues. In old age a deposit of lime salts occurs in the walls of the arteries, in the costal and laryngeal cartilages, in the walls of the capillaries of the lungs, stomach wall, and kidneys. This phenomenon is explained as due to an excess of lime salts in the blood, resulting from an excessive absorption of lime salts from the bones. Preceding the deposit of lime salts there occur certain retrograde changes characteristic of old age—hyaline change of the blood-vessel walls, etc. This calcification of old age is of such common occurrence as to warrant its being regarded as physiological. The resorption of lime salts from one tissue and their deposit in another is known as *metastatic calcification.* Calcification of the mature placenta is also of such frequent occurrence as to be regarded as physiological. The presence of brain sand in the choroid plexus and pineal gland is so universal that this may also be included under the head of physiological.

Calcification occurs most frequently as a sequel to fatty degeneration, hyaline change, cloudy swelling, simple or caseous necrosis. It is found in sclerotic vessels, endocardial thickenings, hyaline thickenings of dura, peritoneum, pleura, and pericardium, in the interstitial tissue of hyaline goitre, in corpora fibrosa of the ovary, old tubercles, gummata, old abscess cavities, inflammatory exudates, and in thrombi (arterioliths or phleboliths). A deposit of lime salts may occur in anæmic or hemorrhagic infarcts, focal necroses, in dead ganglion cells, in encysted trichina, and in the necrotic areas of tumors. It occurs also in osteoid and hyaline connective tissue of tumors, and in psammomata. The connective-tissue stroma of both carcinomata and sarcomata not infrequently shows calcification (*sarcoma* and *carcinoma petrificans*). Myofibromata of the uterus very frequently

Digitized by Microsoft®

show a greater or less degree of calcification. Lime salts are also deposited in the dead fat cells in cases of fat necrosis. Calcification of the renal epithelium follows the cloudy swelling produced by such poisons as mercuric chloride, carbolic acid, bismuth, aloin, etc. Retained decidua or chorion, or portions of the dead fœtus and its membranes, may become calcified (lithocelyphopaedion), or the sac may rupture and the fœtus escape into the peritoneal cavity, later becoming calcified (lithopædion). In diseases of the bones characterized by a resorption of the lime salts, the latter may be deposited in other tissues of the body.

www.libtool.com.cn

Calcified tissues are hard and white and sharply outlined; the area affected may be large or small. The lime salts may be dissolved out by the action of acids, in the case of carbonates with the formation of carbonic acid. Microscopically, deposits of carbonates or phosphates stain deep blue or violet with hæmatoxylin.

A deposit of uric-acid salts occurs particularly in gout. The gouty deposits consist chiefly of sodium urate with small amounts of carbonate and phosphate of lime. The tendon sheaths, synovial membranes, ligaments, articular cartilages, kidneys, skin, and subcutaneous tissues are chiefly affected, but the deposits may ultimately be found in nearly every organ of the body. The larger deposits, called *tophi*, form large rounded masses, of a white, plaster-like substance, which are found particularly in the joints and tendons.

The individuals exhibited in museums as "petrifying" or "ossifying," are either cases of myositis ossificans or of scleroderma.

Petrifaction of the tissues of the body after death may occur under certain conditions, but is probably very rare. The majority of cases reported as such are in reality examples of adipocere formation. Very little is known with certainty regarding the petrifaction of the cadaver. Petrified or fossilized bones of the human race are very rare. Such have been reported to have been found in caves and in bog deposits whose waters were impregnated with iron and lime. In old bones there may sometimes occur a crystalline arrangement of phosphate of lime, or the bony structure may become so impregnated with mineral elements that its color and consistency become greatly changed. It is very probable, however, that a complete replacement of the elements of the bone or of the body tissues with mineral constituents is of very rare occurrence. (See also *Calcification*.)

Aldred Scott Warthin.

PETROLATUM.—The word *petrolatum* stands, both in Latin and in English, as the official title in the United States Pharmacopœia for an unctuous derivate of petroleum, obtained by distilling off the lighter and more volatile constituents of the oil and purifying the residue. Three grades of petrolatum are official, the difference being in consistence only. They are entitled, severally, *Petrolatum Liquidum*, Liquid Petrolatum; *Petrolatum Molle*, Soft Petrolatum; and *Petrolatum Spissum*, Hard Petrolatum. The first of these grades is of the consistence of oil; the second is soft, like lard, and corresponds to the well-known proprietary substances *vaseline* and *cosmoline*; and the third is hard, like cerate. When the word "petrolatum," without modification, is used in prescription, "soft" petrolatum is dispensed. Petrolatum consists principally of a mixture of paraffins (hydrocarbons of the formula C_nH_{2n+2}), but probably also contains some olefins (hydrocarbons of the formula C_nH_{2n}), which, by their softer consistence, tend to increase the unctuousness of petrolatum. Petrolatum is a whitish or yellowish material, more or less fluorescent, tasteless, and with no odor, except when heated when a faint odor of petroleum is perceptible. It is entirely amorphous, and, in fluid condition, makes a transparent liquid. It is neutral in reaction. It is insoluble in water; scarcely soluble in alcohol, or in cold absolute alcohol; but soluble in boiling absolute alcohol, and readily soluble in ether, chloroform, disulphide of carbon, oil of turpentine, benzin, benzol, and in fixed or volatile oils. When heated on platinum foil, it is completely volatilized without emitting the acrid vapors of burning fat or resin.

Petrolatum owes its medicinal value to its combining with the physical attributes of the semi-solid fats the chemical peculiarity of the paraffins, of being practically unalterable and indifferent to chemical agents. Petrolatum neither hardens nor turns rancid by exposure, and can be treated with any chemical likely to be prescribed medicinally in an ointment without being itself attacked thereby. The substance is therefore available, either by itself as a simple unguent, perfectly bland and changeless, or as the fatty basis for medicated ointments.

Edward Curtis.

PETROSULFOL is a sulphur-containing bituminous product closely resembling ichthyol, but with a less disagreeable odor. It is miscible with water or oil, and is used as a general succedaneum for ichthyol.

W. A. Bastedo.

PHAGOCYTOSIS.—Phagocytosis is the term applied to the ingestion of solids by living cells. That leucocytes were capable of taking up inert particles when introduced into the animal body or even when mixed with the freshly drawn blood of such animals as the newt had long been known, when Haeckel pointed out the similarity between such processes and the engulfing of food particles by unicellular organisms. Roser went further in suggesting that resistance to infection by bacteria and other living irritants was due to the phagocytic properties of the cells of immune animals.

It is to Metchnikoff and his followers, however, that we are indebted for much of our knowledge concerning this particular physiological function of cells. In his researches on the comparative pathology of inflammation phagocytosis in many types of organisms was studied and the capacity of their cells for dealing with various solid particles determined.

It does not lie within the scope of this article, however, to give *in extenso* the opinions held by Metchnikoff and others relative to immunity excepting in so far as they bear upon the mechanism of phagocytosis, the factors which influence it, the fate of the matters enclosed by cells, and the value of the process as illustrated in the life histories of organisms.

The Mechanism of Phagocytosis.—Before the ingestion of solid particles by cells is possible the two must be brought together. In the case both of the amœboid unicellular organisms and of the wandering cells of the higher animals, this is brought about by the attraction of the cell to the particles. (See the section on Leucocytes, under *Blood*.) The attraction exerted by particles upon motile cells is probably operative only over a limited area, and although there is some difference of opinion concerning the matter, it would appear that a certain amount of the solid particles being dissolved in the fluids containing the cells may stimulate them to approach the particles or under other conditions to repel them.

Amœbæ or other single-celled organisms are brought into the sphere of influence of food particles and bacteria by diffusion currents, and micro-organisms may by their own motility come into such a position as to be more easily engulfed. Jennings and Moore have shown that when paramecia and other infusoria pass by their own movements from a less attractive into a more attractive solution, they tend to remain there because their movement in the initial direction is arrested and reversed just as they are about to leave the agreeable environment. By a series of reverses they are kept swimming backward and forward across this attractive sphere and thus accumulate, not by initial attraction toward, but by inability to go away from, the agreeable environment. It remains to be proved whether any such explanation can be adapted to the accumulation of leucocytes in the neighborhood of bacteria and their toxins.

In the higher organisms provided with lymph or blood channels or both, the transportation of wandering cells to the vicinity of foreign particles is passive, although

Digitized by Microsoft®

their arrest at the margin of the vessel walls and their later emigration is an active process in response to stimulus. Fixed cells like the endothelium of the lymph- and blood-vessels, serous cavities, and the spleen pulp may throw out pseudopodia and entangle and ingest bacteria which are brought to them by the circulation. They may even bud off the large mononuclear leucocytes which are so markedly amœboid and phagocytic, but proof that these after engulfing bacteria or other particles may again become fixed is wanting. It is a common thing for a wandering phagocytic cell to be later engulfed with its contents by fixed cells, especially endothelial cells.

www.libtool.com.cn

Phagocytosis is to be observed in a multitude of ways, but perhaps as simple a demonstration as any is a modification of that used by Kanthack and Hardy. A drop of fluid from the posterior lymph sac or peritoneum of a frog is withdrawn by a capillary pipette, placed in the centre of a clean cover-slip and lightly inoculated with a fresh culture of *bacillus anthracis, bacillus filamentosus*, or some other large non-motile organism. The drop is inverted over a vaselined hollow ground slide, or, better still, a ring of filter paper may be placed upon a slide and the drop of inoculated lymph inverted over the hole (Miss Greenwood's method). The filter paper should be thick enough to prevent the drop from coming in contact with the slide, and should be moistened with water from time to time to prevent the desiccation of the lymph. This method provides plenty of oxygen. Such a preparation may be kept under observation for hours at room temperature, and the leucocytes, of which in the frog there are fewer varieties than in mammals, remain active and may be seen to attack the bacteria according to a definite plan. A better method, especially for demonstration to large classes, is to inoculate a culture directly into the peritoneum of the frog and to withdraw drops for microscopic study from time to time. Observation may be made while the cells are living as outlined above, or smears stained with eosin and methylene blue may be prepared at various stages.

It will be seen that the coarsely granular oxyphile (eosinophile) and hyaline (large mononuclear) leucocytes are actively attracted to the chains of bacilli, the former being generally the first to attach themselves. Their granules exhibit streaming movements before, and usually disappear immediately after contact. The lymphocytes (small mononuclears) seem to take no active part, although they become included in the plasmodium formed by the other two varieties of leucocytes and the chains of bacilli which become bent into sharp angles and finally tightly compressed. The individual cells seen to become a part of the plasmodium, soon lose their outline, and in unstained specimens cannot be differentiated. The plasmodium later breaks up, and the component cells again become free in from five to nine hours. The coarsely granular oxyphile cells which have lost their granules and whose protoplasm has become amphophilic upon contact with the bacilli sometimes regain their granules with their oxyphilic reaction. In the hyaline (large mononuclear) cells, however, at this stage frequently one or more vacuoles can be seen which contain chains of bacilli doubled upon themselves so that from two to five or more bacilli are included. The included bacilli are undergoing degeneration as evidenced by their swollen, granular, or generally "wilted" appearance. Kanthack and Hardy after a very extended series of observations concluded that with fully virulent bacilli the coarsely granular oxyphile cell is called into action first, and through contact with the bacilli, by a process of "extra-cellular" digestion or neutralization, works them harm, after which phagocytosis on the part of the hyaline cells becomes possible. They maintained that this is true not only for frogs but for mammals, and were convinced that phagocytosis as the initial movement is possible only where non-virulent bacteria or other relatively inert particles are employed.

The difference in the *modus operandi* of these two leucocytes has been very graphically illustrated in a more recent publication by Hardy in which he was able to measure accurately under the microscope the rate of growth of chains of bacillus filamentosus (non-virulent) which had been introduced into a drop of frog lymph and observed under the microscope for a number of hours. He found that in those bacilli which had come into contact with coarsely granular oxyphile cells no growth took place. Those in contact with hyaline cells or lymphocytes grew out into long filaments, as did also the free bacilli. Where one end of a chain was enclosed within a vacuole of a hyaline cell growth in that direction was arrested, although division of the bacilli at the other end of the chain went on. It will be seen that the material ("slime") extruded or exuded by the coarsely granular oxyphile cell at the time of the disappearance of its protoplasmic granules, or perhaps, more correctly speaking, that contact of the bacilli with the changed protoplasm—true phagocytosis not taking place—had the same inhibitory effect upon the growth of bacilli as had the contents of the digestive vacuole of the hyaline cell. The vacuoles of phagocytic cells probably all contain a ferment. Such has been shown to exist in the food vacuoles of the amœba by Krukenberg, Reinke, and Greenwood. Further, the ferment fluid has been shown to be acid, although secreted by an alkaline protoplasm. In these vacuoles whatever is capable of digestion goes into solution and serves as food for the cell, while the insoluble remnants are extruded.

It is impossible to hazard any opinion concerning the exact nature of such digestive fluids or mechanism, particularly when considering the destruction by phagocytosis of bacteria against which animals have been rendered immune. It has been suggested by Ritchie as quite possible "that by virtue of one set of powers a phagocyte may kill a bacterium, by virtue of another set of powers it may digest it, and the latter process may be the same as ordinary proteolysis, as it occurs in connection with the intestinal glands of an animal." It must be remembered, however, that typhoid bacilli will develop in solutions of pancreatic ferment possessing sufficient activity to digest fibrin, and it is well known that in artificial digestions with all the common ferments antiseptics must be employed in order to prevent overgrowth of putrefactive and other bacteria. Certain observers, including some of the Pasteur school, even go so far as to suggest that nearly all kinds of ferment activity in the animal body are facilitated by, if not largely dependent on, the presence of bacteria.

One is therefore forced to ask whether the phagocytic inclusion and digestion of bacillus typhosus by the cells of an animal immunized against that micro-organism is accomplished in exactly the same manner and by the same ferment activity as would be the cholera vibrio had the animal been rendered resistant against that organism. It does not seem possible that by repeated immunizing doses of a given micro-organism the phagocytic cells can be so altered as completely to change their digestive mechanism. It is well known, however, that bacteria are frequently engloberl, and later during their growth, or by their production of substances which may neutralize or destroy the digestive ferment, the phagocytes may be destroyed, although similar cells may later by a process of immunization acquire the property of seizing and also digesting the same bacteria.

Further discussion of these matters will be necessary in considering the questions of what cells are phagocytic, the fate of enclosed bacteria and other masses, the economic uses of phagocytosis, and the relation of phagocytosis to present-day theories of immunity.

What Cells are Phagocytic?

In unicellular organisms phagocytosis affords a means of securing food and for defence. In more highly developed organisms with the greater specialization in other functions that of phagocytosis is assigned to certain cells, particularly those of mesodermal origin. When micro-organisms or particles obtain access to the body fluids they may be carried to any part of the body unless dis-

Digitized by Microsoft®

www.libtool.com.cn

posed of or arrested. Similarly, when irritant particles or micro-organisms are localized in the body, phagocytic cells and those with other defensive activities may be hurried to the front by way of the lymph and blood channels. It may be well to consider first the free or wandering cells which are phagocytic, and secondly those which are fixed.

1. Phagocytosis in Free Cells (see also section on Leucocytes under *Blood*). If we look upon phagocytosis as an active process the red blood cells may be excluded.

Lymphocytes (small) are not phagocytic. Their protoplasm is so scanty as to leave no room for inclusion of particles nor have they been shown to be actively motile.

Coarsely granular oxyphile cells (eosinophile), although infrequent in normal blood, are more plentiful in lymph, and in tissue spaces they are abundant. Kanthack and Hardy consider them to be never phagocytic. Mesnil, a pupil of Metchnikoff, states that they may be phagocytic. I have always looked upon them as never phagocytic until two years ago we encountered one undoubted case of inclusion in, and partial digestion of, *B. filamentosus* by one of these cells in an exudate resulting several hours after an intrapleural injection of the organism into a guinea-pig. The eosinophile granules were perfect, and the bacilli were contained within a vacuole. Phagocytosis on the part of these cells must be extremely rare. They appear to act rather by a process of extracellular paralysis or digestion of bacteria.

The finely granular oxyphile (polymorphonuclear) leucocytes, or "microphages" of Metchnikoff, are the chief phagocytes of the blood. Where irritants are applied to vascular areas these cells very quickly appear in the foci, emigrating rapidly from neighboring vessels. In pus formation, in the fibrinocellular exudates of diphtheria and pneumonia, and in exudates in serous cavities and many other sites, these cells are present in vast numbers. In pneumonia there may be present in the hepatized area many times the total number of these cells normally present in the whole body. Where do they come from? In certain infections the manufacture of these cells in the marrow of the long bones is tremendously stimulated (Muir, also Roger), so that following the initial temporary diminution of leucocytes in the blood the increased output is sufficient to supply all demands. The subcutaneous injection of staphylococcus pyogenes aureus into the tissues of rabbits, and serial observations on the resulting abscess formation (Hohnfeldt) afford an excellent opportunity of studying chemotaxis and phagocytosis in connection with these cells. Their phagocytic properties and modes of action may be studied in smears of gonorrheal pus, in purulent fluid in cases of cerebrospinal meningitis, and in pus from abscesses. The sequence of changes in inflammation in which finely granular oxyphile cells bear a part may be well observed when fluid from the abdomen is withdrawn from time to time after intraperitoneal injections of various micro-organisms (Pfeiffer, Durham, and others). These cells possess the capacity for engulfing carbon and other insoluble pigments and of digesting pieces of fibrin, cell débris, bacteria, and other soluble materials. Vacuoles, evidently digestive, may often be seen surrounding the particles, although not always. This variety of leucocyte is, in short, instrumental in the removal of inhaled pigment particles, hemorrhages into the tissues, fibrinous exudates, and other detritus, while in resisting the pyogenic micro-organisms it is probably the chief factor.

The hyaline (large mononuclear) leucocytes or "macrophages" of Metchnikoff are seemingly derived from the endothelium of vessels and from the spleen and lymphatic glands. The phagocytic work in those tissues where the transportation facilities of the blood stream are not readily available is dependent to a great degree upon these cells. Kanthack and Hardy believed that only in case of feebly virulent bacteria and non-irritant particles are they capable of immediate action. That they do operate after other cells have been engaged is evidenced by the fact that other cells, such as the finely granular oxyphiles, are very frequently found in various stages of disintegration enclosed within them. The intraperitoneal or intrapleural inoculation of non-virulent bacilli into guinea-pigs illustrates this well. Mallory believes that where an irritant of a low grade of virulence is present, proliferation of the fixed cells and phagocytosis are prominent features. In typhoid infection this is true, and hyaline cells are especially active phagocytes, the finely granular oxyphiles being inconspicuous. In tuberculosis and leprosy phagocytosis is common, and endothelial cells are particularly active. In purulent infections the finely granular oxyphile and not the hyaline cell is the chief phagocyte. In the lungs inhaled carbon pigment and broken-down blood pigment—in pneumonia of heart disease—are contained in large amounts in large flat cells with rounded or oval nuclei. Whether these are hyaline leucocytes or desquamated alveolar epithelium cannot always be determined. Hyaline cells are the connecting link between endothelium and leucocytes, and Muir has pointed out that in inflammatory leucocytosis increased activity in and production of hyaline cells can be found evidenced in the lymphatic sinuses of lymph glands and by the mitotic figures in free hyaline cells.

Other varieties of leucocytes have not been recognized as phagocytic, and, in fact, little is known concerning their activities.

2. Phagocytosis in Fixed Cells.—The endothelial cells are markedly phagocytic for bacteria and other particles which are brought to them in the blood or lymph. They engulf particles by throwing out pseudopodia, and within limits they are quite amœboid. It has been suggested that in extremely small vessels where the endothelium composes a large part of the vessel wall, vaso-constriction or dilatation may depend upon thickening or thinning of these cells as a response to direct stimulation by materials flowing in the blood or lymph. This, if true, has an important bearing not only on inflammation, but upon the vascular phenomena of fever. In considering the finding of pigment particles in fixed connective-tissue cells as in those of the supporting tissue of the lung, or in glands, there is a question as to their exact mode of entrance. It is among the possibilities that free leucocytes act as phagocytes and wander by way of blood or lymph channels or between or through other cells until the particles ultimately reach the location in which they are found. Or the original phagocytic leucocytes may have died and set free the pigment to be taken up by a second leucocyte, or by an endothelial cell, or by a connective-tissue cell. Or the original leucocyte with its contained particles may have been bodily engulfed by a growing connective-tissue or other fixed cell. Evidences of such a process are not wanting. In phagocytosis on the part of epithelium—superficial or in glands—the problems are just as complicated. When bacteria enter the liver through the portal circulation and are then engulfed and killed or attenuated by the liver cells and ultimately extruded or excreted into the bile capillaries, it is likely that the endothelial cells of the portal capillaries act first and that these yield up their contents to the liver cells. Whether epithelial cells such as those in the milk glands can take up living bacilli and excrete or secrete them in a virulent condition so that they are eliminated through the ducts, is a question. Adami has suggested that such is the case where tubercle bacilli are found in the milk of cows whose udders bear no evidence of tuberculosis. Many other matters bearing upon this question might be discussed, such as the methods of excretion of bacteria and solid particles by way of the kidney, tonsillar infection in tuberculosis, etc., but they do not lie within the scope of so limited an article as this.

The Fate of Enclosed Particles.—When insoluble pigment particles are found in situations to which they could not have been swept by currents of lymph or blood, amœboid phagocytes have probably been the carriers, and such cells may set free their contents either before or after death.

Undoubtedly through phagocytosis many bacteria are killed, but, as we have seen, not all of those which are

Digitized by Microsoft®

taken into the interior of phagocytes are destroyed. Metchnikoff has isolated single leucocytes which contained micro-organisms, and in a drop of broth under the microscope he has watched the bacteria increase within the cell until it was filled and finally destroyed, the micro-organisms escaping into the broth. In many cases of infection observation would warrant the belief that bacteria may be engulfed and carried considerable distances by phagocytes, which are then destroyed, the bacteria liberated, and a new focus of infection is set up. In many infections phagocytosis is pronounced throughout the whole course of the disease. This has constituted a difficulty for those who advocate the phagocytic theory of immunity. In such chronic diseases as leprosy, tuberculosis, and glanders, bacilli, apparently many of them living, are to be found enclosed in phagocytes. In epidemic cerebro-spinal meningitis and gonorrhœa—diseases of a more acute nature—one of the diagnostic points in connection with microscopic examination is the demonstration of the diplococci within the cells (finely granular oxyphile). It would therefore appear that while phagocytosis is undoubtedly an important factor in resistance to infection, there are distinct steps, namely, attraction of leucocytes which then engulf bacteria and later digest them. That digestion of bacteria does not always follow their enclosure in phagocytes is apparent.

The Factors which Influence Phagocytosis.—Anything which checks chemotaxis interferes with phagocytosis. It has been conclusively shown that highly virulent bacteria are less apt to attract wandering cells and induce phagocytosis than are more attenuated microbes of the same kind. For instance, if attenuated anthrax bacilli be inoculated in one ear of a rabbit and virulent anthrax bacilli be inoculated in the same manner and dose in the other ear of the same rabbit the results are quite different (Metchnikoff). In the one ear the attenuated bacilli induce a tremendous accumulation of leucocytes, while in the other ear fluid is poured out into the tissues with little or no attraction of leucocytes.

The state of resistance of the animal is also important. Immunization to anthrax renders an animal capable of responding to a dose of virulent bacilli by an accumulation of leucocytes, while a similar dose in an untreated animal induces a huge outpouring of fluid.

The presence of soluble bacterial products in a definite locality tends to favor the attraction of leucocytes from the neighboring blood-vessels, while the circulation simultaneously of the same materials in large quantities in the blood stream tends to prevent it. This is illustrated (Roger, Ruffer) by inoculating the bacillus of symptomatic anthrax into the subcutaneous tissues of a rabbit when leucocytes rapidly accumulate at the site of inoculation and abscesses result. If another rabbit be similarly inoculated, while in addition an intravenous inoculation is made, there is tremendous outpouring of fluid, but no leucocytosis at the site of the subcutaneous injection, and death results in a few hours. Hence phagocytosis is apt to occur when the invading bacteria are not too virulent, when the resistance of the host is great, and when the irritants and soluble products are present in much greater abundance at a point or points outside the vessels than in the circulating blood.

The economic uses of phagocytosis have been dealt with more or less fully in the preceding portions of the article, and need be only mentioned here. As a factor in nutrition evidences of the importance of phagocytosis decrease as we ascend in the scale of development. For instance, in the amœba observation would tend to show the extreme importance of phagocytosis in this connection, while in the higher animals proof that it takes a great share in the securing and assimilation of food is wanting, although such may yet be forthcoming. As has been stated, pigment and solid débris, such as exudates, hemorrhages into the tissues, dead cells, and tissues of all kinds are largely removed by phagocytes. In the spleen phagocytic inclusion of dead blood cells and animal and vegetable parasites is always demonstrable. Many more examples could be quoted were it necessary. In their attraction to, inclusion of, carrying away, and destruction of invading organisms the phagocytic cells may be exhibiting characteristics largely acquired in exercising their more physiological functions.

Phagocytosis in Relation to Present-day Theories of Immunity.—Ehrlich's brilliant experiments and deductions (see article on *Immunity*) have necessitated a remodelling of many of our ideas, and Metchnikoff in accepting Ehrlich's views has attempted to harmonize phagocytosis with the activities of complements and immune bodies. Ehrlich believes that immunity against bacteria (or other cells) depends upon the original possession or artificial induction of a special substance, "immune body," which firmly unites with the bacteria and thus enables another substance, "the complement," which is present normally in the animal to kill the bacteria. The immune bodies are more resistant to heat than are the complements. In the serum obtained from an immunized animal both immune body and complement may be found, although Metchnikoff believes that both are liberated from leucocytes (microphages and macrophages) by "phagolysis," and that in the body the final action of the complement on the bacteria takes place only within the cell during phagocytosis, even should the immune body have been free in the fluids.

It has long been known that bactericidal substances are more abundant in the leucocytes than in the fluids of the body. More recent work of Denys and Leclef seems to show that from rabbits immunized against streptococcus the serum when mixed with leucocytes from such an animal was no more destructive for streptococci than when mixed with the leucocytes of a normal rabbit, while by itself it was practically not bactericidal at all. Two antibodies seemed essential for the destruction of the streptococci: one was to be found in the immune serum, and the other was afforded equally well by the leucocytes of the normal or treated rabbit.

Bulloch's work on hæmolysis tends to show that in the rabbit an increase of finely granular oxyphile cells in the blood accompanies the formation of complement and that activity of mononuclear leucocytes is related to the formation of immune body.

There seems to be as yet no information available concerning the *exact* source of complement and immune body. We are not justified in assuming because a substance is bactericidal in test-tube experiments that it is operative as such in the body. We have seen already that the coarsely granular oxyphile cell acts deleteriously upon virulent bacteria, and that it is not markedly phagocytic. There are doubtless other cells which are antibacterial and non-phagocytic. In assuming that the same cells produce both immune body and complement, Metchnikoff is not borne out by the observed facts, although he admits that the former is more likely to be liberated into the body fluids than the latter.

The digestion of bacteria by phagocytes Metchnikoff apparently considers to be due to a ferment which seems to be the same sort of thing as Ehrlich's complement.

It is not quite clear whether his "cytases" include complement which remains fixed in the phagocytes, the immune body which under some conditions escapes into the fluids, and in addition special "stimulines," which acting on the phagocytes cause them to approach bacteria and engulf them. Ritchie, in his admirable critical review of the subject, asks very pertinently how the so-called education of leucocytes is brought about. He suggests that in the case of immunization by repeated intraperitoneal injections of cholera vibrios it is perhaps possible that in the later injections the especially active phagocytes may have been the same individuals engaged in the former encounters with the vibrios.

Although the life history of a leucocyte is probably short, he suggests that such "sensitized" leucocytes might even be attracted from distant parts of the body. It is easily seen that while admitting such possibilities he leans to the view that the active leucocytes in each succeeding injection are new ones probably derived from the bone marrow or lymphatic sinuses.

Digitized by Microsoft®

To limit the formation of the active substances of Ehrlich to the phagocytic cells of the body as Metchnikoff has done, further complicates an already complicated but otherwise satisfactory theory of immunity. There seems to be ample evidence that there are many other active factors in the protective mechanism than those afforded by phagocytosis. Phagocytes are undoubtedly important, but not all the phenomena of immunity can be expressed in terms of phagocytosis. *F. F. Wesbrook.*

PHARMACOPŒIA.* — (Greek φαρμακοποιία, from φάρμακον, medicine, remedy, and ποιεῖν, to make, to prepare; Latin, *pharmacopœa* or *pharmacopœia*; German, *Pharmakopöe*; French, *pharmacopée*; Spanish, *farmacopea*, etc.). A *pharmacopœia*, in the modern sense, may be defined as a work published by some recognized authority, for the purpose of securing uniformity in the kind, quality, strength, and composition of simple and compound remedies used in the practice of medicine. It may either be of a local character, or it may apply to a whole country. During the early history of pharmacopœias, the term was also often applied to works written or published by individuals, without the official sanction of governmental or professional authority. The Greek word φαρμακοποιία occurs in later Greek medical writings under its proper meaning, "the preparation of medicines," or "the art, or business, of preparing medicines." As the title of a book treating of this subject, however, it is probably not older than the beginning of the sixteenth century.

Ancient and Mediæval Precursors of Pharmacopœias.— While the ancient nations did not possess any works which could be fully set side by side with our modern pharmacopœias, yet the gradually accumulating mass of facts relating to the preparation and practical use of medicines resulted in the composition of numerous works which treated at least incidentally of this subject. In giving an account of the literature relating to the latter, we shall confine ourselves to those works the influence of which has, in one way or another, extended to our times.

Egypt has furnished us the oldest existing documents containing formulas and directions for the preparation of medicines. The oldest known is the *Papyrus Ebers*, dating from the year 1552 B.C. (see *Med. Rec.*, 11, pp. 247–251), which mentions a large number of simple remedies, and also contains numerous formulas of compounds, often in the form of regular pharmacopœial recipes, accompanied by signs and terms expressing weights or measures, precisely as is customary at the present day.

The *Medical Papyrus of Berlin* (see Woenig, "Die Pflanzen im alten Aegypten," Leipsic, 1886), written about 1350 B.C., contains a great number of formulas, with exact statements as to ingredients, and weights and measures. These formulas are for both internal and external remedies, including enemata. The remedies are mostly simples, plant parts, gums, resins, etc., with a few metals, liquors, and well-known liquids, including urine, bile, blood, and fæces of various animals.

In addition to these written documents, there existed also formularies sculptured in stone, one having been found upon the walls of a regular pharmaceutical laboratory or *asi t* (see Woenig, *loc. cit.*, 372) in the temple of Edfu.

India.—An examination of the oldest Indian literature, that of the Vedas, Brahmins, and Sutras, reveals little but superstition as to both diseases and remedies. The principal medical works of the Hindoos, viz., those of Charaka and Susruta, cannot be traced back beyond the eighth century A.D. (see *New Remedies*, 1876, 229), the foundations evidently having been derived from the Greeks. Most of these medical works are characterized, and their meaning is obscured, by the poetic or metrical style employed in them. Four or five centuries then elapse before we meet with any other notable writings of this kind. Among the later medical treatises the most important are "Ashtângahridaya," by Vâgbhata, and the "Bhâvaprakâça," by Bhâva, both of them only a few centuries old. These contain likewise many formulas interwoven in the text. Regular treatises on pharmacy, or formularies, are not numerous (to the former belongs the "Prayogâmrita" of Vaidyachintâmani, and others); but treatises on materia medica or glossaries of simples are much more common. The most extensive of these is the "Nighanturâja," by Narahari, of Cashmere, being a dictionary of products of nature, etc., with synonyms. Another smaller but useful work is the "Madanavinoda" of Madanapâla.

Greece.—The writings of Hippocrates (about 460–377 B.C.) were the first, as well as the most important, in the early history of Greek medical literature. Although none of his genuine writings is devoted exclusively to the preparation of specific medicines, numerous such directions are contained in them, and the pharmaceutical art became developed during the succeeding centuries in proportion as the rational treatment of disease, upon the foundation laid by Hippocrates, spread through the cultivated nations of Europe and Western Asia.

Of those works which are known to have exerted a permanent influence upon the formularies of later times, that of Andromachus of Creta, Nero's court physician, next requires mention, being a sort of poetic formulary. He also wrote a poem on Theriac and its preparations, which for centuries was highly influential in medical practice. About 65 A.D., Servilius Damocrates composed similar pharmacological poems, his compound of theriac, thus treated, being subsequently known as "Confectio Damocratis." In about 78 A.D., Dioscorides wrote his famous Ὕλη ("Materialia"), a most valuable cyclopædia of simples, which became one of the chief sources of pharmacological writers down to the Middle Ages.

The next important Grecian medical writer was Claudius Gallinus (131 to about 210 A.D.). His numerous writings exerted an influence equal to that exerted by the works of Dioscorides. Two of them treat especially "on the composition of medicines according to the places" (of application) "and according to classes." His numerous complex mixtures gave origin to the term "Galenical."

Of later writers, the more important are: Aëtius, of Amida, in Mesopotamia (sixth century A.D.), who gives numerous formulas for plasters, salves, etc.; Alexander, of Tralles, in Lydia (525–605 A.D.), and Paulus, of Ægina (seventh century A.D.), both of whom likewise quote many formulas in their writings. Passing now over several centuries, we find no author worthy of mention until we come to Nicolaus Myrepsus, of Alexandria (second half of thirteenth century A.D.), who compiled an "Antidotarium" (δυναμερόν), or formulary, containing not less than two thousand six hundred and fifty-six formulas, in forty-eight chapters. This work was written in Greek, but only the Latin translation has been published (first edition, Basle, 1549). It is also entitled "Antidotarium Magnum" (not to be confounded with the "Antidotarium Parvum" of Nicolaus Præpositus). In spite of its encyclopædic character, this formulary did not acquire as much reputation as the less extensive works of Mesue or of Nicolaus Præpositus.

Rome.—Previous to C. Plinius Secundus (23–79 A.D.) only the writings of M. Porcius Cato (234–149 B.C.) interwoven in agricultural treatises, need be mentioned. In the great work on "Natural History" by the former, many subjects relating to materia medica are treated. The "Compositiones Medicæ of Scribonius Largus" (first century A.D.) is the first literary production, having the nature of a formulary, of Roman origin. It contains the first correct description of the method of obtaining opium. A treatise by Rufus of Ephesus on cathartics was for a long time influential. Many other more or less important works by Romans were written in Greek.

Arabic Countries.—The Arabs were the first to develop the art of the apothecary and to establish regulations re-

* This article is practically a reprint of those contributed by Dr. Charles Rice to the preceding edition of this work and to the Supplement (Vol. IX.); the records, I might add, have been brought up to date, and a few changes have been made in the interest of economy of space. *Henry H. Rusby.*

Digitized by Microsoft®

garding the quality and price of his medicines, and specifying which of them were to be kept in stock for instant use. Their advent infused new life into the torpid condition of the medical and other sciences.

At the end of the ninth century, Shâbûr ben Sahl wrote a sort of dispensatory under the title of "Ibdâl" (Haji Khalfa, ed. Flügel, i., 142), and about the middle of the twelfth century Abû'l Hassan Hibet-allah ibn Talmîd composed a similar work, entitled "Krabadin" or "Grabaddin" (Arabic, *qarâbâdîn*, or *qrâbâdîn*), which was commonly followed by Arabic apothecaries. The most important of these works was that composed by the younger Mesue (Mâswiyah el-Mârdînî, died 1015 A.D.), of Maridin, on the Euphrates, and of which only the Latin translation is extant, under the title "Antidotarium, seu Grabaddin Medicaminum compositorum." This remained for a long time the chief canon of pharmacy. It contains a large number of formulas arranged in twelve chapters, each treating of a different form (for instance, Pilulæ, Cerata, etc.) under which medicines are applied or administered. Not less than four Italian translations of this work appeared previously to the year 1500, and the Latin text was often reprinted.

The writings of the most celebrated of all Arabic physicians, viz., Avicenna (Abû 'Ali Hussain ben Abdallah, Ibn Sinâ, 978–1036 A.D.), also contain many formulas which were incorporated in subsequent collections.

Other writers, whose works contributed in this direction, were Ibn Wâfid el-Lachmî (about 1050 A.D.), called Albenguefit in mediæval literature, whose work on simples has been published only in Latin translation. Serapion the younger (Ibn Serâbî, about 1070 A.D.) was the author of a similar work, but this was much more esteemed and made use of than the former.

The most important Arabic writer on materia medica is Ibn Baitâr (about 1197–1248 A.D.). His work on simples and foods, based on his own observations and on the works of Greek, Arabian, Persian, and Syrian writers, is a perfect storehouse of information, and has exerted considerable influence upon the development of therapeutics and pharmacy among his countrymen.

Persia has little of interest to present in this direction. If we except a treatise on materia medica, based upon Greek, Arabian, and Indian sources, written by Alberwi (ninth century A.D.), we meet nothing of interest until the close of the seventeenth century, when Father Ange de la Brosse, de St. Joseph, published at Paris (in 1681) the "Pharmacopœa Persica, ex idiomate Persico in Latinum conversa." That this is no translation of an original Persian work has been recognized many years ago by Dr. Hyde, who supposed it to be the work of Père Matthieu. Leclerc ("Histoire de la Médecine Arabe," Paris, 1876, ii., 481) reports that it is a translation of an Arabic work existing in manuscript in the National Library at Paris. It bears internal evidence of the intimate acquaintance of the author with European medicines, some of which were probably then unknown to Persians, while others which were known (such as opium) are omitted. In 1771 Mîr Mohammad Hussain, of Khorasan, wrote a Persian pharmacopœia, and subsequently an encyclopædia of materia medica ("Makhzan el-adwiya," "Treasury of Medicines") of considerable merit.

Mediæval Europe.—Up to about the fifteenth century the apothecaries in European countries situated to the north of the Alps did not prepare many compounds themselves, owing to the difficulty of importing the numerous, often bulky, and perhaps scarce, crude materials. They were in the habit of obtaining the finished preparations from Italy, where the art of pharmacy was in a flourishing condition. Among the works written during the Middle Ages, which either served themselves as pharmacopœias or formularies or at least contributed to their compilation, may be mentioned the following: The "Antidotarium" (also called "Antidotarium parvum," to distinguish it from the "Antidotarium" of Nicolaus Myrepsus) of Nicolaus Præpositus, of Salerno (first half of the twelfth century), consisting of about one hundred and fifty alphabetically arranged formulas for compounds. This compilation, together with Mesue's "Grabaddin" (see under Arabic countries), constituted the most celebrated formulary of the Middle Ages (first edition, Venice, 1471). Other important works of this period are the following: "Compendium Aromatariorum" (1st edition, Bologna, 1488), by Saladinus Asculanus, a useful and much used work, in which much attention is devoted to the description of drugs and their mode of preservation; "Luminare Majus," by Manlius de Boscho (1st edition, Venice, 1496), a highly esteemed dispensatory. A counterpart of this is the "Luminare Minus" (Venice, 1517), of Quiricus de Augustis de Torthona. The "Antidotarium Florentinum" (1st edition, Florence, 1489; often reprinted) is the first pharmacopœia or formulary published in Europe under governmental authority.

History of Pharmacopœias. — The literature of pharmacopœias is very extensive, and an exhaustive account is beyond the limits of this work. Yet, since a reliable list or sketch of at least the more important pharmacopœias is often of great use to those who have to consult medical works published in previous years, a condensed account of them is here given, arranged by countries; among the latter being included, for the sake of completeness, most of those which possess no regular pharmacopœia of their own, but use some other work either from choice or by command.

Note.—In quoting editions of the less important pharmacopœias, only the date of the first one is usually given. A plus sign (+) behind the date indicates that several editions followed. In some cases the date of several or of all editions is given. The word "pharmacopœia" is usually abbreviated to save space.

Argentine Republic.—This country possesses no pharmacopœia, although commissions have long been maintained, at least nominally, for preparing one. The "Farmacopea del Pais," although a mere fiction, has been legally recognized, and the French, Spanish, and Italian authorities are variously followed.

Austria-Hungary.—In 1729, the Vienna Pharmaceutical Society published a dispensatory under the title of "Dispensatorium Pharmaceuticum Austriaco-Viennense," which was repeatedly revised and reprinted. In 1739 appeared the "Dispensatorium Medico-Pharmaceuticum Pragense," which also saw several editions. An official pharmacopœia prepared by order of Government by Stoerck, Jacquin, and Well, was published in 1774 under the title "Ph. Austriaco-Provincialis." This was several times revised, and also translated into German as well as into Dutch, the Netherlands at that time forming a part of the Austrian empire. After the loss of the Dutch provinces a fresh start was made, and the first pharmacopœia proper appeared in 1812, under the simple title, "Pharmacopœia Austriaca." The subsequent editions appeared in—1814 (ii.), 1820 (iii.), 1834 (iv.; this being full of misprints was republished in 1836); 1855 (v.); 1869 (vi.).

A supplement to the Austrian Pharmacopœia was published in 1879, and a new edition (Editio VII.) went into effect on the 1st of January, 1890. The Austrian Pharmacopœia is rather small, comprising only five hundred and seventy-eight titles. Its text is in Latin. From the year 1795 a special military pharmacopœia was maintained, its last revision dating from 1872.

Up to 1871 the Austrian Pharmacopœia was valid for the whole empire, but in that year a separate volume was supplied for Hungary, and this was republished in 1888 under the title "Magyar Gyogyszerkonyv, Masodik Kiadas." This work comprises five hundred and sixteen articles, and possesses both Hungarian and Latin texts on opposite pages.

The first Croatian pharmacopœia was published in 1888, under the title "Hrvatsko-Slavonska Farmakopea," being practically a duplicate of the Hungarian in Slavonic and Latin texts.

Belgium.—Previous to 1823, there existed the Pharmacopœia Belgica of 1659, and various pharmacopœias representing the different cities, as those of Brussels (1639 +),

Digitized by Microsoft®

Gand (1652+), Leyden (1638+), Liège (1741), Lille (1640+), Antwerp (1661, 1665, 1812), as well as the Austrian Pharmacopœia which was official from 1774 to 1805, when it was superseded by the Pharmacopœia Batava. Owing to changes in political conditions these cannot be considered to be Belgian national works in the present sense. Such a one, however, appeared in 1823, republished in 1854 as the "Pharmacopœia Belgica Nova," of which a "second," and the latest, edition appeared in 1885. This work closely resembles the French Pharmacopœia, though without its conspicuously numerous blunders. The text is in Latin and French, the former being specified as the official.

www.libtool.com.cn

Bolivia has no pharmacopœia. The French is that mostly used, though in the western portion the Spanish is common. Through the works of Cernowicz, the Portuguese Pharmacopœia has considerable influence in the eastern provinces.

Brazil also is without a pharmacopœia, though many attempts to compile one have been made. The Spanish, Portuguese, and French works are largely used, and the work of Cernowicz is highly influential.

British Empire.—Up to the year 1864, England, Scotland, and Ireland possessed each its own pharmacopœia. That for England was first published in 1618, under the title "Ph. Londinensis," by the London College of Physicians. It was several times reprinted with slight alterations, until 1650, when its second revision was published. The succeeding revisions appeared in 1677 (iii.); 1721 (iv.; in this edition vegetable drugs were for the first time defined as to origin); 1746 (v.; in this edition a great advance was made; many of the old complicated formulas were curtailed and shorn of useless material); 1788 (vi.); 1809 (vii.); 1824 (viii.); 1836 (ix.); and 1851 (x.). Besides the official editions, the text was incorporated into many other works, such as commentaries or dispensatories, either written for it alone or for all the British Pharmacopœias together. It was also translated into various other languages, even into Hindustani (Calcutta, 1824).

The first pharmacopœia for Scotland was published by the Edinburgh College of Physicians in 1699, under the title "Pharmacopœia Collegii Regii Medicorum Edinburgensis." The subsequent editions or re-issues were very numerous.

The first pharmacopœia for Ireland appeared at Dublin in 1807, under the title "Pharmacopœia Collegii Medicorum Regis et Reginæ in Hibernia." Previously, however, a specimen pharmacopœia had been prepared and circulated already in 1794, and again in 1805. The Dublin Pharmacopœia was revised in 1826 and 1850.

In 1864 appeared the first "British Pharmacopœia" under the medical act of 1858. Many inconsistencies occurred in that work, chiefly due to the difficulty encountered in reconciling the differences between the three countries. In 1867 a new edition was produced by the general medical council, and to this a supplement, containing thirty-four additions, was published in 1874. In 1885 a new edition was produced by Professors Attfield, Redwood, and Bentley, under the direction of the Medical Council. Although showing a great advance over its predecessor, this work was far from satisfactory, owing to the fact chiefly that the editors were not empowered to avail themselves of the assistance and experience of other experts. Some of the principal errors were corrected in a subsequent supplement. In 1886 Attfield was appointed "reporter on the British Pharmacopœia to the Medical Council," his duty being to submit to the Medical Council annually a synopsis of current publications bearing upon the contents of the British Pharmacopœia, and making suggestions for its future improvement. The third reprint of the British Pharmacopœia appeared in 1888, and a supplement thereto in 1890, containing forty-four new articles. In the preparation of this supplement the pharmaceutical profession of Great Britain was graciously invited to suggest desirable additions or improvements, but not yet to assist in the actual work of revision. The fourth and last edition of this work was published in 1898, and is by far more satisfactory than any of its predecessors. It shows not only a much broader relation with other modern pharmacopœias, but its editors have evidently profited greatly by the suggestions emanating from the British medical and pharmaceutical professions. The metric and English equivalents of weights and measures stand side by side in the text as well as do the Fahrenheit and Centigrade equivalents of temperature. The nomenclature of the titles is excellent, the name of the special article preceding that of its class, as "Cardamomi Semina." In this practice it is at an agreement with the United States, but not with the German Pharmacopœia. In the botanical nomenclature of its definitions, no principles, properly speaking, are followed, current custom in Great Britain, even when erroneous, being taken as the guide and facts and principles being twisted when necessary to constitute a defence. The descriptions are sufficiently full, and are given in simple and judicious, yet not unscientific style. The tendency in this, as in other modern pharmacopœias, is toward the elimination of antiquated and worthless articles, as well as those of complex composition.

The usefulness of the British Pharmacopœia is restricted by a wholly selfish, unscientific, and unprofessional refusal to permit the quotation of any portion of its text, even for purposes of comment or criticism.

One of the dependencies of Great Britain, viz., *India*, has a pharmacopœia of its own. In 1842, Dr. W. B. O'Shaughnessy issued, by order of Government (under the authority of the East India Company), "The Bengal Dispensatory" (Calcutta), as a precursor to "The Bengal Pharmacopœia and General Conspectus of Medicinal Plants" which he published at Calcutta in 1844. In 1868 a "Pharmacopœia of India" was published at the same place by Dr. Ed. J. Waring, under authority of the Secretary of State for India. This is now in force, alongside of the new British Pharmacopœia. The main object of issuing a separate pharmacopœia for India was officially to encourage and authorize the employment of East Indian drugs, among which are many possessing very valuable properties. A most useful companion to this work is the "Supplement to the Pharmacopœia of India," by Moodeen Sheriff, published by order of the Government of Madras, in 1869. This work contains synonyms of the pharmacopœial articles in fourteen languages. A revision of the pharmacopœia of India is in contemplation.

In 1887 the British Pharmaceutical conference produced the "Unofficial Formulary," containing thirty-seven articles, to which nine were added by a supplement published in 1889. The abbreviation of the title of this work is "U. F. B. P. C."

Central American States.—These states have no pharmacopœias, and there is the greatest want of uniformity in the authorities followed, the Mexican Pharmacopœia not wielding the influence which would naturally be expected of it.

Chili.—In 1886 appeared the "Farmacopea Chilena," prepared by Dr. Adolfo Murillo, and published in Leipsic. Its text is Spanish, and it bears much resemblance to the French Pharmacopœia, though containing far fewer errors.

China.—This country has, of course, no official pharmacopœia, though there are numerous works of an unofficial character treating of such subjects, the best known and most extensive being "Pen tsao kung mu," of Lis hi-chin, published about 1560 A.D. While containing much of value, its basis is of course largely superstitious.

Denmark.—In 1658 the "Dispensatorium Hafniense" was published at Copenhagen, and this was several times reprinted. The first official pharmacopœia appeared in 1772, the second in 1805, and the third in 1830. The last mentioned was, however, counted as the first work, the others not being regarded subsequently as deserving of the name. Hence the next edition, published in 1868, was designated as "Editio Secunda." Supplements to it appeared in 1874, 1876, and 1886. On August 1st, 1893,

Digitized by Microsoft®

a new edition went into effect. The text of the work is in Danish, the titles are in Latin. Much similarity exists between the Danish, Norwegian, and Swedish pharmacopœias, which is the result of deliberate design, as these countries are closely allied in customs, traditions, and language. A separate military pharmacopœia is in existence.

www.libtool.com.cn

Ecuador.—The statements made concerning Bolivia apply also to Ecuador.

France.—In 1353 King John, "the good," commanded the apothecaries to follow the "Antidotarium" of Nicolaus Præpositus. Strict regulations regarding the practice of pharmacy were made in 1536, and frequently afterward. As early as 1546 a "Ph. Lugdunensis" was published at Lyons, which was several times reprinted. A French "Paraphrase sur la Pharmacopée" was issued by Briçon Bauderon, of Mascon, in 1588+. In 1590 the Paris Faculty of Medicine was directed to prepare a dispensatory; but, as nothing was done, Parliament, in 1597, ordered twelve members of the faculty, designated by name, to prepare the work. The order was, however, not obeyed. Several French cities early possessed pharmacopœias of their own, thus: Burdigal ("Ph. Burdigalensis," 1643); Strasburg (Ph. Argentoratensis," 1725+); Toulouse ("Codex Medicamentarius, seu Ph. Tolosana," 1648, 1695); Valenciennes ("Ph. Valentianensis," 1651). A new "Pharmacopée de Lyon" was also published by Vitet in 1788. The last-named work, to a slight extent, answered the purpose of a revised edition of the last Paris Pharmacopœia in some localities. In 1637 the "Ph. Parisina" appeared as a precursor to the first official Paris Pharmacopœia, which was issued in 1639 under the title "Codex Medicamentarius, seu Ph. Parisiensis, in lucem edita a Ph. Harduino." Revisions of this appeared in 1645, 1732, 1748, 1758. No further revision appeared then until, after an interval of sixty years, a national pharmacopœia was issued in 1818, under the title: "Codex Medicamentarius, seu Ph. Gallica," the text being in Latin. In the second and following editions the French language was chosen for the text, only the synonyms of the titles being given in Latin. These editions appeared in 1827 (ii.), 1839 (iii.), 1866 (iv.), and 1884 (v.). The last revision was a very unsatisfactory one, as the revisers did not seem to have paid attention either to the other new pharmacopœias (United States and German) which had appeared a short time previously, or to the copious literature relating to pharmacopœial improvements. Immediately after the work had been issued very numerous errors were discovered in it, so that the Government was compelled to make a fresh issue, in which one hundred and thirty-two alterations were incorporated; and a special pamphlet entitled "Erratum," was shortly afterward sent out, in which eighty-three additional changes were directed to be made. But this list of errata is not only itself not free from errors, but is far from being complete. In connection with the French Pharmacopœia should be mentioned the well-known work of Dervault, "L'Officine," constituting an exhaustive commentary and supplement to the pharmacopœia. In some foreign countries, which do not possess a pharmacopœia of their own, this work is frequently followed as the principal authority, being used either in the original French or in Spanish translation.

Germany.—The first official formulary published in Germany was that of Valerius Cordus, published after his death by the city of Nuremberg in 1546, under the title "Pharmacorum omnium quæ quidem in usu sunt conficiendorum ratio; vulgo vocant Dispensatorium pharmacopolarum" (see *Am. Drug.*, 1887, 21). The work contains formulas of Galenical preparations, taken chiefly from ancient writings, with few simples. Some of the titles continue to the present day, though in some cases the composition has utterly ceased to correspond therewith. The work was often reprinted at home and abroad. There is a Paris edition of 1548, three of Lyons (1552, 1559, 1599), two of Venice (1556, 1563), etc. In the Nuremberg edition of 1592, great advances were made, several American drugs (sassafras, sarsaparilla, and tobacco) being introduced, chemicals first appearing (alum, borax, saltpetre, etc.), as well as some artificial salts from ashes of plants and other substances. Extracts and distilled waters were also added. Equally important changes occurred in the next edition (1598), white arsenic, corrosive sublimate, calomel, and oil of vitriol being among the additions. The next edition (1612) was little changed. The fifth and last edition appeared in 1666, and showed great changes, many for the worse, some for the better, such as the introduction of cinchona, jalap, balsams of Peru and Tolu, tinctures and many new chemical salts, under the then prevailing alchemistic nomenclature. This edition contained nearly all classes of preparations of which we still make use, organic proximate principles being of course unknown. It certainly formed the basis upon which subsequent European pharmacopœias were constructed.

In 1538 the physicians of Augsburg prepared a sort of pharmacopœia under the title, "Conclusiones et Propositiones Universam Medicinam Complectentes," containing formulas which were afterward generally followed. Augsburg was at that time the chief *entrepot* of the German trade with Italy and the Levant; hence many of the imported medicines came by way of Augsburg. In 1564 the first edition of the "Ph. Augustana" was published, which was often revised, and Cologne followed the example in 1565, by the publication of a "Dispensatorium," which was replaced by a "Ph. Coloniensis" in 1627.

The disunited condition of the countries inhabited by the German nation up to within recent times has been the means of bringing into the world a large number of independent pharmacopœias, for separate cities or principalities, of which a list follows here: Stralsund ("Actuarium Ph. Stralsundensis," 1645); Quedlinburg ("Quedlinburgensis Officina Pharmaceutica," 1665); Brandenburg ("Dispensatorium Brandenburgicum," 1698, forming the starting-point of the later Prussian pharmacopœias); Hanover ("Ph. Hanoverana," 1706; last edition, 1861); Hamburg ("Dispensatorium Hamburgense," 1716; "Codex Hamburgensis," 1835, 1845); Ratisbon ("Disp. Pharm. Ratisbonense," 1727); Munster ("Disp. Monasteriense," 1739); Würtemberg ("Ph. Wirtembergica," 1741; last edition, 1847); the Palatinate ("Disp. Med.-Pharm.," 1764); Brunswick (Disp. Pharm. Brunsvicense," 1777); Würzburg ("Pharm. Herbipolitana," 1778; last edition, 1796); Westphalia ("Disp. Westphalicum," being identical with Piderit's "Pharmacia Rationalis" [see under Saxony], 1779); Fulda ("Disp. Fuldense," 1787); Bremen ("Pharm. in usum . . . Bremensis," 1792); Schaumburg-Lippe ("Disp. Lippiacum," 1792); Oldenburg ("Ph. Oldenburgensis," 1801); Hessen ("Disp. Electorale Hassiacum," 1806; "Pharm. Hassiæ," 1827, 1860); Erfurt ("Neue Pharmakopoë" . . . von Trommsdorff, 1808, was introduced by order of the French in place of the "Prussian Ph."); Saxony (in 1806, Piderit's "Pharmacia Racionalis," Cassel, 1779–81 was prescribed as Ph. In 1820 appeared "Ph. Saxonica," the last edition in 1837); Bavaria ("Ph. Bavarica," 1822, last edition in 1859); Schleswig-Holstein ("Ph. Slesvico-Holsatica," 1831); Baden ("Ph. Badensis," 1841).

Many of these were revised and republished a number of times.

The most important of all former German pharmacopœias has undoubtedly been the Prussian. This had its beginning in the "Brandenburg Dispensatory" of 1698, the last revision of which, or the sixth edition, appeared in 1781. In 1799, the first "Ph. Borussica," was published. The next editions came out in 1801 (ii.), 1813 (iii.), 1827 (iv.), 1829 (v.), 1846 (vi.; this is considered to have been the best pharmacopœia of its time); 1862 (vii.). Four editions of a separate Military Pharmacopœia were also published, the last one in 1868.

The problem of a united pharmacopœia for all German states had often been agitated, but in vain. In 1861 Dr. Walz proposed the publication of a German Pharmacopœia by private enterprise, which was to be recommended for adoption, or at least as a pattern, to the different German States. The work appeared in 1865, under the

Digitized by Microsoft®

title "Pharmacopœa Germaniæ." Among the compilers were two Austrians, as it was at the time believed that the work might be accepted by all German-speaking peoples. But the war of 1866 rendered the project, as originally conceived, nugatory. A second edition was published in 1867, in which the Austrian members were omitted. Yet even this failed of recognition. It was only after the establishment of the German empire that the desired object was attained. In 1872 was issued the first "Ph. Germanica," superseding all the separate pharmacopœia at that time in force in German countries. Some amendments to this were published in 1873. When the time for a new revision arrived the Government invited all medical and pharmaceutical bodies and prominent individuals in both professions to submit proposals regarding the new revision. Contributions were received from a large number of sources, and these were printed by Government in a large folio volume of six hundred and ninety-one pages. The Committee of Revision, consisting of thirty-three members, under the presidency of Dr. Struck, held only a few personal meetings, but the work of the commission was much facilitated by the fact that the Government from time to time issued printed circulars among the members. The final draft of the work having been first printed in German (fol.), the work appeared in its official Latin garb in 1882, and went into force on January 1st, 1883. An official German translation was likewise published; and an English translation, by C. L. Lochman, appeared at New York in 1884.

www.libtool.com.cn

A standing committee, appointed by the German Pharmaceutical Association, almost immediately undertook a critical revision of this work, and in 1887 a permanent pharmacopœia commission was created by the Government. In 1890 the third edition appeared under the title, "Arzneibuch für das Deutsche Reich. Dritte Ausgabe. Pharmacopœia Germanica. Editio III." The Latin language was abandoned and the text made wholly German, with the exception of the titles of the articles. In the work of its revision the pharmacopœia committee of the German Pharmaceutical Association was of the greatest value.

The example set by the United States (1886 to 1888) and Great Britain (1887), in preparing national formularies of unofficial preparations was followed by the pharmacists of Germany in 1891, when the German Pharmaceutical Association published a similar work under the rather awkward title: "Arzneimittel welche in dem Arzneibuch für das Deutsche Reich (Dritte Ausgabe; Pharmacopœia Germanica, Editio III.) nicht enthalten sind" (= "Remedies which are not contained in the Arzneibuch," etc.). This contains eight hundred and eleven articles.

The fourth and last edition of the German Pharmacopœia was published in 1900. It exhibits the degree of progress which might reasonably be expected at the close of a decade so noted for research and criticism as that between 1890 and 1900. An unfortunate departure, however, is that of the uniform omission of the authorities of botanical names. In those cases in which there is but one such authorship, hence but one interpretation of the name, the omission is not serious; but there are some instances in which actual doubt as to what plant is intended may exist. Another unfortunate custom is that of placing the class name of a drug in advance of its individual name, in the title, as "Flores Malvæ" instead of "Malvæ Flores."

The influence of the German Pharmacopœia extends far beyond the geographical limits of the German empire. Outside of the United States Pharmacopœia there is probably no other, even not excepting the British, which is so frequently drawn upon by prescribers in this country.

Greece.—The first Greek Pharmacopœia was published in Athens under King Otto I., in 1837, under the title, "[illegible] φαρμακοποιία . . . παρὰ [illegible], Ξα[illegible] [illegible], [illegible] Σαρτωρίου," etc. ("Greek Pharmacopœia . . . by Joannes Bouros, Xaverios Landerer, Joseph Sartorius," etc.). It was based on the French, Bavarian, and various other German pharmacopœias existing at that time. The text is in Latin and modern Greek, side by side. Synonyms are given in Italian, French, English, German, and Turkish, wherever possible, but among them are many mistakes. In 1868 Professor Landerer had the work reprinted, with a supplement (παράρτημα) of the newer preparations, an etymological glossary, and a table of antidotes. This reprint was officially recognized by Government. In general it must be said that the work is very far behind the time.

Hayti has no pharmacopœia of its own. The French Codex is mostly followed.

Hawaiian Islands.—The United States Pharmacopœia is generally followed.

Hungary.—See Austria.

Italy.—Italy was the first country in Europe in which an official pharmacopœia was published. This was the "Antidotarium Florentinum," first published at Florence in 1498. Other similar works appeared at Mantua ("Antidotarium Mantuanum," Venice, 1559); Bergamo ("Ph. Bergomensis," 1580); Venice ("Ph. Veneta," 1617; "Codice pharmaceutico," 1790); Messina ("Ph. Messanensis," 1629); Naples ("Antidotarium Neapolitanum," 1649); Turin ("Ph. Turinensis," 1736); Sardinia ("Ph. Sardoa," 1773; the last edition, "Farmacopea per gli Stati Sardi," of 1853 is still in force); Bologna ("Antidotarium Coll. Med. Bononiensis," 1783); Genoa ("Formulario farm.," 1791); Ferrara ("Farm. Ferrarese," by Campana, 1799, etc.); Parma ("Ph. Parmensis," 1823; another edition of this appeared in 1839 for Piacenza, Parma, and Modena together). The Church States, Tuscany, Lucca, and many other Italian provinces follow a dispensatory published by Orosi, under the title "Farmacologia teorica e practica ovvero Farmacopea Italiana." Lombardy and Venice use the Austrian Pharmacopœia; Naples uses, besides other works, the "Ricettario farm. Napolitano," 1859. Throughout Italy a new work by Ruata, entitled "Farmacopea Nazionale e Generale, Materia Medica e Terapia" (Verona and Padova, 1883) is now frequently employed.

Although a commission for the publication of a national pharmacopœia was appointed years previously, the draft, under the presidency of Professor Canizzaro, was not reported until 1884, and the work was not published until 1892. Meanwhile, different portions of the country used such works as were prescribed by their local authorities, the army using the Sardinian Pharmacopœia of 1853. The present work is entitled, "Farmacopea ufficiale del Regno d'Italia" (8vo, Roma). This work was one of the first to introduce statements regarding the percentages of active constituents of drugs such as belladonna, jaborandi, and colchicum; yet methods of assay are not prescribed, so that the utility of the procedure is questionable.

Japan.—In 1880 a commission of twenty-one members, several of them Europeans in the service of the Japanese Government, under the presidency of Mr. Hosoakwa, undertook the work of preparing a pharmacopœia, which was published in August, 1886, as an octavo volume of nearly four hundred pages, the text in Japanese, under the title, "On yaku zuki Nippon yaku kiyoku ho." It consisted of an introduction, preface, and body, the latter comprising four hundred and seventy-five titles, followed by general directions for keeping certain drugs and preparations, lists of reagents and volumetric solutions, lists of articles always to be kept on hand, list of separanda, maximum doses, tables of specific gravity and of elements, a Japanese and Latin index, list of errata, table of doses for adults and children, then another list of errata. The official text was in Japanese, the scientific chemical, botanical, and zoological terms in Latin, in Roman characters, with Japanese transliteration. In the treatment of the subject, the United States, British, and German Pharmacopœias were mostly followed, but the text showed also independent and careful work on the part of the compilers. The sign [illegible], placed under an unusual quantity of a powerful remedy, is to be used by prescribers for the same purpose as the exclamation

Digitized by Microsoft®

point in European practice, viz., as an evidence that the prescriber intentionally ordered a large dose. The second edition of this work appeared in 1891, under the title "Pharmacopœia Japonica. Editio Altera. Tokyo, Anno xxiv. Meiji (1891)." It is wholly in Latin. It resembles its predecessor in general appearance and construction, but in the nomenclature of chemical substances, the last German and Austrian pharmacopœias have been followed as guides.

www.libtool.com.cn

Liberia.—The United States and British pharmacopœias are usually followed.

Mexico.—The Pharmaceutical Society of Mexico, in 1874, published a pharmacopœia which was officially recognized by Government. It was one of the best pharmacopœias of its time. In 1884 a second edition was issued by the same society, the text of which was already completed at the close of 1881. Its title is "Nueva Farmacopea Mexicana de la Sociedad Farmacéutica de Mexico." It presents among other special features a very copious materia medica, paying particular attention to native products. The text is in Spanish in two columns. In general the work rather corresponds to what we would call a dispensatory, as it treats also of the medical properties and uses of the several drugs and preparations, and covers a good deal more ground than is usual for a pharmacopœia. It is a very carefully prepared and meritorious work.

Netherlands.—The frequent political changes in the Low Countries were not without influence upon the existence or validity of its pharmacopœias. Among the earlier works of this kind which may be mentioned here are the following, in cities now belonging to the Netherlands: Amsterdam ("Ph. Amstelodamensis," 1636; last edition, 1792, see below); The Hague ("Ph. Hagana," 1652; last edition, 1758); Utrecht ("Ph. Ultrajectana," 1656; last edition, 1749); Louvain ("Ph. Lovardensis," 1687; last, 1745); Haarlem ("Ph. Harlemensis," 1693; last, 1741); Dort ("Ph. Dordracena," 1708; last, 1766); Rotterdam ("Ph. Roterodamensis," 1709; last, 1835); Alcmar ("Ph. Alcmariensis," 1723); Groningen ("Ph. Groningana," 1724, '30). At one time the Netherlands belonged to Austria, hence the "Ph. Austriaco-Provincialis" was made official and a Dutch translation of this was published in 1781. After the establishment of the Batavian republic (1795–1806) a commission was appointed to draft a pharmacopœia. This was completed and published in 1805 under the title "Ph. Batava," and was a work of great merit, being by far the best of its time. This work has been extended and commented upon by Niemann (1811, second edition, 1824) in an excellent manner. In 1851 appeared the first "Ph. Neerlandica," the text being both in Latin and in Dutch. It had much resemblance to the French Codex. A revised edition, both in Latin and in Dutch, appeared in 1871, the Latin version being, as in the first edition, the official text. It contained six hundred and fifty-five titles. In 1884 a Government commission was appointed for revising this work, and a new edition appeared in 1889 under the title, "Nederlandsche Pharmacopee. Derde Utgave (= third edition), 's Gravenhage, 1889." Excepting the titles of the articles, the text is entirely in Dutch. A Latin edition soon appeared under the title "Pharmacopœia Neerlandica. Editio tertia. Haga Comitis, 1889." It was specially decreed, however, that the Dutch edition was to be considered the official one.

In 1891 the Rotterdam branch of the Netherlands Pharmaceutical Society (Nederlandsche Maatschappij ter Bevordering der Pharmacie) followed the lead of other countries, by issuing an unofficial formulary under the title: "Supplementum op de derde Utgave der Nederlandsche Pharmacopee . . . 's Gravenhage, 1891." It contains five hundred and seventy-three articles.

Norway did not possess a pharmacopœia of its own until 1854, the Swedish Pharmacopœia being used in the country up to that time. The "Ph. Norwegica" was revised in 1870, and this second edition was reprinted with additions in 1879. It contains some five hundred and ten titles. The text is in Latin. It much resembles the Swedish and Danish pharmacopœias, but the influence of the German Pharmacopœia is clearly perceptible.

Paraguay.—The French, Spanish, and occasionally other pharmacopœias are usually consulted.

Peru.—The French, Spanish, United States, and British pharmacopœias are usually drawn upon.

Poland.—See *Russia*.

Portugal.—In 1704, Cætano de Santo Antonio published a "Pharmacopea Lusitana Galénica" at Coimbra. This was republished at Lisbon (as "Ph. Lusitana," or, "Ph. Ulissiponense") in 1716, and twice reprinted. In 1785 appeared de Poiva's "Farmacopea Lisbonense." The first official pharmacopeia was published by Dr. Tavares in 1794, under the title "Farmacopeia Geral para o Reino e Dominios de Portugal." In 1825 this was supplanted by the "Ph. Lusitana," and this was followed in 1838 by the "Codigo Pharmaceutico Lusitano" (revised 1858). Finally a new "Pharmacopêa Portugueza" was issued in 1876. This is a very good work, prepared with care and judgment. The text is in Portuguese, except the synonyms of titles, which are in Latin. It has been shorn of the obsolete rubbish of the therapeutics of former times.

Roumania issued a pharmacopœia in 1861, under the title "Pharmacopœa Romana." A second edition, revised, appeared in 1874. The text throughout is in Roumanian, without Latin synonyms. It bears some resemblance to the Austrian Pharmacopœia, but has some distinctive features of its own.

Russia.—Up to the year 1866 Russia had no official national pharmacopœia, except one for the army which was first issued in 1765. In 1779 a revised and much improved edition of the latter appeared, under the title "Ph. Castrensis Rossica." This was followed in 1789 by a special pharmacopœia for the navy ("Ph. Navalis," last revised in 1869). Both of these were superseded in 1808 by the "Ph. Castrensis Ruthenica," edited by Wylie, of Moscow. This was several times revised, last in 1866. A civil pharmacopœia appeared as early as 1778 at St. Petersburg (reprinted in 1782), under the title of "Ph. Rossica," and a second edition in 1798 (reprinted 1803); but these were not officially recognized, the pharmacists being compelled to consult almost every prominent European pharmacopœia when putting up prescriptions. That which was most followed, generally, was the "Ph. Borussica." In 1866 the first official civil pharmacopœia was issued. This was followed by new editions in 1871, 1880, and 1891. The title is "Rossiiskaya Pharmakopeya," edited by the Medical Council in the Department of the Interior, by order of his Imperial Majesty, etc. Great care was bestowed upon the two last editions, the best features of the German Pharmacopœia being incorporated into it. The text is in Russian, the main titles and synonyms, however, and the names of the ingredients entering into the preparation being in Latin. A special pharmacopœia for the use of the imperial court was published in 1874. Hence there are four Russian pharmacopœias in existence—the military, the naval, the civil, and the court pharmacopœia. The military work is in some respects a sort of dispensatory, as it goes more into details.

A separate pharmacopœia was published for Poland, in Warsaw, in 1817, under the title, "Ph. Regni Poloniæ," but this does not seem to have long remained in force. On the other hand, Finland published a pharmacopœia of its own ("Ph. Fennica") in 1819 (at Abo). Later editions of this appeared at Helsingfors in 1850 (ii.), 1863 (iii.), and 1885 (iv.). The text of this is in Latin. It is closely allied to the several Scandinavian pharmacopœias, and in certain features still more closely to the last German Pharmacopœia. In extent, it is one of the smallest, comprising only about four hundred articles.

Spain.—Previous to the appearance of a national work, local pharmacopœias had been in existence in the following cities: Salamanca ("Ph. Salamanca," by J. Bravo, 1588); Barcelona "(Ph. Catalana," 1686); Almeria ("Ph Almeriana," 1724); Saragossa and Valencia ("Officina Medicamentorum," 1601, 1698, 1739); Madrid ("Ph. Ma-

Digitized by Microsoft®

tritensis," 1729 +). In 1521 was published at Madrid the "Examen Apothecariorum," composed in 1497 by Pedro Benedicto Mateo, which has been found by Mallaina to be a veritable pharmacopœia. The first national pharmacopœia ("Ph. Hispana") appeared in 1794. This and the next three editions, viz., of 1798, 1803, and 1817, were written in Latin. The fifth (1865) and sixth editions (1884) are in Spanish with Latin synonyms of the titles. The "Farmacopea Oficial Española" appears to have made the least progress of any. Even the last edition, here and there, betrays an adherence to unscientific, empirical, or obsolete remedies and methods. Besides, it bears internal evidence of the influence of the new French Codex. In the number of articles, of which it contains nearly one thousand seven hundred, it is only exceeded by the last-mentioned work.

Attempts have been made to prepare a separate pharmacopœia for *Cuba*, but no tangible results have been reached thus far.

Sweden.—A "Ph. Holmiensis" was published at Stockholm in 1686. The first work, bearing the title "Ph. Suecica," appeared in 1705, but without special authority. The first official pharmacopœia appeared in 1775, and the succeeding editions in 1779 (ii.); 1784 (iii.); 1790 (iv.); 1817 (v.; in this edition the chemical portion was edited by Berzelius, and the botanical and zoölogical by Swartz; it was the most advanced and perfect pharmacopœia of its time); 1845 (vi.), and 1869 (vii., with supplement of 1879). The last edition has been several times reprinted with amendments. It has much resemblance to the Danish and Norwegian (see under Denmark). The text is in Latin, and the number of titles is six hundred and seventy seven.

Switzerland.—A "Ph. Helveticorum" was published at Geneva in 1677. In 1684 there appeared in the same city an edition of Charas' "Pharmacopea Regia Galenica et Chymica," which was followed as authority for a long time. The Basle Medical Society, in 1771, published a "Ph. Helvetica" (containing an introduction by A. de Haller). A "Ph. Genevensis" appeared in 1780, and was reprinted several times afterward. In 1852 an elaborate draft of a pharmacopœia for the Canton of Berne was published at Berne under the title "Pharmacopœæ Bernensis Tentamen." This may be regarded as the precursor of the "Ph. Helvetica," published in 1865 at Schaffhausen, by the Swiss Pharmaceutical Society. The latter work has been recognized by law in most of the cantons, but not in all. A second edition appeared in 1872, and a large supplement in 1876.

The text of this pharmacopœia is in Latin, and has much in common with the German Pharmacopœia. A new work, "Pharmacopœia Helvetica, Editio III.," was issued in 1893.

The Canton of Tessin has a pharmacopœia of its own, published in 1848. Geneva uses the French Codex.

Turkey.—The Imperial Medical School at Constantinople has directed the use of the French Codex. Other foreign pharmacopœias, however, are also in use.

Uruguay.—The French and Spanish pharmacopœias are chiefly in use.

Venezuela.—The French and Spanish pharmacopœias are mostly in use. Long since, the medical faculty at Caracas took initiatory steps to prepare a national pharmacopœia, without result so far.

Charles Rice.
Revised by *Henry H. Rusby.*

PHARMACOPŒIA, UNITED STATES.—HISTORY.—The first pharmacopœia in the United States was published at Philadelphia, for the use of the Military Hospital of the United States army, located at Lititz, Lancaster County, Pa., in 1778, under the title, "Pharmacopœia simpliciorum et efficaciorum in usum nosocomii militaris ad exercitum fœderatarum Americæ civitatum pertinentis, hodiernæ nostræ inopiæ rerumque angustiis, feroci hostium sævitiæ, belloque crudeli ex inopinato patriæ nostræ illato debitis, maxime accommodata" ("Pharmacopœia of the more simple and efficacious [preparations] for the use of the Military Hospital of the Army of the United States of America; specially adapted to our present poverty and distress, due to the ferocious cruelty of the enemy and to the bloody war unexpectedly brought upon our fatherland"). Only one copy of this edition is known to exist, which is in the surgeon-general's office at Washington. Of a second edition, there appears to be likewise only one copy known (see *Am. Jour. Pharm.*, 1881, 483). This was issued in 1781. Upon the title page appears the name of Dr. William Brown, as author. It is entirely in Latin, in thirty-two pages. It contains eighty-four internal and sixteen external remedies. Previous to the year 1820, various European pharmacopœias, chiefly those of London, Edinburgh, and Dublin, were used in the United States, though the want of a national pharmacopœia was, to some extent, filled by Coxe's "American Dispensatory" (first edition, Philadelphia, 1806 +), and Thacher's "American New Dispensatory" (first edition, Boston, 1810 +). In 1808 the "Pharmacopœia of the Massachusetts Medical Society" was published at Boston, and in 1816 the "Pharmacopœia of the New York Hospital" at New York. The first impetus to a national pharmacopœia was given in 1817, by Dr. Lyman Spaulding, in a plan laid before the Medical Society of the County of New York. (For details of the history of the "Pharmacopœia of the United States of America," consult the latter work, sixth edition, New York, 1882, pp. v.–xiii.). The first convention for the formation of a national pharmacopœia assembled at Washington on January 1st, 1820, at which time the several drafts previously prepared by the several district conventions were consolidated and revised. The finished work was published at Boston, on December 15th, 1820, both in Latin and in English. A second edition appeared in 1828. Before adjourning, the convention provided for a future revision of the work, by arranging for the call of a convention in 1830. Owing to a misunderstanding, however, two separate conventions were held in this year, one meeting at New York, and the other at Washington, and two separate pharmacopœias resulted from this, one being published at New York in 1830, the other at Philadelphia in 1831. Fortunately, the bodies who had met at New York subsequently abandoned the plan of continuing a separate revision in the future, and in 1840 the third general convention assembled again at Washington. The Committee of Revision appointed at this convention was authorized to request the co-operation of the colleges of pharmacy, and this resulted in the contribution of much valuable material. The new revision was published in 1842, the text being for the first time only in English, the Latin being restricted to the titles and synonyms. At the next convention, in 1850, the incorporated colleges of pharmacy were for the first time invited to participate in the deliberations. Previous to this, only incorporated medical societies had been invited to send delegates. The fourth edition of the work appeared in 1851, and a second edition of this in 1855. The next two conventions met at the appointed time, in 1860 and 1870, and the fifth and sixth editions of the pharmacopœia were issued in 1863 and 1873, respectively. Several years before the next succeeding convention (in 1880), a very lively interest was awakened in the proposed new revision of the work, and several plans were advanced, looking toward a radical change in the manner of revising and controlling the revision of the pharmacopœia. A large amount of preliminary work was also bestowed, principally on the part of the American Pharmaceutical Association, upon the plan and contents of the next edition. The convention which assembled at Washington, in 1880, was the most representative of any that had so far been held, and after a general plan of revision had been adopted, a Committee of Revision and Publication was appointed, consisting of twenty-five members, residing in various parts of the United States. This committee has made a detailed report of its proceedings in the preface to its work, which appeared toward the end of 1882 (see "United States Pharmacopœia," 1882, pp. xxvii.–xxxiii.). The title page designates this as

Digitized by Microsoft®

the "Sixth Decennial Revision"; consequently, this was the *seventh* edition of the work. In this revision radical changes were made, the intention being to render the work as independent of commentaries as was possible. The arrangement was alphabetical throughout, all crude drugs and chemicals being defined and accompanied by descriptions or by tests of identity and purity. Actual weights and measures were replaced by a system of parts by weight, except in the case of fluid extracts. Many obsolete articles were dropped, and many new ones admitted, the total number of accepted titles being nine hundred and ninety-seven. The general verdict of all competent critics, both at home and abroad, was that this was one of the best pharmacopœias ever issued, and that it did not suffer by comparison with works that appeared later.

It having been long felt that the pharmacopœia contains a considerable number of preparations which are not frequently prescribed, and are retained only in order that, if called for, their uniform composition may be insured, the American Pharmaceutical Association undertook the compilation of a "National Formulary of Unofficial Preparations," primarily designed to establish uniform formulas for any compound used in legitimate pharmacy or prescribed by physicians, and for which there is no recognized official standard. It was believed that this formulary might eventually be made the repository of all such pharmacopœial articles as are no longer deemed of sufficient importance to be included in the official list. This work was published in 1888, under the above title, and has proved very useful. In May, 1890, the Decennial Convention for Revising the Pharmacopœia met at Washington, and resulted in the election of a committee of revision, consisting of twenty-six members, located in different sections of the country, and gave instructions for the "Seventh Decennial Revision, or the "Eighth Edition," which was published by the committee itself, and went into effect on January 1st, 1894. The most important features introduced into this work were the substitution of the metric system of weights and measures for "parts by weight"; the reference of the standardizing of preparations by chemical assay, and of such assay processes to the discretion of the committee, the committee subsequently deciding upon the adoption of such standards for only a few drugs and preparations; volumetric methods were made to replace, as far as possible, gravimetric methods; articles protected by proprietary rights were excluded; important changes in chemical nomenclature and notation were adopted, though radical measures were rejected; in botanical nomenclature the Rochester code was adopted as authoritative; ninety articles were dropped and eighty-eight were added; the word *official* was adopted to replace "officinal." This work was received universally as representing the most advanced, yet sufficiently conservative standard among pharmacopœias, and the advances in it have so far commended themselves to the medical and pharmaceutical professions during the decade since its appearance, that further progress in the same directions has been generally urged, particularly in that of an extension of the list of assayed drugs and preparations. It may be safely said that the Pharmacopœia of 1890 has done more than any of its predecessors for general pharmaceutical education, and to only a lesser degree for medical education. At the present time (January 1st, 1903), the work of the Eighth Decennial Revision is nearly completed. Soon after the meeting of the convention of 1900, death removed the beloved and highly talented chairman of the revision committee, Dr. Charles Rice, and Prof. Joseph P. Remington was elected as his successor. The interest in this revision, throughout the country, has been general and hearty, and the committee has worked with the greatest enthusiasm. Of the many important changes in the pending publication some are fairly radical. The work of revision and that of publication have been assigned to distinct bodies; the former to a committee of twenty-five members, as before, the latter to a board of trustees, a regular incorporation having been effected for this purpose. Among the special features of this revision the following are worthy of note: Whenever possible, articles are to be standardized on the basis of chemical assay; physiological standards may also be represented in the requirements for antitoxin, notwithstanding the instructions of the convention to the contrary, the committee having decided that the importance of the subject demands even so dangerous a precedent as this; although the descriptions of crude drugs are to retain, so far as is consistent with clearness and accuracy, the simple language of the preceding edition, yet simple descriptive terms are to be introduced, wherever necessary, to facilitate the detection of elements of adulteration entering into powdered drugs; a wonderful advance over the instructions of 1880, which forbade the introduction of any characters which could not be seen with a lens magnifying "about ten diameters"; doses are to be specified, and, finally, the revolutionary principle has been accepted that proprietary rights of limited duration in a meritorious drug, provided that the conditions render it amenable to standardization and resulting control, do not constitute an objection to its recognition by the Pharmacopœia, and a sub-committee has been appointed to determine what proprietary articles can properly be admitted under this rule.

Authority of the Pharmacopœia.—The authority of a pharmacopœia may be legal or professional, and may be established either before the existence of the work, by the legal or professional appointment of its compilers, or thereafter, through its adoption by a government or by a representative professional body. In either case it occupies a special office, and all matters pertaining to it are therefore denominated *official*, or, according to older usage, "officinal." Thus we have official and unofficial drugs, medicines, reagents, and other substances, as well as official titles, synonyms, definitions, descriptions, tests, formulas, processes, doses, etc. The professional authority of the Pharmacopœia is not compulsory, except as a violation of such of its provisions as have professional sanction involves professional disrepute. Its legal authority, established by statutes, with penalty attached, is of course so. In this way the United States Pharmacopœia has been made the legal authority in many States, as well as wherever the jurisdiction of the national Government extends.

Objects and Scope of the Pharmacopœia.—In the definition given under *Pharmacopœia*, it is stated that the standards named apply to the "medicines used in the practice of medicine"; not merely to those whose merits justly entitle them to such use. The object of the book is to provide a means of assuring the user of a drug or medicine that he shall receive that for which he calls. The right of each individual to such assurance, regardless of whether his selection of the article is well advised, is obvious, and constitutes the chief basis of procedure in the preparation of the book. The selection of the articles to be made official is thus based upon the fact of their common use. Since very many worthless or very inferior articles are in common use by physicians as well as among the laity, the recognition of such in the Pharmacopœia is thus called for. On the other hand, many valuable drugs are brought forward without ever attracting much attention or coming into general use, so that the mere fact that the compilers of a pharmacopœia believe a new drug to possess merit does not justify them in recognizing it. Such a drug must first establish at least a probability of coming into general use before it shall receive recognition. From the above, it follows that "the recognition of a drug by the Pharmacopœia is not evidence, *prima facie*, that it possesses merit, nor the absence of such recognition that it does not." It also follows that the Pharmacopœia is not to be regarded as a guide to the practitioner in the selection of his remedies, but rather as an index to the general conditions of practice in such respect and as an authority for testing the genuineness of the articles treated by it. A knowledge of the merits of the articles, and an ability to make a judicious selection, are supposed to be gained from a

Digitized by Microsoft®

study of text-books and other literature relating to therapeutics. It may be added that experience in the United States has repeatedly demonstrated the fact that the introduction of an article to the Pharmacopœia has very little weight by itself in extending its use.

www.libtool.com.cn

In spite of these considerations, the compilers of our Pharmacopœia do recognize a certain responsibility for favoring the worthier articles; so that at their periodical revisions they are disposed to employ a liberal construction of the above guiding principles and to lean toward the expurgation of the more worthless articles and the introduction of meritorious ones whenever the conditions will possibly justify them.

There is another class of important articles which many physicians, even among the more intelligent, see with surprise to be denied a recognition in the Pharmacopœia, notwithstanding that such denial is a natural necessity; such articles, namely, as are, for one reason or another, not subject to any official definition, description, or standardization. Of this class the most conspicuous examples are found among copyrighted articles. In these cases it is the names alone which are copyrighted and which have a fixed identity. Absolute ownership of these names is conferred by the copyright, and there is no stipulation as to the use which is to be made of them, except that they shall be arbitrary, that is, not descriptive of the article to which they are applied. They may be meaningless, or they may be devised with the object of misleading the public, as by naming the syrup of a well-known fruit, whereas, if such were the real origin of the preparation, its name would be descriptive and would at once lose the copyright protection. Furthermore, the substance to which the name is applied may be changed or substituted at the will of the owner of the name and as often as he desires. Manifestly, control and standardization by a pharmacopœia of an article so named is an impossibility. The case is quite different with those articles which are protected by patents of limited duration, either upon the product itself or upon the process by which it is prepared. Such protection provides for publicity and freedom at the end of the patent period. Ethical views regarding such protection have of late undergone a very great change. Here, as in many other parts of the medical field, rationalism has replaced blind and arbitrary ruling, and the *cui bono* standard has come to be applied, with the result, as stated below, that certain important, not to say absolutely necessary drugs which enjoy limited protection are to be recognized in the forthcoming edition of our Pharmacopœia.

Official Names and Definitions.—The official Latin and English titles call for little discussion. They constitute, like other names, a basis for specifying the respective articles, and their use in preference to that of any other names by which the articles may be known, enables the prescriber to secure the support of official, and in many cases of legal authority, which he might find it difficult to obtain if he used an unofficial title, subject to different applications in different localities, and perhaps even in professional literature. In special cases, when the latter condition exists so as to involve special danger of misunderstanding, the Pharmacopœia may also recognize one or more synonyms.

The official definition is intended to be a full statement of what constitutes the article named by the title and at the same time limits it by the exclusion of all else. In the case of pure chemicals or pure substances of natural origin, as alkaloids and glucosides, the chemical formula usually constitutes a complete definition. If the article is not required or expected to be absolutely pure a statement of the allowable amount, and perhaps of the nature, of the impurity frequently forms a part of the definition. In the case of animals or plants or their parts, the definition states clearly what part or parts shall be employed. The terms used in naming such plants and parts are those authoritatively employed in zoology and botany. In cases in which zoological or botanical authority is divided, as in the rules of botanical nomenclature, the compilers decide which method and rules shall be employed, and a statement to that effect is incorporated into the introduction of the book. The family or natural group to which the animal or plant pertains is also named in the definition. This is, strictly speaking, superfluous to a definition, but proves convenient and instructive.

When the living part is to be taken or collected in some particular stage or condition, as "in full bloom," "in the second year of its growth," "when full grown," "fully ripe," etc., this fact also is stated in the definition, as is any change which is to be made in it in preservation or preparation, as "the dried root," "a prepared exudation," "an inspissated juice," a bark "kept one year before being used," or "not kept longer than one year," etc. In special cases, a note may be appended to a definition specifying some danger to which the article is peculiarly liable, and stating how the same may be avoided. In a few cases, when the facts regarding the origin of an article are unknown, as in the case of the root of an unknown species of Smilax, or when the number of species yielding the article is indefinite or inconveniently large for specification, the definition cannot be made fully to accomplish its purposes. The best possible must then be done with it and the description must be relied upon, to accomplish the remainder.

Official Standards.—The standards of the Pharmacopœia are physical, chemical, and physiological, and are incorporated into the descriptions.

The description, in other cases than those referred to above, is not to be regarded as partaking of the same nature as the definition, but as a statement of the tests which are to be applied by one having the article in hand, for the purpose of employing the specified standard. These standards and tests may be qualitative or quantitative. The ordinary physical test is included in the description of the drug as regards color, surface, and other external appearances, hardness, weight, fracture, structure, odor, and taste. Chemical standards, qualitative or quantitative, do not differ from those ordinarily employed in chemistry. Physiological tests are by many regarded as excluded by the general nature and uses of a pharmacopœia. Nevertheless, many of the physical tests, such as peculiar effects upon the nose or tongue, the pupil and other organs, may fairly be denominated as physiological and the extension of this class of standards in the pharmacopœia in the future is to be anticipated.

Preparations.—Among the several preparations to which drugs are subject the Pharmacopœia makes a selection, in each individual case, based upon the nature of the article, on both pharmaceutical and therapeutical grounds, and these preparations are enumerated just after the description. In those cases in which a small amount of the drug enters into some other article or preparation merely as an adjuvant, and not especially for its own medicinal effect, such article or preparation is not regarded as a preparation of that drug and is not thus named. Proximate principles, such as alkaloids, glucosides, fixed and volatile oils, also, are not treated as preparations. There are a number of instances in which neither pharmaceutical nor therapeutical considerations can determine a selection, and here no preparation is specified, though opinions are not wanting to the effect that at least one official preparation ought to be supplied for every official drug. The preparations thus named are then treated, in the regular alphabetical order of their titles, as official articles, their formulas and methods of preparation being given in full detail and in some cases definite standards being supplied, similar to those above described for the drugs themselves. The question has been much mooted as to whether a preparation can be considered to be official if, made strictly in accordance with the formula and of a quality fully equal to that resulting from the official process of manufacture, it differs merely in some variation from the latter. The question is a delicate and not unimportant one. It is urged upon the one hand that the principal object of prescribing an official process is to insure the quality of the preparation, and that if departures from it be permitted, a tendency

Digitized by Microsoft®

to laxity may be encouraged. Upon the other hand, it is clear that in large manufacturing operations the methods of the retail pharmacist are impracticable, and even that a better result may be otherwise attained. The view of this subject, which has always been taken, at least in modern times by the revisers themselves, is that a deviation from the process is permissible, provided that a satisfactory preparation is insured.

Doses.—The United States Pharmacopœia has never heretofore been willing to assume the responsibility involved, or which might be involved in particular cases, by the adoption of doses. The possibility that the prescribed dose might in individual cases act disastrously, and that the compilers of the Pharmacopœia might be held responsible for having authorized it, has always acted deterrently. At length, however, a method has been devised by which, according to the highest legal advice, a system of official dosage can be adopted which will be free from this danger. Doses are therefore to be introduced into the forthcoming edition, although their exact limitations have not yet been made public.

The Appendix.—The Appendix of the Pharmacopœia containing lists, definitions, descriptions of reagents, tables of atomic weight, thermometric equivalents, alcohols, acids, and other important chemicals, of saturation, equivalents of the English and metric systems of weights and measures, is of great importance, possessing an authoritative value for accuracy and a facility for reference which, without any regard to the subject matter found in the body of the work, entitles the latter to a convenient position upon the shelf or table, not only of every physician and pharmacist, but of every person whose work brings him into contact in any way with physical or chemical science.

Use of the Pharmacopœia.—The use of the Pharmacopœia by pharmacists is incomparably greater than that by physicians, and to this fact is in great part due the higher degree of accuracy and care and the more definite knowledge of the former profession regarding the materia medica. Not only is this true, but it is undeniable that the most serious shortcomings of the medical profession in matters therapeutical might be largely eliminated were they to rely more fully upon reference to this work. While it is true that the Pharmacopœia provides no information directly concerning therapeutics, yet it contains very full information, and of the most reliable character, concerning materia medica, fundamental to therapeutics and, in turn, the highest teachings of therapeutics constitute its basis as to preparations and dosage, and as to a majority of the drugs treated.

Henry H. Rusby.

PHARMACOPŒIAS, GENERAL AND INTERNATIONAL.—Many works have been published, which are designed to comprise the text of all, or at least the most prominent pharmacopœias. Among the earlier authors of such works are Lemery, Charas, Spielmann, Swediaur, Quincy, Brugnatelli, etc. Of more recent works the following deserve special mention: A. J. Jourdan, "Ph. Universelle" (Paris, 1828, second, ed. 1840); P. L. Geiger, "Ph. Universalis" (Heidelberg, 1835-45); B. Hirsch "Universal-Pharmakopöe" (Leipsic, 1885, vol. i.).

Many years ago efforts began to be made to bring about greater harmony in the different pharmacopœias, and the proposition was finally made to inaugurate an International Pharmacopœia. Opinions differed greatly for a long time, not only as to whether the plan was feasible at all, but also in regard to details. Steps were finally taken to have a draft of the work prepared, but national jealousy on several occasions rendered its acceptance impossible. It was not to be expected that each civilized nation would abandon its own pharmacopœia, specially adapted to the habits of its own people and its own domestic resources, for one elaborated without regard to such considerations, and possibly introducing unfamiliar preparations or changing the strength of such as were in common use. The utmost that could be expected was that the different nations, whenever revising their own pharmacopœias, would gradually approximate such preparations as were regarded worthy of international regulation to the proposed standard. Another hope which was expressed was this, that the International Pharmacopœia might be used and followed as an *independent* work in different countries in this way, that prescribers would designate preparations contained in it in their prescriptions. A plan has been presented for the establishment of a common pharmacopœia for the American continent. This is too wide a scope to be feasible at present. But it *is* feasible to prepare a pharmacopœia for all the Spanish-speaking countries in Central and South America, provided all political differences are waived for the sake of the benefit which may accrue from the result. After some uniformity has been reached in Central and South America, it remains to be seen how much further it can be carried. At the International Pharmaceutical Congress, held at Brussels in 1886, the draft of an international pharmacopœia was presented by the president of the International Commission, Baron A. von Waldheim, of Vienna. Yet, in its preparation the other members of the commission had not been sufficiently consulted, and the draft was not accepted. Other meetings of this Congress have been held since, the seventh taking place at the close of the meeting of the American Pharmaceutical Association in Chicago in 1893. At this time what may be regarded as the first practical step toward reaching an international agreement was taken when the American Pharmaceutical Association appropriated $1,000 toward defraying the expense of preparing and publishing an international pharmacopœia, to be confined to the treatment of potent remedies. In 1897 the Congress met again at Brussels, but did not approve of this proprosition for a restricted pharmacopœia, and again indorsed the idea of a large and comprehensive work. In the mean time, no steps have been taken toward carrying out that plan, and the less visionary representatives, led by the American and British contingents, have gone ahead with the initial steps in the direction of preparing a work treating of potent remedies. A report on this subject has been submitted to representative bodies in the different countries, and there seems to be some prospect that important results may follow.

Instead of attempting the almost impossible, the advocates of uniformity in medicines appear to be willing to bring about the desired end by natural means, that is, by first causing the consolidation of the pharmacopœias of contiguous countries, particularly those in which the same language is spoken. Thus, Germany has long ago displaced the host of local pharmacopœias in existence previous to the establishment of the empire by a single national work. Italy has done the same. The Scandinavian countries also contemplate doing this. It is easy to foresee that there never will be an international pharmacopœia which will replace each individual national one. The best that can be hoped for is a work containing the description, definition, requirements of purity and strength of what may be called international remedies, single or compound, and even this cannot be introduced without risking danger from the administration of preparations the strength of which as contained in the international pharmacopœia differs from that prescribed in the national pharmacopœia of the dispenser.

Universal Pharmacopœia.—In this place should be mentioned the work by Dr. Bruno Hirsch, of Berlin, entitled, "Universal-Pharmakopöe. Eine vergleichende Zusammenstellung der zur Zeit in Europa und Nordamerika gültigen Pharmakopöen" (Universal Pharmacopœia. A Comparative Digest of the Pharmacopœias in force at the present time in Europe and in the United States). This work contains practically the whole text of the several pharmacopœias (except that of Portugal) in such a way that the similarities and differences of the requirements of the several texts are shown at a glance

Digitized by Microsoft®

in connection with each subdivision of an article. It is a work of reference indispensable for every revision committee in this and other countries for many years to come. *Charles Rice.*

PHARYNX, ANATOMY OF. See *Tonsils, etc.*

www.libtool.com.cn

PHARYNX, DISEASES OF: ACUTE INFLAMMATIONS.—In the text-books, generally, the use of the term pharyngitis is somewhat confusing, as tonsillitis, uvulitis, and palatal inflammation, as well as inflammation of the pharynx proper, are loosely included in the term. While in nearly all inflammations of the pharynx the contiguous structures anteriorly are involved, yet, as diseases of these structures are considered elsewhere in this work, the term pharyngitis, as here used, will be definitely limited to inflammations of the pharynx proper, except in treating of the throat complications of the acute fevers.

Simple Acute Pharyngitis.—Acute inflammation of the pharynx is usually accompanied by inflammation of other portions of the upper respiratory tract, and there is commonly more or less nasal occlusion. Acute inflammation, not septic or traumatic, strictly limited to the pharynx, is very rare.

Etiology.—As a rule the acute disease is either the lighting up of a subacute inflammation or an extension of acute nasopharyngitis. As etiological factors may be mentioned: bad air, poor food, sedentary habits, alcoholic intemperance, excessive use of tobacco, and in general anything that tends to lower the vitality. Digestive disorders, nasal obstruction, sudden atmospheric changes, influenza, and tonsillitis are frequent causes. Heredity plays an important part, and rheumatism and gout are sometimes factors. As traumatic causes may be noted, irritant poisons, flame, hot water, steam, foreign bodies.

Pathology.—There are hyperæmia and congestion of the blood-vessels in the submucosa, with pressure on the mucous glands and lessening mucous secretion during the first stage. In the second stage, congestion is somewhat relieved and the secretion is poured out, the tenacity of the latter depending on the amount of fibrin present. If the amount of fibrin be very great, there is formed a false membrane which is non-infectious.

Symptoms.—The attack is usually sudden and is ushered in by a feeling of malaise and chilliness rather than a distinct chill. The temperature rarely goes beyond 101°–102° F. The digestive system is usually deranged, the appetite is lost, the bowels are constipated, the tongue is furred, and the breath is foul. Pain in the muscles of the neck and back is common; there is generally headache and often there is aching of the joints. At first there is dryness of the throat and the surface of the mucous membrane is shiny and smooth. Later, the secretion becomes abundant and the membrane thickened and rough from hypertrophy of the lymphoid follicles. The voice becomes thick and husky and there is fatigue on talking, even when there is no apparent involvement of the larynx. In the attempt to get rid of the mucus the patient hawks and hems rather than coughs, while the dryness, or later the thickening, causes frequent efforts at swallowing. The feeling at first is as though there was a hair in the throat; later, it is that of a larger foreign body. Pain is a constant symptom, being increased by the efforts at swallowing. When the group of follicles just back of the posterior pillar is much involved, pain referred to the ear is usual, being conveyed through Eustachian involvement or by means of the glossopharyngeal or Jacobson's nerve. The sense of taste may be decidedly obtunded, especially if the lingual tonsil is involved; but this symptom is rather an accompaniment of nasal obstruction. The color of the mucous membrane varies from pink to dark red, and the superficial blood-vessels show much enlargement. The attack may be limited to one side, but it is nearly always bilateral.

Prognosis.—This is favorable, but at the same time the disease manifests a strong tendency to become chronic, by reason of the continuance of the exciting causes and the impossibility of putting the organ at rest. The duration varies from three or four days to two weeks, according to the severity of the attack and the general health of the patient.

Treatment.—This should begin with a saline cathartic, preferably preceded by one or two grains of calomel in triturate. Tincture of aconite in one-minim doses hourly seems to have a special action in pharyngeal inflammation; but, if the pain is considerable, phenacetin, five to eight grains every three or four hours, or Dover's powder, may be given. If there be a rheumatic diathesis, the salicylate of strontium, five grains every three hours, will prove of value, while in tonsillar complications salol, five grains every four hours, or salipyrin, ten grains at like intervals, will be better.

Quinine is recommended, but it is most likely to be of service when the tonsillar involvement suggests mild sepsis. In the early stage cold externally by wet compresses or a cold coil will give relief; later, heat will be more agreeable. A four- to six-per-cent. solution of nitrate of silver brushed lightly over the pharynx is useful, but one of the newer albuminous silver compounds, as protargol in ten-per-cent. spray, will be less irritating and just as good. Lennox Browne pronounces guaiacol —fifty per cent. in sweet almond oil, used with brush or spray—to be the best of all local applications. This burns sharply, but is followed by an anæsthetic effect. While gargles do not reach much of the posterior wall of the pharynx they do reach the contiguous parts, and any one who has personally used a gargle knows the comfort which follows its use. If a patient does not know how to gargle it is not well to rely on the method, as in such cases it is nothing more than a mouth wash. The best gargles are on the order of the Dobell solution, used hot. If carbolic acid is disagreeable, it may be omitted and the solution made up with equal parts of cinnamon water and peppermint water. In the early stage a spray of mentholated benzoinol, from two to four grains of menthol to the ounce, may be more agreeable than a watery application. Later, a gargle or spray of tincture of chloride of iron will hasten recovery.

Demulcents in the form of lozenges are often grateful. They may contain menthol in minute dose combined with guaiacum or eucalyptol.

Shurly recommends, for the mitigation of local distress, a tablet of biniodide of mercury (gr. $\frac{1}{60}$ to gr. $\frac{1}{30}$) to be held in the mouth till dissolved, the dose being repeated every two or three hours till five or six have been taken. In the second stage, if the secretion continues profuse for too long a period, atropine or aconitine, gr. $\frac{1}{1000}$ to gr. $\frac{1}{500}$ every two or three hours, will hasten recovery. Steam inhalations are generally worse than useless, although sometimes temporarily soothing in the earliest stage.

Gangrenous Acute Inflammation of the Pharynx. —This disease is ordinarily classed under infective or phlegmonous pharyngitis, the severer forms being accompanied by sloughing. Including all forms under this title, one writer will give the prognosis in infective pharyngitis as very grave, while another, limiting the term to the milder cases, will state that the prognosis is uniformly favorable. The gangrenous form of infective pharyngitis is very likely to arise from localization of the infecting germ in typhoid, diphtheria, scarlet fever, and other infectious diseases. In such cases the infecting material probably reaches the point of localization through the blood instead of from absorption through the mucous membrane, as seems to be the case in the milder, more superficial forms in which the streptococcus is the infecting germ. The prognosis is very grave, both from the severity of the local process and from the development of septicæmia. Treatment is directed chiefly to the systemic infection, elimination being encouraged and stimulants given. Locally, mild antiseptic solutions are of most use.

Gouty Pharyngitis.—This occurs as a manifestation of the general disease, but may appear quite independently of involvement of other parts.

Lermoyez and Gasne give the following diagnostic

Digitized by Microsoft®

data: (1) Sudden onset, acute evolution, and sudden disappearance. (2) Sharp febrile symptoms, depression. (3) Very acute pain, out of proportion to the local appearances. (4) Tendency of inflammation to diffuse itself over the pharynx and spread toward the larynx, ordinary quinsy being more localized. (5) Dark red and œdematous appearance of pillars of fauces, uvula elongated, and posterior wall of pharynx swollen. (6) Absence of exudation. (7) The glands at the angle of the jaw not involved. Colchicum is to be used in the treatment of such cases. Locally, soothing gargles, or preferably sprays, are indicated.

www.libtool.com.cn

Herpetic Pharyngitis.—(Synonyms: Common membranous sore throat; Aphthous sore throat; Benign croupous angina.) Herpes of the throat, which is a milder disease than the skin affection, appears as a discrete eruption, the individual spots measuring 6–8 mm. in diameter and being located on the posterior wall of the pharynx or anterior surface of the faucial pillars. The *etiology* is varied. The local manifestation is probably due to a peripheral degeneration of the nerves of the affected area. The general condition has a very considerable etiological significance, disorders of the alimentary tract and many febrile diseases acting as causes.

The earliest *symptoms* are dryness of the throat and pain of a burning or stinging character. The constitutional symptoms are as a rule slight, fever if present being of mild grade. The eruption may be unilateral or bilateral. The vesicular stage is seldom observed, the vesicles rupturing early and the excoriated mucous membrane becoming covered with a thin, soft membrane which is easily wiped off. Labial herpes is usually also present. The disease lasts for from eight to sixteen days, but has a very considerable tendency to recur. *Diagnosis* is made from other membranous anginas by the mildness of the symptoms, the labial herpes, and the thinness and superficial character of the membrane.

Little local *treatment* is necessary; bland sprays or gargles, and applications of silver nitrate (two or three grains to the ounce), or of resorcin (ten grains to the ounce of glycerin) will be found useful. If pain is considerable orthoform may be used.

Membranous Pharyngitis.—Non-diphtheritic membranous pharyngitis, the term being limited to cases in which an actual pseudomembrane develops on the pharynx,—whether or not the tonsils and palate be also involved,—is a very rare disease. In nearly all individuals there is a well-developed strip of glandular tissue lying just back of the posterior faucial pillar. In ordinary lacunar tonsillitis it is quite common to find this follicular area involved in the exudative process. The exudation from the several follicles in the strip may coalesce and give the appearance of a narrow membranous strip on either side of the pharynx. This condition, which is frequently spoken of as a membranous sore throat, is properly only an acute exudative follicular pharyngitis. Kyle describes a membranous pharyngitis: "An acute infectious process in which there forms on the mucous membrane surface a highly coagulable albuminoid material which constitutes a false membrane and occurs along with desquamation of the superficial epithelium." Such a condition must be very rare.

Emil Mayer in 1900 described a case due to Friedländer's bacillus, and was able to collect thirteen of the same kind from the literature. In measles there is sometimes developed in the pharynx a streptococcal membrane which resembles very closely the membrane that is formed in diphtheria; its presence constitutes a grave complication.

The *diagnosis* of membranous pharyngitis is not always easy. Localized areas of epithelial necrosis, or herpetic pharyngitis after the vesicles have ruptured, cannot be distinguished by the naked eye from false membrane. This frequently leads to mistakes in diagnosis, and the terms herpetic pharyngitis and membranous pharyngitis are frequently used synonymously. The greatest care is needed in differentiating this condition from diphtheria, and it is commonly accepted that any case of membranous sore throat is to be treated as diphtheria until a diagnosis is positively reached.

The *prognosis* is generally favorable except in the streptococcal variety, in which the outlook is more serious.

Treatment.—The systemic treatment should be the same as for diphtheria in the severer varieties. Locally, disinfectants and detergents are indicated. A spray of pyrozone, hydrozone, or any high-class hydrogen peroxide solution is of value. The ordinary commercial solutions of hydrogen peroxide are sometimes very irritating to the throat and should never be used. Löffler's toluol solution is also effective. It should be applied with a swab, and care should be taken to squeeze out the excess.

Pemphigus.—Cases of pemphigus of the pharynx are occasionally reported. The bullæ are rarely seen before rupture. The acute disease is attended by headache, pain, and fever. The duration is from one to three weeks, but there is a strong tendency to recur and become chronic, especially in the aged. The disease is differentiated from diphtheria by the bacteriology, the easy removal of the exudate, the absence of glandular enlargement, and the mildness of the constitutional symptoms. Adhesions are very likely to form and should be carefully guarded against. The *treatment* is about the same as for herpes.

Rheumatic Pharyngitis.—Rheumatism of the pharynx is occasionally observed, but perhaps not so often as the descriptions would ordinarily lead one to believe. It is claimed that extensive ulceration of the pharynx may result directly from rheumatism. The diagnosis is made from the history of the patient; from the sharp pain, especially on swallowing, which is out of proportion to the redness of the mucous membrane, and varies in severity as a rule several times in the twenty-four hours; and from the prompt relief afforded by the salicylates. The local treatment should consist of hot gargles, together with the external use of a chloral liniment or a twenty-five-per-cent. ointment of ichthyol.

Traumatic Pharyngitis.—This is an acute inflammation of the pharynx due to wounds, foreign bodies, caustics, and the inhalation of dust or vapors. Children are especially liable owing to their frequent mistakes in swallowing hot or caustic fluids. Persons working in dust or in caustic vapors are also liable to pharyngitis of this type. Any foreign body that may become lodged in the throat or may lacerate the mucous membrane as it passes through the pharynx may give rise to inflammation with œdema and at times abscess formation. In any traumatic pharyngitis there is danger of the inflammation and œdema extending to the glottis with fatal results. In the aged or enfeebled the irritation caused by the swallowing of a bit of crust or a small piece of eggshell, or any such material, may give rise to fatal inflammation.

Treatment.—In the case of a foreign body, if it be still present, prompt removal should be effected through the natural passages if possible; if not, by external pharyngotomy. Often, however, it is found that the offending body has been removed or swallowed, and that only the effects are to be combated. Soothing applications should be made—oily sprays containing from three to six grains of menthol to the ounce, Dobell's solution, and adrenalin chloride, 1 to 4,000, to be repeated every two hours or oftener. Bland fluids only should be swallowed, all solid foods being avoided. If œdema threaten, scarification should be done to a sufficient extent to afford relief.

Urticaria of the Pharynx.—Urticaria may make its appearance in the pharynx either after or before its occurrence on the skin, but always in conjunction therewith. Those cases of supposed urticaria localizing themselves in the pharynx are probably cases of angioneurotic œdema (which see).

The causes of pharyngeal urticaria are naturally those of the affection in general, *e.g.*, shellfish, small fruits, stings of insects, drugs (copaiba, cubebs, quinine, capsicum, turpentine), the neurotic, rheumatic, and gouty states, genital disorders, pregnancy, constipation, etc. There is a form of acute febrile urticaria which develops suddenly and usually appears at the same time on the

Digitized by Microsoft®

chest and in the mouth. The characteristics of the affection in the pharynx are the sudden invasion with cough, dyspnœa, and local irritation. Locally the mucosa shows a condition resembling that of inflammatory œdema.

The *prognosis* is never bad except in those rare cases in which the malady extends to the larynx, when we may have a dangerous dyspnœa. At times the tongue is badly swollen.

www.tbtool.com.cn

At the onset of the attack the system should be cleared out with emetics and purgatives, enemata, etc., so as to remove the exciting cause. Large doses of the alkalies should then be given. Locally ice pellets, weak sprays of cocaine, adrenalin, antipyrin, etc., will generally give quick relief. The occurrence of dyspnœa must lead us to prepare for either intubation or tracheotomy. It must be remembered that articles of food ordinarily harmless may at times precipitate an attack.

Intubation or tracheotomy may become necessary if the swelling increases rapidly. Insufflations of morphine sulphate, gr. ⅙–gr. ss. in an inert powder, may be required for pain, or, if there be much abrasion of the mucous membrane, orthoform may be more effective. In the case of escharotics the indications are practically the same; viz., to use anodynes and emollients.

Ulcerative Septic Pharyngitis.—(Synonyms: Infective pharyngitis; hospital sore throat; suppurative pharyngitis.) This is a form of infective pharyngitis which occurs in persons reduced in health by hard work in unsanitary employments. Work in the dissecting room, exposure to septic secretions from wounds, attendance on diphtheria or scarlet fever patients, are frequent causes of the disease in medical students and physicians. The streptococcus is the usual infecting organism, but the staphylococcus is generally associated with it.

Pathology.—The ulceration is the result of the action of the infecting bacteria on the epithelium: they first cause necrosis of the superficial cells; then, entering the deeper layers, they obstruct the blood supply and cause further necrosis. According to the virulence of the infecting organism and the resistance of the tissues the ulceration may remain superficial or may extend deeply, in the latter case resulting in the phlegmonous or gangrenous form.

Symptoms.—The attack usually begins with languor and headache, quickly followed by a rigor, high temperature, rapid pulse, and other accompaniments of fever. If the deeper tissues are involved, all symptoms are graver and delirium occurs early. The tongue is heavily coated and the breath is foul. Locally, the first symptom will be dysphagia, the throat gradually becoming dry and swollen, and filling up with foul mucus, requiring constant clearing and causing the patient much suffering. The pain may be felt in the ear and may extend low down in the pharynx. Both tonsils are involved, the inflammation being as a rule superficial, but the cervical glands are frequently much swollen and painful. The ulcers which are usually lenticular in shape and covered with a grayish exudate are often seen on the tonsils and palate as well as on the pharynx. The local lesions are often so slight as scarcely to seem a sufficient cause for the great systemic disturbance.

Diagnosis.—Any acute pharyngitis may be accompanied by ulceration, but the local and systemic symptoms are not so severe as in the septic form. The rapid development and the determination of the precise character of the invading bacteria will aid in diagnosis.

Prognosis.—In the more superficial form this is favorable provided the sufferer be removed to more hygienic surroundings. If the disease penetrate to the deeper tissues, the prognosis is exceedingly grave on account of the liability to sloughing, to extension to the larynx, and to the development of septicemia.

Treatment.—Constitutional treatment with active tonics—iron, strychnine, quinine, etc.—is very necessary. Alcoholic stimulants are often required. The antistreptococcus serum should be of especial value in these cases, but clinical evidence of this is not yet assuring. Locally ice internally and externally is indicated in the earliest stage, but later if the symptoms become more severe, hot applications should be used. Alkaline sprays or gargles should be used frequently. If any astringent applications be made to the ulcers they should be of the mildest character and very gently applied. A spray of four or five grains of menthol to the ounce of benzoinol will sometimes prove grateful. If the pain be very severe, orthoform in powder should be used two or three times daily. Careful attention to the cleansing of the throat by the nurse, who thus largely relieves the patient of the necessity for voluntary muscular action of the parts, will add greatly to his comfort.

Pharyngitis in the Exanthemata and in Other Fevers.—*Erysipelas.*—Erysipelas of the pharynx and contiguous structures may appear as an independent disease or as a complication of a cutaneous attack. If it occurs consecutively to erysipelas of the skin the infection may extend to the pharynx by way of the nose, mouth, or ears, or by metastasis.

The attack begins with fever, and there are sharp pain in the throat and difficulty in swallowing. Immediately, or after one or more days, the pharyngeal mucous membrane becomes swollen and glistening and covered with ropy mucus or muco-pus. Vesicles, filled with serum, blood, or pus, and varying in size from one-sixteenth to one-half of an inch in size may appear. In severe cases abscesses or gangrenous areas may develop. Involvement of the tonsils, accessory sinuses, and middle ear is very likely to occur. The glands of the neck are swollen and tender. Early *diagnosis* is difficult unless there have been a previous erysipelas of the skin. Later, the very general involvement of the pharynx and the characteristic appearance just described serve to make the diagnosis clear. The *prognosis* is grave, as extension to the larynx may occur with fatal result.

Treatment.—The general treatment should be the same as for erysipelas elsewhere; it should be of a supporting character, with large doses (twenty to thirty minims) of tincture of chloride of iron every three hours. Locally, ichthyol is of value; from ten to thirty per cent. in glycerin should be painted on the inflamed mucous membrane three times daily. Alkaline cleansing sprays should also be used. Ice internally and externally may be soothing and useful early; at a later stage heat will be better.

Influenza.—In nearly all cases of influenza of the respiratory tract the pharynx and fauces are involved. A reddened area passing down on either side of the soft palate is frequent enough to be of considerable value in the diagnosis of the disease. The tendency to pass into a chronic inflammation is rather stronger than it is in simple acute pharyngitis. The inflammation may be very intense, and superficial necrosis of the epithelium on the anterior pillar of one side, with whitish exudation which looks like a very thin membranous deposit, may be very suggestive of diphtheria. The local treatment is that of simple acute pharyngitis. The following formula, which is to be used as a spray every two hours, has been found by the writer to be very serviceable in this and other infectious forms of pharyngitis: ℞ Pyrozone, fl. ʒ i.; borolyptol, fl. ʒ vi.; water, q.s. ad fl. ℥ iij.

When the inflammation is more intense, soothing alkaline solutions will be found to answer better, while tincture of chloride of iron, two minims to the teaspoonful of glycerin and water, swallowed every two hours, will hasten resolution.

Intermittent Fever.—It is well recognized that a pharyngitis may be due to malarial poisoning. The *symptoms* are those of simple inflammation, except that pain may be sharper and redness less marked. *Treatment* is that of the systemic disease with simple alkaline gargles or sprays for the local condition.

Measles.—Inflammation of the pharynx and fauces is generally so marked in measles that a diagnosis can often be made from the pharyngeal picture alone, before the eruption appears on the skin. The mucous membrane is deeply injected, the eruption appearing in blotches or points, while the surface presents a distinctly rough appearance. A membranous exudation due to the streptococcus sometimes forms on the pharynx and tonsils and

Digitized by Microsoft®

constitutes a very serious complication. True diphtheria may appear as a complication, rendering the prognosis much graver than in either disease alone. The *treatment* of the usual throat condition should be by alkaline sprays, such as Dobell's solution, followed by an oily spray of one or two grains of menthol to the ounce of benzoinol.

www.libtool.com.cn

Pneumonia.—The pneumococcus seems at times to enter the blood through the pharynx and tonsils, determining an attack which is characterized by the irregular range of temperature, varying from 100° to 105° or 106° F. one or more times in twenty-four hours. There is little or no cough, the symptoms being purely those of a blood infection. The disease may run a course of seven to ten days without localizing in any organ, or it may after three or more days localize as a lobar pneumonia, much simplifying the attack; or it may localize in any of the parts of the body now recognized as subject to the invasion of the pneumococcus. Careful inspection of the throat will detect redness of the pharynx and fauces, the redness of the anterior pillars being not so bright as in influenza and following more closely the border of the tonsil. A culture taken from the throat will reveal the pneumococcus in almost pure culture and will render explicable some otherwise obscure fevers. The cases seen by the writer have been in children, ranging in age from fifteen months to five years. Local treatment is of doubtful value, mild detergent sprays being indicated if anything be used.

Scarlet Fever.—The pharynx and tonsils furnish almost the earliest manifestations of the disease. Before any rash has appeared on the skin the vivid red of the pharynx and fauces will suggest the onset of scarlet fever. A little later a bright rash will appear on the soft palate, while the previously reddened pharynx and tonsils will become darker and covered with thick mucus. The involvement of the tonsils and pharynx is fairly typical of the severity of the disease, the milder cases showing only slight redness and moderate tonsillar folliculitis, while in malignant cases there will be an intense inflammation of all the tissues of the pharynx with more or less membranous exudation and with great swelling of the glands below the jaw. Between these two extremes will be seen all grades of inflammation. The inflammation is very likely to extend to the pharyngeal tonsil and through the Eustachian tube to the middle ear. Ulceration of the tonsils may appear early, while ulceration of the pharynx or pillars is a later manifestation of the disease, rarely occurring before the fifth day and often much later. In the case of a membranous deposit the membrane may be diphtheritic, caused by the Klebs-Loeffler bacillus, or it may result from the action of streptococci or other micrococci.

Deep inflammation and even sloughing are more likely to result from streptococcal infection, and lymphatic involvement is more pronounced in such infection. It has been strongly urged recently that scarlet fever must be recognized as an etiological factor in perforations of the faucial pillars and the soft palate. Generally such perforations are accepted as positive evidence of syphilitic disease; and while in the vast majority of instances this is undoubtedly the causative factor, yet it is well to remember that scarlet fever may cause the condition.

Treatment.—Attention to the throat early and sedulously is essential in the management of this disease. In case of severe neck symptoms the ice-bag or a Leiter coil may be used, to be followed later by hot applications. The use of an alkaline spray alternating with an antiseptic spray, such as the pyrozone mixture previously mentioned, will prove very satisfactory. The tincture of muriate of iron in glycerin, as ordinarily prescribed in these cases, is very efficacious; two or three drops to the drachm of glycerin is quite strong enough.

Smallpox.—As in the other eruptive fevers the throat manifestations are quite marked in smallpox. Redness with inflammation may appear several days before the skin eruption, but the rash is usually apparent on the skin before it is seen in the throat. In hemorrhagic smallpox, however, ecchymoses may be seen in the pharynx before the skin eruption appears. In severe cases there may be pseudomembrane with much pain. The *treatment* is that of any acute pharyngitis—detergent and disinfectant sprays or gargles. Severe pain may require applications of orthoform, cocaine, or menthol.

Typhoid Fever.—Inflammation of the pharynx is not uncommon in typhoid. There is usually some injection of the mucous membrane, with dryness and sometimes a difficulty in swallowing. A faucial exudation is occasionally seen during the third week. This pseudomembrane is very thin, but is adherent and is characterized by the presence of staphylococci. As true diphtheria occasionally complicates typhoid a bacteriological examination may be necessary for diagnosis. In case of considerable involvement of the pharynx and fauces, detergent washes will be beneficial. Involvement of the larynx is much more serious than that of the pharynx.

Varicella.—Some involvement of the pharynx and palate is usual if the skin eruption be at all marked. The vesical stage is short, the vesicles breaking early and leaving excoriations. If there be much pharyngeal discomfort a gargle, such as the following, is of value: ℞ Sodii biborat., sodii bicarb., āā gr. l.; acid. carbol., gr. xvi.; tr. myrrhæ, fl. ʒ iv.; glycerinæ, fl. ℥ ij.; aq. cinnamom., q.s. ad fl. ℥ viij. M. Sig.: Dilute with an equal part of water and gargle every two hours.

Gustavus P. Head.

PHARYNX, DISEASES OF: ACUTE PHLEGMONOUS PHARYNGITIS.—(*Ludwig's Angina.*) Various names have been applied to this affection. Among them may be mentioned the following: erysipelas of the pharynx, diffuse cervical abscess or phlegmon, submaxillary bubo, infectious submaxillary angina, sublingual abscess or phlegmon, subhyoid phlegmon, gangrenous induration of the neck, cynanche cellularis maligna, cynanche sublingualis rheumatica. While early writers asserted a specific individuality for this disease, later authorities regard it as a septic sore throat with a peculiar localization, not differing etiologically from phlegmonous pharyngitis, erysipelas of the pharynx, or acute œdema of the larynx, all of which seem to represent merely different degrees of virulence of the same infecting agent.

The question of primary development and localization depends probably upon the seat of original infection, and it is difficult to distinguish definitely a line of demarcation between the purely local and the less complicated, as distinguished from the œdematous and purulent forms. The application, clinically, of general bacteriological principles to this group of septic inflammations harmonizes to a certain extent former conflicting views.

Ludwig's angina is a diffuse phlegmonous inflammation of the floor of the mouth and of the intermuscular subcutaneous tissue of the submaxillary region. It may end in resolution, abscess, or gangrene.

Gerster defines it as a phlegmonous destruction of the submaxillary gland characterized by alarming and extensive dense œdema, caused by the unyielding character of the fascial envelope of the gland, which œdema is most manifest about the latter vicinity, namely, the floor of the mouth.

Its possible epidemic character can be explained by the simultaneous exposure of various patients to the same septic influence. As a sequel to or complication of infectious maladies, it has been observed more often in typhus fever.

As yet no special pathogenic germ of the disease has been found, and where examinations have been made only the ordinary microbes of suppuration have been present. It is only in respect to the site of the disease that it may claim special consideration. The location in which the pus originates is a triangular pyramidal space with the following boundaries: The apex (below) corresponds to the point where the mylohyoid muscle borders the genioglossus. The base (above) stretches along under the tongue. The external wall (oblique) is made up of the internal face of the inferior maxilla and the mylo-

Digitized by Microsoft®

hyoid muscle, the internal wall (vertical) by the genioglossus and the hyoglossus. The mucous membrane of the floor of the mouth and the *glandula sublingualis* close its cavity on top. It is through this channel, however, that the infection gains entrance, so that the affection of the submaxillary gland is in many, if not all, instances secondary.

www.libtool.com.cn

The *symptoms* are constitutional and local. The former are in general those of pus formation, but it is important to bear in mind that the pathological process may also give a distinctly asthenic type of symptoms, with an overwhelming prostration and low temperature.

The local symptoms, in addition to the prominent swelling of the neck, present the following diagnostic points: First, and most diagnostic of all, there is a peculiarly hard and wooden-like induration of the affected region, sharply defined from the surrounding normal tissue; second, the thrusting forward and upward of the tongue toward the palatal vault by the accumulating inflammatory products; third, severe dyspnœa, with the possibility of laryngeal œdema; fourth, the sensation of pressure as from a hard pad or button like swelling at the inner aspect of the dental arcade. With all of these there are associated the ordinary features of a phlegmon. Swallowing is painful, if not impossible, on account of the muscular infiltration, and the patient may not be able to open the mouth.

The *prognosis* is always grave and the rate of mortality high, one series of cases reporting over fifty per cent. of deaths. Death most frequently results from sepsis, or from suffocation due to laryngeal œdema.

The condition must be differentiated from osteomyelitis of the lower jaw, simple adenophlegmon of the submaxillary gland, and the rare disease known as Fleischman's hygroma. In the first there is no limited focus of inflammation. The entire bone is affected, the inflammatory process is more generalized, and the subhyoid region is rarely involved. In the second, adenophlegmon, the inflammation is superficial, the gland and its capsule are easily accessible, there is no wooden-like hardness, superficial incision gives exit to pus, and the process is localized at the outset behind the internal face of the maxilla. In the third the diagnostic points are suddenness of onset, location in the median line, and lack of either constitutional or local evidences of inflammation.

The *treatment* must be based upon three principles: First, early and free incision; second, careful subsequent antisepsis; and third, constitutional support. The condition is one of ptomaïn poisoning. The cause must be removed, and the effects already produced must be vigorously counteracted.

Gerster demonstrates that the object of the incision is not so much to evacuate pus as to relieve tension. He supports the modern view that the submaxillary gland is the focus of the disease, and attaches much importance to the fact that pressure over the œdematous area rarely causes pain except directly over the gland. If such evidences appear, delay in operating is not justifiable.

The operation must be done under general anæsthesia, for deep tissues must be explored, in close proximity to important vessels and nerves.

Fluctuation may be delayed because of the pus being confined within a fibrous capsule. Early incision may evacuate nothing more than an ichorous discharge, while pus may form later, but tension is thus relieved and the consequent dangers of suffocation are much lessened.

Deep lateral incision over the submaxillary gland, operation through the mouth, and even external incision in the median line are all to be condemned.

The most effective method is that suggested by Gerster, namely, to lay bare the entire submaxillary region by a careful dissection before making the incision for evacuating the abscess.

To be effective the incision must penetrate the mylohyoid muscle.

Following incision irrigation with bichloride (1 to 1,000) or boric acid (1 to 100) must be carefully carried out, and stimulants and tonics administered according to indication. The application of cold to the neck, if of any value at all, can be of service only in the very earliest stages.

Hydrogen peroxide may assist in the separation of the sloughs.

A good *résumé* of the literature of this subject is given by J. E. Newcomb in the New York *Medical Journal*, November 23d, 1895. *D. Bryson Delavan.*

PHARYNX, DISEASES OF: CHRONIC AFFECTIONS.—1. Simple Chronic Inflammation.—In this form of inflammation the morbid process usually localizes itself on the pharyngeal mucosa proper, the surrounding structures escaping. Occasionally it localizes itself in the faucial pillars and may then be properly called chronic faucitis.

A frequent cause is the continuous action of irritants such as excess in alcohol, tobacco, dusty occupations, etc. Many cases are associated with chronic nasopharyngitis. In many cases also the malady is but one feature in a general catarrh affecting the entire food tract, for to the latter and not to the respiratory tract does the pharynx functionally belong. Acid fumes, over-use of the voice, abnormal humidity of the air, high temperatures, are all to be reckoned as possible causes. It may be difficult to isolate the exciting factor, for many of the cases come on so gradually that it is difficult to determine any special reason for their occurrence. Undoubtedly the modern method of living in overheated houses is a powerful predisposing agent.

The changes set up in the mucosa are those of a proliferative inflammation. The vessels may show an initial hyperæmia, but the essential change is the formation of new connective tissue in the deeper layers of the membrane. Mucous glands are here scanty, but secretion from the membrane as a whole is increased, and in view of the abnormal surroundings it soon becomes viscid. Occasionally nodular veins may be seen coursing over the posterior wall of the pharynx.

The most prominent symptom is local irritation, but actual pain in swallowing is rare. Owing to the co-involvement of the stomach, there are more or less morning retching, nausea, and even vomiting. These conditions may make examination of the throat extremely difficult. The breath may be sour and offensive. Constipation and flatulency are frequent. Cough and huskiness of the voice are not uncommon. Hemorrhage occasionally takes place from a ruptured capillary. The mucosa is dark and beefy in appearance, but this feature does not extend farther forward than the posterior pillars. The pharyngeal wall may be covered with tenacious secretion. The grade of severity of the symptoms is generally conditioned on the amount of accompanying nasopharyngitis.

Treatment should be first directed toward the correction of any vicious habits in eating or drinking. Excesses in tobacco and all alcohol must be cut off short. The former are indicated by a dry glazed look, and the latter by a red, angry appearance of the mucosa. To facilitate a thorough examination of the throat, we may use ice-water gargles, bromide sprays, bromides internally, and even weak cocaine sprays. I have generally found it necessary to interdict, during treatment, tea, coffee, and all very hot or highly seasoned fatty and greasy foods. All food must be thoroughly masticated, and but little fluid should be taken at meals. Attention is now to be given to the gastro-enteric tract. Cholagogues, salines, alkalies with bitters, etc., here find a proper application. Attention in detail to the foregoing matters will often obviate the necessity for local treatment. For topical use we may employ solutions (twenty grains to the ounce) of silver nitrate, the zinc salts (the chloride excepted), alumnol, or protargol. For such remedies as are applied by cotton carriers, the oleostearate of zinc, made of zinc stearate in mentholated albolene, forms an agreeable viscid menstruum. Before any of these are applied, the mucosa should be thoroughly cleansed with a

Digitized by Microsoft®

warm, alkaline spray. Gargles are of secondary value here, as the puckering of the throat surfaces, incident to their use, gives only a partial contact with the mucosa.

2. Chronic Follicular Inflammation.—This variety practically limits itself to the pharyngeal wall proper, the faucial structures not being involved. It is of clinical importance because the symptoms are out of all proportion to the mild appearance of the lesion.

www.libtool.com.cn

The brunt of the process falls on the lymphoid follicles and is one expression of "lymphatism" or the tendency of all lymphatic structures to take on overgrowth during the earlier periods of life. While during the very early years this tendency is more noticeable in the nasopharynx, it may become localized, as time goes on, in the pharynx proper. Bad hygiene is an important causative factor. The subvariety of the disease called "granular," because the smallness of the follicular enlargements gives the mucosa a granular appearance, has been referred to a systemic hyperacidity; but this view is objectionable, in that it invokes the relation of the mucous glands to the condition, they becoming stopped up by the action of the acidity which precipitates their mucin. Improper vocal effort, both overuse of the voice and use under improper conditions, may lead to follicular enlargement; hence the familiar name of "clergyman's sore throat."

As noted above, the follicular enlargement may be granular or may occur in the form of large masses like red beads on the pharyngeal wall. At times it may be localized behind the posterior pillars, the appearance presented being not unlike that of columns or bead-chains. This is the "pharyngitis lateralis" of some writers. These longitudinal deposits may fuse with the pillars, but are generally of a darker hue. The follicles nearest the mouths of the muciparous glands are the most involved. In all cases the process is essentially a hyperplasia, an actual increase in the number of lymphoid elements, especially about the efferent channels of the nodes themselves. This hyperplasia may involve the entire thickness of the mucosa or it may confine itself to projections from the surface. At first the enlargements are soft, but they harden and become smaller with time. The process seems to involve the tendrils of the sensory nerve fibres, though whether merely by compression or in some other way not understood is uncertain. This nerve involvement accounts for the relative severity of symptoms.

The most prominent symptom is pharyngeal dysæsthesia increased by swallowing or vocal effort. Secretion is not as a rule increased. It may be blood-streaked by the rupture of a superficial vessel. The tonsils often become adherent to the faucial pillars, and from the frequent efforts at hawking the uvula becomes elongated. The voice is husky and a nervous, irritable cough is present. The patients become very neurotic, and this fact in turn aggravates pre-existing symptoms. The disease continues indefinitely unless treated, though it does not seem to predispose to lesions of the air tract below.

Treatment calls for the same general measures as for simple chronic pharyngitis, and in addition for the destruction of the enlarged follicles. Any of the caustic acids or the electro-cautery may be used for this purpose. A small iron wire, heated in the flame of a spirit lamp, will answer. A drop of a two-per-cent. solution of cocaine injected into the area of puncture makes the latter practically painless. Six or eight punctures may be made at each sitting, an antiseptic spray being used on the intervening days. The minute sloughs should be allowed to come away before treatment is resumed. Curetting of the entire area has been advised. Internally we may give the iodides in small doses and the various alkaline mineral waters freely. It is unlikely that the latter are of real service unless they correct some underlying diathesis. Tobacco should be cut off. Alcohol may be used sparingly. Nervous patients need arsenic, strychnine, and phosphorus.

3. Chronic Atrophic Inflammation.—In this variety there is an actual atrophy of glandular tissue and of the other elements of the mucosa. Some authorities look on the process as merely the terminal stage of the ordinary catarrh; others as a separate affection. It may occur alone, but is more often associated with similar lesions in the nose and nasopharynx. It may be a sequel of severe local acute conditions such as occur in the exanthemata and diphtheria, and is not infrequently a feature of diabetes and chronic Bright's disease.

There may be a proliferation of new connective tissue, so that in the earlier stages, before the follicles have atrophied extensively, they appear to lie on a whitish bed and the whole membrane is very dry. This is the so called "pharyngitis sicca."

The main symptoms are an uncomfortable feeling of dryness with more or less pharyngeal dysæsthesia. The mucosa may be covered with thick, dry, tenacious secretion. Removal of this, which strings down from the nasopharynx, may uncover a rather red subacutely inflamed area.

Treatment calls for restoration of the nose and nasopharynx to the normal and for the correction of any vicious habits. Persistent dryness should always lead to an examination of the urine, for the underlying cause may thereby come to light. The dried mucus should be removed by warm, alkaline sprays, and for home treatment the patient may inhale mentholated steam or the vapor of menthol in association with eucalyptol and compound tincture of benzoin. For topical application we may use ichthyol in glycerin (ten to thirty per cent.) or the familiar Mandl's solution—iodine gr. v., potassium iodide gr. x., carbolic acid ♏ij., and glycerin ℥ ss. The writer has had much satisfaction with solutions of mucin. This comes in the form of tablets containing gr. v. each of mucin and bicarbonate of soda, and gr. i. of menthol, the latter giving an agreeable odor and flavor, and serving to keep the solution in warm weather. For the latter purpose thymol may also be used. Mucin seems to restore moisture to the mucosa and maintain it simply in virtue of its hygroscopic properties. The above tablet, which has the appearance and odor of pepsin, may be added to half an ounce each of sterilized water and sterilized lime water, shaken well, and applied either on a cotton carrier or in spray. If the latter be used, the spray tube should be flushed out with clean water at intervals so as to prevent clogging. The tablets may also be given to the patient for use as troches.

It must be remembered that treatment is at best only palliative, for advanced stages of the affection present a condition practically irremediable.

4. Rheumatic and Gouty Inflammations.—A. *Rheumatic Inflammation.*—Rheumatic pharyngitis occurs in two forms: (1) acute, and (2) chronic.

In the acute form we find the same list of predisposing and exciting causes as for rheumatism in general. The local changes follow the same sequence as in acute catarrhal inflammation, except that the grade of inflammation is less severe, is apt to be localized in patches, and causes an amount of pain out of all proportion to its apparent intensity. An inflammation of the fibrous fascia of the pharynx is possible.

The course of an attack is somewhat as follows: Local symptoms—burning, dysphagia, and dryness—first appear, and are followed by a mild attack of fever and constitutional depression. After two or three days these disappear, the pain suddenly shifting to the muscles of the neck, back, or extremities, possibly to some joint. The swallowing of the saliva continues to be annoying. Inspection may show livid patches or streaks in the throat. The pain is somewhat peculiar and stinging, so that those affected learn to recognize it. The sudden onset, the character of the pain, the history of rheumatism, and the sudden shifting of the local storm area form a fairly definite clinical picture which lasts for four or five days. In the writer's opinion, a diagnosis from mere inspection of the fauces cannot be made. Some writers have reported pharyngeal ulcerations which proved to be resistant to every other mode of treatment, but healed under anti-rheumatic measures.

Treatment calls for the exhibition of the usual remedies

Digitized by Microsoft®

www.libtool.com.cn

for rheumatism, together with local anodynes and sedatives.

In the chronic form we find the same list of causes as for chronic muscular and joint rheumatism. It is more common in men than in women, and the period from the twentieth to the sixtieth year marks its age limits. The onset may be sudden, but it is generally very gradual, and patients come under observation only after months or even years of indefinite pharyngeal pain. This is often referred to the region of the hyoid bone. Ingals finds the lesion more common on the right side. From this site the pain may radiate to or be felt on one side of the larynx, in the tonsils, trachea, side of the base of the tongue, etc. The parts within reach are painful on pressure, and are generally so during swallowing or phonation. Continuous speech is especially tiresome. Curiously enough the pain may disappear during eating. It is very capricious as to character, localization, and intensity. All combinations in these respects are possible. The gastro-enteric tract is generally sluggish. Inspection reveals nothing constant. An area of congestion may surround the painful spot. The affection may be confounded, as far as subjective symptoms go, with almost any common inflammation of the throat, and each must be ruled out by exclusion, special stress being laid, for rheumatic pain, on the shifting of the area of annoyance, a change of severity according to the weather, and a history of the rheumatic diathesis.

The treatment is identical with that of the chronic rheumatic state in general plus the use of local sedatives. To the areas of tenderness we may apply solutions of aconite, morphine, metallic astringents, etc. Ingals advises the use of applications of the following mixture: Morphine sulphate, gr. iv.; tannic acid, gr. xxx.; carbolic acid, ♏ xxx.; and glycerin and water, of each fl. ℥ ss. This may be used as a spray by the physician or applied in one-half strength by the patient at home. Internally he gives three grains each of salol and extract of phytolacca every few hours.

B. Gouty Inflammation.—As in rheumatism gouty manifestations in the pharynx may be either acute or chronic.

The acute form occurs in those of a lithæmic diathesis, in heavy eaters who indulge in but little exercise, and in those who have lead poisoning or renal changes. The outbreaks are more common in cold weather and follow dietetic excesses, over-indulgence in wine, heavy mental or emotional strain, etc. Most of the patients are between thirty and forty years of age.

So far as concerns pathology, nothing more than a catarrhal inflammation can be found. There is a patchy hyperæmia with redness and œdema of the pharyngeal wall, possibly with swelling of the soft palate and uvula. The tonsils may be moderately enlarged and the larynx congested.

The *symptoms* are pain, out of all proportion to the apparent severity of the inflammation, irritable pharynx, coated and flabby tongue, scanty and high-colored urine. After a series of such attacks the teeth may appear large from retraction of the gums and they have a yellowish appearance. Diagnosis must be made from rheumatism and from simple neuralgia. Assistance is derived from the presence of tophi or other gouty manifestations elsewhere. The pain may suddenly leave the throat and appear in the joints, usually bearing the brunt of gouty outbreaks.

Treatment calls for the exhibition of colchicum and the use of local sedative washes, as for rheumatism.

In the chronic form of gouty pharyngitis we find a dark-red discoloration of the uvula, soft palate, faucial pillars, and tonsils, the "angina uratica" of the older writers. Occasionally an acute œdema of the parts is added. At times the process localizes itself in the corner between the posterior and lateral pharyngeal walls, which may be swollen and red. In young patients the mucosa may be covered with mucus or muco-pus; in older patients it is more apt to be dry and glazed, with a network of enlarged vessels or scattered livid spots. In one case there was a daily casting off of lime salts from the mucous follicles.

The *symptoms* consist of attacks of sharp pain radiating to the ears, irritable cough with the expectoration of pellets of viscid mucus, intense throat irritability, and disordered gastro-enteric tract. Possible symptoms are spasmodic obstruction of the nose (alone or with coryza), dysphagia, laryngeal spasm, modification of voice, and rapid vocal fatigue. There is always a tendency to acute exacerbations. The urine shows an excess of oxalates, phosphates, and urates.

Treatment comprises an anti-gout regimen and local sedatives. The mineral waters are of especial service. One of the best local applications consists of menthol gr. x., and terebene ♏ xv. in liquid paraffin.

5. Syphilitic Inflammation.—For information as to present-day views of the nature of the syphilitic virus, other articles in this Handbook must be consulted. It may be said in passing that acute and chronic inflammations of the pharyngeal mucosa distinctly predispose to specific infection.

The initial lesion may appear on either the soft palate or the tonsils. A chancre, more or less indurated, is present with later erosions from irritation or ulceration. There is invariably enlargement of the cervical glands, and in due time constitutional symptoms develop.

Erythema appears in from the sixth to the sixteenth week or later. The mucosa on the lips, cheeks, tonsils, uvula, soft palate, and posterior pharyngeal wall has the appearance of passive congestion. The areas involved vary in size from a pea to a penny. The erythema is symmetrical and shows a sharp demarcation from the surrounding tissue. This demarcation and symmetry are strongly suggestive, for otherwise the mucosa appears as if only ordinarily inflamed.

The mucous patch may occur at any time, though it is generally one of the "secondary" manifestations. It poisons the buccal secretions and is therefore especially dangerous. The patches are ovoid and shallow, possibly symmetrical, and represent areas with an exudate of serum and a free supply of imperfectly developed cells. Without treatment these areas and their surrounding zones of tissue ulcerate and cicatrize, the cicatrix being stellate.

The gumma appears in from five to fifteen years after infection. Its favorite site is on the posterior surface of the soft palate. This lesion rarely passes over anatomical boundaries, that is, it does not extend directly in front of the faucial pillars, above the pharyngeal tonsil, or to the larynx. It appears as a diffuse infiltration, may form rapidly, and may undergo rapid destruction. It may be nodular, in which case there is a bulging of the superjacent mucosa. There is an infiltration of the tissues and vessel walls with small round embryonic cells embedded in a gelatinous basement substance. The mutual crowding of these cells shuts off the blood supply, and the whole mass breaks down into a cheesy consistency surrounded by a zone of granulation tissue, which later becomes fibrous. Abscess formation is rare. Destruction does not pass beyond the confines of the original deposit. Large areas may give way while bands of fibrous tissue pass from one point to another, thus distorting the parts. Fluids may therefore regurgitate into the nose and the soft palate becomes adherent (rarely completely so) to the posterior pharyngeal wall. The hard palate may become involved and perforated and occasionally a large vessel is eroded. Gummata are more rarely absorbed in the pharynx than elsewhere. Occasionally the course is so acute that immense destruction occurs in a very few days.

The *symptoms* of the initial lesion are painful swallowing and enlarged glands, that is, nothing outside of what may accompany an ordinary sore throat. The diagnosis is often indecisive until cutaneous lesions appear. In erythema we find a peculiar stiffness of the throat muscles and painful swallowing. In the mucous patch there is extreme sensitiveness increased by all irritants and by overuse of the voice. Nutrition may be interfered with.

Digitized by Microsoft®

Fresh patches appear in groups occupying, in order of relative frequency, the soft palate and uvula, anterior surface of anterior pillars, tonsillar convexities, and anterior surface of the posterior pillars. A patch on one side may by contact symmetrically reproduce itself on the other side. A fresh patch is strongly suggestive of a recent application of silver nitrate. A few cases have been seen with a thick exudation suggestive of diphtheria and attended with marked constitutional symptoms.

The *symptoms* of the gumma are mainly mechanical. After ulceration has occurred pain may be severe. The typical tertiary ulcer is deeply excavated with sharply defined edges, surrounded by an angry red zone and covered with bright yellowish pus.

The *diagnosis* of the advanced lesions is not difficult; but the same is not true of the earlier ones. At first sight the patients may present nothing but the lesions of an ordinary sore throat. A most careful examination should be made, together with an investigation into the possibility of infection. All apparently simple catarrhal cases not yielding to treatment must be regarded as suspicious, and also those cases presenting a persistent dysphagia without apparent cause.

Treatment must be prompt and energetic. Alcohol, tobacco, condiments, and all irritants must be given up. The tooth brush must be used regularly and followed by rinsing with some weak antiseptic. If deglutition be extremely painful a weak cocaine solution may be used before eating. The patient must be told that he is a potential source of danger to others, and strict hygiene in every sense must be enforced. Local lesions should be cleansed with an alkaline spray and dusted with orthoform, or argyrol (silver vitellin) may be applied in thirty-per-cent. watery solution. For home use as a cleansing agent we may order bichloride solution, 1 to 3,000, or black wash. Each mucous patch should be touched with silver-nitrate stick. Indurated areas may be painted with a solution of bichloride, two grains, in sulphuric ether, five drachms. On fissured ulcerations a ten-per-cent. solution of iodoform in ether may be sprayed. Small palatal perforations may heal under the combined effect of constitutional treatment and the application to their edges, thrice weekly, of mono- or trichloracetic acid fused on a probe. Sometimes an obturator may be fitted, with advantage to the act of swallowing.

Constitutional treatment must be adapted to the existing stage of the disease (see article on *Syphilis*). Deformities and stenoses must be treated according to the requirements of each individual case.

6. Tuberculous Inflammation.—In the vast majority of cases pharyngeal tuberculosis is secondary to deposits in other parts of the body. The primary form is, however, possible, and forms about one per cent. of all cases of acute tuberculous inflammations of the upper air passages. As opposed to this rarity is the virulence of the disease. Favorite seats of invasion are the uvula and soft palate, especially the anterior surfaces of these structures; then come the tonsils, posterior pharyngeal wall, and hard palate.

The general causes are those of tuberculosis in general. The exposed position of the parts would seem to predispose them to infection, but their constant movement in normal function tends to clear away morbid material before it has had time to penetrate the tissues. Some authorities believe that the saliva offers a distinct barrier to the acclimatization of the tubercle bacillus, while other forms of bacterial life, with which the oral cavity swarms, are also inimical to bacillary growth. Infection may come through the blood and lymph, through the inspired air, and through foodstuffs.

The disease may manifest itself in two forms: (1) the ordinary miliary tubercle; and (2) a papular lesion confined to small areas, and especially apt to settle on the anterior surface of the soft palate. In both the microscopical picture is the same, viz., a small round-celled infiltration of the connective tissue gradually extending into the vessel walls. Then follow endarteritis, obliteration, cheesy softening, and ulceration. It is difficult to find either bacilli or giant cells in scrapings from the surface or in bits of tissue removed.

On inspection we may note either the miliary deposits studding the mucosa and apparently shining through it as white points, or there may be the larger papular masses extending in the primary cases as a fringe of small excrescences along the anterior pillars. After a while these deposits break down into characteristic ulcers. These may by their coalescence involve a large area. The uvula becomes swollen, œdematous, and exquisitely painful. Cases of perforation of both the soft and the hard palate are on record. The general appearance of other pharyngeal surfaces is one of anæmia due either to the endarteritis or possibly to a toxic vaso-constriction.

The most constant *symptom* is early and constant pain in the affected areas. The palatal muscles are swollen and stiff with resulting dysphagia. Food accumulates in the pharyngeal recesses and may get into the nasopharynx. Cough is present and the accumulation of saliva is excessive. Speech is hesitating, but the voice is not changed unless the larynx is involved. Later the cervical glands are enlarged. If the process is confined to the tonsils the difficulty in swallowing is much less. Owing to the latter symptom the patient is loath to take food, and the emaciation incident to the constitutional malady is hastened.

Diagnosis is based upon the characteristic appearance of the parts and the coexistence of tuberculous lesions in other parts of the body. Syphilis must be excluded in doubtful cases by the results of treatment. The two diseases may coexist. The typical tuberculous ulcer is shallow, with a surface flush with the surrounding mucosa, with the same color, covered with ropy mucus and possibly with a periœdema; in cases complicated by syphilis the ulceration is extremely sluggish, has a dirty-looking secretion, and is but little painful.

The *prognosis* is as a rule bad, though a few recoveries have been reported. The local condition is but one feature of a constitutional involvement. Healing of the ulcerations will greatly conduce to the tolerance of living, even though the constitutional deterioration goes steadily on.

Every hygienic and tonic measure possible should be instituted. Climate does not seem to be of much service in pharyngeal tuberculosis. All sources of buccal irritation should be removed, the teeth placed in order, and the food should be pultaceous. The patient will often find it easier to gulp food down than swallow it in the conventional way. The plan most in vogue at the present time for treating the ulcers is to curette them thoroughly under cocaine and then rub in solutions of lactic acid in water, beginning with say ten per cent. and gradually increasing up to eighty per cent., or even the pure acid. The ulcerated surfaces should be regularly cleansed with hydrogen peroxide, then with a weak alkaline solution, and finally dusted with some such powder as aristol. Enzymol, a proteid ferment, may be substituted for the peroxide. It is less irritating and just as efficient. Menthol in olive oil, twenty per cent., has its advocates. Morphine with cocaine or tannin may be cautiously applied, but the use of the first-named remedy should be avoided as long as possible. For the cough we may give heroin in one-twelfth grain doses every three hours. Orthoform is here used as a local anodyne with great advantage. It may be dusted on with equal parts of stearate of zinc or subcarbonate of bismuth. To insure its contact as long as possible with the affected parts we may use the excellent formula of Freudenthal, viz.: Menthol 10 gm., expressed oil of almonds 30 gm., yolks of two eggs, orthoform (12½ gm.), and water to make 100 gm.

7. Actinomycosis of the Pharynx.—This is an infectious, parasitic, and inoculable disease primarily attacking domestic cattle, but communicable from them to man. The original source of infection is grain. Bollinger says that oats grown on newly ploughed land are the main carriers of contagion, but that rye and other grains are at times similarly affected. In man the infection may

www.libtool.com.cn

Digitized by Microsoft®

arise by inoculation from animals, possibly from infected cereal foodstuffs, and doubtless often from the frequent habit of field workers of chewing bits of hay, straw, etc. Flies may carry the contagion. In one instance kissing was the method of conveying the disease.

It is difficult to swww.libtool.com.cnpharynx is affected, as reliable statistics on this point are lacking. We may refer to the figures of J. Israel, who found that out of five hundred cases the head and neck were involved in fifty-five per cent, and the throat and lungs in twenty per cent. Figures as to localization in the pharynx are not given. In the latter site the disease may be primary or secondary.

The infecting agent is an organism called the "ray fungus." Its exact place in classification is still a matter of dispute. By some it is called streptothrix actinomycotica; by others, actinocladothrix. It appears in the suppurative foci (hereinafter described) aggregated in small masses of a yellowish color. It can be cultivated in gelatin and more quickly in agar and beef serum. Its favorite temperature is about 95° F. For examination a bit of the suspected material should be smeared or teased on a slide, carefully dried in a flame and then stained a few minutes in a solution of picrocarmine, washed in water or alcohol, and mounted in glycerin. Sections of tissue are handled in the same way and mounted in glycerin or Canada balsam. The fungi appear yellow and the remainder of the field red. The actinomycotic tufts and single nodes may be recognized, scattered about in the field, and easily distinguishable from the surrounding red.

According to Leumann each of the yellowish masses may be subdivided into three zones: (1) An outer zone made up of club-shaped, wedge-like rays with rounded bases appearing when viewed in section to be set on star fashion and surrounded by large cells or by cells seeming to contain fragments of the fungi in their substance; (2) a middle zone made up of branching mycelial threads (furcated) passing from the centre to the periphery; and (3) an inner zone made up of cocci in chains. The threads are the active portion of the organism and the portion capable of artificial growth.

Certain observers have noted the presence of structures known as Rainey's or Mieschler's corpuscles. These are cylindrical tube-like bodies and are supposed to be due to the growth of the ray fungus inside muscular fibres. They are therefore rather a result than an essential element of the process.

When once infection has occurred extension is probably not through the lymphatics but by destruction of the vessel walls and the consequent easy access to the inner organs by the blood stream. The accompanying glandular enlargement is due to the admixture, with the ray fungi, of pus micro-organisms, notably the streptococcus pyogenes aureus.

Undoubtedly the mouth is the most frequent portal of infection: especially the alveolar processes of the lower jaw. Israel has found the fungi in the lacunæ of healthy tonsils, but they are harmless in the absence of solution of tissue continuity.

The first manifestation of infection is generally a periosteal abscess running the usual course and leading in about six weeks to true periostitis. The surrounding tissues are invaded, and suppuration appears between the chin and the hyoid bone, produced, be it remembered, not by the fungi but by pus cocci. Other cases begin as a gingivitis with spongy gums and alveolar stomatitis. From the foregoing sites the lesion attacks localities farther back, notably the pharyngeal wall. The tonsils and palatal arches are but rarely involved. Not infrequently the cheeks suffer. When once the pharynx becomes invaded, either primarily or secondarily, we note small reddish elevations looking not unlike a subacute pharyngitis upon a mucosa previously the seat of chronic changes. The adjacent tissues swell and then seem to lose their appearance of acute inflammation, becoming more like a zone of chronic infiltration, irregular in surface and firm to the touch. Suppuration soon appears with the development of angry-looking sinuses with undermined edges.

Aside from general pharyngeal discomfort, there are no *local symptoms*; actual pain is not constant. Later, comes the general deterioration due to the suppuration, but it is not accompanied by any special features. The characteristics, therefore, of the disease are: (1) The remarkable extension and induration of the parts; (2) the slow dragging course of the inflammation; (3) the extension of the process to the surface, after the lapse of several months, by a softening and final spontaneous evacuation, the pus being sero-sanguinolent; and (4) the quick healing of the local focus with apparently a favorable outlook, but the appearance of the infection in the neighborhood, or at a distance, with fresh vigor. Fatal symptoms are always tardy in development.

Diagnosis is called for from syphilis and from malignant disease, especially sarcoma. Sections of the latter may present appearances which strongly suggest actinomycotic tissue, but in the latter the microscope will reveal the ray fungi.

Treatment calls for radical excision if this is possible. Internally, large doses of the iodide of potassium have been given, and have apparently cured some cases. The internal use of silver nitrate has also been advised. Nearly every antiseptic has been used locally, but there is no specific. Without doubt bichloride is as efficient as any.

8. Glanders.—Glanders is a disease primarily affecting horses, and may be communicated from them to man and from one man to another. The exciting agent is the Bacillus mallei, resembling morphologically the B. tuberculosis, though somewhat shorter and thicker. Infection may be conveyed from an infected animal by the fine spray of coughing or sneezing, or by the handling of articles used about the animal.

In man the nasal structures are generally the portals of infection, and the process extends to the pharynx. It begins with evidences of a low-grade inflammation, and changes with the formation of granulation tissue containing the characteristic bacilli in swarms. Suppuration soon follows along the avenues of lymphatic distribution. Pus intoxication rapidly develops, the suppuration showing a distinct tendency to burrow. Cartilage and bone may be attacked.

The *symptoms* are those suggested by an area of local infection. Following the latter we have, within a few days, pain and swelling with degenerative changes. When the pharynx becomes affected we have interference with deglutition and phonation. There is a breaking down of the cervical submaxillary and sublingual glands, with occasional fistulæ opening externally. Finally, the general picture of septicæmia develops.

In these days of early examination of all suspicious discharges there is not much danger of overlooking a case of acute glanders, but there are cases in which the only evident changes are those of a subacute pharyngeal catarrh with variable pain, slow glandular involvement, and indefinite and remitting constitutional symptoms. The pharynx shows reddened elevated areas, over which are scattered small undermined ulcers from which dirty pus exudes. At first the pharyngeal functions are not greatly hampered, but increase of the infected areas may mechanically block the breathing and food channels so that death follows from general exhaustion.

Diagnosis is called for especially from the destructive lesions of syphilis. A history of possible glanders infection will of course put us on our guard. This we supplement by the detection of the Bacillus mallei. Some of the chronic cases have been mistaken for ulcerating sarcomata; in such doubt inoculation tests should be made.

The acute form of the disease is rapidly fatal. The use of mallein, an artificial product from potato culture of the Bacillus mallei, may be used for purposes of diagnosis, as it gives a reaction similar to that of tuberculin. Its curative properties are still *sub judice*, but in

Digitized by Microsoft®

view of the gravity of the situation it should always be tried. No positive means of cure is at present known. Supporting treatment merely retards the inevitable end.

Some of the chronic cases are said to have ended in recovery, but the vast majority have been fatal within two years. In these cases treatment should consist of thorough curetting of the infected area, the use of antiseptic washes, and the administration of strychnine and iron in full dosage. Some authorities recommend the pushing of the iodides as in tertiary syphilis.

www.libtool.com.cn

9. Retropharyngeal Abscess. — These cases are often overlooked, because no digital examination is made of the pharynx, the observer contenting himself with mere inspection. The affection should always be suspected in a child with difficulty in breathing and swallowing without apparent cause.

The phlegmon forms in a flat shallow cavity behind the pharynx and œsophagus, limited posteriorly by the spinal aponeurosis and anteriorly by a connective-tissue sheath. Its lateral boundaries are sheaths which stretch from the aponeurosis to the lamellar spinal sheaths. Above is the basis cranii, and below, the mediastinum. The contents are sympathetic ganglia and lymph nodes receiving drainage from the neck, nasopharynx, and pharynx. Externally are important vessels and nerves. The above is the most frequent site of the abscess, but lateral sites are possible; many of the latter are doubtless but "pointings" from a central focus.

The inflammation begins in the lymph nodes and extends to the cellular tissue. It may, however, begin in the latter from irritation, as from instruments or a foreign body. In children in whom the disease is far more common than in adults, infection may come from such conditions as otitis media, erysipelas, pharyngitis, etc. An antral empyema is recorded as the cause of one case. In children of the tuberculous, syphilitic, and lymphatic diatheses, there is always a lessened resistance to infection, and it is in just such children that the malady is most common.

In infants the first symptom may be refusal of the nipple; then follow a metallic cry, dysphagia, and dyspnœa. In older children there is the usual sore-throat symptom complex, and inspection may at once reveal the nature of the trouble, but *palpation should never be omitted*. This may reveal a soft, boggy tumor, which pushes forward the soft palate, and in which perhaps fluctuation may be felt. Lateral cervical swelling is also possible.

The main danger previous to rupture lies in possible laryngeal œdema with bulging of the entire larynx forward, and consequent asphyxia. Burrowing may lead to infiltration of the cervical tissues and death from sepsis. The most common danger is rupture during sleep, escape of the pus into the lower air passages, and speedy asphyxia.

Pus accumulation may occur within twenty-four hours after initial symptoms; other cases may last several weeks, or even several months if they are tuberculous in origin. Diagnosis is called for from coryza, tonsillitis, croup, and even diphtheria.

Immediate evacuation of the pus is necessary. The child must be held in a good light with open mouth, a gag being used if necessary. With a protected blade an incision should be made from the middle of the fluctuating area to its bottom. *Immediately after incision, the child which has been held with its head forward should be inverted so as to allow the pus to run out of the mouth.* Meanwhile the finger which was *in situ* directing the incision, should be passed into the sac so as thoroughly to open it and thus prevent refilling. Lateral pressure of the pus will direct the large vessels outward so that there is little practical danger of injuring them. In one case sudden death occurred as the incision was made. Œdema of the glottis was not present, but the pneumogastric nerves had been stretched by the pressure of the pus. Death was ascribed to reflex syncope. In cases with much cervical swelling lateral incision from the outside has been suggested. Some have even recommended this procedure for central fluctuation, the escape of pus into the lower air passages being thereby prevented.

10. Pharyngeal Mycosis.—Over one hundred organisms are found in the healthy mouth. The most common are the oïdium albicans, actinomyces, aspergillus fumigatus, bacillus fasciculatus, the fungus causing nigrities linguæ or "black tongue," and various species of leptothrix. By common usage the term pharyngeal mycosis, when used without modification, refers to the affection characterized by the growth of the leptothrix. It was first described by Fraenkel in 1873, receiving the name mycosis tonsillaris benigna. It occurs on the tonsils, tongue, pharyngeal wall, faucial pillars, epiglottis, and rarely in the nose, nasopharynx, and larynx.

The fungus clings to the epithelia and often prefers a healthy to a diseased surface, above which it appreciably projects. It is of horny consistency and is removed with difficulty. Threads may connect the isolated deposits so that the general appearance is that of roots with running tendrils. If a portion be teased out and examined in glycerin under the glass, we note a mass of epithelia surrounded by irregular granules in which are embedded the spores of various species of leptothrix. These spores are arranged in link-like processes, their ends being rounded or club-shaped. The processes vary in length, and may be curled up at the ends in hair-like filaments. Besides these bodies there are round or oval, highly refractive bodies arranged in colonies or scattered among the branching spores. The link-like processes are the mycelia of the fungus, and staining with methyl blue will show alternating colored and uncolored segments. The fungus has never been cultivated outside the human body.

As clinically seen the affection follows previous pharyngeal inflammation, deposits of tartar on the teeth, altered reaction of the buccal fluids, disordered digestive states, etc. There is no reason to believe that rheumatism or gout has any direct causative relation. Incidentally it may be said that the same fungi have been found in fœtid bronchitis, tracheal ozæna, pulmonary gangrene, rhinoliths, tonsilloliths, vesical calculi, the tongue coating of low febrile states, in the lachrymal duct, intestines, vagina, and fæces. At any site they may precipitate lime salts from fluids holding the same in solution.

In 1895 Siebenmann advanced a different view as to the nature of the familiar pharyngeal mycosis, claiming that it was essentially a hyperkeratosis of the mucosa. All tonsils exhibit this in a varying degree, and this collection of hyperkeratosed epithelium is a constant menace to the integrity of surrounding structures.

The *symptoms* are pharyngeal dysæsthesia, cough, difficulty in swallowing, sensation as of a foreign body, and occasionally reflex pain in the larynx. Possibilities are fever, enlarged submaxillary glands, and congestion of the palate and uvula. Periods of improvement and relapse succeed each other without any treatment whatever. The affection is in no wise dangerous, and it alarms patients out of all proportion to its gravity.

Treatment.—In treating a case the teeth must be placed in proper condition, the digestion regulated, and for a time at least all sweets must be cut off. Climatic changes may give surprisingly favorable results. Nearly every caustic has been suggested for the destruction of the roots of the fungi; mere superficial clipping off is useless. The only reliable measure is the use of the galvano-cautery plunged into each crypt harboring a root of the fungus. If the cautery is unavailable, chromic acid fused on a probe will answer.

PHARYNX, DISEASES OF: MALFORMATIONS, DEFORMITIES, AND NEW GROWTHS.—The consideration of this subject naturally requires its division into two parts: (1) Malformations and Deformities; and (2) New Growths.

Digitized by Microsoft®

REFERENCE HANDBOOK OF THE MEDICAL SCIENCES.

I. Malformations and Deformities.

There are two kinds of malformations which affect the pharynx—stenoses and dilatations. We will take up these subjects in the order named.

Stenoses may be congenital or postnatal, and they may be incomplete or complete. The congenital stenosis or atresia is accompanied by pocket-like dilatations or pouches. These malformations are to be ascribed to prenatal anomalies of development. The constrictions are most often found in that part of the pharynx which lies adjacent to the cricoid cartilage of the larynx, but they have been met with also in the upper part of the pharynx, at the junction of the oral and nasal portions of this cavity.

Fig. 3803.—Diaphragm of the Pharynx. (Case of Dr. S. S. Bishop.)

The lower constriction appears as a ring-like septum of mucous membrane, which may reduce the calibre of the tube by one-half or more of its diameter, and cases of complete atresia have been reported. Fortunately, these stenoses may exist without being productive of suffering so long as they do not become the seat of an inflammatory process.

The palatal, or high, stenosis is formed by a membrane which stretches from the soft palate backward and outward to join the posterior and lateral walls of the pharynx. Cases of diaphragm of the pharynx resulting from scarlet fever, such as the writer has reported, and syphilitic adhesions, may be mistaken for congenital stenoses, but a close examination may reveal scar tissue, which is indicative of a previous inflammation.

Postnatal malformations are the result of two classes of causes, intrinsic and extrinsic. Intrinsic causes, or those which have their origin in the pharynx, are such as scarlet fever, lupus, syphilis, diphtheria, and traumatisms. Extrinsic causes, or those which operate from without the pharynx, are in the nature of deformities of the spine, tumors, and abscesses.

Intrinsic stenoses are most often due to syphilitic adhesions which spread out above the oral pharynx and connect the posterior pharyngeal wall and posterior columns of the fauces with the soft palate. The diaphragm thus formed may be partial or complete. The appearance of this adventitious tissue, and the presence of suggestive scar tissue, together with more or less inflammatory destruction of the adjacent soft parts, will simplify the diagnosis. The differentiation is still further facilitated when perforations of the hard palate are present, for these sequels are particularly characteristic of syphilis.

Syphilitic membranous adhesions are sometimes found connecting the posterior pharyngeal wall with the base of the tongue, or a syphilitic stenosis may be formed at a point opposite to the cricoid cartilage of the larynx, where the congenital stricture is most often located. These membranous diaphragms are perforated, and, like the prenatal stenoses, they may cause little or no inconvenience so long as they are not involved in any inflammatory action, and they are not prone to such attacks.

Scarlet fever is sometimes responsible for these membranous obstructions. Such a case was reported, with an accompanying photographic illustration (Fig. 3803), by the writer in 1898.* The subject was a young lady who had had an attack of scarlet fever when she was a small child. The age at which she was sick could not be ascertained. The nasal pharynx was found to be separated from the oral portion by an adventitious membrane, which extended from the posterior columns of the fauces and the arch of the soft palate downward laterally and backward to the lateral and posterior walls of the pharynx opposite to the base of the tongue. Its general direction from the palatal attachment, instead of being nearly horizontal, closely approximated a vertical plane. In the centre of this diaphragm was an oval opening, the long diameter of which was vertical. Through this perforation the posterior wall of the pharynx was visible, and nasal respiration took place. The patient complained of no serious inconvenience resulting from this anomaly, except that food would lodge behind the membrane and demand her attention to wash it out so as to prevent decomposition and its results.

Suppurative processes of the pharynx in the course of other diseases may produce anomalies similar to the one which I have just described. Such diseases are diphtheria, smallpox, lupus, and erysipelas. In such instances the pharyngeal symptoms become very prominent and distressing during the inflammatory stage. The constitutional disturbances are pronounced, the cervical glands may be involved, the difficulty of swallowing is marked and becomes evident to the patient's friends. Inspection of the throat reveals the characteristics of an intense degree of inflammation: redness and tumefaction of all the surfaces involved, œdema of the soft palate and uvula, and, in the advanced stage, suppuration and ulceration. These characteristics of inflammatory affections which eventuate in pharyngeal stenoses should put the practitioner on his guard against such results.

Traumatic causes of pharyngeal stenoses are in the nature of scalds, such as the accidental drinking of hot liquids by children, and the chemical action of caustics, such as carbolic acid, potash, etc.

Treatment.—The treatment of stenoses of the pharynx may most conveniently be considered under two headings—general and local. In the case of syphilitic adhesions general treatment should first be instituted, and should consist of the exhibition of the iodides and mercury according to the principles laid down in the article on syphilis. The local treatment formerly consisted of systematic dilatations by means of graduated bougies, but the firm, fibrous character of the membrane does not lend itself encouragingly to this method of treatment, for the stenosis returns after the dilatations are discontinued. The knife also was much in vogue in early days for the eradication of these anomalies, but we now have, in the electric cautery, a much safer and more certain means of removing adventitious tissue.

A practically bloodless and painless operation is possible by means of the electric-cautery dissection after the application of suprarenal extract and cocaine to the field of operation, as follows: A fresh or preserved saturated solution of the suprarenal gland is applied to the periphery of the membrane which is to be removed. The writer reverses the method usually employed in the application of suprarenal solution and cocaine, and applies the suprarenal preparation first for the following reasons: If the blood-vessels of the tissues to be operated upon are first contracted, the blood current is so far diminished in volume as to reduce to a minimum the amount of cocaine that is taken into the circulation. Hence there is less liability to the toxic manifestations of cocaine. Moreover, when it is possible to contract the tissues before applying cocaine to them the anæsthetic penetrates relatively deeper and produces a more profound degree of anæsthesia. By observing this rule of procedure it is possible to employ a stronger solution of cocaine than would be safe if the order of application of the remedies were reversed. I have demonstrated the importance of these facts in a long series of operations.

Cocaine should be applied to the surfaces to be severed, not by means of a spray, but by the cotton applicator, care being taken that the surplus of the cocaine solution is expressed from the cotton pledget on the carrier before the application is made. This is necessary in order to prevent any excess of cocaine from running down into the larynx or the œsophagus. Strong solutions of this very toxic remedy must be either avoided, or employed in the pharynx with the greatest caution. For the sake of emphasizing this statement it is excusable to cite a case which was brought to the attention of the writer by a former clinical assistant. He was about to operate on a patient's throat after having applied cocaine, but before he began the operation alarming symptoms developed, and the patient suddenly expired in his chair. It must be kept in mind that in these throat operations an extensive surface must be cocainized, and that, therefore, a large amount of the drug may be absorbed. The writer has seen numerous cases of collapse and acute mania result from its employment in operations where the surfaces requiring anæsthesia were of much smaller area, but these unfortunate manifestations were probably due to the use of sprays that medicated other parts, in addition to those which were operated upon. I believe that such accidents can be avoided by the use of weaker preparations than those commonly employed, since they are often of twenty or thirty-three per cent. strength, and by taking the precautions already advised. The writer attributes to these reasons the fact that he has never had any such distressing experiences as those mentioned above. It is better not to apply to the pharynx solutions of cocaine stronger than from four to eight per cent. I speak in detail of these matters here in order to avoid repetition in treating of pharyngeal procedures under local anæsthesia later. The operation, after cocainization, consists of passing a bent electrode, at a white heat, through the periphery of the obstructing membrane, carrying the electrode, as it burns its way, throughout the whole circumference of the diaphragm. Care must be exercised not to encroach upon the surrounding tissues, which we do not wish to attack. After the membrane has been thus severed, if any hemorrhage occurs, the suprarenal extract must again be applied; but if the electrode is properly used and is not allowed to cool before being removed from the tissues, little or no hemorrhage follows.

It is advisable to keep the patient under observation for a few hours after the operation in order to anticipate any secondary bleeding that might occur. Should any tendency to the formation of exuberant granulations appear, they may be suppressed by the application of the silver-nitrate pencil. If a ten-per-cent. solution of this remedy be painted over freshly operated surfaces, there is far less danger of hemorrhages, and the desired effects of the operation are enhanced.

Little in addition need be said regarding stenosis due to lupus, but the present indications are that we are justified in expecting beneficial effects from the *x*-ray treatment.

Extrinsic causes of pharyngeal stenosis may consist of tumors, such as an aneurism or a goitre, or the cervical portion of the vertebral column may be deformed or diseased, or a retropharyngeal abscess may encroach upon the lumen of the cavity; but the treatment of these conditions obviously does not lie within the limits of this article.

Dilatation of the pharynx may affect the whole, or only a part, of the cavity. It generally exists in the form of a pouch, which is comparable to the aneurismal distention of an artery. The congenital variety is to be attributed to an intra-uterine developmental anomaly.

The acquired, or postnatal, form probably occurs in consequence of an imperfectly developed, or weakened, area of the tunic of the pharynx, which yields to undue pressure. Contributory to these causes are the habits of improperly masticating food, and a hasty manner of forcing large and irregular boluses of food down the gullet. It is easy to conceive that these repeated distentions of the pharynx tend to carry the mucous membrane between the surrounding muscular fibres, especially where the latter may be weak or defective. A pouch so formed may continue developing until it becomes several inches long. It is most likely to be found extending downward and backward between the vertebræ and the œsophagus. Generally this diverticulum consists of the mucous and submucous coats of the pharynx, but it has been found to be enclosed in the œsophageal cellular membrane. Occasionally these pouches extend to one side, and are sufficiently prominent to appear as a tumor in the side of the neck.

The most prominent and constant symptom is a difficulty in swallowing. Food lodges in the pouch and forms a temporary tumor, which obstructs the act of deglutition, until the pouch is emptied automatically or by the patient. He generally learns, however, that by digital pressure and manipulation of the tumor he is able to express the contents and enjoy relief. Unless this is done the imprisoned food may decompose and set up an inflammatory condition. Indeed, such an inflammatory process has given rise to the formation of adhesions which have resulted in a closure of the sac and a consequent permanent cure. But a less fortunate termination of such an inflammation may be the occurrence of sloughing of the surrounding tissues.

Other distressing symptoms arising from the ejection of food retained in the pouch are in the nature of an irritation of the lower respiratory tract. For example, the emptying of food into the larynx occasions violent spasms of coughing, and some particles may even reach the bronchial tubes and cause attacks of bronchitis or pneumonia.

The *diagnosis* of this condition is made with comparative facility. The obstruction to swallowing, the tumor which disappears and recurs, or which can be dissipated by pressing out its contents, the ejection of undigested food in the absence of actual vomiting, the entrance of particles of food into the larynx subsequently to, instead of during, a meal, together with the results of an examination with the throat mirror and digital exploration, afford a mass of evidence that is of a pathognomonic character.

The *prognosis* is not a cheering one. Without operative interference the condition is rarely corrected. In an occasional instance an inflammatory process is instituted which eventuates in a spontaneous closure of the pocket and a resulting cure. But there is always the danger of retention and putrefaction of food. In some cases patients must needs subsist on a fluid diet in order to avert such results; but in conditions that lend themselves favorably to operative measures the anomalies may be corrected.

Treatment.—We may best consider this subject under two divisions—palliative and curative. Palliative treatment rests mainly with the patient. By avoiding hurried

Digitized by Microsoft ®

www.libtool.com.cn

eating and imperfect mastication he removes the principal cause of acquired pharyngeal pouches, for it is the forcing of boluses of food through the cavity that distends the mucous coat of the pharynx and pushes the membrane between the fibres of its muscular tunic. After a meal during which ingesta enter the pouch he should manipulate the distended sac with his fingers until it is emptied, and he may even be able to wash it out by means of a properly curved syringe. By this means the fermentation and decomposition of retained food may be prevented.

When the diverticulum is situated at the side of the neck the patient may be able to prevent it from filling if he will press upon it with his fingers, or if a compress be worn over it at meal time. If these means do not suffice, and if the symptoms become urgent, it may become necessary to resort to an operation.

Operative Treatment.—The simplest and most promising measure of this nature consists in the application of the electric cautery to the periphery of the pharyngeal mouth of the sac. Cocaine should first be applied to the field of operation, the surgeon being careful to observe the precautions already mentioned. After this preparation for the adhesion of the adjacent borders of the pouch rectal alimentation is resorted to for a few days. In certain cases it may be necessary to operate after the methods employed in pharyngotomy or œsophagotomy, suturing the edges of the divided mucous membrane to hasten recovery and insure the subsequent integrity of the pharyngeal cavity.

II. New Growths.

Neoplasms of the pharynx will be considered under the following classification:

1. *Epiblastic and hypoblastic.*	2. *Mesoblastic.*
Papilloma	Fibroma
Adenoma	Lipoma
Cystoma	Angioma
Carcinoma	Sarcoma

Fortunately the pharynx is not so often the seat of neoplasms as are the nose and some other areas; but when growths do occur in the pharynx they give rise to warranted apprehension, even if they are of a benign nature, since, as Virchow has observed, they may take on a malignant character. More particularly is this true of tumors situated, as these are, in a passageway which renders them subject to frequently repeated disturbances and irritation. A still further important consideration is the hindrance which they may cause to the acts of swallowing and breathing, and the consequent impairment of nutrition and deficient oxygenation of the blood. To these genuine reasons of anxiety may be added the tendency to recurring attacks of inflammation to which these growths predispose the subject, and the proneness of the inflammatory process to invade the larynx and lungs.

Papilloma.—This is an epithelial tumor of a benign character, which occurs less frequently in the pharynx than in the larynx and mouth. The structure consists of epithelial cells, with a framework of connective tissue beneath the epithelial proliferation. Within this tissue, and separated from it by the membrana propria, is the vascular area. What has been said relative to the transformation of innocent tumors into malignant ones applies with especial appropriateness to papillomata, since no other growths are so likely as these to undergo degeneration. Add to this fact the exposed situation in the pharynx and the frequently repeated irritation to which their location subjects them, and all of the conditions favor their malignant transformation. Aside from the pillars of the fauces and the tonsils, the most common location of papillomata in the pharynx is the posterior wall. They vary in size from a hempseed to a cherry.

The *diagnosis* of pharyngeal papilloma ordinarily presents little or no difficulty, particularly when no inflammatory process is present. But since they are often associated with an inflammatory condition, or follow it, in such cases there is room for doubt. Then a section should be taken from the base of the tumor, or tumors if they are multiple, for a microscopical examination. The growths have a warty or cauliflower shape, and are of a pale pink or gray color when not made red by irritation or inflammation. Their glistening appearance is due to the reflection of light from the secretions which moisten their surface.

Unless they attain to a considerable size they do not provoke any symptoms sufficiently marked to call attention to their presence, such as a sense of a foreign body in the throat, or impeded deglutition or respiration.

The *prognosis* of papillomata of the pharynx is favorable, provided that they do not undergo a transformation into carcinomata or sarcomata. They rarely become larger than a small-sized grape, and so long as they remain of an innocent nature no suffering is experienced.

Treatment.—Treatment consists in extirpation and cauterization of the seat of attachment. This is best effected by means of the electric cautery, which accomplishes both purposes at the same time. Or the tumor may be severed close to the surface from which it springs, by means of the scissors, knife, or the cold snare; but the base should be well cauterized afterward either with the electrode, or the silver nitrate, or one of the other chemical caustics, in order to lessen the likelihood of a regeneration or degeneration of any tumor tissue which may remain.

Adenoma.—True adenoma does not occur in the pharynx proper. Adenoid vegetations in the nasopharynx are discussed under the heading of *Tonsils.*

Cystoma.—The true cystic tumor, or that in which the wall of the cyst is produced from a matrix of embryonic cells, and the products of tissue proliferation of the cells lining the cyst wall constitute the contents of the sac, is rarely, if ever, met with in the pharynx. Retention cysts, however, occur as the result of an inflammatory process, which causes a stenosis or closure of the duct leading from a gland, with the result of distending the duct, as the glandular secretions accumulate behind the stricture until the consequent tumefaction becomes apparent. The continued accumulation of the contents of the sac causes sufficient pressure on its walls to account for the degeneration of its epithelial lining and for the atrophy which is present in the attenuated membrane. These cysts are generally found in adult life, or in those who have passed the meridian of life.

Treatment.—A simple and effective method consists in opening the sac and destroying its walls. This may be accomplished by an electrode, which serves the double purpose of dividing the wall and destroying the cyst after the contents escape. Or the opening may be made with a knife, after which the walls of the sac are destroyed by a curette. Then the parts had best be treated with tincture of iodine or a ten-per-cent. solution of silver nitrate.

Carcinoma.—When cancer exists in the pharynx proper it is generally either secondary to the same affection of adjacent tissues, such as the tonsils, the soft palate, the œsophagus, or the larynx, or it is associated with such an affection; and as diseases of these structures are considered in other sections, in order to avoid repetition the reader is referred to their proper headings.

Fibroma.—Fibromata are found in various parts of the pharynx, but they are more common to the nasal portion than to the oral division of the cavity; and they more frequently spring from the basilar process of the occipital bone. A fibroma is a representative tumor of the mesoblastic type. Like the submucous tissue from which it takes its origin it is a connective-tissue growth, and is the offspring of a highly vascular area. It is made up of mature fibrous tissue from a matrix of fibroblasts. The growth of this neoplasm is always slow, and frequently there is a tendency toward a myxomatous degeneration, or it may undergo transition into a sarcoma. As it is most often seen in the superior portion of the pharynx it is pear shaped (Fig. 3804), but it may be sessile, and it is a product of youth rather than of old age,

Digitized by Microsoft®

for it is rarely encountered above the age of thirty or forty years.

The *symptoms* referable to pharyngeal fibromata are determined by the position and size of the tumors. Located in the upper or nasal portion of the pharynx they interfere with nasal respiration and impair the resonance of the voice. They sometimes attain to enormous proportions, extending forward into the nasal fossæ, crowding forward the nasal and orbital bones, protruding and separating widely the eyes so as to constitute the unsightly deformity known as "frog face," and giving rise to persistent headache. Extension of the growth upward causes encroachment on the cranial cavity, evoking cerebral symptoms. If the direction of the tumor is principally downward it causes frequent efforts to swallow, and it may produce sufficient pressure on the soft palate to impede its movements in speech and deglutition. When it reaches the aperture of the larynx it may even threaten suffocation. Mouth-breathing is a prominent symptom, and hemorrhages frequently occur as the tumors are exceedingly vascular. Impaired respiration, mental torpor, and "thick speech" characterize large growths; and when pressure is produced on the orifices of the Eustachian tubes, the proper ventilation of the middle ears is interfered with and the hearing becomes defective. A copious muco-purulent discharge is sometimes present.

www.libtool.com.cn

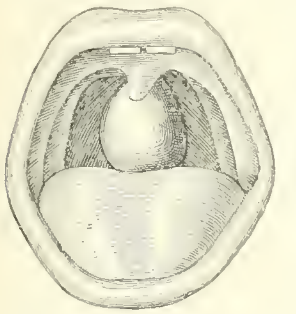

Fig. 3808.—Fibroma of the Pharynx.

The *diagnosis* of fibromata is not attended with serious difficulties. Their occurrence in young persons and their slow growth are characteristic. From mucous polypi they are recognized by their firm, dense substance. They are distinguished from adenoid growths in the vault of the pharynx by the soft, spongy, lobulated appearance of the latter and their occurrence in the very young only. Fibromata are dense, smooth, and of a dark red color.

Prognosis.—It should not be forgotten that, as Virchow says, "fibroma only needs an increase in the size of its cells and a diminution of the cement substance to change it into a sarcoma." The location of a fibroma in the pharynx subjects it to a great amount of irritation; hence it is thereby predisposed to a degenerative transition into a sarcoma and to attain to large dimensions. Unless the growth can be removed, or unless its development can be repressed until the patient has passed his twenty-fifth year, the prognosis is grave.

Treatment.—Curative results have been claimed by numerous writers from injections of alcohol, caustic potash, chloride of zinc, dilute acetic or hydrochloric acid, etc., into new growths. It is asserted that if alcohol will produce contraction and atrophy of tissues, as occur in the cirrhotic liver of the inebriate, it will have a similar effect on a neoplasm, into the parenchyma of which it might be injected. While some observers believe that the curative effect is produced, when the alcohol is injected into the interior of the tumor, by causing the formation of new connective tissue, with the obliteration of blood-vessels, lymphatics, and the parenchyma, others inject it into the circumference, maintaining that the new connective-tissue formation, girdling the periphery of the growth, will choke the afferent and efferent blood-vessels, cut off nutrition, and thus cause atrophy.

Electrolysis is especially indicated for growths having a sessile formation, which precludes the use of torsion or the snare. For this purpose a strong current is employed under general anæsthesia. Much has been claimed for the method of introducing medicaments with the electric current, or cataphoresis; but whenever it is practicable to remove the tumor in its entirety, this procedure should be preferred.

Operations.—There are several methods of operating from which to choose according to the size and situation of any given tumor. However, before detaching the growth it should be secured by passing a strong thread through it, in order to prevent it from falling into the laryngeal region of the throat and producing suffocation when the attachment is severed. The old method of removal by the cold wire snare is in quite general use, but on account of the great vascularity of these tumors and the consequent operative hemorrhage the electric snare recommends itself, since it sears over the tissues and closes the mouths of the blood-vessels with coagula as the tissues are being severed. For the same reason, in those cases in which the form and position of the attachments of these neoplasms lend themselves to such a procedure, the use of the electric knife at a white heat is advantageous. Torsion can be practised when the tumor is distinctly pedunculated.

Certain cases of pharyngeal fibromata can be operated on through the natural oral or nasal passageways by the method mentioned above. Others, either on account of peculiarities of attachment or by reason of excessive or irregular development, must be removed through the soft or hard palate, or by means of resecting the nasal bones or the superior maxilla. Sufficient room for operating may be obtained by dividing the nose along the side of the septum, beginning at the nasal process and cutting from within outward. If more room is required, the nasal process is resected; still better access is afforded by incising the upper lip in the middle line and separating its attachments liberally. The tumor is then detached by one of the methods already described, or by the periosteal elevator, or by blunt-pointed scissors, when it is drawn out with strong forceps. These are very bloody and dangerous operations, and may require a preliminary tracheotomy and ligation of the common carotid artery. However, since the details of these operations, as devised and modified by König, Dieffenbach, Langenbeck, Rouge, Ollier, Kocher, and others are given in other articles in this Handbook, they will be omitted here.

D. Bryson Delavan strongly favors the employment of electricity both for the purpose of cutting off the blood supply of fibromata and shrinking them preparatory to their removal, and for their extirpation as well. Electrolysis is recommended, either by the unipolar or by the bipolar method. Either one is attended with pain. The first is the more painful and slower of the two. The bipolar method is less painful and more rapid and extensive in its destructive effect. Some operators make use of so strong a current as from 80 to 340 milliampères. After reducing the volume of the tumor it is removed, preferably, by the incandescent wire snare, with the electric current of sufficient strength to burn its way slowly, so as to destroy the tissues thoroughly at the attachment, and to close the mouths of the severed blood-vessels. Delavan gives credit to Lincoln for introducing this method into America after the suggestions of Voltolini and Michel, and he presents, in addition to many cases collected by others, statistical data compiled by himself, which bear out the claims for the superiority of operations by the electrolytic needles and the electric snare through the natural passageways.

The statistical tables referred to cover the decade from 1891 to 1901, and include 30 cases operated upon by various surgeons who performed preliminary operations, such as resections of the nose, the superior maxilla, and the palate. There were 106 cases in which the method of operating was through the natural passages. Of these, 48 are classed as surgical and 58 as electrical procedures. Eliminating all of those cases in which the operators forgot to inform their readers regarding the nature of the results of their work, we have remaining 89 cases which are of actual value in determining the relative merits of the various methods employed. This shows 13 operations involving a preliminary intervention, with 54 per cent. of cures, 23 per cent. of deaths,

Digitized by Microsoft®

23 per cent. of grave hemorrhages, and 17 per cent. of recurrences of the tumors. There were 29 cases in which various surgical procedures through the natural passages were resorted to, and the results were made known. The cures amounted to 86 per cent., the failures about 7 per cent., www.libtool.com.cn 17 per cent., and there were no deaths reported. There were 47 cases in which electrical operations were performed and the results recorded. The percentages were as follows: Cured, 81 per cent.; improved, 16 per cent.; failures, 2 per cent. No deaths were recorded. By combining all of those operations which were performed by way of the natural passages, for the purpose of comparing the results with those obtained after preliminary procedures, it will be found that the percentages are as follows: Cured, 83 per cent.; improved, 9 per cent. A comparison of the various methods is afforded by the following table:

ANALYSIS OF METHODS.

LIPOMA.—A lipoma is a tumor composed of fatty tissue produced from a matrix of lipoblasts and may be either circumscribed or diffuse. Its occurrence in the pharynx is exceedingly rare, and the symptoms to which it gives rise are characteristic of a foreign body in the throat. When the growth is soft, it may be mistaken for an abscess; but the symptoms and history of pus formation are lacking, and an exploratory puncture is decisive of this question.

If the tumor is pedunculated, it can be removed by one of the methods described for fibroma, viz., by the cold or the hot snare or by the electric knife; otherwise electrolysis is to be preferred.

ANGIOMA.—This term is used in a broad sense by throat specialists to include all vascular tumors, in conformity with the classification of Virchow. Strictly speaking, the growth consists of new blood-vessels that communicate with the surrounding vessels, of interstitial tissue like that from which the tumor springs, and of the blood within the vascular spaces. In contradistinction to this definition, tumors that are made up of lymphatic vessels are designated as lymphangiomata. The oval group of veins beneath the mucous membrane at the back of the pharynx, known as Cruveilhier's submucous venous plexus, has been found so greatly engorged and tumefied as to cause a sensation as if a foreign body were in the throat, and an annoying cough. The surface presents a hard, lobulated, and purple appearance. Varicose veins are not uncommonly met with in the pharynx, and they may become so numerous and distended as to form groups that are comparable to clusters of currants or blackberries. Hemorrhages may be expected from these growths, particularly following any irritation, such as a digital examination.

Treatment.—If angiomata attain to a considerable size they may cause much discomfort and apprehension on the part of the patient, and they may even so encroach upon the surrounding parts as to impair their functions. A constant desire to swallow, embarrassed respiration and deglutition are not the worst features to consider, but profuse hemorrhages may demand an operation in order to insure the safety of the patient. In such cases the tumor should be completely extirpated. It is rarely sufficiently pedunculated to admit of removal with the cold or the hot snare; hence electrolysis is the most feasible method. Should thyrotomy be resorted to, it may be necessary to perform a preparatory tracheotomy.

SARCOMA.—As a primary disease of the pharynx sarcoma is rarely seen. It springs from the submucous connective tissue, and generally depends from the inferior surface of the body of the sphenoid bone into the pharynx. It is an atypical proliferation of connective-tissue cells from a matrix of fibroblasts of congenital or postnatal origin. Owing to the rich supply of lymphatic structure in this locality and its invasion by the sarcomatous cells the tumor may show a transition into the variety termed lymphosarcoma.

Like fibroma, a sarcomatous growth produces symptoms referable to respiration, swallowing, and the voice in degrees commensurate with the location, size, and shape of the tumor. The nasopharyngeal secretions are increased in quantity, to which is added, after ulceration occurs, a viscid, foul, and bloody discharge. If pain is present, it is in proportion to the amount of pressure exerted on adjacent structures. Although the discharge, which appears after ulceration takes place, is of a sanguineous character, the history of the growth may not present hemorrhages to a serious extent. In order to make a positive differential diagnosis, resort should be had to the microscope. The prognosis is unfavorable; the progress is toward a fatal termination.

Treatment.—If all of the diseased tissue can be removed, this should be done, provided that metastasis has not occurred. It is useless to operate if a part of the growth be left, for rapid reproduction will occur; and if metastatic tumors have formed in other situations nothing will avail from operative procedures on the primary tumor. But if the growth can be enucleated from a circumscribing pseudo-capsule, leaving no remnant of diseased tissue, and if no metastasis has occurred to render nugatory the result of the operation, it should be performed. Otherwise there is little to be accomplished beyond making the conditions as tolerable as possible by the use of cleansing, disinfecting, and astringent applications. *Seth Scott Bishop.*

PHARYNX, DISEASES OF: NEUROSES.—Neuroses of the pharynx consist of disturbances of sensibility, secretion, and motion.

ANÆSTHESIA OF THE PHARYNX.—This appears as a complete loss of the sensibility of the pharyngeal mucous membrane, or as a diminution of the same, and can be of either central or peripheral origin. When of central origin it is due to hemorrhage, tumors of the brain which cause compression of the vagus and glossopharyngeus nerves, inflammation of the brain, bulbar paralysis, tabes, or lateral sclerosis. It is seen in connection with epilepsy, after influenza, in anæmia and in hysteria, and is one of the sequelæ of severe general diseases, as pneumonia and especially diphtheria. Cocaine, eucaine, morphine, chloral, bromide of potassium, carbolic acid, and menthol, when used locally and internally, bring about anæsthesia of the pharynx. The reflexes usually fail, and there is occasionally a feeling of general pain, even in the presence of local anæsthesia.

The *diagnosis* is made by direct examination. In the case of anæsthesia of one side only, one-half will have the natural sensibility, while the affected portion will be insensitive to mechanical, thermal, or chemical irritations. When the anæsthesia is complete, the mucous membrane is everywhere affected. When the result of diphtheria,

Digitized by Microsoft®

www.libtool.com.cn

anæsthesia is often accompanied with paralysis of the muscles of the larynx and pharynx.

The *prognosis* depends entirely upon the cause, and is sometimes good and sometimes bad.

The *treatment* is based on the cause. Associated with diphtheria, the treatment is that of the general paralysis of diphtheria, and consists of measures to keep up the nutrition of the parts; careful feeding to prevent the introduction of particles of food into the larynx; the use of the constant and induced electrical current; and strychnine internally.

HYPERÆSTHESIA OF THE PHARYNX.—By this term is understood an increased sensibility due to central or peripheral irritations, whereby an extreme sensitiveness of the pharyngeal mucous membrane is brought about, which is described as pain, or is evident in the form of coughing, choking, retching, vomiting, and explosive belching of gases from the stomach.

Hyperæsthesia of the pharynx is a common manifestation, daily seen when an attempt is made at a laryngoscopic or rhinoscopic examination. It is often extreme, many persons retching, gagging, and almost vomiting whenever any instrument is brought near to the pharynx. Even the opening of the mouth and the drawing out of the tongue frequently elicits the strongest reflexes before the instrument has touched any part of the pharyngeal wall. It is common in persons apparently absolutely sound, but is more so in those who are very fat, in drinkers, smokers, and nervous persons. Local diseases, hyperæmia, acute or chronic catarrh, general hyperæsthesia, and increased general nervous sensibility intensify all the manifestations.

While it is a condition difficult to cure by any method of treatment, most persons after a while become used to manipulations in this region, and the treatment of the pathological condition present usually diminishes the sensibility.

Treatment consists in the local use of cocaine, menthol, chloral, bromide of potassium, various gargles, tannin, alum, and adrenalin, and in the avoidance of alcohol and tobacco.

PARÆSTHESIA.—Under this term are included various abnormal sensations, which are described as burning, pressure, itching, dryness, abrasions, lumps, or a sensation as of the presence of a foreign body in the pharynx. Among the foreign bodies complained of are pieces of bone, hairs, toothbrush bristles, needles, pieces of bread, cotton, portions of feathers—in fact, any substance that could possibly stick in the throat. Originally something may have lodged there, but as a rule it has been removed by retching or coughing before the physician was called. Hysterical and nervous persons of both sexes frequently complain of a lump in the throat (globus hystericus), of a burning pain, or of a feeling of icy coldness during the breathing.

Another one of the common forms of paræsthesia is the belief that there is a carcinoma in the throat, the circumvallate papillæ having been felt by the finger; and it is often extremely difficult to rid the mind of the individual of the idea that a new growth is present.

A feeling of extreme dryness, without material objective change, is frequent in mouth-breathers; in chlorosis, anæmia, and diabetes; and in users of morphine, atropine, or belladonna.

Paræsthesia is a more or less constant accompaniment of the chronic pharyngeal catarrhs. It is found in connection with tonsillar affections and with the various pathological changes of the nose and nasopharynx. Inflammations of the interarytenoid region, neuralgia of the superior laryngeal nerve, and affections of the central nervous system are also causative. It can occur as a reflex condition accompanying anæmia, chlorosis, hysteria, uterine and ovarian diseases, early phthisis, and hypochondriasis.

The *diagnosis* is dependent upon a careful examination of the entire pharynx, which must include an examination of the nasopharynx, tonsils and larynx as well, so that no possible source of irritation, direct or remote, shall be overlooked. The patient will usually tell whenever a painful area is touched with the probe. Sometimes there are several of these points, which disappear upon painting the area with ten per cent. cocaine. The course is very chronic.

Treatment must depend entirely upon the cause. So far as anything local can be found, appropriate treatment is to be given; while for general nervousness and hysteria the treatment appropriate to this condition must be applied.

SECRETORY NEUROSES.—Hypersecretion of the pharynx is a condition which not infrequently occurs, especially in singers. Individuals with apparently completely normal mucous membranes complain of an increased secretion of slimy mucus in the pharynx, nasopharynx, or larynx, making it necessary to swallow very often, and to spit a great deal when talking, the swallowed secretion being frequently vomited early in the morning. Examination shows more or less of this mucus on the back of the pharyngeal wall and around the velum palati. This condition is sometimes observed in old people. Its cause seems to be some disturbance in the nervous control of the secretory glands.

Treatment is only partially successful. The condition sometimes disappears of itself, but is liable to return. Belladonna has been recommended. Small doses of iodide of potassium or the syrup of hydriodic acid frequently do good by increasing somewhat the secretion of the glands, so that the slimy mucus is less thick and therefore less complained of.

There is also a condition of nervous lessening of secretion, with a feeling of great dryness, seen in connection with hysteria or the use of morphine or belladonna, and found in sufferers from diabetes.

NEUROSES OF MOBILITY. Cramp-like spasm of the constrictors occurs occasionally, most frequently in persons suffering from dyspepsia or some stomach affection; in general functional neurosis; occasionally in granular pharyngitis, hypertrophy of the side walls, and in connection with inflammatory processes at the base of the tongue. Cramp-like constriction of the muscles, interfering with swallowing, is found in connection with diseases of the brain, and is an accompaniment of tabes. It is most commonly seen as a tonic cramp in hysterical dysphagia. The muscles of the œsophagus are affected at the same time. In cramp of the muscles of swallowing, the passage downward of the mass of food is more or less interfered with. In hysterical dysphagia the swallowed mass is temporarily arrested at some point, usually with a sense of pressure and pain in the neck and around the sternum, then without further hindrance it passes into the stomach, or else with a feeling of suffocation, choking, and explosion of gases from the stomach it is vomited out. The swallowing of solid substances may be impossible for days or weeks

Cramp of the muscles of the soft palate occurs comparatively seldom. When of a tonic nature the velum is in close contact with the posterior pharyngeal wall, resulting in an altered tone and impossibility of breathing through the nose. The cramp may be of a clonic nature, affecting only single muscles of the velum, as the levator or tensor or the azygos uvulæ. The causes are very various, consisting of true alterations in the nerve supply, central and peripheral irritations, and pathological processes in the immediate neighborhood.

The *diagnosis* of the various forms of cramp-like action of the muscles is not always easy, since hysterical dysphagia can simulate many affections. It can be differentiated from true paralysis of the muscles of the pharynx by its intermittence, as the phenomenon is not constant. The use of the sound, careful observation of the patient, and the study of all the possible causes will usually enable one to make a diagnosis.

Prognosis depends entirely upon the pathology, as does also the *treatment*.

PARALYSES OF THE PHARYNX.—These are mostly of central origin. Acute and chronic inflammation of the brain; tumors; hemorrhages which bring about compres-

Digitized by Microsoft®

sion of the vagus, accessorius, and glossopharyngeus nerves and their branches; as well as degenerative processes of the brain and medulla, such as bulbar paralysis, tabes, progressive muscular atrophy, and facial paralysis; lead intoxication; phthisis; grippe; pressure of carcinomatous glands upon the vagus or its branches—all these may have muscular disturbances of the pharynx as their sequelæ. Of the peripheral causes diphtheria and scarlet fever are the most frequent. Syphilis and general neuritis are also causative.

www.libtool.com.cn

Paralyses of sensation and of motion often occur together. Paralysis of the soft palate is the most frequent, and may be one-sided or double-sided, complete or incomplete. When it is one-sided, the palate is drawn sometimes toward the sound and sometimes toward the diseased side. The arch of the paralyzed side is deeper, while on the sound side the arch is higher and narrower. During phonation the velum comes toward the sound side. When the uvula alone is paralyzed, which is a frequent condition in pharynx or larynx catarrh and in paralysis of the vocal cords, it goes toward the sound side. In double paralysis of the velum, it hangs with the uvula straight down and shows no sign of active movement except in respiration, when the uvula moves slightly backward and forward; during phonation there is a slight attempt for it to reach the posterior wall. The voice has a very nasal tone. There is seldom difficulty in swallowing.

Paralysis of the constrictors of the pharynx, with or without accompanying paralysis of the velum and of the œsophagus, is most frequent in connection with diphtheria, scarlet fever, and the other infectious diseases and in bulbar paralysis. When the paralysis is limited to the constrictors, particles of food lodge at the base of the tongue and in the adjacent sinuses, and fluids pass easily into the larynx, producing intense cough and suffocation. If the superior constrictor alone is paralyzed, the particles of food may be thrown into the nose.

The *diagnosis* of paralysis of the muscles of the pharynx is very easy, but the condition is often overlooked, especially when the paralysis is incomplete. The incomplete paralysis often suggests adenoid vegetations or polypi in the nose. When brought about through inflammatory or mechanical causes there are redness, swelling, œdema, ulcers, and cicatrices. The cause of the paralysis is often difficult to find.

In central paralysis the electro-motor excitability is normal and can remain so. In complete peripheral paralysis the electro-motor excitability very rapidly diminishes and can be lost by the third week.

Hysterical paralysis begins suddenly, disappears suddenly, and comes again without apparent cause.

The *prognosis* and the treatment must depend entirely upon the cause. Prognosis is not good when the condition is of central origin, but good when of diphtheritic, rheumatic, infectious, or of local inflammatory origin.

Electricity is the best remedy. The faradic current can be used to advantage, although the galvanic current is preferable. When the paralysis has lasted any length of time both are indicated, as the faradic current helps maintain the nutrition of the muscle while the galvanic directly stimulates the nerve. When electricity is used one electrode should be placed on the cervical vertebræ or the anterior surface of the neck, the other on the pharyngeal wall against the paralyzed muscle. The pharyngeal electrode should be one in which the current can be turned off and on. Strychnine internally, and remedies which promote the general nutrition both of the local part and of the general constitution are to be used in addition to the electricity.

George L. Richards.

PHENACETIN.—(*Para-acet-phenetidin.*) This well-known and popular derivative of coal tar was introduced in 1887 by Dr. O. Hinsberg and Prof. A. Kast.[1] Its chemical formula is $C_6H_4OC_2H_5NHCH_3CO$. In the last revision of the British Pharmacopœia it was recognized as an official drug. The chemical relation of phenacetin to allied compounds will be readily understood by reference to the following formulæ:

Acetanilid, $C_6H_4\begin{cases}H\\NHCH_3CO.\end{cases}$

Exalgin, $C_6H_4\begin{cases}CH_3\\NHCH_3CO.\end{cases}$

Methacetin, $C_6H_4\begin{cases}OCH_3\\NHCH_3CO.\end{cases}$

Phenacetin, $C_6H_4\begin{cases}OC_2H_5\\NHCH_3CO.\end{cases}$

Phenocoll, $C_6H_4\begin{cases}OC_2H_5\\NHCH_2NH_2CO.\end{cases}$

Phenazone, or antipyrin, which is therapeutically allied to the above, is related only so far as all are derived from phenyl compounds; its formula is

$$C_6H_5N\begin{cases}COCH\\NCH_3CCH_3.\end{cases}$$

Phenacetin forms in white, glistening, scaly crystals, without odor or taste. It is slightly soluble in cold water, 1 part in 1,500; more soluble in hot water, 1 part in 70; and freely soluble in rectified spirits, 1 part in 16; it is also soluble in glycerin. The crystals melt at 275° F. A recognized test for phenacetin is the production of a deep red color when chromic acid is added to a cooled and filtered solution of one grain in twenty minims of hydrochloric acid diluted with ten times its volume of water. Sulphuric acid should dissolve it without color, and burned with free access of air it should leave no residue. The presence of paraphenetidin may be detected by melting forty grains of chloral hydrate in a water-bath, and adding eight grains of phenacetin and well shaking; a solution takes place which is colored violet, reddish, or bluish in tint, according to the proportion of the impurity present. Another test, though less delicate, is to add eight grains of phenacetin to one and a half drachms of iodine solution, 1 to 20,000; when filtered a pure salt yields a colorless liquid; a pink tint indicates the presence of paraphenetidin. Phenacetin does not form a bromine compound as acetanilid does, and this reaction furnishes a test for the presence of the latter salt; the addition of bromine water to a saturated solution of the suspected salt, imparts a yellow color; if acetanilid is present the solution becomes turbid, if it is absent it remains clear. The presence of acetanilid, exalgin, or methacetin may be detected by adding two grains to twenty minims of concentrated hydrochloric acid; phenacetin remains undissolved, the other salts enter into solution.

Phenacetin was introduced as an analgesic and antipyretic much superior to the other similar compounds, on account of its freedom from any toxic action. It rapidly established a reputation as one of the most safe of the numerous new antipyretics, and has been very extensively employed in all febrile diseases, and for the relief of pain in all its forms. Its action is not accompanied by the numerous unfavorable symptoms that are common to the coal-tar derivatives. The most frequent undesirable effect that may be caused by its use is the onset of sweating, more or less profuse. Although its composition is such that it may cause the alterations of the blood that are produced by exalgin, acetanilid, etc., the instances in which any such condition follows its use are extremely rare. Some cases, however, are reported in which there were paleness and coldness of the extremities, free perspiration, precordial pain, dyspnœa, shallow respiration, feeble pulse, cyanosis, and other evidences of collapse. Many of these cases of poisoning occurred in females, and generally followed the employment of large doses; but in one case only three doses of seven grains each were given. The presence of impurities, especially paraphenetidin, is undoubtedly the cause of many of the unfavorable symptoms. Very large doses have been given without any ill effects. A case is reported in which sixty grains were given daily for two weeks, as an anodyne; in another case one ounce and one drachm were given during one week to a patient with neuritis, and in

Digitized by Microsoft®

a case of tetanus one ounce and five drachms were given in nineteen days. During experimental research upon animals, it has been given for a prolonged period in doses equal to one and two-thirds grain per pound of body weight without producing any derangement of the system, or causing any irritation to the mucous membrane of the stomach.[1]

www.libtool.com.cn

A series of experiments on animals by Drs. Cerna and Carter[2] have led them to the following conclusions: (1) Phenacetin in moderate doses causes a rise of the arterial pressure by acting upon the heart, and probably likewise by exerting a stimulating influence on the vaso-motor system. (2) In large amounts it causes a reduction in the pressure, which is largely of cardiac origin. (3) In small doses it increases the force of the heart by a direct action. (4) It increases the pulse rate chiefly by cardiac stimulation, and possibly also by influencing the cardio-accelerating apparatus. (5) In large quantities the drug reduces the number of pulsations, primarily by stimulating the cardio-inhibitory centres, and later by a depressant action on the heart. They also found that in large amounts it caused a marked quickening of the respiratory movements by a direct action on the medulla, and that where sufficient quantities were given to produce death it was due to respiratory failure. (See also *Phenocoll.*)

As an antipyretic it is given in doses of from five to ten grains, every hour or every two hours. It reduces the temperature slowly and effectively; during the first and second hours there is not much influence on the fever, but in the third hour its greatest effect is manifested. The continuation of the afebrile state varies, but usually after the fourth or fifth hour the temperature begins to ascend. The fall of the temperature results chiefly from a decrease in heat production, with a slight increase in the heat dissipation. The slow action of the drug is thought to depend on its insolubility. In chronic febrile troubles its action is not so marked, and a tolerance of the drug appears to ensue upon its prolonged administration. When there are pain, restlessness, and insomnia accompanying the fever, the beneficial effects of the drug are most marked. A sense of ease and comfort is produced, and a calm, refreshing sleep follows. By some it has been supposed to exert a decided hypnotic action, but careful observations in melancholia and mania have not confirmed this view. In typhoid fever it has proved of great service. From five to eight grains are generally sufficient to reduce the temperature to normal in about three hours; when it begins to rise again a second dose will prevent any hyperpyrexia for twenty-four hours. Many prefer to employ it in smaller doses frequently repeated—two grains every two or three hours and continued throughout the period of pyrexia; in this way it maintains the temperature at a low point and the fever runs a mild and uncomplicated course. In children it proves beneficial in all febrile disorders; single doses of two grains will produce a lowering of temperature, or it may be given in fractional parts of a grain every two or three hours; one-third of a grain having proved sufficient to subdue the fever and allay restlessness. For "*la grippe*" it has proved very serviceable, and has replaced the older antipyretics to a very great extent. In this disease the small and frequently repeated doses were of little avail, a single dose of ten or fifteen grains being generally sufficient to relieve the fever and the severe cephalalgia with which it was usually accompanied. One of its earliest applications was as an anti-rheumatic. It has no influence in warding off the cardiac and other visceral complications, but it reduces the fever and lessens the pain and swelling in the joints; to be of any benefit it must be employed in much larger doses than in any other febrile affection. At least fifteen or twenty grains must be given three times daily, and some state that a better effect is produced by thirty grains given twice in the day. In children five grains three or four times a day may be required. In painful affections unaccompanied by fever, and in the various forms of neuralgia, it requires to be given in the same full doses to secure a relief from suffering. A single dose of from fifteen to twenty grains will prove sufficient when any benefit is to be derived, while small and frequent doses exercise very little, if any, action in controlling the pain. Phenacetin has also acquired a reputation as a remedy for whooping-cough. It is given in doses of from half a grain up to two grains every four hours, and affords rapid relief to the severe paroxysms. It is also supposed to shorten the duration of the disease.

Compared with the allied drugs, phenacetin may be said to be more pleasant and safe, but less powerful and slower in its action; and perhaps less certain, as it frequently fails to produce the desired effect.

Iodophenacetin or *iodophenin* is a compound of iodine and phenacetin introduced by Dr. Scholvein, at a meeting of the Berlin Pharmaceutical Society, 1891. It contains fifty per cent. of iodine, and forms in steel-blue crystals, with an odor of iodine and a burning taste. Water decomposes the salt, liberating the iodine in a free state. It possesses the active germicidal and antiseptic properties of iodine, and owing to the looseness of its combination it was suggested as an intestinal antiseptic. The local irritation proved a source of discomfort, and toxic symptoms frequently followed its employment. It is now seldom employed. *Beaumont Small.*

[1] Centralb. f. gesam. Therap., April, 1887.

PHENACETIN, POISONING BY. See *Synthetic Poisons, Organic.*

PHENALGIN—ammonio-phenylacetamid—is a fine white powder of ammoniacal odor and slightly alkaline taste. With water it makes an alkaline solution. It is a proprietary remedy of uncertain composition, stated to be an efficient analgesic, antipyretic, and antiperiodic. The ammonia present is intended to prevent depression of heart and respiration. Dose 0.3–1.3 gm. (gr. v.–xx.). *W. A. Bastedo.*

PHENAZONE. See *Antipyrin.*

PHENEGOL. See *Egols.*

PHENOCOLL.—(Amido-acet-para-phenetidin.) During the past few years our knowledge of the chemistry of modern antipyretics has so far advanced that new synthetical remedies are produced, the therapeutic properties of which have been carefully considered beforehand. Such a one has been prepared by German manufacturers and introduced under the name of phenocoll. It is said to be an antipyretic, possessed of all the favorable qualities of phenacetin, and devoid of any of its undesirable effects. It is obtained by replacing in phenacetin one hydrogen atom of the acetyl group by the amido group NH_2. Its formula is

$$C_6H_4OC_2H_5NHCOCH_2NH_2 + H_2O.$$

Phenocoll, the base, forms in white acicular crystals which have a tendency to mat themselves together. It is readily soluble in alcohol and warm water, but only slightly in chloroform, ether, and cold water. Dilute caustic alkalies, or dilute acids when cold, have no power to split up the compound, but by prolonged boiling it is resolved into its constituents. The most important characteristic of this compound is its power of combining with acids and forming soluble salts.

The *hydrochlorid of phenocoll* is the salt generally employed, but salts have also been formed with other acids. The *salicylate* occurs in long needles; it has a sweetish and not disagreeable taste, and is supposed to add some of the therapeutic properties of salicylic acid to phenocoll. It has been introduced to the profession under the name *salocoll.*

Phenocoll hydrochloride is a white, minutely crystalline powder, with a bitter, saline, but not disagreeable taste. It is soluble in cold water, about one part in sixteen, forming a neutral, stable solution. It is still more soluble in hot water and in alcohol.

Digitized by Microsoft®

The superiority claimed for it over other antipyretics was based not only on its greater solubility and more rapid action, but also on its perfect harmlessness. The result of experiments by Dr. Isaac Ott, however, shows that in very large quantities it produces the same effects as phenacetin and similar compounds. He reports: (1) that upon frogs it produces a general paralysis, due to an action upon the cerebrospinal axis; (2) upon rabbits it produces a cyanotic condition of the ears, and reduces the force and frequency of the heart; (3) it kills through an action upon the centre of respiration.

www.libtool.com.cn

The investigations and clinical reports upon the action of this new remedy have been chiefly made in Germany and Italy, but Drs. Cerna and Carter, of Philadelphia, have done some very thorough experimental work, to determine the comparative action of antipyrin, phenacetin, and phenocoll. The following are their conclusions regarding its action on the heart and circulation:

1. Phenocoll, in ordinary amounts, has practically no effect upon the circulation.

2. Large doses diminish the blood pressure by influencing the heart.

3. Phenocoll reduces the pulse rate by stimulating the cardio-inhibitory centres. It then increases the rapidity of the pulse by paralyzing said centres. The final diminution is of cardiac origin.

4. Upon the blood itself phenocoll has no action.

As to the relative action of the three antipyretics that were experimented with, they sum all as follows:

1. Antipyrin, phenacetin, and phenocoll all fail to produce any effect on the heat functions of the normal animal.

2. Antipyrin produces a decided fall of temperature in the first hour after its administration in the fevered animal. This reduction is due to a great increase in heat dissipation, together with a fall in the heat production.

3. Phenacetin, both in septic and in albumose fevers, produces a very slight fall of temperature during the first and second hours after its ingestion by the stomach, but the greatest reduction occurs during the third hour after its ingestion. The fall of temperature results chiefly from a decrease in heat production, with a slight increase in the heat dissipation. The increase in dissipation is not as great as with antipyrin. Probably the delayed action of the drug depends on its insolubility.

4. Phenocoll causes in fever a very decided fall in temperature, which occurs during the first hour after the administration of the drug by the stomach. This reduction is the result of an enormous diminution of heat production, without any alteration of heat dissipation.

Phenocoll has been recommended as an antipyretic, analgesic, antirheumatic, and antiperiodic, but has not proved itself of particular value. Its action resembles that of phenacetin, but phenocoll requires to be given in larger doses. In some instances ill effects have followed its employment. Excessive sweating, dyspnœa, marked depression, rashes, darkened urine, and many other unfavorable symptoms have been reported.

Beaumont Small.

PHENOL-BISMUTH — $C_6H_5O.Bi(OH)_2$ — is a practically odorless and tasteless, white, non-irritant, and nontoxic powder, containing nineteen per cent. of phenol. Like other bismuth preparations, it is used as a mechanical sedative and antiseptic to the gastro-intestinal tract, but in addition, as shown by the urine, sets free some of its phenol. No poisonous effects have been noticed (Jasenski) from taking 5 gm. (gr. lxxv.) a day for three weeks. R. W. Wilcox says that it is superior to all other forms of bismuth in fermentative dyspepsias and in chronic gastritis marked by pyrosis, or boulimia. The dose is 1–5 gm. (gr. xv.–lxxv.) daily. *W. A. Bastedo.*

PHENOLPHTHALEIN — $C_6H_4.CO.C(C_6H_4OH)_2.O$ — is prepared by digesting ten parts of phenol, five parts phthalic anhydride, and four parts concentrated sulphuric acid for several hours, boiling the residue with water to remove soluble matter, and then boiling the remaining resinous substance in benzol. Phenolphthalein is a yellowish-brown powder, which, in 1 to 30 alcoholic solution, serves as an acid-alkali indicator in volumetric analysis. Colorless in acid solutions, it turns a brilliant pink on neutralization with an alkali. It is not, however, a safe indicator for the carbonated alkalies.

At the British Medical Association, 1902, Tunnicliffe reported over one thousand cases of its use as a cathartic. It may safely be employed in renal disease as it is excreted by the intestines and not by the kidneys. The dose is 0.15–1 gm. (gr. iiss.–xv.) in tablets, 0.3 gm. (gr. v.) being usually sufficient to purge an adult.

W. A. Bastedo.

PHENOL, POISONING BY.—This substance, now a very familiar antiseptic, is known more generally as carbolic or phenic acid, also as coal-tar creosote. True creosote, the characteristic ingredient of wood-tar, especially that from beech-wood, is not identical with phenol.

Phenol, as the common name indicates, has some acid properties, but is, more strictly speaking, an alcohol. Its formula is C_6H_5HO. When pure it is a colorless, crystalline, deliquescent mass, soluble in water, alcohol, and glycerin, with a well-marked odor, and a burning taste. The *crude carbolic acid* of commerce is variable in composition, and often consists of little else than neutral tar oils, which are destitute of any antiseptic qualities.

Applied to the skin, phenol produces a white superficial eschar; on the mucous surface the effect is more severe. A number of cases are recorded in which death has resulted from external application, even to a limited surface. The introduction, at a comparatively recent date, of phenol in antiseptic surgery has been responsible for several fatal cases.

When phenol is swallowed in moderate concentration an intense burning sensation is immediately experienced in the throat, œsophagus, and stomach, the mucous membrane becoming white and hardened. Vomiting of a frothy mucus occurs. The skin becomes cold, the lips and ears livid, pupils contracted and insensitive, and breathing difficult; the pulse may be 120 and irregular. The urine becomes dark-colored, and may be suppressed. These symptoms are soon followed by insensibility, with stertorous breathing. The appearances after death are largely those of local action of the poison, but the train of symptoms shows that, as in the case of nearly all other poisons, there is a distinct action on the nervous system to which the fatal result is largely due.

The fatal quantity is somewhat difficult to fix, owing to the great variation in strength of the commercial solutions, in which form the acid is generally encountered in cases of poisoning. In one case noted by Taylor a woman died in about half an hour after swallowing a wineglassful of, probably, a weak aqueous solution of phenol. The minimum fatal dose is given by some authorities as one drachm, but recovery from such an amount is possible. Half an ounce is almost invariably fatal. Fatal results have several times occurred rather rapidly, that is, in less than an hour.

The best antidote is alcohol—the strong commercial spirit for external application, common whiskey, or the commercial spirit diluted considerably, for internal use. The alcohol not only stops the action of the poison, but if the damage be not very great, it restores the condition of the tissues. Other chemical antidotes that have been advised are magnesium sulphate, sodium sulphate (these are supposed to form less active sulphonates), syrup of lime, and even vinegar. The manner in which the last-named acts is not explained, but it has been strongly recommended by some persons. After the severe symptoms have abated, the stomach should be washed out with tepid water. It is not advisable to attempt to produce vomiting either by emetics or by hypodermic use of apomorphine. *Henry Leffmann.*

PHENOL-SODIUM SULFORICINATE is a yellowish liquid soluble in water and alcohol, and recommended by Von Tovolgyi for tuberculous laryngitis. Used like lac-

Digitized by Microsoft®

tic acid without preparatory anæsthetization of the throat, it reduces the tuberculous infiltration and favorably influences the dysphagia. It has also been used for diphtheritic throats and in skin diseases. *W. A. Bastedo.*

PHENOLURIA. See Urine. www.libtool.com.cn

PHENOSAL—$C_6H_4.OC_2H_5.NH.CO.CH_2.O.C_6H_4COOH$—is the aceto-salicylate of phenetidin, and occurs in sparingly soluble needles or plates of acidulous taste. In the alimentary tract it breaks up, yielding fifty-seven per cent. of phenetidin and thirty-four per cent. of salicylic acid. It is antipyretic, and is especially recommended in rheumatism. The dose is 0.3–0.7 gm. (gr. v.–x.) three or four times a day. *W. A. Bastedo.*

PHENOSALYL.—This compound antiseptic is the result of a series of experiments upon various antiseptics by Dr. de Christmas, in the Pasteur Institute, Paris. He has shown that when certain antiseptics are associated together in one and the same solution, the microbicide power is greater than that of the sum of the solutions of each acting separately. The preparation to which he has given the name phenosalyl is considered by him to be a most efficient antiseptic, its action on the various bacteria being exceeded only by sublimate. It has the following composition: Carbolic acid, 90 parts; salicylic acid, 10 parts; lactic acid, 20 parts; menthol, 1 part.

The three acids are heated up to the point of liquefaction, when the menthol is added. It is very soluble in glycerin, and in water to the extent of four per cent. *Beaumont Small.*

PHENOSUCCIN—pyrantin, para-ethoxy-phenyl succinimide, $C_6H_4.OC_2H_5.N(COCH_2)_2$—obtained by the action of succinic acid on para-amido-phenol, occurs in colorless needles which are insoluble in water and ether, but soluble in alcohol and acetic acid. It is antipyretic and antineuralgic in dose of 1–3 gm. (gr. xv.–xlv.) daily, clinical experience showing that it has no depressing effect except in large quantities. The sodium salt forms a sweetish solution with water. *W. A. Bastedo.*

PHENYL-ACETIC ACID—alpha-toluic acid, $C_6H_5.CH_2.COOH$—is obtained by boiling benzyl cyanide with potassium hydroxide solution. It occurs in white glassy scales of burning aromatic taste and soluble in hot water and alcohol. It is given in dose of 0.06–0.15 gm. (gr. i.–iss.) with cod-liver oil for tuberculosis of the lungs. *W. A. Bastedo.*

PHENYLHYDRAZINE—$C_6H_5.NH.NH_2$.—a colorless oily liquid which solidifies into tabular crystals. It is slightly soluble in water. An hydrochloride forms in colorless scales which are readily soluble in water. Phenylhydrazine is an intermediary product in the preparation of many antipyretics, notably antipyrin and hydracetine, but its toxic action is too marked to allow of its employment as a therapeutic agent. *Phenylhydrazine levulinic acid*, under the registered title of *antithermin*, was employed as an antipyretic in doses of five grains. It is now but little used, as its action is uncertain, and is not so safe as that of antipyrin and other similar preparations.

Phenylhydrazine is best known as a test for the presence of sugar in urine, and is known as Fischer's test. It was discovered by Prof. Emil Fischer, and depends upon the property of the sugar forming, in the presence of phenylhydrazine, crystals of phenylglucosazone. *Beaumont Small.*

PHENYL-SALICYLIC ACID—ortho-oxy-diphenyl-carboxylic acid, $C_6H_3.OH.C_6H_5COOH$—is a white powder, slightly soluble in water and more so in alcohol and glycerin, and is employed as an antiseptic dusting powder. *W. A. Bastedo.*

PHILADELPHIA, PA.—Philadelphia, founded by William Penn, was the first capital of the United States. The population was estimated January 1st, 1903, at 1,347,712. The city, situated at the confluence of the Delaware and Schuylkill Rivers, in latitude 39° 57' north, is nearly on a line with Madrid and Lisbon, and is about sixty miles from the sea in a direct line. The intervening portion of the State of New Jersey is almost a level plain, abounding in pine, oak, and other timber of second growth. To the westward the land rises gradually and the nearest mountain ridges are from fifty to one hundred miles distant. The highest elevation within the limits of Philadelphia is 450 feet. The mean annual temperature is 53° F., with extremes of —6° F. (1889) to 103° F. (1901). The extremes in 1902 were 12° F., February 5th, and 95° F. July 9th. Precipitation, 49.76 inches. Days with precipitation of 0.01 inch or more, 128. Snowfall, 32.2 inches, distributed as follows: January, 7.7 inches; February, 14.3 inches; March, 4.2 inches; December, 6 inches.

Clear days, 131; partly cloudy, 103; cloudy, 131. Thunderstorms, February, 1; March, 3; April, 1; May, 3; June, 8; July, 13; August, 9; November, 1; total, 39.

The prevailing direction of the wind was northwest and the maximum velocity was 52 miles an hour, from the north, on December 5th. While the mean temperature for the year is about 5.7° F. higher than at London, the mean for January is 3° F. lower, and for July 15° F. higher. The relative humidity at 8 A.M. and 8 P.M. is 75 per cent. and 68 per cent. The rainfall averages 43 inches, considerably greater than that of London (24.84 inches). London, however, exceeds Philadelphia, as well as New York, Boston, Chicago, and all the principal cities of the United States in the number of rainy days. There are about 129 clear days each year in Philadelphia, which is less than at Baltimore (141), at Denver (150), or at Phœnix, Arizona (259). The spring opens in Philadelphia two or three weeks earlier than at Boston, and autumn lasts longer. Roses may bloom through November. The winters are not generally severe. Comparatively little snow falls, yet there may be days or weeks of temperature below the freezing point. Philadelphia has 36 parks, the largest, Fairmount Park, containing over 3,300 acres, through which flows the Schuylkill River, spanned by four bridges. Within the limits of the park the river reaches a width of about one-fourth of a mile. At the northernmost boundary of the East Park the romantic Wissahickon stream empties into the Schuylkill, and the beautiful paths along its borders are favorite resorts for driving, riding, cycling, and walking, while the well-wooded hills that rise just beyond are attractive places for picnics. There is excellent boating on the Schuylkill and on the Wissahickon. Throughout the park at convenient places are houses of rest, restaurants, dairies, and playgrounds. The natural beauties of the grounds are preserved as far as possible. At the southwestern border of the park is the extensive Zoological Garden.

Fairmount Park is of inestimable value to the citizens of Philadelphia, and doubtless exerts a controlling influence on the death rate, particularly among children.

The general death rate of Philadelphia in 1902 was 17.67 per 1,000 population. It was lower than that of New York City (18.74), and reflects credit on the energetic measures adopted by the Bureau of Health. Careful and minute attention is paid to disinfection after contagious disease has been reported. Vaccination has been vigorously carried out. During the past year (1902) the deaths from smallpox numbered 231; from scarlet fever, 143; from diphtheria, 435; from diseases of the heart, 1681; from pulmonary tuberculosis, 2845, and from pneumonia, 2976. The deaths from consumption have recently fallen to second place, owing to a wider knowledge of the principles governing the spread of the disease and to the distribution of pamphlets showing how the disease may be prevented. The Pennsylvania Society for the Prevention of Tuberculosis has assisted in this way to limit the spread of the disease.

Great good will accrue from the recent gift of $1,000,000 by Mr. Henry Phipps for a systematic effort in Philadelphia to eradicate tuberculosis by the establishment of

Digitized by Microsoft®

public clinics, sanatoria, and the dissemination of information as to the means of prevention. This will greatly aid the work of the Free Hospital for Poor Consumptives. The recent gift of Mr. Andrew Carnegie of $1,500,000 for thirty branches of the Free Library of Philadelphia, and the completion of the Boys' High School, a building which cost with its equipment $1,500,000, and which is probably the finest school building in the world, are notable steps toward the city's progress in education.

www.libtool.com.cn

Philadelphia is in a transition state with reference to great municipal improvements. Chief of these is the construction of enormous filtration beds at Torresdale, on the Delaware front, in the northeastern portion of the city, at Roxborough in the northern portion, and at Belmont in the northwestern portion. These are partially completed and will cost over $17,000,000, and they will insure a satisfactory water supply.

The Philadelphia Hospital, with its insane department and almshouse, is situated on the lower Schuylkill, and comprises within its walls a total population of about five thousand. Steps have recently been taken to remove the hospital for the insane and the almshouse to a new location below Torresdale, and on the property known as Blockley a new Philadelphia General Hospital will be erected. The original buildings constructed in 1834 will be torn down and new buildings erected in accordance with modern plans.

The Municipal Hospital for Contagious diseases will shortly be removed to a new site in the northeastern portion of the city. There are over fifty hospitals in Philadelphia. Chief of these is the Pennsylvania Hospital, the oldest institution of the kind in the United States.

The Medical Department of the University of Pennsylvania was established in 1765 by Dr. John Morgan, Dr. William Shippen, Dr. Adam Kuhn, and Dr. Benjamin Rush, who constituted the first medical faculty in America. The number of its graduates is 12,361, and with the sister schools of Jefferson College, the Medico-Chirurgical, and the Woman's Medical College, this school has had a strong influence in maintaining the high standard of medical education in the United States.

Philadelphia has long been famous for its teachers of medicine and surgery, and their contributions to medical literature, issued by the well-known medical publishers of the city, have carried the fame of American medicine throughout the world. The names of Benjamin Rush, Shippen, Physick, Wistar and Horner, Barton, Chapman, Pancoast, Gross, Stillé, Hodge, Pepper, Wood, Da Costa, Agnew, and Mitchell are household names in the medical history of our country. *Guy Hinsdale.*

PHLEGMON.—Definition.—To set exact limits to the term phlegmon is far from easy. Etymologically the word signifies no more than inflammation (the idea of "heat" or "burning" being equally present in both terms —*φλέγειν*—inflammare). Naturally, therefore, it has ever been loosely used. The concept has been merged, on the one side, into that of the so called cellulo-cutaneous erysipelas; on the other, into that of the localized abscess.

French and German surgeons use the word in its widest sense. By phlegmon they mean any pyogenic inflammation beginning in the subcutaneous cellular tissue; even furuncle and carbuncle are by some described as varieties of the class phlegmon. In this idea they usually classify phlegmons as (*a*) simple or circumscribed, a localized inflammation resulting in a localized abscess; and (*b*) diffuse or spreading.

English and American surgeons, however, have come rather generally to attach to the word almost exclusively the latter signification, that of a diffuse process.

Inclining to the latter view the writer would adopt Ziegler's definition and restrict the term phlegmon to that pathological process in which there occurs a more or less extensive inflammatory exudate of sero-purulent or sero-fibrino-purulent nature (often called purulent œdema), spreading rapidly in the subcutaneous or in any of the submucous tissues over a somewhat large area. The causative agent is, so far as we know, always bacterial. The process may spread deeply and involve muscles, fascia, and even periosteum, and may lead to pyæmia or septicæmia.

In this sense the term must include those cases which are usually called "phlegmonous erysipelas," for the pathological and even the clinical pictures are practically identical, and the etiological factor is the same. Phlegmonous erysipelas, however, will be found discussed under *Erysipelas* in this Handbook.

On the other hand, we have those comparatively mild cases of "cellulitis" which, after showing some tendency to spread, subside easily under hot applications, or spontaneously, without causing material anxiety. These, too, must be considered to be phlegmonous, though of a mild type, because their nature pathologically and bacteriologically is the same as that of the more severe destructive process with which we usually associate the idea of phlegmon. The essential—that of a spreading inflammatory exudate caused by pyogenic organisms—is the same; and the difference, one only of degree.

While the process usually has its main seat in the subepithelial structure, it may at times involve principally deep areas of areolar tissue, such as the mediastinum, the prevertebral, or the deep perineal region. In such cases the atrium of infection may not be evident.

Etiology.—Phlegmons are in all cases due to the invasion of micro-organisms in a soil unable to resist their growth. It is with reference to both our bacteriological and our clinical knowledge that the writer would suggest the following classification*:

I. Those caused by streptococci, staphylococci, or both; also those ascribed to rarer organisms, *e.g.*, pneumococcus, gonococcus, etc.

II. Those in which the entrance of gas-forming bacteria, with or without (but most often with) the above-mentioned organisms, leads to the development of a subcutaneous emphysema and gangrene in addition to the inflammatory signs of the ordinary phlegmon. This class is called "progressive gangrenous emphysema," "gangrène foudroyante," or "gas phlegmon."

III. Those caused by the extravasation of urine.

Such a classification is naturally far from arbitrary. The classes frequently overlap. For instance, a urinary extravasation is no doubt often, in part, a streptococcus phlegmon, and may be also in part a B. aerogenes capsulatus infection. The last-named is mostly combined with an infection of Class I. Class I. affords by far the greatest number of phlegmons.

It is evident that the discussion of the etiology of phlegmons must be almost entirely bacteriological. It will be in place, however, to say first a few words in regard to the *mode of entrance* of the organisms concerned. In general the *atrium* is a wound of some sort—from the most insignificant abrasion to the most complicated injury. As a matter of fact we find that phlegmons develop most frequently in connection with the more severe injuries. The contusion of the tissues in such cases renders them less resistant, while the recesses of large wounds offer greater opportunities, both for the entrance of infective matter and for the development of anaërobic bacteria, and also render cleansing less easy.

The classical descriptions of severe phlegmon, especially of the gaseous form, are those furnished us by military surgeons of the two preceding generations. Gunshot wounds and open fractures are clinically the injuries

* In the following discussion I have avoided the term "malignant œdema" because of its lack of exactness. It has evidently hitherto been used in a loose sense, to designate cases both of gas-bacillus infection (*i.e.*, gangrène foudroyante, progressive emphysematous gangrene, etc.) and of severe strepto- or staphylococcus phlegmon, as well as of phlegmon due to the bacillus of malignant œdema (Koch). Further, the term in itself suggests that the bacillus of malignant œdema is the causative factor, whereas late investigation has shown that this bacillus is but rarely at fault.

Digitized by Microsoft®

most frequently complicated by phlegmon, punctured wounds less frequently, clean cuts least often of all. Two or three cases are on record of the development of gas phlegmon following a hypodermic injection, or the subcutaneous injection of saline solution. In some cases the wound of entrance is not in the skin but in a mucous membrane. Finally, in some cases, no point of entrance can be found.

www.libtool.com.cn

Going on to discuss more in detail the bacteriology of phlegmon, we shall have to treat particularly of: (*a*) the relative rôles of the pyogenic cocci; (*b*) the bacillus aerogenes capsulatus and other gas-forming bacteria; and (*c*) the nature of the phlegmon of urinary extravasation.

(*a*) Since the work of Ogston and Rosenbach in the early period of bacteriology (1880–85), it has been taught, and is still generally believed, that, while the staphylococcus is nearly always the cause of circumscribed abscesses, phlegmonous inflammation is due to the streptococcus pyogenes. More extended knowledge, however, has shown us that such a proposition, while possibly true in many cases, must suffer numerous exceptions. It would carry us beyond the proper limits of this article to go fully into the question of the streptococcus as a disease-producer. Nevertheless, inasmuch as the phlegmon has hitherto been considered a streptococcus inflammation *par excellence*, it may not be amiss to consider here whether such a conclusion is quite justified or not.

What is the relative etiological importance of these organisms in the causation of phlegmon? When we come to examine the literature of the subject, we find really a very small number of phlegmons, comparatively speaking, in which the streptococcus pyogenes has been found as the causative agent. Janowski[1] in his monograph upon suppuration, says: "Numerous experiments have shown that the streptococcus is not necessarily more virulent than the staphylococcus; on the contrary, that it produces decidedly less often than the staphylococcus its effect upon the organism of the host. It has been found also that whereas the streptococcus alone, or more frequently combined with the staphylococcus, occurs in many cases of small abscesses, it is discovered comparatively seldom in phlegmons, for which in particular it was claimed (Ogston and Rosenbach) to be characteristic. Thus Steinhaus,[2] examining 10 cases of phlegmon, found the streptococcus only once, and in that case combined with staphylococci. In the other 9 cases the latter alone were present. Janowski,[3] in 8 phlegmons found the streptococcus only once alone, in 4 cases staphylococci alone, and in 3 the two combined. Szczegolew[4] examined 21 cases and found the streptococcus alone only in 7."

In 19 cases occurring during late years in the Royal Victoria Hospital, Montreal, the bacteriological examinations revealed the staphylococcus (mainly aureus, or albus, or both) in 8; streptococcus pyogenes in 8; and in 3 a mixed growth.* It may thus be inferred that the staphylococcus (aureus or albus) plays at least as great a rôle in the causation of phlegmon as does the streptococcus pyogenes. I have been unable to find in the literature of the last few years any special discussion upon this point.

(*b*) *Gas Phlegmons.*—That variety of acute phlegmon which produces gas in the subcutaneous tissues has ever been greatly dreaded by the surgeon. The term *foudroyante* (gangrène foudroyante), given to it by Maisonneuve, expressed its terrible character. It was the "progressive gangrenous emphysema" of the older surgeons, and indeed still goes by that name. The Germans call it "Gasphlegmon."

With the modern method of treating wounds it is becoming a much rarer disease than formerly. The chapter of its etiology is still far from being closed; nevertheless, the researches of Welch and Nuttall, Flexner, and several others in this country, and of Fraenkel in Germany, have thrown a flood of light upon the question.

In 1891 Welch and Nuttall,[5] of Baltimore, discovered the organism to which they gave the name "bacillus aërogenes capsulatus." In 1893 Fraenkel,[6] ignorant of Welch's work, discovered the same organism independently, and gave to it the name of "bacillus phlegmonis emphysematosæ." It is by Welch's name that it has come to be most widely known. This organism is a strict anaërobe; and it is possible that the comparative paucity of thorough anaërobic work, both before and since 1892, may account for the fact of its not having been earlier discovered, and also for the fact that there exists still, after ten years, but a comparatively small literature upon the question. Up to a late period the bacillus of malignant œdema was held to be accountable for practically all cases of "gangrène foudroyante." In the last few years, owing to the publications of Welch and Fraenkel, the pendulum has swung to the opposite extreme, and the bacillus of malignant œdema is allowed but slight if any part in the causation of the gaseous phlegmon. Welch,[7] in a thorough discussion of the subject, in which he reviews forty-six cases of bacillus aërogenes infection, remarks on the need of a more accurate knowledge concerning the malignant œdema bacillus. Neither he nor Fraenkel could find it in their comparatively numerous cases of emphysematous gangrene; and he believes that older investigators worked with insufficient methods.

Fraenkel[8] regards the disease caused by his bacillus (which is identical with Welch's) as one *sui generis*, and that due to the malignant œdema bacillus as quite a different clinical entity, because in animal experiments the latter produced no gas.

Hitschmann and Lindenthal,[9] on the contrary, believe that gangrenous emphysema is an anatomico-clinical entity, but due to different infections. Of these the bacillus of malignant œdema would be the one most frequently found; Welch's bacillus next; while finally the bacillus coli communis and the proteus might be responsible for a few cases.

The most recent work upon this question is that of Silberschmidt.[10] His conclusions, based on extremely thorough and straightforward work, certainly carry weight. In three cases of phlegmon accompanied by the development of gas, he found in one the bacillus œdematis maligni; in another, an organism belonging to the "group of malignant œdema bacilli"; and in the third an undetermined non-pathogenic anaërobe. In all cases there was mixed infection; in the first with B. coli communis, in the second with streptococcus pyogenes, and in the third with staphylococci and streptococci. He concludes that the B. œdematis maligni may certainly cause the formation of gas in "gangrène foudroyante."

In a fourth case of infection and death, following the opening of a cold abscess of the femur, in which there occurred a gradual formation of gas in the course of the six days subsequent to the operation, Silberschmidt found, in addition to the ordinary staphylococci and streptococci, a strictly anaërobic streptococcus which produced a foul odor. He comes to the conclusion that gangrène foudroyante may be caused by a number of different organisms. He is inclined to ascribe typical gas gangrene to anaërobes alone. He contests the strict classification of Welch and Fraenkel, and agrees with Lindenthal and Hitschmann that the same clinical picture as is recognized to be due to Welch's B. aërogenes capsulatus may be produced by other anaërobes and in especial by the bacillus of malignant œdema.

There is some evidence in late literature to show that other anaërobic bacteria besides Welch's bacillus and the bacillus of malignant œdema may produce gas in the tis-

* The possibility of some degree of error in figures such as those quoted must be admitted. The difficulty of growing the streptococcus pyogenes on artificial media; the fact that, as Marmorek has shown, they soon exhaust the medium and refuse to grow further; their liability to be outgrown by the hardier staphylococcus; the frequent failure on the part of bacteriologists to examine stained slides of the original pus; and finally the fact that some streptococci are strict anaërobes, whilst anaërobic cultures are rarely set up as a routine practice,—all these points render an unqualified acceptance of statistics upon the point in question impossible, save in cases in which we know that very careful work has been done. Nevertheless the figures are extremely suggestive.

Digitized by Microsoft®

sues *intra vitam*. Lindenthal[11] found an anaërobic bacillus (in conjunction with the B. coli communis) belonging to the group of the œdema bacilli, which both *in vitro* and in the tissues produced gas. He isolated it from cases of colpohyperplasia cystica, characterized by the formation of gas cysts in the vaginal wall with surrounding necrosis and cell infiltration.

www.libtool.com.cn

It has been claimed by various observers that the B. coli communis may cause gas formation in the tissues, especially in cases of diabetes. Such statements, in the light of our general knowledge concerning B. coli infections and concerning the rôle of anaërobes in gas production, must be viewed with considerable scepticism. The observations thus far have not been based upon sufficiently thorough work. The same may be said of the proteus Hauseri, for which similar claims have been made.

In this question of etiology we have been discussing the seed only. But the soil has also a great importance. These gas producing anaërobic organisms are ubiquitous in their nature; they are found in practically any specimen of earth, or dung, or dust. J. C. Friedman[12] has found seven different anaërobes in the cæcum and appendix of man, of which the B. aërogenes capsulatus was the most frequent. Why then are gas phlegmons comparatively so rare? The reason must be sought in the unsuitability of the soil. The seed is constantly being sown; but the soil nearly always destroys the seed, or at least refuses nourishment. Its resistance must be diminished before the seed can grow. And thus as a matter of fact we find that these infections nearly always complicate severe injuries; in the majority of cases recorded it is an open fracture. There is nearly always some chemical or mechanical lesion of the tissues. This was well proved experimentally by Berson.[13]

Symbiosis is also, without doubt, an extremely important factor. An old observation shows that the virulence of the streptococcus may be enormously increased by growing it with the B. prodigiosus. The greater number of the more severe septic processes are found bacteriologically to show mixed infections. In all six cases of severe infection reported by Silberschmidt there was mixed aërobic and anaërobic infection; and it is especially in the case of these anaërobic organisms that this question of symbiosis becomes of importance. For it has been demonstrated in the test tube that even a strict anaërobe will grow well enough in the presence of some oxygen, provided a hardy aërobic organism is inoculated with it. The latter probably uses up what oxygen is present, and thus creates a partially anaërobic atmosphere.

Practically the commonest germs found with the gas-producing bacilli have been the pus cocci, B. coli communis, B. typhosus, and putrefactive bacilli. For the B. aërogenes capsulatus, or the B. œdematis maligni to be found as the sole organism in severe or fatal cases of gas phlegmon is of rare occurrence.

It goes without saying that, apart from local injury and the symbiosis of bacteria, all such general diseases as reduce the vitality of the patient predispose to the development of a soil favorable to the invasion of disease germs. Thus, for instance, a phlegmonous erysipelas may be fatal in the advanced stages of tuberculosis or cancer; and the urinary extravasation of the strictured alcoholic is notoriously dangerous to life.

(*c*) In *urinary extravasation* the urine infiltrates the perineum, scrotum, penis, and frequently also spreads to the upper part of the thigh, the groin, and the lower abdominal region. Aseptic urine in the subcutaneous tissue in small quantities has been shown experimentally to produce but slight inflammatory reaction, or none at all. Nevertheless, clinically, the infiltration of urine seems to produce almost in every case a most decided inflammation. In many cases no doubt the urine is already infected. Even if not infected at the moment, as in cases of wounds of the healthy urinary tract, it is usually given every chance to become so by the necessary catheterization. Moreover, it is driven into the tissues not only with great force, but also in great quantity, the bladder muscle acting as a *vis a tergo*. Some of the organisms which most frequently infect the bladder decompose the urine with the formation of ammonium carbonate and often also of free ammonia. The B. coli communis, B. lactis aërogenes, or other bacteria belonging to the same group; the diplococcus ureæ liquefaciens, the proteus Hauseri are those most often found. The staphylococcus and streptococcus are also not seldom present, and would render still more acute the inflammatory process set up. When we consider what a powerful combination of factors for ill we have in these cases,—the mechanical distending action of the urine, the chemical action exerted by the products of its decomposition, the special inflammatory action of the bacteria present, and finally the run-down condition of most of the subjects,—we can understand how virulent the process often is, and how the patient so rapidly succumbs to the sepsis engendered.

Clinically we usually find the extravasation taking on a phlegmonous character very rapidly. A painful, vividly red swelling appears, and it needs no long time for the decomposed, frequently ammoniacal urine to cause breaking down and putrefaction of the tissues, with the formation of foul-smelling pus and very frequently gas. High fever soon sets in, and the general condition becomes rapidly bad. Frequently operation, even early operation, comes too late, and death follows with septic symptoms.

One point, that of the frequent presence of gas in these phlegmons, remains rather unsettled. Whether the colon bacillus can be accused is very doubtful; at the most it might produce gas in diabetics. It is possible again that the gas represents in part at least free ammonia from the decomposition of the urea.

Anaërobic bacteria, such as those concerned in gas phlegmon elsewhere, may be at the bottom of it, but I have been unable to find literature upon that point. Welch, in his exhaustive article[7] upon cases of gas-bacillus infection, shows that the B. aërogenes capsulatus may not only gain entrance to the body by way of the urinary tract, but also set up its own infection in the tract itself. The gas produced "may be either free in the cavity of the bladder, ureters, or renal pelvis, or contained within submucous blebs, or in both situations." But though the presence of this bacillus in the urine is well attested *inside* the urinary tract, I can find in a somewhat careful search of the literature no record of its having been demonstrated in urine *outside* the tract—I mean in extravasations. This is a point for future investigation.

Morbid Anatomy.—In discussing the morbid changes which occur in this disease, we take as our type the acute phlegmon of a limb which occasionally complicates a severe injury, and which is due to the ordinary pyogenic cocci.

The gross and microscopic changes in the tissues are practically the result of a very intense inflammatory process, and involve principally the subcutaneous cellular tissue, but also the true skin and in some cases the deeper structures. The skin becomes deeply red, and there often occurs a decided lymphangitis, so that clinically we see the well-known red lines running toward the neighboring glands. In the cellular tissue the organisms advance rapidly along the lymphatics and connective-tissue spaces, while the host reacts with a copious outpouring of inflammatory lymph. The parts become so infiltrated that there is imparted to the examining finger the hard sensation of brawn—a brawny œdema. The skin later assumes a dusky red tint, and exudation proceeds to the point of threatening gangrene. Occasionally gangrene actually occurs, the skin becoming marbled with purplish-red areas and being thrown off finally, either in patches or over larger areas.

If incisions are made in the early stage, say within the first day or two, there exudes nothing but a thin serum which may or may not be slightly turbid from admixture of leucocytes and flakes of fibrin. If the process has gone on to the "brawny" stage the cut surface shows a pork like aspect, or sometimes more like orange pulp, especially at the area of greatest intensity. A little later,

Digitized by Microsoft®

vesicles filled with a turbid fluid may form in the skin, owing to localized exudation in the rete.

Meanwhile in the cellular tissues, if the case be severe, the inflammatory process goes on from mere infiltration to a coagulation necrosis. The necrosis is due not only to the mechanical distention of the exudate, with the venous thrombosis and general circulatory stasis which it produces, but also to the accumulation of bacterial toxins. It seems to be a frequent property of the organisms usually concerned (virulent streptococci or staphylococci) to cause intense and rapid necrosis of the parts infiltrated, while their peptonizing power remains in the background. Nevertheless, after the necrosing process has continued a variable time, there succeeds—if the patient have not succumbed to a fulminating septicæmia—a certain amount of liquefaction or peptonization, so that in the course of a few days we have in the subcutaneous tissues what might be called a lake of pus, in which float shreds and masses of sloughy tissue. After incision these shreds often have to be pulled or cut off, and resemble strands of "wet tow" or "wet chamois leather." If the liquefying process has been less active, we get a series of small ponds, or irregular bayous of pus, separated by isthmuses or peninsulæ of wholly or partly dead tissue.

If incision does not give vent to the pus, it requires no long time for the latter to find its way out through the skin. In such cases sloughy ulcers persist, through which shreds of necrotic tissue and pus are discharged, and healing takes place slowly by granulation. In rare instances it may burrow deeply and invade joints, destroy muscles and tendons, or corrode arteries. If deeply situated and covered by strong fasciæ—such as in the pelvirectal space, the retroperitoneal tissue, the mediastinum or under the fronto-occipital fascia—it may not seldom break through into hollow viscera, or attack the serous membranes.

The *microscopical phenomena* are largely those of ordinary inflammation—outpouring of inflammatory serum, diapedesis of leucocytes, phagocytosis, the accumulation of round cells in groups in the corium and in the septa between the fatty masses of the panniculus; the reactionary proliferation on the part of the lymphoid and fixed tissue cells; and the dilatation of the lymphatics, which are filled with organisms.

The microscopical appearances in detail will vary according to the severity of the infection. In mild cases, subsiding rapidly under incision, there is evidently comparatively slight reaction of the body cells; pus may not be found; and the exudate is reabsorbed. In the typical severe case the early extreme serous exudation becomes in the course of a few days invaded by a large number of leucocytes; the proteolytic ferments of the pyogenic bacteria come into play; necrosed tissue is liquefied, and pus is formed. This pus is not localized, but is distributed over considerable areas as an infiltration. Finally, in the fulminating cases we find again but slight evidence of any cellular reaction. The bacterial toxins kill before the individual defenders of the body can marshal to resist. Welch[7] has found this last-mentioned state of affairs to be especially true of pure infections with the B. aërogenes capsulatus. This bacillus, if pure, leads mainly to necrosis, the nuclei disappearing by karyolysis, while leucocytes and cellular reaction are remarkable by their absence.

The characteristic points, however, in ordinary phlegmon are the excessive primary exudate of serum, the comparatively late proliferation and advance of the leucocytes and other body cells, and the marked necrosing power of the microbic toxins.

While the above would represent the changes in the average severe case of phlegmon, many other less frequent types might be set up, dependent upon the situation of the process and its degree of virulence. Thus we have the deep phlegmon, situated underneath the deep fascia, in which the pus accumulates in the intermuscular septa, which it may infiltrate in long strands. The superficial structures meanwhile may show for many hours or for many days no sign of the underlying infection; yet sooner or later œdema develops. In mild cases the exudate may never become purulent and may be finally reabsorbed if incisions have not been made. At the other extreme, we meet the very malignant type in which the whole limb becomes, within twenty-four to forty-eight hours, intensely œdematous, while the patient succumbs, or the limb is amputated, before pus has time to form. Such cases are due probably to the extremest degree of virulence of the pus cocci.

In cases of emphysematous gangrene the above picture becomes more or less typically modified. The wound secretion, hitherto comparatively healthy, becomes increased and smells horrible; thin, fairly clear serum flows from the drainage openings; the parts around the wound become swollen; the neighboring skin begins to show, in spots or in patches, a purplish or blue-black coloration; air collects in the interstices of the subcutaneous tissue, giving to the examining finger a sensation of fine crackling. This emphysema, accompanied by extreme œdema, spreads rapidly up the limb; the skin takes on a special coloration, which was particularly noticed by the first observers and was compared to that of a dead leaf, or to that of Florentine bronze. Sometimes it looks like a week-old ecchymosis. The distended veins stand out in blue against this dark-brown background; here and there show up patches of a darker color, beginning gangrene, which, in this form of phlegmon, tends greatly to become extensive. The emphysema may extend so rapidly that its advance has been followed for inches during a few minutes' observation.

Clinical Course.—This will vary to some extent according to the nature and degree of virulence of the causative factor. If we take, as before, an ordinary case of rather severe wound infection, the signs are somewhat as follows. They may be considered as (*a*) local, and (*b*) constitutional.

(*a*) *Local.*—At a variable period following the infliction of the wound, but usually within three or four days, inflammatory signs appear in its neighborhood. The edges grow red and œdematous; the same condition spreads rapidly up the limb, invading the subcutaneous cellular tissue *per continuum*; at the same time pain of variable intensity is usually felt in the parts. The lymphatics may show as red lines in the skin leading up to the nearest lymph glands. The œdema may involve a whole extremity within thirty-six to forty-eight hours. Vesicles frequently form and are filled with turbid serum.

If numerous incisions are made at an early stage, the process may frequently be arrested and subside with or without the formation of pus. The converse of this picture is seen in those cases in which, in the absence or failure of operation, the inflammation extends rapidly beyond the limits of the extremity involved and attacks the trunk. *Exitus letalis*, within a very few days, is then the most frequent ending.

(*b*) *Constitutional.*—The symptoms are usually grave. Even the cases of slight or moderate severity are ushered in with chilliness, fever, general malaise, etc. In the very severe cases the chill is marked, the fever high, the pulse rapid; the patient may become somewhat delirious, and after a variable lapse of time sink into a typhoid condition and die of acute general sepsis. In other cases, especially in those whose resistance has been weakened greatly, the course may be of an asthenic type from the beginning, and the patient shows neither locally nor constitutionally any appreciable effort at throwing off the *noxa*. Cases of this nature are to be set down, in the present state of our knowledge, to infection with the streptococcus pyogenes, the staphylococcus aureus or albus, or to a combination of both; with the additional presence, in some cases, of still other bacteria, such as those of the colon group and proteus.

The ordinary severe case, left to itself or operated late, is characterized in its later course by the results of the extensive cellular necrosis. Through spontaneous or operative perforations pus and shreds of slough are discharged for many days or many weeks. If finally the wounds granulate up, the structures involved—skin,

Digitized by Microsoft®

muscles, tendons, fasciæ, nerves, and arteries—are all involved in the reparative scar; and the patient may be left with an impotent limb. In some cases healing does not occur; suppurative fever continues; pyæmia or septico-pyæmia develops and ultimately leads to the death of the patient.

www.libtool.com.cn

When Welch's B. aërogenes capsulatus or, less often, the bacillus of malignant œdema enters the field, either alone or combined with the pyogenic cocci, the clinical picture is usually more grave. Our classical clinical descriptions are given by Maisonneuve and Pirogoff. In their day, with the abundance of military surgery, cases were much more frequent than now. Pirogoff divides the cases into two clinical groups. As I am unable to get access to the original literature, I paraphrase from Welch:[7]

"(*a*) In the very virulent there is but slight local reaction while the part goes on into crepitating gangrene. The emphysema and necrosis spread rapidly and the patient usually dies in a few days with symptoms extremely toxic and asthenic. (*b*) In the other group there is reaction. The emphysema is preceded and accompanied by local œdema or purulent infiltration, as well as by febrile reaction; it appears later after the injury, and spreads less rapidly. All gradations are, however, observed."

The cases in which phlegmon has been ascribed to the invasion of bacteria other than those mentioned above are very rare. Almkvist[14] describes a case of extensive infiltrating abscess of the foot in which gonococci alone were found. He refers to four similar cases in the literature.

A cellulitis of the orbit has been described as due to the influenza bacillus.[1] Netter[16] reports a case of phlegmon due to Fraenkel's pneumococcus.

Other than these I have been unable to find in the literature.

In addition to the above general consideration of phlegmon the writer has thought it advisable to make a few remarks upon the characteristics of phlegmon, in its various localizations, before going on to the questions of prognosis, diagnosis, and treatment.

Phlegmons of the Scalp.—The anatomical peculiarities of this region give an especial interest to the question of phlegmon. The parts are so unyielding that inflammatory processes tend to spread widely and to infiltrate. This is true of inflammations both above and beneath the fronto-occipital aponeurosis, but especially of the latter. The subaponeurotic connective tissue being continuous with the cranial periosteum, phlegmon, when it attacks the former, is extremely apt to destroy the latter and so lay bare the bone. The dangers of the subjacent, more or less inevitable, bone inflammation, or of vein thrombosis, are evident. The internal periosteum (*i.e.*, the dura mater) may easily become involved. Von Bergmann refers to cases of deep-seated brain abscesses arising solely by infection transmitted by contiguity along thrombosed veins. As compared with the superficial soft parts, the aponeurosis, together with the connective tissue binding it to the periosteum, necroses very easily. This is due largely to the manner of its blood supply. Whereas the main vessels of the superficial parts run horizontally to the surface and thus frequently escape injury in lacerated wounds, those supplying the aponeurosis and periosteum run mainly vertically to the parts nourished, and are apt to be torn across in wounds of the scalp. Moreover, the tension which the tight aponeurosis exercises upon any large exudate leads mechanically toward death of the tissue.

Diffuse phlegmon, therefore, of the scalp, especially if deeply situated, is one of the most formidable complications of contused and lacerated wounds. Fortunately, aseptic surgery has made it rare. The accompanying fever is high, and the resulting abscesses are numerous, while the liability to intracranial suppuration is not small.

The erysipelas which attacks deep scalp wounds is especially to be feared. The subaponeurotic connective tissue is in such wounds the part most injured, and the *locus minoris resistentiæ* thus created attracts, so to speak, a superficial erysipelas into the deep parts, and thus gives rise to a phlegmonous erysipelas.

Phlegmon occurs usually as a complication of wounds of the head, but also follows osteomyelitis of the cranium; or, again, it may be an extension from face phlegmons. Pain, swelling, high fever, and especially the swelling of glands behind the ear are the early *symptoms*. Early *diagnosis* is important, because here, if anywhere, is early and deep incision—down to the bone if the phlegmon is deep—necessary, if both extensive necrosis and also the danger of intracranial mischief are to be avoided. The incisions must be kept well open with gauze or drainage tubes.

Phlegmons of the Neck.—Inflammatory processes in the neck are usually circumscribed and end in abscess. The diffuse phlegmon is comparatively infrequent; it may arise primarily as such, or may be secondary to a localized inflammation.

It is caused by infection of wounds by extension from neighboring inflammations, either by contiguity or by the lymphatics through an adenitis. Rarely can it be ascribed to a hæmatogenic infection, as in pyæmia.

The clinical picture varies somewhat according to the anatomical region involved. Of these the most important is the *submaxillary phlegmon*, for which the ordinary term is *Ludwig's angina*. It is certain that Ludwig's angina is a name which has been too loosely used. Most frequently it has been confounded with other inflammatory processes which have as their most striking symptom an œdema of the glottis, such as phlegmonous erysipelas of the larynx, or acute perilaryngeal infection dependent on other causes. As a matter of fact the disease described by Ludwig, in 1838, was an acute infection of the connective tissue of the submaxillary spaces secondary to an adenitis of this region, the original lesion being usually a carious tooth, a mucosal ulcer, or a tonsillitis. The depth of the inflammation, the extreme pressure exerted on the exudate by the unyielding deep fascia covering the space, and the liability therefore toward involvement of neighboring organs (in especial the larynx) gave the disease a characteristic picture—that of a severe and frequently fatal infection. The term Ludwig's angina should be reserved for cases showing the above pathological condition.

Bacteriologically the streptococcus is found most frequently. In four cases reported by Leterrier the streptococcus was found twice, the staphylococcus aureus once, and in the fourth an undetermined bacillus. In four examined by Gasser, the streptococcus, combined with a very virulent B. coli communis, was found in each case (quoted by Jordan in the "Handbuch der praktischen Chirurgie").

Pathologically there are found a purulent infiltration of the connective tissue of the space, and an extensive inflammatory œdema of the floor of the mouth, the larynx, and the pharynx.

The *symptoms* are in general those of the acute phlegmon anywhere. But the local conditions add the characteristic signs of difficult or impossible deglutition, great dyspnœa, impossibility of opening the mouth, salivation, and *fœtor ex ore*. Death frequently follows in a few days with symptoms of general sepsis, or from laryngeal œdema if tracheotomy be not quickly done. The infection may kill in from two to three days. Such fulminating cases are due to an extremely virulent streptococcus toxæmia, and the earliest surgical interference may be insufficient to prevent death. In some cases of a milder degree of infection a localized abscess results, and breaks into the mouth or through the skin.

The *prognosis* has certainly brightened of late years. Delorme in 1893 was able to report a series of seven recoveries in cases operated early.

Treatment.—Incision should be practised at the earliest possible moment, even before pus can be diagnosed. It is best made a finger's breadth below and parallel to the alveolar border of the jaw. After superficial incision it is best to proceed deeply with a blunt-pointed instru-

Digitized by Microsoft®

ment. With great dyspnœa tracheotomy should be done without hesitation.

Phlegmons may develop at the angle of the jaw and in the submental region; but in these situations they tend to localization and heal easily upon incision. Phlegmons may arise in the loose areolar tissue surrounding the large vessels of the neck, the vessel sheath. They come in frequency next to those of the submaxillary region, and originate most often from the deep cervical glands following anginal affections, carious teeth, otitis, etc. While infection in this region is frequently of the comparatively mild, circumscribed type, yet when the severe spreading type does occur, it is one of the most dangerous conditions possible. The swelling is deep and hard and may extend rapidly from the ear down to the clavicle, and from the spine to the trachea. The skin becomes reddened rather late, and wry-neck and trismus come on. Frequently death occurs from sepsis before pus forms. When abscess forms, the pus may sink into the mediastinum or axilla, and may cause compression of the trachea, œsophagus, large vessels and nerves, and these complications may be the immediate cause of death.

The *prognosis* is bad. *Treatment* consists in very early multiple incisions.

Complications.—Besides those already mentioned there may occur erosion and perforation of vessels. In the case of a vein, bleeding may be absent, if the vein has been occluded by a thrombophlebitis; in the case of an artery, however, there follows not infrequently fatal hemorrhage, although at times the bleeding is moderate and repeats itself at intervals. The carotids have been ligated in continuity in such cases with success.

Reclus[24] has described under the name of "phlegmon ligneux du cou," a rather chronic form of phlegmon, developing very slowly, of very hard consistence, and involving a large area on one side of the neck. It may simulate closely a new growth.

Phlegmons of the Axilla.—These are either subcutaneous or subfascial. They have their origin usually in a lymphangitis running from a primary infection in the hand, arm, or breast. Frequently the atrium of infection is scarcely to be found, and the first symptom is pain and swelling in the axillary glands.

The subcutaneous phlegmon is easy of diagnosis; more difficult is it when the phlegmon begins deeply under the pectoralis and spreads toward the axilla. With the ordinary constitutional disturbance we get a dull pain and a restriction of shoulder movements, especially of abduction. It is only after several days usually that a dilatation of superficial veins and a slight swelling over the pectoral region are seen.

Incision should be made, as soon as the affection is diagnosed, at the posterior edge of the great pectoral through the deep fascia, and then blunt dissection should be continued with the finger under the muscle, until the pus is reached.

Phlegmons of the Upper Arm.—In this region phlegmons of a comparatively mild nature and insidious onset are not infrequent on the inner side of the arm, and originate in inflammatory conditions of the lymphatics or lymph glands in the bicipital sulcus or in a bursitis olecrani.

Apart from the ordinary subcutaneous phlegmons Jaboulay[25] distinguishes cases in which the process is situated under the deep fascia running in the sheath of the vessels, thus forming a band along the inner side of the arm to the axilla, which upon abduction of the arm is painful. Naturally the fascia must always be split in order to lay open the focus.

Phlegmon of the Fingers and Hands.—Phlegmonous processes in the hand require especially early diagnosis and thorough treatment in view of the too frequent loss of function, sometimes of "earning power" (as the Germans call it), following upon failure or neglect in this particular.

The panaritia, confined to the terminal phalanx, are hardly to be considered here. Nor do the infections beginning in the periosteum and confined to one of the phalanges properly come into our classification of phlegmons. It is true that either of them may lead to phlegmonous processes, but to discuss them would lead beyond the limits of this article.

The important phlegmons of this region are those which involve the tendon sheaths, either primarily or secondarily. It is necessary to remember with regard to phlegmonous processes, whether in finger or hand, the anatomical peculiarities of the subcutaneous connective tissue. On the dorsal surface the connective-tissue bands, uniting skin to fascia, run at an acute angle, in fact nearly parallel to the long axis of the limb, thus allowing of a great deal of elasticity in the subcutaneous tissue. On the palmar surface the reverse is true; the connective-tissue bands run mainly vertical to the long axis of the limb, and are characterized by thickness and density. The result is that any inflammatory exudate occurring on the palmar aspect meets with great resistance in its spreading toward the surface, but finds an easy path toward the dorsum. Thus it happens that a marked cellulitis, with great redness and œdema, frequently appears on the dorsum of the hand, while the focus is really situated on the palmar surface and may, if beneath the palmar aponeurosis, have occasioned on that aspect of the hand no sign at all suggestive of inflammation. No doubt the cyanotic œdema of the dorsum in such cases is caused partly also by pressure on the deep dorsal veins as they pass forward between the metacarpals to join the palmar arch.

In such cases an exact examination is required, lest dorsal incisions be counted sufficient, and the one really necessary palmar incision down to the focus be overlooked. The one criterion available is an exact localization of the point of greatest tenderness. The whole hand should be examined for this area with a blunt-pointed probe. The point of greatest tenderness will always correspond with the primary spot of infection; and as a matter of clinical experience that focus is in the great majority of cases on the palmar side.

With regard to infections of the tendon sheaths we must remember their anatomical relationships to each other. The thumb sheath runs up to a point under the annular ligament, while that of the little finger extends under the annular ligament, and in some cases a short distance up the arm. Both communicate with the large palmar bursa. Infection of either of these two may lead by continuity, even in the absence of direct communication, to involvement of any or all the others.

The course is frequently very acute. In a very few days the sheath may be filled with pus; and, being normally but poorly nourished, it necroses very readily. In such cases the necessity for the promptest surgical interference is exceptionally evident; expectant treatment is apt to leave a practically useless hand. If not opened early the infection may spread to the deep connective tissue and cause an extensive phlegmon of the palm; it may extend from here up beneath the annular ligament and cause a deep phlegmon between the muscles and tendons of the forearm. The possible further danger of septic thrombophlebitis and pyæmia is well known. Even nowadays such progressive phlegmons, which might have been arrested in the hand by proper interference, lead occasionally to amputation of the arm. Failing this, convalescence extends over months, and at the end the patient is left with an arm whose usefulness is largely destroyed. The importance of early interference in, for instance, the case of a workingman is enormous. Rather too long and too deep a cut than too small or too late a one. It is scarce possible for it to be too early. It is wise in incising the palm for a deep infection, to push forward bluntly with a pair of forceps after getting through the skin. A counter opening on the dorsum with through-and-through drainage is often advisable. General anæsthesia is probably the best for these extremely painful phlegmons of the hand.

With regard to after results a certain amount of fixity of the tendon involved is scarcely to be avoided. Yet if massage, hot bathing, passive movement, and electrization of the corresponding muscles be instituted as soon

Digitized by Microsoft®

as possible, a satisfactory amount of function may not infrequently be recovered. The endothelium clothing tendons and tendon sheaths (as indeed everywhere in the body) possesses a large capacity of regeneration, provided function be restored early; but if fibrous tissue be allowed to contract into a scar and produce adhesions, it can evidently never be replaced by endothelium. Thus orthopedic measures to be successful must be instituted as early as possible.

www.libtool.com.cn

Phlegmons of the dorsal surface are much rarer and less dangerous.

Phlegmons of the Foot.—Deep phlegmons, underneath the plantar aponeurosis, cause, as in the hand, inflammatory signs on the dorsum, long before anything appears on the sole, and may lead, if care is not exercised, to incision in the wrong place. If the process invades the tendon sheaths in the neighborhood of the ankle-joint there is apt to follow rapid extension up the leg.

Incisions should be made when possible so that the scar will not be exposed later to pressure.

Periproctal Phlegmons.—The atrium of infection in this important class of phlegmons is in the great majority of cases in the rectum. Slight abrasions from the passage of fæces, scratches produced by hard and pointed bits of food—such as fish bones—small ulcerations caused by stagnation of fæces in the lacunæ of Morgagni—all these represent opportunities for the invasion of pathogenic germs. Moreover, it must be admitted that infection may occur with an intact mucosa, through the lymphoid tissue in the wall, in analogy with the same process in the tonsils. Catarrhal inflammation, ulcers of any kind, inflamed hemorrhoids, may be the starting-point of a phlegmon. Infection of the anal skin, *e.g.*, eczema; extension of inflammations of neighboring organs, such as urethritis, Cowperitis, prostatitis, and in the female Bartholinitis—all these may give rise to a phlegmonous periproctitis.

The intelligent treatment of these phlegmons is inseparable from a knowledge of the anatomy of the parts. Without going too deeply into this question, we must remind the reader that the perirectal connective tissue—that tissue namely in which phlegmons mainly run their course—is divided into an inferior or superficial, and a superior or deep portion; the former called the ischiorectal fossa, the latter the pelvirectal space.

It is the levator ani muscle with its enclosing fasciæ, the superior and inferior diaphragmatic fasciæ (or, as it usually appears in English literature, the two layers of the triangular ligament), which divides the two spaces.

Phlegmons, therefore, may be superficial (*i.e.*, situated in the ischiorectal fossa), or deep (*i.e.*, in the pelvirectal space); or they may spread sometimes through both regions. In the first case they may extend to the perineum, scrotum, groin, or thigh, while in the second case they spread by direct continuity into the pelvic and thence into the abdominal retroperitoneal areolar tissue, and so up to the kidneys or in front over the anterior abdominal wall. These are naturally much the more dangerous. Portions of the peritoneum, even of the bowel, may become gangrenous, and septic peritonitis develop. Death most often results in from two to ten days. Such phlegmons are fulminating in character. Inasmuch as virulent anaërobic gas-producing bacteria are invariably to be found in the fæces, it becomes evident that periproctal phlegmons may at any time assume the fulminating type of emphysematous gangrene, or "gangrène foudroyante." The bacteriological aspect of the question has already been discussed.

Another type, described especially by Kraske in connection with a wound, is characterized by gas formation, but with a much milder course. It is said that the B. coli is the etiological factor; but such a conclusion, in view of recent work upon the anaërobes in gas phlegmons, must appear at least dubious.

The onset is insidious; locally the wound shows often nothing but a breaking down of the granulations and slight œdema in the neighborhood. Fever is slight or absent. Gradually, however, there develops a tissue emphysema and small gas-containing abscesses, with necrosis of the tissues near the wound surface. At times metastases develop, even in the absence of fever or chill. Ultimately the patient becomes both restless and sleepy (if the apparent paradox be allowed), then somnolent, and in the course of weeks usually succumbs. Recovery is quite rare.

Some authors describe a third form, characterized by gangrene, called the "diffuse, gangrenous phlegmon." This is, however, merely a variety of the fulminating type of phlegmon.

In the above we have been speaking especially of the severe spreading forms of the disease. They may be complicated, or not, by gas formation, and their *prognosis* is an extremely bad one. When infection is less virulent we get a more circumscribed inflammation, with early formation of abscess. The acute ischiorectal abscess is often styled a phlegmon, but within the limits of this article it can hardly be considered such.

Infections of the pelvirectal space are much more frequently spreading in type. *Diagnosis* is here difficult on account of their deep situation. Still, careful digital examination will often discover an inflammatory mass causing the rectal wall to bulge inward. Even before such swelling occurs, the presence of rectal and vesical tenesmus with deep pelvic pain should lead to a probable diagnosis of pelvirectal phlegmon. If left alone, or diagnosed late, the condition is apt to cause extensive abscesses and break through into neighboring organs or the skin, when it does not lead to a fatal issue.

Treatment.—This is of course early incision. This should never be made through the rectal wall, no matter how tempting a pointing abscess may be; for in such case drainage is poor and fæces enter the abscess cavity. The incision, both in ischiorectal and in pelvirectal infections, should be through the ischiorectal fossa. When the abscess is deep—*i.e.*, pelvirectal—the levator ani should be exposed, and then a blunt instrument should be passed between the two heads of the muscle, where they reunite beneath the prostate. The opening should be made secure by a large stiff drain.

Phlegmons of the Testicle.—Phlegmons in this region acquire a special interest from their tendency to gangrene. They originate mostly from phagedænic ulcers or wounds of the penis, urethra, and perineum; or from suppurative cavernitis of the corpus cavernosum; or from urinary extravasation, or as a result of suppurative periproctitis. They are characterized by an extremely tense swelling of the scrotum, with frequent ending in gangrene of the skin, the inflammation often spreading rapidly on the abdomen and the thigh, and also deeply to the tunica vaginalis and the cord. In this last case it leads on not infrequently to phlegmon of the pelvic cellular tissue and even to peritonitis.

In virulent infections, and especially with urinary infiltration, also when the phlegmon connects with paraproctitic processes, there frequently develops gas in the infiltrated tissue. Especially in these cases is the gangrene apt to be deep and extensive. The bacteriology of this condition has already been described.

It is a point of considerable practical interest and importance that an ordinary infective phlegmon, arising from some focus in the anal gut or the ischiorectal fossa, may spread with great rapidity and severity over the perineum, scrotum, and the neighboring parts, and thus simulate a urinary extravasation so closely as to induce surgeons of experience to do median perineal cystotomy.

Phlegmons of the Thoracic Wall.—These are fortunately rare, for the *prognosis* is always grave. They usually spread from a purulent axillary adenitis and invade most often the anterior wall, lying upon the fascia underneath the greater pectoral. They may arise primarily in the deep fascia from penetrating wounds. Usually they break through the skin, rarely into the pleura. Kümmell,[25] of Hamburg, describes one case which, extending from an empyema, spread over the whole of the

Digitized by Microsoft®

right side of the back and down over the gluteal region, as far as the great trochanter.

Diagnosis may be extremely difficult in the early stages. The one symptom at that time is extreme pain over the whole side of the chest, so severe as to make respiration difficult. This, with the accompanying fever and chill, causes the condition to be mistaken for pleurisy. It may be several days before redness of the skin, or fluctuation at some point, renders the diagnosis unmistakable. A careful consideration, however, of the nature of the pain, and of the severe constitutional signs, ought to permit fairly early diagnosis.

www.libtool.com.cn

Kümmell[25] reports that of ten cases in the Eppendorf Hospital only two recovered; the rest all died of general sepsis. No doubt some of these belonged, however, to the old days of "expectant" surgery. At the present day earlier diagnosis and radical incisions ought to save a much greater proportion.

PHLEGMONS OF THE ŒSOPHAGUS.—Phlegmon in this region is situated in the submucous tissue and is very rare, but may be extensive. Some cases described as phlegmons are evidently small localized abscesses. When pus has formed it tends to break through into the œsophagus or the trachea, rather than to spread through the mediastinum or into the pleural cavity. It may follow the arrest of a foreign body in the œsophagus, or represent the extension of a phlegmonous gastritis. In a few cases no cause can be ascertained.

The *symptoms*, apart from those of constitutional disturbance, are mainly of local origin—difficulty of deglutition, with pain along the course of the œsophagus, especially behind the sternum and radiating to the back; nausea; cough; occasionally vomiting of purulent material.

Diagnosis is extremely difficult except in cases in which the history of the stoppage of a foreign body is clear.

Treatment.—With the œsophagoscope a prominent abscess may be discovered and opened. In severe cases the question of external incision must be considered, if the symptoms indicate a lesion above the thoracic cavity. Apart from these indications treatment must be expectant.

GASTRIC PHLEGMON.—Cases of this kind are usually diagnosed with certainty only post mortem. The phlegmon complicates carcinomatous disease not infrequently, simple ulcer but rarely. Occasionally it is caused by foreign bodies or traumatism. It involves mainly the submucosa. The stomach wall is usually immensely thickened, inflamed, and œdematous. Perforation may occur in either direction. Clinically the picture is that of acute gastritis with peritoneal symptoms and fever.

Kinnicutt[29] has lately described a striking case.

PHLEGMONS OF THE LARYNX.—In perilaryngeal phlegmons the symptom which dominates the clinical picture is naturally that of a dangerous œdema of the larynx. And yet, for the sake of an exact knowledge of the subject, the writer feels inclined to offer a prefatory note of protest against the loose, slipshod way in which the term "œdema of the larynx" or "œdema of the glottis" has been so generally used, as if it represented a disease entity, instead of being, as it is, merely a symptom. It may be due to entirely non-inflammatory causes, such as severe nephritic or cardiac disease, in which it appears as part of a general anasarca; or to the pressure of a tumor causing local stasis. When of inflammatory origin the œdema may be the result of a primary infection in the submucosa, occurring in the course of infectious diseases as a metastasis; or of a primary local erysipelas (if we admit that such really does occur). On the other hand, it may be caused secondarily by extension of some inflammation of neighboring parts. It is under this heading that the laryngeal phlegmon is ranged; such a phlegmon may have arisen in the floor of the mouth, or in an adenitis at the angle of the jaw; or it may have developed from a peritonsillar or peripharyngeal infection, or, from an infection located in the connective tissue of the neck; or finally its starting point may have been in the areolar tissue of the submaxillary triangle, this last representing Ludwig's angina in the strict sense of the term.

These phlegmons are accompanied by the usual local and constitutional signs. In this place it is necessary to speak only of the dominating sign of local laryngeal œdema, when it is of any severity. The symptoms depend mainly on the diminution of the laryngeal opening. The obstruction occurs usually by swelling of the aryepiglottic folds. Thus we have inspiratory dyspnœa and hoarseness. Pain may be constant, but is increased by swallowing.

The one point upon which emphasis must be laid is that the submucous infiltration may develop with extraordinary rapidity. While this is true of infective œdema, it is especially so of the traumatic œdema. The breathing must be constantly watched. A tracheotomy may become necessary at any moment, and indeed many patients have died for lack of it. von Ziemssen's rule was, "never under any circumstances to leave a patient suffering from œdema of the larynx, and rather to do a tracheotomy with a penknife, if proper instruments are not at hand, than to let him suffocate."

While the *prognosis* of phlegmons generally is never especially bright, it becomes decidedly darker when they become complicated, as in this region, by laryngeal œdema. Sestier (quoted by von Bruns in "Handbuch der prakt. Chir.") found in 213 cases of œdema glottidis (no doubt of various causation, not solely of phlegmonous origin) 158 deaths. Of the total number 30 had had a tracheotomy done. No doubt present-day methods would show much more favorable results.

As regards *treatment*, besides the matter-of-course incision for the original phlegmon, the surgeon must be constantly in readiness to do a tracheotomy for the secondary œdema laryngis. Where the necessity stops short of a tracheotomy, ice should be given, and the ice-bag kept applied externally. Intubation is contraindicated.

COMPLICATIONS.—These are mainly of the nature of metastatic inflammations. Suppurative synovitis and arthritis complicate phlegmonous erysipelas not uncommonly. The same result may be brought about by direct extension of the inflammation into the deep structures. An infective pneumonia has been described as due to a streptococcus metastasis from phlegmonous erysipelas. Endocarditis and albuminuria are rare.

Septicæmia, pyæmia, or septico-pyæmia not infrequently develop from a phlegmonous focus. Septic inflammations of the various serous membranes may come on, especially following streptococcus infections—pleurisy, empyema, peritonitis, meningitis. The B. aërogenes capsulatus may also cause peritonitis or meningitis.

DIAGNOSIS.—There is really no other disease from which it is necessary to differentiate phlegmon when superficial, as it usually is. The question of diagnosis comes in only as between its own various forms. It is desirable, however, to distinguish these, both for therapeusis and for prognosis. The rapid development of gas and of gangrene and its fulminating character distinguish easily cases of *gangrène foudroyante* from those of ordinary phlegmon (Class I.); but less easily from cases of urinary extravasation. A late case in the Royal Victoria Hospital, Montreal, of a B. aërogenes capsulatus phlegmon, starting from the rectum and involving scrotum, penis, and groins, simulated so perfectly a urinary extravasation that it was only at post-mortem that the absence of the latter could be made quite certain. Still, in most cases, a diagnosis should be made from the previous history of urinary trouble, and from an examination of the urinary tract.

The diagnosis of a deep, subfascial phlegmon may occasion considerable difficulty. The deep pain, the fever, and other signs of constitutional disturbance will point plainly enough to an infected condition; but to determine the exact localization of the process, whether it is in the soft tissues or in the bone, *i.e.*, an acute osteomyelitis, may be far from easy. In acute osteomyelitis the pain is apt to be more severe, more localized; while subcutaneous œdema develops to a less extent and rather later.

Digitized by Microsoft®

Moreover, acute osteomyelitis occurs almost constantly during adolescence and develops at an epiphyseal end. As a matter of fact it is really nothing more nor less than a phlegmon of bone; and its treatment is the same as for phlegmon of the soft parts.

In the case of phlegmons of Class II.—gas phlegmons—a very early diagnosis is of great importance for successful therapeusis. Bloodgood[26] has reviewed these cases from the surgical standpoint in a very thorough manner, and I quote from him.

"Unquestionably in gas-bacillus infections an early diagnosis is always possible, and not at all difficult. In any recent wound with symptoms of infection, one should at once make cover-slips from the fluid in the wound. The presence of large bacilli, morphologically like the gas bacillus, even with the absence of gas bubbles or emphysema, is practically, in the majority of cases, pathognomonic of a gas-bacillus infection. If one finds in addition air bubbles in the fluid, or emphysema in the tissues, plus the presence of bacilli in cover-slips, there is practically no question about the diagnosis."

Under the head of treatment I shall quote further remarks of Bloodgood, which are a corollary to the above.

I suppose we may assume that a phlegmonous erysipelas, *i.e.*, a phlegmon of the deeper structures developing by extension from a true erysipelas of the skin, is a pure streptococcus infection. If we have any faith in antistreptococcus serum, we must be careful in such cases not to overlook in the general phlegmon the coexistence of the cutaneous erysipelas; for in such cases, if in any, would the serum have a chance to do good.

Prognosis.—The outlook in any of our three classes of phlegmon is usually grave; but by all odds gravest in the phlegmon of gas gangrene. The fulminating cases of ordinary phlegmon (Class I.), which kill in a few hours, are rare. More often the patient dies of the infection during the first week or two after the onset. If he escapes then, he may die later of chronic suppurative fever and pyæmia. If he recovers, he may be left with a functionally impotent limb.

In cases of gas gangrene (Class II.) the prognosis, without operation, is practically always toward a fatal ending. With early and proper treatment it is by no means so black as our predecessors have painted it; and it is yearly becoming less grave. The earlier and more thorough the operation is, the brighter becomes the outlook.

Welch[7] says that results are better after amputation than after incisions only. Of the cases collected by him of emphysematous gangrene, affecting primarily the extremities, the recoveries numbered 68 per cent. after amputation, and 33⅓ per cent. after incision without amputation.

Treatment.—The treatment of phlegmon may be considered under the three headings—non-operative, operative, and serum-therapy.

Non-Operative.—Naturally this can be thought of only in the mildest cases. Take, for example, a cellulitis orginating in an infection of the hand, and spreading with greater or less rapidity up the forearm. The surgeon incises such cases almost invariably as soon as he sees them, and counts the disfiguring scars—so disfiguring, especially on the back of the hand—as not to be weighed for a moment in the balance. Let us admit, upon the whole, that he is right. And yet, how often does the general practitioner apply in these cases hot antiseptic formentations alone, and see his conservatism, or the patient's disinclination to the knife, justified by the event! There is room here for the exercise of the nicest surgical judgment. The writer believes that in the early stages of these spreading cellulitis cases, mild types of phlegmon as they are, hot antiseptic applications or the hot continuous bath should be tried first; that, however, both the local and the constitutional symptoms should be watched carefully and almost continuously. If, after a variable number of hours, to be judged by the intensity of the process, the infection is evidently advancing, multiple incisions should be practised.

Some surgeons prefer cold applications, especially in phlegmons of the deeper regions, such as the perilaryngeal or periœsophageal. Elevation of the part and absolute rest are matters of course.

It may be mentioned at this point that Credé's ointment[27] (a salve containing fifteen per cent. of soluble metallic silver) has been strongly recommended by some in the treatment of septic infection of wounds. It is usually rubbed into the skin after the fashion of the mercurial ointment in the treatment of syphilis; and it is claimed that the formation in the blood of powerfully bactericidal silver salts effects a general antisepsis of the entire organism (Werler[28]). The writer is unable from personal experience to give any opinion upon the question; but the method of treatment has not come into wide use.

Operative.—This will vary, according to the case, from a few superficial incisions to the amputation of a whole extremity. Multiple incisions are the rule in moderate cases. After incisions the parts should always be kept enveloped in hot, wet antiseptic dressings or in the continuous bath. The value of the latter in severe local infections has been particularly demonstrated by the experience of the great Hamburg clinic, and more lately by that of various hospitals elsewhere.

Incisions in the early stages must be numerous and they must enter the subcutaneous tissue, so as to allow of the escape of as much of the infected serous exudate as possible. In the later stages, with a large amount of pus present, they must be extensive enough to secure a free opening for the pus wherever it may happen to be; that is, the pus must be followed relentlessly into all recesses, and counter openings must be freely made. Necrotic tissue should be removed as thoroughly as possible. Rubber drains of a good size should be inserted into the main openings. Copious hot irrigation with bichloride solution should be used. Care should be taken not to place the incisions too near each other, for fear of gangrene of the intervening skin from lack of blood supply.

Verneuil prefers to incise with the thermo-cautery in order to avoid the considerable bleeding which frequently occurs. This is of doubtful advantage. A certain amount of bleeding is more likely to do good than harm, by relieving the congestion of the part, and also by removing some part of the infective material.

The serious question of amputation must often be weighed. The tendency of the inflammation to spread rapidly and deeply over the larger part of the limb must be our main guide to the virulence of the infection and the necessity for amputation. The constitutional disturbance, in especial the height of the fever, has less significance, for in the grave asthenic cases reaction may be comparatively slight. In general it may be said that when we have an intense œdema, steadily and rapidly advancing, which has approached the proximal joint of the limb and which shows the dusky hue of threatening gangrene; and when the constitutional signs are severe, or when the patient is in an asthenic typhoid condition—in other words, when clinically we have before us the excessively severe, fulminating, or almost fulminating, type of infection, then amputation at the joint is urgently called for. In most of such cases the indication for such radical procedure will have been made absolute by the failure of previous multiple incisions to arrest the advance of the œdema. It will be a question for individual judgment whether an earlier amputation through the shaft of the humerus or the femur may not be advisable.

Even when the infection has spread beyond the limb on to the trunk, amputation at the joint should still be done; for recovery in such cases has been recorded, and indeed not so very infrequently. Amputation through the forearm or leg must be a rare thing. It might be considered in cases of fulminating gangrene or spreading emphysematous gangrene; but the lesion in such cases has usually spread beyond the knee or elbow by the time it is accurately diagnosed, so rapid is its advance.

The above remarks are applicable especially to cases of Class I., those of ordinary phlegmon. Cases of Class II., gas gangrene, require, from their especial virulence, con-

Digitized by Microsoft®

sideration apart. Bloodgood in his admirable article in "Progressive Medicine," 1900, has summed up the indications so well that I need only quote them:

"If the infection is recognized early and the destruction of the soft parts and bones is not extensive, free incisions with immediate continuous bath treatment should be tried. If the general symptoms of infection are not immediately relieved, amputation should be done. If, however, the infection is recognized late, one should take no risk, but amputate at once. An early diagnosis will often save life; and from many observations an amputation may not always be necessary."

The treatment of cases of Class III., urinary extravasation, is treated of elsewhere in the HANDBOOK. Here it need only be said that multiple incisions and free drainage, as for any other kind of phlegmon, fulfil the main indications.

Serum-therapy.—The question of serum-therapy in streptococcus affections is one which is yet far from settled. It is well known that Marmorek prepared his original antistreptococcal serum from a streptococcus obtained from a case of pseudomembranous angina. Great expectations were entertained of the new serum in all diseases supposed to be caused by the streptococcus, and Marmorek went so far as to request of accoucheurs that it be used in puerperal sepsis to the exclusion of the tried clinical methods of curetting and irrigation. These early hopes were doomed to disappointment. Clinically it soon became evident that the new serum had but little curative power, while experimentally it was shown that Marmorek's serum was totally inefficacious against diseases of streptococcus causation other than that of the original one. Thus cases of phlegmon, erysipelas, and puerperal sepsis remained nearly always unbenefited.

Since these early experiences, large numbers of isolated cases of all kinds of supposedly streptococcus infection have been reported. With the exception of a certain number of favorable, occasionally even of brilliant results, these reports tend to demonstrate the general inefficiency of the serum. Petruschky examined the question especially in regard to phlegmon, and came to a conclusion entirely unfavorable to Marmorek's serum.

The conclusion generally arrived at[17] was that the streptococcus genus was composed of a number of species, which, however similar in morphology or cultural characteristics, differed materially in the matter of their immune sera. Of late years a close study of the streptococci has discovered a considerable number of these more or less differentiated species. Van de Velde,[18] in Denys' laboratory at Louvain, has endeavored by immunizing with a number of these different streptococci simultaneously, to overcome this difficulty, and to produce a serum which he calls "polyvalent"—a sort of shotgun serum which if it missed one streptococcus might hit another. This "polyvalent" serum, it is said, has met with slightly more success than the original, but has not come into general use.

On the other hand, within the last year or two, various workers have tried to demonstrate the essential unity of all the various streptococci with the exception of that of *Pferdedruse* (our *Strangles*). Streptococci cultivated from cases of tuberculosis, measles, erysipelas, scarlatinal angina, abscesses, phlegmons, puerperal sepsis, angina in acute rheumatism, ulcerative endocarditis, and *Pferdedruse*, were examined thoroughly by Meyer[19] in respect to their morphology, virulence, hæmolysis, growth in filtrate of their own culture medium, and their specific immunizing sera. Similar investigations have been conducted by Widal and Besançon,[20] Menzer,[21] and Marmorek.[22] All tend to prove the "unity" of all the various streptococcus families, except that of Pferdedruse. If they are a unit, why then should any antistreptococcus serum fail to do good? Much further investigation is needed.

The whole question is beset with difficulties. There is the one already mentioned, that one variety of streptococcus apparently will not immunize against another. So long as it is impossible to say to which particular streptococcus a given infection is due, the use of Marmorek's serum or of any other antistreptococcus serum remains largely a matter of chance. Further, it is becoming more and more evident that the streptococcus does not play such a dominating rôle in many infections as has been believed. Certainly in the case of phlegmons we have reason to believe that the staphylococcus, Welch's gas bacillus, the bacillus of malignant œdema, and other less known organisms, may either singly or in symbiosis with each other or with the streptococcus, cause infections which it has hitherto been the custom to ascribe, usually without thorough bacteriological investigation, to the streptococcus alone.

Phlegmons, in which bacteriological examination carefully conducted both aërobically and anaërobically has shown infection with but one organism, are rare; and it is reasonable to believe that in many cases in which antistreptococcus serum has been given with negative results the infection has been one, not of the streptococcus, but of one of the other organisms mentioned; or, at least, of a symbiosis of the streptococcus with these others in which the streptococcus played the minor part. In this connection a case[23] reported from St. Petersburg is interesting. It refers to a septicæmia treated without the least benefit with antistreptococcus serum. Following this insuccess, antistaphylococcus serum was administered, with brilliant results. The writer refers to another case in St. Petersburg, one of ulcerative endocarditis, in which antistaphylococcus serum gave a similar good result. Unfortunately cultures were not made; yet the facts are suggestive. We have been in the habit of ascribing without careful investigation the causation of many diseases to the streptococcus, and perhaps quite wrongly.

Another point which may explain the general insuccess of the serum is this: that if we are to believe Aronson,[24] the antistreptococcic sera on the market contain comparatively very small quantities of anti-bodies.

In view of all these difficulties, all that can be said is that the practitioner, in desperate cases, may use antistreptococcus serum on the off-chance of its doing good; but he must await more certain bacteriological knowledge before he can use it with judgment or with any sure hope of its success. His main reliance must be placed on early diagnosis, and prompt and thorough surgical treatment.

Edward Archibald.

PHLORIDZIN.—$C_{21}H_{24}O_{10}.2H_2O$. A glucoside obtained from the root-bark of the apple, pear, cherry, and other fruit trees. It forms in fine, colorless, silky needles,

Digitized by Microsoft®

soluble only in one thousand parts of cold water, but freely soluble in boiling water. It is only slightly soluble in alcohol. It melts at a temperature of 222° F., but becomes solid again at 226° F., and melts a second time at 335° F. Phloridzin is very similar to salicin, and heated with potash it yields phloretic acid, which is homologous with salicylic and anisic acids.

It has been employed as an antipyretic in doses of fifteen to thirty grains, but is not now used.

Phloridzin is utilized in physiological research, as it has been found to induce artificial diabetes. When given to the extent of eight grains per pound of body weight it causes polyuria and an excretion of sugar which continues for twenty-four or thirty hours, and is not influenced by diet. It sometimes produces diarrhea, but no other ill effect has been detected, unless the drug is administered for a prolonged period, when marked emaciation and debility supervene. Phloridzin acts directly upon the renal epithelium, permitting the escape of sugar from the blood and lessening the amount of sugar held in solution in the blood. *Beaumont Small.*

PHONATION. See *Larynx, Physiology of the.*

PHOSOTE—creosote phosphate—is a colorless syrupy liquid, containing eighty per cent. of creosote, but with only a slight odor and taste of this substance. It is employed in tuberculosis as an easily borne form of creosote, and is given in dose of 0.7–1.3 gm. (gr. x–xx) three times a day. *W. A. Bastedo.*

PHOSPHATOL is a thick, reddish-yellow liquid prepared by the action of phosphorus trichloride on creosote in alcoholic soda solution. It has a burning taste, is slightly soluble in water, and is readily soluble in alcohol and oil. It can be given in milk or wine or in capsule in the same dosage as creosote. *W. A. Bastedo.*

PHOSPHORIC ACID.—By *phosphoric acid* is signified, in medicine, a solution of common or orthophosphoric acid (H_3PO_4) in water. Two grades of strength of such solution are official in the United States Pharmacopœia, as follows:

Acidum Phosphoricum, Phosphoric Acid. This preparation represents eighty-five per cent., by weight, of orthophosphoric acid and fifteen per cent. of water. It is a colorless fluid, without odor, but with a strongly acid taste. Its specific gravity is 1.710. It mixes in all proportions with water or alcohol. It should be preserved in glass-stoppered bottles.

Phosphoric acid is intensely acid and irritant, but does not immediately corrode living tissues and coagulate albumin, as do the majority of the strong mineral acids. In any considerable quantity, however, this grade of the acid would prove a sharp, and very likely fatal, irritant poison if swallowed without dilution. This strength of acid is rarely prescribed in medicine, being official simply as a convenient solution to be kept in stock by the druggist for the making of the following, the commonly prescribed preparation:

Acidum Phosphoricum Dilutum, Diluted Phosphoric Acid. This grade of the acid is compounded by mixing one part, by weight, of the foregoing strong acid with seven and a half parts of distilled water. The solution thus contains ten per cent. of orthophosphoric acid, and has the specific gravity 1.057. This acid resembles in general properties the other diluted mineral acids (see *Sulphuric Acid*), but is distinguished by having a pleasanter flavor (its acidity resembling that of the fruit acids) and by being, as a rule, better borne by the stomach than its congeners. It may, therefore, be used for the common purposes of the mineral acids, to allay thirst, improve digestion, repress tendencies to sour fermentation of the contents of stomach or bowels, and to check morbid sweating. By many it is further claimed that phosphoric acid, ingested, tends to revive an exhausted nervous system, to excite the sexual function, and generally to enhance nervous activity and power. By such claimants the acid is regarded as the therapeutic equivalent of uncombined phosphorus; but certainly it fails in that most pronounced therapeusis of free phosphorus, the frequent cure of neuralgia. A special claim for phosphoric acid, of capability to lessen the excretion of sugar in diabetes, is now probably pretty generally abandoned. Diluted phosphoric acid may be given in doses of from twenty drops to a teaspoonful or more, three times a day, the dose to be largely diluted with water, or with syrup and water. The precaution obtaining with the giving of other mineral acids, of taking the draught through a tube and rinsing the mouth after the swallowing, need not be insisted upon in the case of this acid.

Edward Curtis.

PHOSPHORIDROSIS.—Luminous sweating is a decidedly rare affection. Cases have been reported in which this curious phenomenon was observed after the ingestion of phosphorus and the eating of phosphorescent fish. It is probable that the phosphorescence is due to bacilli; for several species of photobacteria have been found, most of them being derived from fish.

Charles Townshend Dade.

PHOSPHORUS.—Phosphorus is available for medicinal purposes in the form of the element itself, or as it occurs in the special compound *zinc phosphide*, a compound that readily yields free phosphorus upon swallowing, under the conditions present in the stomach. Phosphorus is official in the United States Pharmacopœia under the title *Phosphorus*, Phosphorus. It is a solid body, of the appearance and consistence of white wax. It has a peculiar and disagreeable odor. On exposure to air, it gives off white fumes, luminous in the dark and of a garlicky odor. Phosphorus is insoluble in water, but dissolves in 350 parts of absolute alcohol at 15° C. (59° F.), in 240 parts of boiling absolute alcohol, in 80 parts of absolute ether, in about 50 parts of any fatty oil, and very abundantly in carbon disulphide, the latter yielding a solution which must be handled with the greatest care to prevent danger from fire. If left exposed to the air, phosphorus takes fire spontaneously. Accordingly it must be kept carefully under water, in a secure and moderately cool place, protected from light.

In its physiological relations, as in its chemical, phosphorus is unique. It is locally exceedingly irritant—even corrosive, although, strangely enough, in some experiments bits of solid phosphorus have lain embedded in the connective tissue of animals for weeks without exciting any local reaction. Ordinarily, however, upon skin or mucous membrane phosphorus in substance excites inflammation, possibly followed by ulceration and gangrene of the area exposed to contact. Even the fumes of phosphorus may inflame exposed mucous membranes, such as the conjunctiva and the mucous membrane of the mouth and respiratory tract, and inflame even to consecutive necrosis any accessible periosteum. Thus used to arise in match factories, in the days before the use of allotropic phosphorus, cases of necrosis of the jaw, the periosteum being generally reached by the poisonous fumes through the avenue of some defective tooth. Taken internally, even therapeutic doses are very apt to irritate the stomach, as shown by loss of appetite, nausea, uneasiness, and even pain and tenderness at the epigastrium, or, in higher grade, by the additional symptoms of vomiting and diarrhœa. Flatulence and eructations of phosphoretted gases are further disagreeable local effects of the medicine upon the digestive apparatus. Phosphorus when swallowed is readily absorbed, but exactly in what chemical status has not been definitely proven. That it reaches the blood, in part at least, as uncombined phosphorus dissolved by the alkalies of the intestinal juices or by fats is, theoretically, certainly not impossible, and is the obvious suggestion of many chemical considerations. On the other hand, that some portions undergo various grades of oxidation is again perfectly possible and likely.

The constitutional effects that follow the internal tak-

www.libtool.com.cn
Digitized by Microsoft®

ing of phosphorus are symptomatic of modifications of nutrition. In therapeutic dosage in health there is ordinarily little obvious derangement beyond what may be a reflex of the gastric irritation set up by the drug; and, anatomically, the most striking result of the medication is a tendency, proven by dissection of animals,[1] toward increased activity of development of bone. Cartilaginous epiphyses ossify with undue speed and completeness, spongy bone tissues increase in thickness, and compact bone in hardness. And a similar special tendency toward nutritive activity in *nervous* tissues, under the administration of phosphorus, is commonly, and probably rightly, inferred from the two facts, first, that in nerve tissue, as in that of bone, compounds of phosphorus are prominent normal constituents, and, secondly, that many morbid derangements of nerve function which are fairly referable to malnutrition or to exhaustion of nerve tissue, tend to abate under a régime of phosphorus medication. A special aphrodisiac action has been claimed for phosphorus, but cases in which any effect of this nature has been observed have probably been cases of previous debility or exhaustion of the sexual function, in which the renewed sexual desire is simply the natural consequence of restoration of power through improved nerve nutrition. In originally vigorous subjects several series of observations have shown that phosphorus does not produce any direct aphrodisiac effect.[2]

In over-doses, single or continued, phosphorus profoundly deranges nutrition, inducing fatty degeneration of glandular and other tissues, and hemorrhages. Death may result, or an impairment of health from which recovery is slow and difficult. For a detailed discussion of this singular poisonous operation of phosphorus see article *Phosphorus, Poisoning by.*

The therapeutic application of phosphorus is the internal administration of the drug for the bettering of deranged conditions of the nervous and the bony structures. Thus it is among the standard remedies to try in neuralgia. Naturally enough, the more recent the case, the greater the chance of relief and of cure, and unless relief comes within forty-eight hours, the medicine will probably fail altogether (Ashburton Thompson). In other nerve derangements it may be said, broadly, that in such as belong to the category of the naturally curable ones, recovery may perhaps be hastened by the use of phosphorus; but that in the incurable or difficultly curable nervous diseases the agent generally does little or no good. Thus the high hopes at one time formed of the avail of phosphorus in such maladies as epilepsy and locomotor ataxia have utterly failed of realization; but in such conditions as so-called nervous prostration, or incipient dementia, the drug is often of distinct benefit. Similarly phosphorus has been praised in osteomalacia and in rickets.

In the important matter of the *dose* of phosphorus, there is much difference in the practice of different physicians. Some confine their dosage to 0.0006 gm. (gr. $\frac{1}{100}$), thrice daily, while others begin at once with 0.003 gm. (gr. $\frac{1}{20}$), given with the same frequency, and aim to increase to double the amount, under guidance of the effects wrought—curative to the disease on the one hand, or irritative to the stomach on the other. Certainly, the larger of the doses cited are well borne in a very considerable number of cases, and certainly, also, the same may succeed, and speedily too, in curing a neuralgia, where the minute dose of the timid prescriber utterly fails of all impression upon the disease.

The *mode of administration* is an all-important matter in the case of phosphorus, since by faulty prescribing the dose may be unduly irritant or nauseous on the one hand, or inert on the other. In general, phosphorus must not be given in substance, no matter how extreme the subdivision, because of irritation; and in prescription in solution a solvent must be sought that will hold the phosphorus secure against oxidation, and at the same time not furnish too disgusting a potion. The most generally serviceable solvent, where the preparation is to retain the fluid condition, is a fixed oil, freed from contaminating oxygen and water by a preliminary superheating. Squibb has strongly advocated cod-liver oil,[3] fearing vegetable oils because of an alleged tendency of phosphorus in solution in the same to "develop poisonous properties," presumed to be "due to the formation of hypophosphorous acid." Sweet almond oil is, however, the most generally selected of fatty solvents, and has been adopted by the United States Pharmacopœia as the basis of the official oily preparation. Chloroform and ether are inconveniently volatile for the making of a permanent fluid preparation, and carbon disulphide is too disgusting and noxious. Absolute alcohol can be made the basis of an efficient fluid mixture, as in the official spirit of phosphorus and its derivate, elixir of phosphorus. For pills of phosphorus the plan should be followed of actually *dissolving* the phosphorus in some fluid, which either itself hardens, by cooling, to a solid, or which, incorporated with some indifferent powder, will form a pill mass. In either case, the indispensable feature is secured that phosphorus is in true solution still, although the pill as such is of course a solid. An obvious practice for the making of such pills is to dissolve phosphorus in melted resins, which on cooling reacquire the solid condition with, now, the phosphorus held in solution. But while these resinous pills are easy to make and to take, there is strong reason to fear that the contained phosphorus may easily be allowed and even helped to oxidize. The pharmacopœial procedure given below is probably as free from objection as any.

In whatever form or dose phosphorus be given, a cardinal rule, insisted upon by almost all who have had much experience with the medicine, is that the administration should never be upon an empty stomach, nor, on the other hand, *immediately* after eating.

The phosphorus preparations of the United States Pharmacopœia are as follows:

Oleum Phosphoratum, Phosphorated Oil. Phosphorus is dissolved by gentle heat in sweet almond oil which has been previously heated for fifteen minutes to a temperature of 250° C. (482° F.), and then cooled and filtered. After the phosphorus is fully dissolved and the solution cooled, a small charge of ether is added thereto. The finished product contains one per cent. of phosphorus and nine of ether. By measure, one minim represents about gr. $\frac{1}{117}$ of phosphorus (United States Dispensatory). Phosphorated oil should be clear and with a decided taste and smell of phosphorus, and the few drops which will constitute a dose (see remarks on dosage, above) may be given in capsule or in emulsion, flavored by a trace of oil of peppermint, or of gaultheria, or of bitter almond. The official emulsion of *almond* forms a convenient vehicle for an emulsion, flavored as just described. Phosphorated oil must be kept in small, glass-stoppered vials in a cool place, and the phosphorus keeps best when the vials are completely full.

Pilulæ Phosphori, Pills of Phosphorus. Phosphorus is dissolved in chloroform by gentle heat and the solution added to a mixture of acacia and althæa in a mortar. A little glycerin and a little water are next poured on, and the whole is rapidly beaten to a pill mass, which is immediately cut up into the proper number of pills. Each pill is then coated with a solution of balsam of tolu in ether, and when the coating is dry the pills are put up in well-stoppered bottles. These pills contain, each, 0.0006 gm. (gr. $\frac{1}{100}$) of phosphorus, and from one to five pills will constitute a dose. (See remarks on dosage, above.)

Spiritus Phosphori, Spirit of Phosphorus. This is a solution of phosphorus in absolute alcohol of the strength of 1.2 per cent. of phosphorus. It is official for the making of the elixir of phosphorus.

Elixir Phosphori, Elixir of Phosphorus. This preparation is a mixture of the spirit of phosphorus, glycerin, and aromatic elixir, with a flavoring of oil of anise. It is a transparent liquid, containing about 0.00025 gm. (gr. $\frac{1}{250}$) in each cubic centimetre (♏ xvi.). Unofficial, but well known and much used, is an alcoholic solution of phosphorus devised by Ashburton Thompson, of England, and commonly called *Thompson's Solution of*

Digitized by Microsoft®

Phosphorus. It is prepared as follows: One grain (0.065 gm.) of phosphorus is dissolved in fl. ℨ v. (16 gm.)* of *absolute* alcohol by the aid of heat, and the solution added to a *warmed* mixture of fl. ℥ iss. (56.25 gm.) of glycerin and fl. ℨ ij. (6.68 gm.) of alcohol. When the resulting mixture has cooled ♏ xl. (2.13 gm.) of spirit of peppermint is added. The preparation should be a bright, clear, colorless solution, wherein the odor and taste of phosphorus are almost completely masked by the pungency of the alcohol and peppermint. It is essential that the alcohol used to dissolve the phosphorus be literally *absolute;* and in such case the preparation, if kept in well-filled and well-stoppered bottles out of the light, will keep unaltered long enough for the treatment of an average case. If all the phosphorus be and remain dissolved, the solution contains 0.003 gm. (gr. $\frac{1}{20}$ nearly) in 4 c.c. (fl. ℨ i.)—a scant teaspoonful. The dose, averaging from one-third to one small teaspoonful, is best taken clear, but if too sharp in that condition, may be taken in water, the mixture to be made only at the time of each administration.

Under no circumstances should phosphorus be prescribed as an ingredient of extemporaneous composite medicinal mixtures.

Zinc Phosphide: Zn_3P_2. A peculiar compound of phosphorus, which practically amounts to a medicinal preparation of the element itself, is what is official in the United States Pharmacopœia under the title *Zinci Phosphidum,* Zinc Phosphide. This compound appears as a finely crystalline powder, or as crystalline lumps. It is gray-black in color, with a metallic sheen on broken pieces, and gives faintly the odor and taste of phosphorus. It is insoluble in water or alcohol, but dissolves in sulphuric or hydrochloric acid, with evolution of hydrogen phosphide. Zinc phosphide must be kept in small glass-stoppered vials.

This compound is lacking in the vigorously irritant action of phosphorus, yet even in therapeutic doses may easily upset the stomach and even excite vomiting. From its ready decomposition by acids it yields, in the stomach, some medicinally active condition of phosphorus, and its administration is therefore followed by therapeutic results similar to those attained by the use of the uncombined element. The phosphide is, however, not so certain as preparations of phosphorus itself, and is probably most commonly turned to as a last resort in cases in which phosphorus persistently disagrees. Zinc phosphide contains one-fourth of its weight of phosphorus, and the dose therefore ranges from 0.003 gm. (gr. $\frac{1}{20}$) to 0.016 gm. (gr. $\frac{1}{4}$). It may be given in pill form, and, unlike phosphorus, may be prescribed in combination with other medicines, avoiding only acids, which decompose it. After swallowing, however, the certainty of medicinal action will be enhanced by effecting this same decomposition through the agency of an acid draught, such as lemonade or a little vinegar. The most disagreeable features of the drug are a tendency to eructations of phosphoreted hydrogen and to disturbance of the stomach. With the larger of the doses mentioned above nausea is not at all unlikely.

Edward Curtis.

[3] Note on the Administration of Phosphorus, E. R. Squibb, M.D., Proceedings of the Am. Pharmaceutical Assn. for 1876, and pamphlet, Philadelphia, 1877.

PHOSPHORUS, POISONING BY.—It is doubtful if there is another substance among the many common poisons which is of so much interest to the toxicologist as is phosphorus—an interest arising from an historical viewpoint, and because of the desire to discover the mysterious causes of its insidious action on living organisms. Moreover, we meet with the anomaly that, unlike most of the other inorganic poisons, and especially arsenic, antimony, and nitrogen, members of the same group in the Periodic System, this element is toxic in its free or elemental state, while its compounds (save the hydrides) are practically non-toxic.

* In calculating the metric equivalents regard has been paid to the specific gravities of the several fluids.

Phosphorus was unknown to the layman as a poison prior to 1840. Shortly after the popularization of matches, about the year 1833, the public became acquainted with its deadly nature, and because of the ease with which the material could be procured, poisonings by phosphorus became alarmingly frequent. In no country have the number of cases been so numerous as in France, where from 1840 to 1880 there were 336 criminal cases of poisoning by this element. The maximum number in a single year was 94 in 1860, or, if we consider the period 1851–70, we find that out of a total of 793 deaths due to poisons 267, or 33.7 per cent., were due to phosphorus, while during this same period 287 are charged to arsenic. France still heads the list in the number of cases of poisoning by this element, which usually equal, or even exceed annually, those due to arsenic. The substitution of "Parlor" and "Safety" or "Swedish" matches (invented by Böttger in 1852) for the yellow phosphorus match was immediately followed by a decrease in the criminal use of phosphorus; the decrease was also due in part to the fact that it became known to criminals that a process had been devised by which the poison could be easily and surely detected (the Mitscherlich method).

Homicidal poisonings are now rare. The majority of cases are due to attempts at suicide or to accidents among children.

Only "yellow" phosphorus, the hydrides of phosphorus, and the phosphides of certain elements, such as calcium and zinc, are of toxicological interest.

Yellow Phosphorus.—The general properties of this almost colorless, wax-like substance are too well known to require review. A word as to its solubility is, however, necessary. In water pure phosphorus is practically insoluble; in fact, it has been asserted that what is thought to be a solution represents merely exceedingly fine particles in suspension, or else that it is a solution of the vapor. According to Hartmann 1 litre (about ℥ xxxiv.) of water at 38° C. (100.4° F.) will take up 2 mgm. (gr. $\frac{3}{100}$) of phosphorus; while in oils its solubility varies from 1 to 100, to 1 to 10,000 parts, according to the nature of the oil and various conditions, such as temperature, etc. In bile phosphorus is readily soluble, 100 parts of this fluid dissolving 15 to 25 parts.

Because of the low solubility of phosphorus in most of the fluids of the body, only slight action generally follows the ingestion of large fragments of this substance. When taken, however, in a finely divided condition the action is very violent.

Poisoning by phosphorus usually results from matches, phosphorus pastes (vermin killers), or phosphorus oil (Oleum phosphoratum).

Matches.—The modern "parlor" and "safety" matches are usually harmless, so far as poisoning by phosphorus is concerned, owing to the fact that they are made of non-toxic red phosphorus and an oxidizing agent, such as potassium chlorate. The matches of a decade ago, known variously as "friction," "brimstone," "sulphur," "lucifer," "phosphorus," etc., matches, are to be charged with by far the majority of deaths. The heads of these matches contain on an average about five per cent. phosphorus, the limits varying from three to seven per cent. A single head usually contains from $\frac{1}{3}$ to 1.5 mgm. (gr. 0.005 to 0.023). In these matches the sticks after being dipped in sulphur are tipped with a mixture of glue or dextrin containing coloring matter, phosphorus, and an oxidizing substance such as lead nitrate, lead peroxide, nitre, potassium chlorate, or some similar compound. Dissolving these heads in water or a warm liquid yields a liquid in which the phosphorus exists in an emulsion in an exceedingly finely divided condition.

Phosphorus Pastes are now seldom employed, though formerly they were in great demand for destroying rats and other vermin. Here the phosphorus exists very finely divided with flour, lard, and sugar or molasses as a basis.

www.libtool.com.cn
Digitized by Microsoft®

These pastes vary greatly in composition. They contain, on an average, about two per cent. of phosphorus, but may contain as high as five per cent.

Phosphin.—The hydride H_3P is the only one of importance. One-fourth to one-half per cent. in air causes death in animals in twenty to thirty minutes, while 0.2 per cent. will produce symptoms of asphyxia in a few minutes. In man, when it is breathed in very small amount in air for any length of time, the symptoms closely resemble those produced by phosphorus vapors. Under this head there is another possible source of phosphorus, or rather phosphine, poisoning. It has been suggested that there may be a reduction of phosphates in the intestines by bacteria (a form of auto-intoxication well known in the case of reduction of sulphates to hydrogen sulphide). Some have even gone so far as to claim that acute yellow atrophy of the liver is due to this cause. This action of bacteria is well established for sulphur, arsenic, and antimony compounds; but although it is to be expected for compounds of phosphorus by analogy, all investigations have given thus far negative results with pure cultures of powerfully reducing bacteria, the reduction being carried only to phosphites.

Fatal Dose.—The weight of phosphorus which constitutes a fatal dose is quite uncertain. An examination of the records shows such a variation that it is difficult to make an accurate statement. The fatal dose seems to depend, more than is the case with most inorganic poisons, upon the nature of the material containing the poison, the state of division of the phosphorus, the nature of the material in the alimentary canal, and the idiosyncrasy of the individual. As regards matches, we find that a child has died after sucking the heads of 2 matches. In another case 8 heads caused death. Sixteen match heads have caused the death of an adult; and Tardieu cites a case in which 101 matches were immersed for seven or eight minutes in a cup of hot coffee with a resulting solvent action so low as to permit the matches when dry to be ignited by rubbing in the usual manner, yet the poisonous draught caused very dangerous symptoms. Other records show that where death has resulted from swallowing match heads the number of these taken in each case has varied from 60 to 3,000; and that, on the other hand, recovery has followed prompt medical aid where from 3,000 to 4,000 match heads have been taken.

In the case of Oleum phosphoratum it is probable that a dose of 200-250 mgm. (gr. iij.-iv.) will produce dangerous results, and that 500-600 mgm. (about gr. vij.-ix.) will almost invariably prove fatal.

Phosphorus itself, finely divided in hot water, has in a few instances been employed for homicidal and suicidal purposes. Although the smallest fatal dose recorded is about 8 mgm. (gr. $\frac{1}{8}$), this is abnormally low. It is believed that the toxic dose of well-dissolved or exceedingly finely divided phosphorus is probably about 15 mgm. (gr. 0.23), and that the fatal dose lies in the neighborhood of 150 mgm. (gr. ij.-iij.). Recovery has followed a dose of over 300 mgm. Occasionally cases are met with which seem to indicate that phosphorus may at times have a slight accumulative tendency. With animals the doses may be safely set as follows:

	Fatal dose. Grams.	Therapeutic dose. Grams.
Horses and cattle	0.5 to 2.00	0.010 to 0.050
Sheep and swine	.10 to .30	.002 to .005
Dogs	.05 to .10	.0005 to .002
Fowls and cats	.01 to .03	.0005 to .001

The most susceptible animals per kilogram weight are fowls, the next swine, then dogs. According to Naunyn parrots alone seem to be relatively immune.

Fatal Period.—This is quite variable, but there can be no doubt that phosphorus should be classed as a slow poison. The usual period lies between one and four or five days, with most deaths falling on the second or the third day; yet life may sometimes be prolonged until the seventh day, or very rarely until the seventeenth to the twentieth day. Several cases of remarkably rapid death are recorded. Caspar cites the case of a young woman who took 194 mgm. (gr. iij.) of phosphorus in an electuary and died in twelve hours, while Habershon is authority for the statement that death has taken place in thirty minutes.

Symptoms.—The differences in the symptoms between acute and chronic poisoning are chiefly only of degree, and yet at the same time they are quite marked. Even in acute cases it has been shown by Tardieu that it is possible to distinguish three distinct forms, which have been termed common, nervous, and hemorrhagic, according as certain symptoms predominate. The lack of space forbids a consideration of these. Occasionally a patient will show a combination of all these types, the one following the other.

In what may be called for convenience a typical or normal case of poisoning (generally the result of matches), the victim first complains of pain in the throat. Usually, but not always, this pain extends downward with increasing severity, and is most marked in the epigastrium and abdomen. The tongue is enlarged and coated. Nausea in its most acute form sets in, followed later by vomiting of material of a mucous and bilious character. Very rarely at this stage is the vomit tinged with blood, but the ejected material is generally phosphorescent in the dark. There may be annoying eructations with an alliaceous odor and taste; the exhaled breath may even be luminous in the dark and give rise to a thin white vaper upon striking the air. Colic and diarrhœa set in at this stage, in about thirty per cent. of the cases. The pulse may for a short period be accelerated with an accompanying slight rise in temperature, but soon it becomes small, weak, slow, and often irregular. The temperature may fall as much as 3° or even 4° C. Respiration, which also suffered a slight acceleration, becomes slow, oppressed, and sometimes stertorous. This train of symptoms continues for from twenty-four to forty-eight hours when a remission often takes place; nausea and vomiting ceasing and the abdominal pain disappearing save for a few vague twinges. A period of apparent convalescence supervenes for two or three days; then suddenly, when all seems to be going well, the victim is stricken down with the most violent symptoms. Icterus appears, accompanied by hemorrhages, increasing in number and severity, in which practically all channels are affected. Vomiting and purging having again set in, the ejected matters are bloody in character and may at times consist almost wholly of blood; there is bleeding at the nose and even at the ears, and in women there is almost invariably more or less uterine hemorrhage. Up to the present time, in spite of the reputed aphrodisiac action of phosphorus, no venereal excitation has been observed in either sex in acute poisoning. The blood discharged is very thin and fluid. Hemorrhages have been known to continue for several months, the victim becoming weaker and weaker, and sinking into deeper and deeper apathy, being roused only by recurring nervous disturbances. Accompanying the hemorrhages is seen anæmic cachexia and urticaria, and a blotched skin. The eyes are icteric, blood shot, and prominent. Owing to paralysis of the sphincter muscles there may be, in the last stages of the disease, involuntary expulsion of urine and fæces. Prior to this, however, the urine is apt to be suppressed, and when discharged or drawn will be found to contain albumin, peptones, hæmoglobin, bile pigments, biliary acids, fibrin and hyaline cylinders, fatty droplets, often leucin and tyrosin, almost invariably sarcolactic acid, subnormal urea, and abnormal ammonium salts, phosphates, and sulphates. It is quite safe to assert that icterus is absent in exceedingly rapid death only. Death takes place in coma or syncope, occasionally in convulsions preceded by delirium.

In addition to the above-mentioned symptoms there is often quite marked paralysis of the voluntary muscles, especially those of the legs, preceded by coldness or numbness and accompanied by formication and twinges

Digitized by Microsoft®

www.tibtpol.com.cn

of pain. Occasionally there is anæsthesia of the lower extremities, but otherwise there seems to be no loss of sensation.

Recovery from severe acute phosphorus poisoning is rare and takes place only after a long time.

The symptoms seldom appear in less than one to three hours, more often in five to ten hours. There are exceptions, however; for example, Taylor cites a case of a young girl who swallowed a quantity of phosphorus paste, and who at first suffered from symptoms so slight that it was thought that but little poison had been ingested. It was not until the following day that she was taken ill, and on the second day had apparently recovered; on the third day she was stricken with symptoms of poisoning, but these were not violent until the fifth day. Death took place on the sixth day despite the efforts which were made during all this period to save her life.

At one time or another practically all the secretions and excretions have been observed to be luminous in the dark—the exhaled breath, vomited matter, stools, urine, perspiration, etc.

Phosphorus cannot be classed, as is very evident from the above, as a rapid or even moderately rapid poison; and, on the other hand, evidence is lacking which would justify its being credited with any truly latent action.

Acute Poisoning in Animals.—Typical symptoms, similar to those seen in man, are observed in dogs and swine. Horned cattle behave somewhat similarly, but horses and fowls are affected in an entirely different manner. Fowls are exceedingly sensitive to this poison, suffering chiefly from severe thirst, diarrhœa, and chorea. They die without having shown any characteristic symptoms save that they are apt to move with a peculiar hopping gait. Horses die suddenly in a few days, having shown practically no symptoms of poisoning. In cows a cessation of milk secretion is almost invariably observed. In animals, especially ruminants, the first symptoms appear after several hours. The shortest period of illness can be set at about ten to fifteen hours. Most animals die on the second or third day, or on the third to the fifth day. Sometimes death comes on very suddenly through paralysis of the heart following an apparent improvement.

Chronic Poisoning is almost invariably the result of breathing air containing vapors of phosphorus, and is therefore seen in workmen engaged in industries using phosphorus, such as the manufacture of "sulphur" matches, phosphor bronze, etc. In the manufacture of phosphorus chronic poisoning is very rare. Up to 1900, in the great Coignet factory in France, there had been only one case of maxillary necrosis in fifteen years. In the days of the extensive manufacture of sulphur matches chronic poisoning was so alarmingly frequent, especially among workmen in the "drying rooms," that several governments passed laws forbidding the manufacture of this kind of match. Since the introduction of parlor and safety matches chronic poisoning has become very rare.

This remarkable disease is characterized by bronchial catarrh, chronic gastro-enteritis, loss of appetite, constipation often followed by diarrhœa, exquisite toothache, chronic periostitis passing into necrosis of the maxillary bones, cachexia, and fever. In general, we have all the symptoms of acute poisoning, but in much less violent form and coming on slowly and insidiously.

The gums swell; there may be salivation; the teeth ache, decay, loosen, their dentine becomes exposed; there is persistent gingivitis; dental abscesses increase in number and the fistulæ discharge sequestra and fetid pus. The breath is horribly fetid. The victim suffers from pains in the joints and legs, rapidly weakens and wastes away. Hectic fever sets in, and death may occur in convulsions, more often in coma or syncope.

Usually it is the lower maxillary which is first attacked; less frequently and less seriously, at the outset, the upper jaw is affected. As the disease progresses both jaws become diseased. Sometimes the necrosis extends to the nasal bones and even to the base of the skull, when death from meningitis results. In the case of severe necrosis the mortality seems to range in the neighborhood of forty-five per cent. This disease has been incorrectly termed by some European physicians progressive necrosic osteoperiostitis. Following the necrosis there is marked thickening of the affected bones, and the cartilage becomes ossified. Workmen having carious teeth suffer most from maxillary necrosis. In fact, there is reason to believe that, in the absence of penetrating caries, necrosis of the jaw bones is rarely if ever met with. It has, therefore, become an established custom in all well conducted phosphorus industries to employ only men and women having sound teeth. Necrosis of the jaw develops after about six months' exposure to the vapors of phosphorus. Occasionally it may appear in a shorter period, or may fail to appear until after several years. This is only another instance of the remarkable variation in the action of this element.

Contrary to the facts observed with most other substances giving rise to chronic poisoning there are no records showing that the domestic animals frequenting the industries are afflicted with phosphorism.

Antidotes.—The most satisfactory chemical antidotes are copper sulphate, and oxidizing substances such as *old* turpentine, hydrogen peroxide, potassium permanganate, etc. In the case of acute poisoning administer copper sulphate, three grains every five minutes until the stomach has been sufficiently cleared. Follow this by one of the oxidizing agents, as, for example, old turpentine in emulsion in mucilage, one drachm every half-hour combined with the inhalation of turpentine vapor, or wash out the stomach with 0.2- or 0.3-per-cent. solution of potassium permanganate, or with a one- to three-per-cent. solution of peroxide of hydrogen. Magnesium sulphate may also be given to clear the bowels. The efficacy of copper sulphate depends upon its action as an emetic, and upon its property of reacting with phosphorus to form an insoluble copper phosphide and in part to oxidize the phosphorus, metallic copper and phosphoric acid resulting. With old (oxidized) turpentine a turpentine-phosphoric acid of low toxicity results, while with permanganate and peroxide the phosphorus is oxidized to non-poisonous phosphoric acid. Besides the administration of antidotes the patient must receive such treatment as the symptoms require. Administer ice and cold demulcent drinks. The paralysis and the sinking of blood pressure must be counteracted by excitants. All substances and foods containing fats or oils must be forbidden. Some practitioners bar the use of alkaline drinks on the ground that there is danger of the formation of phosphine; others insist upon their use as essential to maintain the alkalinity of the blood.

Prophylaxis.—In all industries using phosphorus, exceptionally good ventilation is imperative. There should be a constant circulation of fresh air in all the rooms. Exceedingly great care should be exercised under the supervision of a competent and conscientious foreman. Every workman should be required to wash and bathe frequently and thoroughly, and especially always to wash the hands before eating. Medical examinations should be made compulsory at stated intervals, and all cases of sore mouth, toothache, etc., should be at once excluded from the workrooms. Only men and women with sound teeth should be employed. A mouth wash containing boric acid, beta-naphthol, and eucalyptol has been found useful as a preventive against necrosis.

Post-mortem Appearances.—In typical cases the appearances after death are very striking and characteristic. Acute yellow atrophy and cirrhosis of the liver are practically the only diseases which yield lesions that can be confused with poisoning by phosphorus. The appearances are almost identical in each of these diseases, yet the symptoms and progress of the diseases are so different that there is little danger of error when the practitioner is in possession of the history of the case.

There is often corrosion and ulceration of the stomach and duodenum. The mucosa of the stomach is soft, swollen, mammillated, and degenerated.

Digitized by Microsoft®

www.libtool.com.cn

The most characteristic feature, however, is the remarkable icteric condition and fatty degeneration of the liver and kidneys in particular, but also of the heart, of the glands of the stomach and intestines, and even of the muscles. The alimentary canal as a whole is usually contracted. Multiple hemorrhages are found in the lungs, heart, and throughout the alimentary canal. Occasionally there is no corrosion nor ulceration of the mucosa of the œsophagus and stomach, but in such cases a hemorrhagic or ecchymosed condition is rarely absent. A similar condition obtains in the mesentery and the peritoneum.

The pleural and pericardial cavities contain bloody serum and the serous membranes are ecchymosed.

The liver will generally be found enormously enlarged, fatty, soft, pasty, and light or dark yellow in color, with the acini enlarged and prominent, while here and there are hemorrhagic spots. When the period of illness has been very prolonged, the liver may be found to be not only no longer enlarged, but even subnormal in size. It may be luminous in the dark.

Although slow poisoning by ammonia, alcohol, arsenic, antimony, cyanides, sulphocyanates, etc., also gives rise to fatty degeneration, the steatosis is seldom so extensive, so marked, nor of so rapid formation as in poisoning by phosphorus. Cases are recorded in which death from phosphorus took place in forty-eight hours, yet in this short period there was marked steatosis of the liver, kidneys, heart, and glands of the stomach.

Rarely death may take place and the autopsy will fail to reveal any noteworthy lesion or marked inflammation of the mucosa.

Mechanism of Action.—As regards this phase of the action of phosphorus, it is to be stated that at the present time no satisfactory theories have been formulated. Because of the lesions and remarkable effects of phosphorus, this substance has long been a most interesting and fruitful field of research for toxicologists and pharmacologists, yet in spite of the many investigations the mechanism of its action is still an *ignis fatuus.*

Phosphorus seems to be resorbed without change, and is carried by the blood either in colloidal solution, in the state of excessively fine emulsion, or the element is vaporized by the heat of the body and the vapor dissolved by the blood. It suffers, because of the high partial pressure of the oxygen in the blood, little or no immediate oxidation. The effects produced upon the tissues cannot be due to the action of hypophosphorous, phosphorous, or phosphoric acids, nor to any alkaline salts of these acids. The hypothesis that hydrides of phosphorus are formed and carried by the blood and are the primary cause of illness seems to be no more tenable than the oxidation theory.

It has been shown repeatedly that while from a chemical viewpoint phosphorus should not be able to exist as such for any length of time in arterial blood, not only is such the fact, but, as already stated, it suffers but little change.

All experiments go to show that phosphorus is to be classed as one of a group of poisons chiefly affecting the metabolism, of which group hydrocyanic acid, oxalic acid, and carbon monoxide are the other best-known types. Bauer has pointed out that the oxygen taken up and the carbon dioxide given off in acute poisoning is always abnormally low (eight to eleven per cent. CO_2 instead of twenty-four to twenty-seven per cent.), and that the respiration curve indicates a powerful disturbance of the metabolism. Moreover, this is further borne out by the fact that peptone-like digestion products are usually eliminated in the urine, that the urea is subnormal, and that the albumin of the food, and also to a certain extent of the organism, is decomposed, and goes to form fat, leucin, tyrosin, and probably sarcolactic acid. The decrease in the amount of urea has been explained on the theory that owing to the formation of acids (lactic acid?) a great part of the nitrogen, which would otherwise be converted into urea, goes to form ammonia to neutralize the acids. Because of this neutralizing action the alkalinity of the blood falls and probably countless blood corpuscles are destroyed; for this latter reason phosphorus is also classed, by some authorities, in the group of so-called "blood poisons." This whole question of action on the blood is very little understood. Cases are reported in which no destruction of blood corpuscles has been observed. In man there seems to be a transitory increase of erythrocytes and a decrease of leucocytes. In dogs the erythrocytes and hæmoglobin are not affected, but the leucocytes seem to be increased. In fowls there is undoubted dissolution of red corpuscles and an increase of leucocytes. Following the destruction of the red blood corpuscles—which, it is assumed, takes place at some stage in poisoning by phosphorus—an abnormal secretion of bile pigments takes place; at the same time the bile becomes thick and viscid and moves through the ducts slowly. To account for the direct cause of icterus several theories have been advanced: one ascribing it to catarrh of the duodenum and cutting off of the ductus choledochus; another to the compression of the tiny bile ducts by the swelling of the liver; still another that the mucosa of the biliary passages becomes diseased, and that there is finally a clogging of these passages through fatty degeneration and rupture of the walls of the vessels. It is likely that all these causes contribute to the retardation of the flow of the bile, and that this fluid overflows into the lymphatics. The cause of the polycholia is, however, not yet understood, but its results are apparent in cerebral disturbances, as shown by coma, etc.

As to what happens to the phosphorus in its long sojourn in the blood we know but little. Only one point is clear. Part unites with many as yet wholly unknown basic products of the metabolism to form toxic compounds. Selmi has succeeded in isolating some of these compounds from the urine, and has given them the name phosphoptomaïns, while Van den Corput has called them toxicomaïns. According to this latter investigator most of the ill-effects of phosphorus are due to the formation of these retention toxicoses. Besides these phosphorus bases in the urine and blood, Kunkel advances the hypothesis that part of the phosphorus is oxidized by the blood, and that the phosphoric acid thus produced is eliminated in the form of esters.

In the matter of the fatty degeneration of the liver the weight of evidence seems to be that we must regard it as the result of two causes: one, the formation of fat in the organ itself, and the other the transportation of preformed fat to this organ. Experiments on animals have shown that the microscope will demonstrate the beginning of fatty degeneration in the liver in as short a time as six to eight hours after the administration of the poison, and in about twelve hours in the kidneys and heart (Kobert).

No satisfactory explanation of the cause of the corrosion and ulceration of the mucosa of the alimentary canal has yet been found. It has been suggested that this may be the result of the nascent action of oxygen acids of phosphorus at the moment of their formation; but since the early formation of these acids is uncertain a better explanation is wanted.

As to phosphorus necrosis, little can be said save that it follows periostitis. It is not the mineral stroma which is attacked, but the cells of osseous tissue. Necrosis often follows an injury to the bones or periosteum, in illustration of which an interesting case, recorded by Wegner, may be cited. A boy working in a match factory rapidly developed periostitis and necrosis of the bone following the breaking of his leg. Wegner's investigations on the action of phosphorus on the bones are of great interest, although they shed but little light upon the mechanism of the action. He found that the administration of very small amounts of phosphorus daily, either internally by the mouth or as vapor, to young animals, caused an abnormally rapid development of osseous tissue, that the bones formed were more compact than usual, that the medullary cavities were much reduced in size, and that the abnormally developed bones did not differ in chemical composition from bones normally grown.

Investigations upon the action on the heart show that

Digitized by Microsoft®

the beating is arrested in diastole in both warm- and cold-blooded animals, that the action is probably directly upon the heart muscles, that the automatic centres are first affected and then the muscles are greatly weakened, although they still respond to artificial stimuli.

Clinical Tests for Phosphorus.—Expose to the vapors given off from the warmed material to be tested two strips of filter paper, one of which has been moistened with silver-nitrate solution, the other with lead-acetate solution. If phosphorus is present, the silver paper blackens while the lead paper should remain unchanged. If both papers blacken, hydrogen sulphide is present and must first be removed before testing. In such an event add to the material to be tested sufficient lead acetate solution to precipitate all the hydrogen sulphide as lead sulphide, and test with the two papers as before. The blackening of the silver-nitrate paper is due to the formation of silver phosphide and metallic silver.

A less satisfactory test consists in boiling the material to be tested with a small piece of roll sulphur. After a few minutes the piece of sulphur, which has taken up most of the free phosphorus present, is removed, washed, and examined in a darkened room. On being gently warmed and rubbed with the finger the sulphur will shine with the peculiar glow of phosphorus, if this latter element is present.

If possible the suspected material should always be tested in the laboratory by the Mitscherlich distillation method.

There are reasons for believing that phosphorus can exist in the body in the free state for about eight weeks. After twelve weeks it can still be detected in the form of phosphorous acid, but after about fifteen weeks it is probable that all the elemental phosphorus has been eliminated or oxidized to phosphoric acid. As regards the detection of free phosphorus after death, it is safe to say that chemical tests usually fail after four weeks; but there are instances in which it has been possible to obtain undoubted proof fifteen weeks after burial.

Emile Monnin Chamot.

PHOTOMICROGRAPHY.—Definition.—The process of obtaining a macroscopic photograph of a microscopic object. It is sometimes incorrectly termed microphotography, which is the reduction by photography of landscapes, portraits, or other gross photographs to collodion positives of minute size, which are subsequently mounted beneath a small convex lens, in watch charms, paper knives, pencil handles, and the like. It is to be noted that this distinction is not universal on the continent of Europe. The above title in German is Mikrophotographie; in French, Photomicrographie.

History.—The first photomicrographs and probably also the first photographs were taken by Wedgewood and Davy. The record of their experiments, published in 1802, some time after the death of Wedgewood, show that they used a solar microscope and obtained images upon paper and leather which had been washed with a silver solution. They were, however, unable to fix the images so obtained and, when exposed to daylight, the entire surface became uniformly dark.

The Rev. J. B. Reade, of England, in 1837, with a solar microscope photographed entomological specimens and sections of vegetable tissues upon paper coated with nitrate of silver solution and fixed the images with an infusion of galls. In 1839, at a soirée given by the Mar-

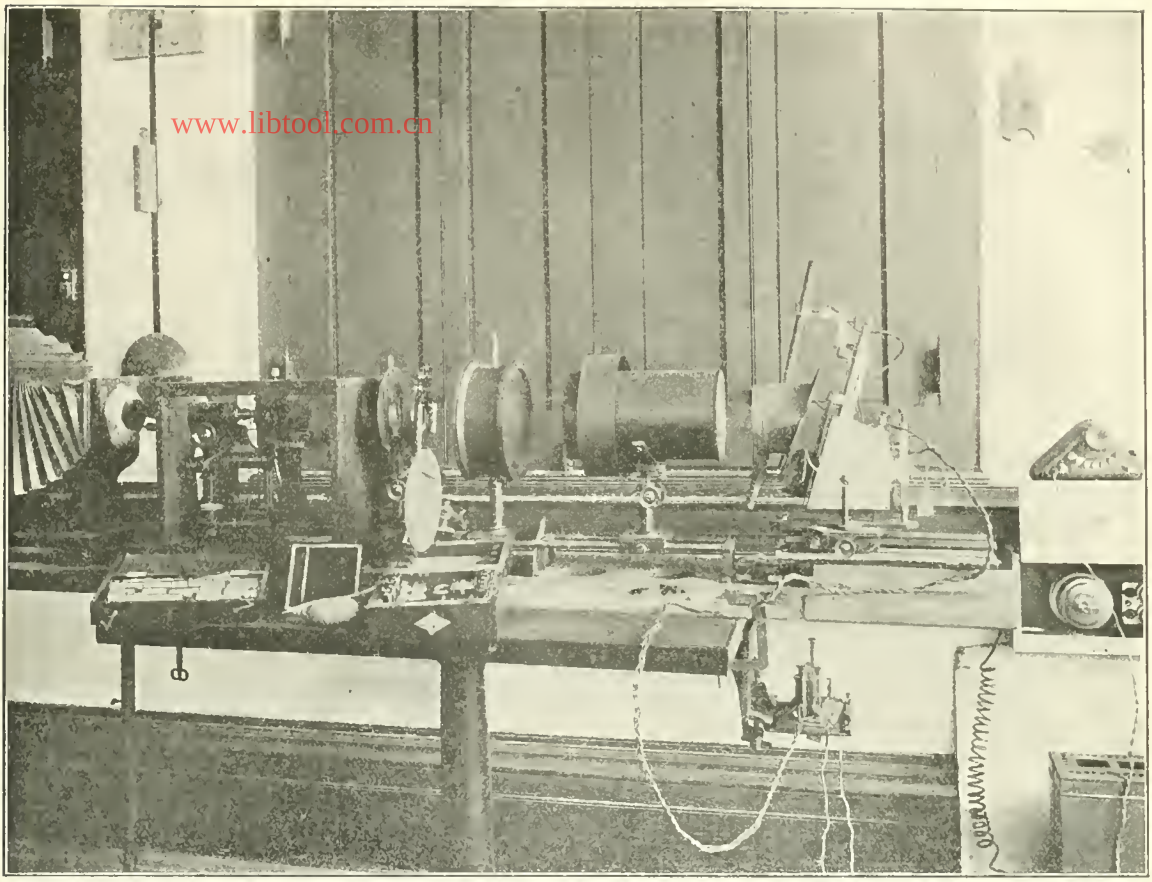

FIG. 3806.—The Optical Bench, Arranged for Photomicrography with the Electric Arc Lamp. The objects are arranged, from left to right, in the following order: end of camera, microscope, screens, shutter, water-bath, condenser system, arc lamp; on the table: battery of oculars and objectives, color screens and bulb of pneumatic release of shutter; under arc lamp—the adjustable shunt coil; at the extreme right, against the wall: switches and rheostat.

In practice a cloth is thrown over the frame which encloses the microscope, for the purpose of shutting out the rays of light from the eyes of the operator, while permitting at the same time all necessary manipulation. The screens, water-bath, condensers, and arc lamp are all enclosed in such a manner as to reduce to a minimum the escape of light into the room.

quis of Northampton, then president of the Royal Society, Mr. Reade exhibited more perfect results, and some of his photomicrographs were on sale at a bazaar in Leeds the same year. It was not until after Daguerre had announced his discovery before the Academy at Paris on the 19th of August, 1839, that attempts to use photography to obtain pictures through the microscope were generally undertaken. In 1840 Mr. Dancer, of England, photographed through a gas microscope upon silvered plates; he also by means of the solar microscope photographed wood sections and fossils on paper and glass plates. Dr. Donné, of Paris, in 1840, presented to the Academy of Sciences photomicrographs on daguerrotype plates; and in collaboration with M. Léon Foucault, in 1845, published an atlas on the study of the fluids of the body, illustrated by cuts from daguerrotypes. One of the first publications in England to use photomicrographs as illustrations was the *Quarterly Journal of the Microscopical Society*, which in 1852 contained prints from negatives by Mr. Joseph Delves. Since these early attempts the practice of photomicrography and its use for illustration have steadily grown. The list of those who have done notable work is a long one, and contains many well-known names.

The Apparatus.—The several parts comprising the apparatus for making photomicrographs are collectively called an installation. In its simplest form it may be a long bellows camera with a photographic lens on the front or on the front of a conical extension, as ordinarily used by photographers for making enlarged copies; such an arrangement is useful when the original object is of comparatively large size and the magnification slight, as the limit of a few diameters is very quickly reached by this method. For most photomicrographic work a microscope is a necessity, as are also the accessory apparatus on the optical bench and, in the present day of rapid dry plates, the camera. Sometimes, in the days when the slow, comparatively non-sensitive wet plates were in use, the room in which the optical bench and microscope were placed formed the camera; the source of illumination was outside the room, and enough diffuse light was admitted through yellow glass to enable the operator to work. Such an arrangement was used by Surgeon-General J. J. Woodward in making his now classical photomicrographs of difficult test diatoms, etc. At the present time, however, the rapid color-sensitive plate demands much greater care in the exclusion of all light not used in taking the picture, and many forms of photomicrographic apparatus have been devised. Some operators, in Europe especially, prefer to work with the vertical apparatus, subsequently enlarging the pictures so obtained; but most of the English and American photomicrographers use the horizontal apparatus, and with the long camera bellows obtain the desired magnification directly. The installation, then, may be described as consisting of the source of light, the optical bench with its accessories, the microscope, and the camera.

The Source of Light.—This may be an oil lamp of one

Digitized by Microsoft®

or more burners, illuminating gas, a Welsbach burner, or an acetylene flame. All of these may be classified as illuminants of a low order, as when high powers are used their illumination becomes too feeble to enable satisfactory focussing of the image. The lime light in any of its modifications forms the next higher order of illuminant; magnesium ribbon or flashlight the next; then may be put the arc light; and, most powerful of all, the sun. When the sun is the source of light, it is necessary to use an heliostat to control the rays used for illumination, as after centring the light it should remain centred without appreciable variation; otherwise much time is wasted and many vexatious failures are inevitable. It is desirable that the heliostat be of comparatively simple construction in order that it may not easily get out of order. I have found that what is known as the Prazmowski heliostat is a very efficient form, being very easily adjusted and quite simple in construction. This instrument carries a single mirror on its axis which is caused to follow the sun by clockwork. The rays, being thrown at a convenient angle by adjustment when starting, are maintained in the same direction. A second mirror on an adjustable stand intercepts the rays reflected from the heliostat mirror and, if the installation is rightly placed, directs them through the microscope and camera. If, however, it is not convenient to have the installation so placed, a third mirror on the optical bench directs the rays in the desired direction (see Fig. 3805). All photomicrographers who have worked with sunlight know, however, how few are the perfect unclouded days when the work can be satisfactorily performed, as even the thinnest cloud passing across the sun's disc practically extinguishes the light with resulting delay and difficulty in making correct exposure; but notwithstanding the annoyances and difficulties attending the use of sunlight, until recent years those accustomed to it generally returned to its use after trying other methods of illumination. At the present time, however, with the electric current almost everywhere available, the use of the arc light frees photomicrography from many of the difficulties formerly obtaining. The essentials for illumination by the arc light are, the continuous current, a simple form of focussing lamp, a rheostat, and a shunt coil of simple form used outside the zone of heat radiated by the lamp, and capable of delicate adjustment. Many of the failures to obtain satisfaction from the arc lamp, aside from too delicate construction, have been due to the fact that the controlling coils were within the lamp body. Now, while such a lamp may work perfectly in the open where its heat is radiated away quickly, when we enclose it so that its light may not escape into the room to the annoyance of the operator, it soon begins to focus irregularly or not at all. The reason is simple: the actuating mechanism of the lamp is controlled by an electro-magnet; temperature has a decided influence on electro-magnets; with a given strength of current, the higher the temperature of the iron core the less will be the amount of magnetism developed therein. The remedy is also simple. A shunt coil with its armature balanced over a contact point and capable of close adjustment is inserted in the circuit anywhere between the lamp and its rheostat. It can thus be put where it will be unaffected by heat, and can be relied upon to perform its functions at all times. The normal current goes as usual by the two main wires to the lamp and back, but when the arc has reached such a length, determined by the adjustment at the shunt coil, that the resistance becomes too great, the current goes from the main wire by a small connecting wire through the shunt coil, actuates its electro-magnet, pulls down the armature, and through the contact mentioned above is shunted through a third wire, which enters the lamp by a separate binding screw and actuates the controlling mechanism. The lamp immediately focuses, and so delicately can the shunt coil be adjusted that the lamp will automatically adjust its focus every other second or two, each time moving the carbons together only a fraction of an inch, and keeping the crater of the positive carbon practically in the optical axis without flickering or change in the steadiness or intensity of the beam of light, the prime requisite of any illumination for photomicrography (see Fig. 3806).

The Optical Bench.—This consists of two parallel rails or V's or a slotted board fixed between the microscope and the radiant (the mirror reflecting the sunbeam, the crater of the positive carbon, or the flame of gas or lamp), and holding the condensers, water-bath to absorb the heat rays, diaphragm stands and screens for various purposes, and sometimes the shutter for the exposures. These are all arranged on stands so that they may be moved to and from the radiant. They should also be adjustable as to height as should the radiant itself.

The Microscope.—The microscope may be of the usual pattern; but for those using as low a power as a three-inch or four-inch lens, a microscope with a body tube of larger diameter and shorter length will be found most convenient. The long focus, low-power lenses can then be used inside the body tube, being held by a cone fitted to screw in place of the draw tube; beside the usual substage condenser there should be an achromatic substage condenser of about 1 N. A. adjustable for centring, a ring with screw thread to hold lenses sometimes used as condensers, and a simple low-power condenser for illuminating large objects when slight magnification is desired. There are also accessory pieces of apparatus, such as prisms, black ground stops, devices for oblique illumination, monochromatic illumination by means of the rays of the spectrum, etc., all fitted to the ring of the condenser carrier so as to be interchangeable. These latter are rarely used except for special lines of work. The stage of the microscope should be large and of the type known as mechanical, moving in any direction in its own plane. The aperture of the stage should be of such size that the high power condenser may be brought close to the object. The front of the stage may be fitted with a sliding carrier for roughly centring the object and a tilting carrier for special occasions. The battery of objectives may consist of any number desired; it will be found, however, that a large number is by no means necessary for widely differing magnifications, as by lengthening or shortening the distance between the microscope and the sensitive plate, various magnifications may be had with the same objective. An amplifier may be used for the same purpose, as also oculars of differing powers.

The Camera.—This may be of any usual make, the size adapted to the wants of the operator, or it may be a specially made long bellows camera. It may be firmly fixed to the same bench or plank that carries the microscope, optical bench, and radiant; or it may have a separate stand of its own and be capable of movement to and from the microscope. It is quite necessary that the connection between the microscope and camera, while excluding all light not used for illuminating the object, should be of such a nature that no vibrations may be transmitted to the microscope when adjusting the plate holder or withdrawing the dark slide. A cone front with cylindrical end is usually placed on the camera, and this may be connected with the microscope by a light-tight sleeve of fabric, or it may fit in, without touching, a double metal cylinder on the eye tube. When using a long bellows camera, some means of focussing both the coarse and the fine adjustments of the microscope from back of the camera must be added to the installation. Various methods of accomplishing this have been described by photomicrographers, each having its advantages. The essential points are that whatever method is used, it must not convey any jar or vibration to the microscope, or bring a strain upon the screws of either adjustment. It must of necessity work smoothly.

Procedure.—It is necessary when first setting up and adjusting the various parts of the apparatus to consider some one part as fixed and adjust all the other parts to it. Generally it will be found best to consider the microscope as the fixed part, and that imaginary line passing through the centres of objective and ocular and indefi-

Digitized by Microsoft®

www.libtool.com.cn

nitely prolonged, called the optical axis, as that line with which the centres of all the other parts from radiant to ground glass of camera must coincide. Suppose we have a long bellows camera, an arc lamp, an optical bench (with a large condenser, a water-bath, and supports for diaphragms or screens) and a microscope, and that we wish permanently to mount them upon a long narrow table or bench, two or three feet wide by about twelve feet long. At one end of our table we would place the lamp, next the optical bench, then the microscope turned to the horizontal position, and finally the camera. Upon the size of the ground-glass screen of the camera would depend the height above the table of the tube of the microscope. This having been determined, the base of the microscope is clamped firmly to the table in its proper position, so that the optical axis passes over a line drawn through the centre of the table in the direction of its length. The camera may now be placed behind the microscope and adjusted roughly as to the centring of ground glass with the optical axis. The same may be done with the optical bench in front of the microscope, and then with the lamp. A quick method of rough centring, which I have found practical, is to cross threads diagonally from corner to corner of the camera back, the ground-glass screen having been removed. This will give the centre of the ground glass screen. From this centre stretch a thread through the camera-tube of the microscope, through a pinhole diaphragm in the stage, and on through like diaphragms on the optical bench, fastening the thread at last to one of the carbons of the lamp. The various parts are now adjusted until the thread, being stretched taut, passes through the diaphragms without touching. The final centring is by the light. Removing the thread, putting a low-power objective in the microscope and starting the lamp, we focus the condensers so that the image of the crater, taken up by the objective, is thrown upon the centre of the ground-glass screen of the camera. After the centring is accomplished we are in readiness to take a picture. The object is fastened to the microscope stage and the low- or high-power substage condenser adjusted. The image may now be thrown upon white cardboard for adjustment, centring, etc., or by interposing ground glass and a color filter between the radiant and the substage condenser to render the light bearable to the eyes, the operator may view the image directly through the microscope in the ordinary way. The camera is then connected as above to the microscope and the final focussing done from back of the ground-glass screen, or, as some prefer, by means of a magnifying glass adjusted to the surface of a plate glass screen, which occupies the same position as the sensitive plate when the picture is taken.

We must now wait a few moments and then re-examine our image. If it is as sharp as we left it, we may proceed to photograph it; if, however, it is not so sharp as when we had finished focussing it, it will be necessary to find the cause and the remedy. The change of adjustment may be caused by jarring, by a worn thread on the micrometer screw, by too strong a spring in the micrometer movement, or by a change in the temperature of the room or parts of the apparatus. The microscope should be so mounted that no jar can be transmitted to it; worn parts should be replaced; and the temperature of the room should always be warm so that the starting of the lamp will not cause a noticeable increase in that temperature. It is always well to start the lamp a few minutes before one is ready to take the picture, and allow the different parts to adjust themselves to any changed conditions. The adjustment of focus, etc., being satisfactory, the exposing shutter is closed. The plate-holder containing the sensitive plate is placed in position and the exposure made. The subsequent operations of developing and printing are purely photographic, and are the same as in ordinary photography.

Special Forms of Apparatus.—Of special forms of apparatus and adaptations to special purposes there are many. Perhaps among the most useful to the laboratory worker in bacteriology, where a limited range of magnification (*i.e.*, from two hundred to one thousand diameters) is desired, is that of the Misses Foot and Strobell. Any of the small vertical cameras may be used and the microscope may be the same one used in ordinary research. The novelty consists in obtaining the focus directly by the eye, observing the image through the microscope with any one of a series of negative lenses placed on top of the eyepiece. The negative lenses used are those test sets furnished by opticians, and number from one to ten dioptries and their fractions. The use of this lens will of course cause the image to vanish and refocussing will be necessary. If the right minus lens has been chosen, upon its removal from over the eyepiece the image will be found thrown upon the ground glass of the camera above as a sharp picture. In each case the minus lens, best adapted to the end in view, must be found by trial. The method is faulty in that no provision is made for removing the negative lens from the eyepiece without some risk of disturbing the focus obtained. It has, however, the great advantage that any light can be used that one would ordinarily view objects through the microscope by, as ordinary diffused daylight. The exposure will of course run into the minutes with its attendant risk of change of focus or displacement. The preliminary wait, after obtaining the focus by this method to allow for change in focus, etc., is more important than with the horizontal apparatus; for the microscope being in the vertical we have the influence of gravity acting directly upon the focussing mechanism.

Photomicrography of Colored Objects.—In former years, when the wet collodion process was in general use, and when later the gelatin dry plates were introduced, the photomicrographer was limited in the selection of subjects to those that were nearly colorless, and was unable correctly to render those objects that contained mixtures of red, or yellow and blue. The chloride of silver of the wet plate and bromide of silver of the dry plate were alike sensitive to the light rays of short wave length (*i.e.*, the blue and violet) and comparatively insensitive to the rays of longer wave length (*i.e.*, the green, yellow, and red). The blue portions of an object would be fully impressed on the plate long before the green, yellow, or red portions made any impression at all; and if an attempt was made by prolonging the exposure to render the latter, the blue portion through over-exposure would be lost. It was not until Vogel announced his discovery that an ordinary gelatin dry plate, when bathed in a solution of an aniline dye, became more sensitive to the rays of longer wave length, that it became possible to represent by the light and shade of the photograph the brilliancy of the various colors as they affected the eye. It was not enough simply to dye the plate. The dye, while rendering the plate more sensitive than before to the yellow end of the spectrum, did not diminish its sensitiveness to the blue which was still in excess. The problem was solved by diminishing, or in some cases entirely cutting out the blue and violet rays by the use of fluids that absorbed them. Such fluids, termed color filters, had previously been in use for just the opposite purpose, *i.e.*, to allow only the rays of highest refrangibility to pass through the object, for the purpose of increasing the resolving power of the objective. It was afterward found that films stained with the proper dyes could be used in place of the fluids, a gain in convenience. Since then the color or colors of the object do not present much difficulty, provided, however, the object is not too thick nor too deeply stained in parts; nor, on the other hand, so lightly stained as not to afford sufficient contrast, as in certain thin pathological specimens where the diseased tissue will not take a good stain. It may be almost impossible to obtain a satisfactory photomicrograph of such objects. It is possible at the present time to go beyond the mere representation of colored objects in monochrome, as by the use of the proper color screens, as first demonstrated by the writer in 1895–96, three separate photomicrographs may be taken of a section stained in three or more stains; and by means of the commercial

Digitized by Microsoft®

three color printing processes now in use, it can be quite faithfully reproduced in its original colors.

Preparation of Specimens.—The special preparation of specimens for photomicrography is not at present so necessary as before the introduction of the color-sensitive plate and the color filter. There are, however, certain requirements that have to be complied with if the best results are to be obtained, as, for instance, sections of tissue must be thin, evenly cut, and, above all, they should be flat. Many an otherwise good specimen cannot be used for photomicrography because sufficient care was not taken to get it perfectly flat upon its slide, and with its cover-glass down upon it. Now it must be remembered that the objective has no depths of focus; that is, only those objects or portions of the object in one plane at right angles to the optical axis can be in focus at one time. Any other plane of the object requires a separate focussing of the objective to render its image sharp; and therefore a section only slightly irregular, and which to the eye, (owing to its power of accommodation, which is involuntarily used) seems quite flat, upon being photographed will give a negative for the most part sharply defined, but containing spots or areas of various shapes which are quite blurred. The photomicrographer cannot by any means short of flattening such a specimen obtain from it a good result; for if he should, by stopping down the substage condenser or when possible the objective seek to render more than one plane of the specimen sharp, he would inevitably introduce errors of refraction which in themselves would spoil the result. Ridges or knife marks, due to the chattering of the knife blade of the microtome when cutting the section, will always show in the photograph. Special staining, as mentioned above, is not necessary, though it is always difficult to secure a good result from a section too deeply or too lightly stained; but in general any section stained so as to show well to the eye in the microscope will make a good photograph.

www.libtool.com.cn

Limitations.—To photomicrography, as to all other things, there are limitations. These are more especially evident when we seek very high magnifications. As we go beyond one thousand diameters, it becomes more difficult to obtain satisfactory images; and while it is possible to obtain sharp images of certain selected objects, such as a portion of the frustule of a diatom, up to five thousand diameters, it will be found that only such objects as lend themselves to the work can be so taken, and that, except as a *tour de force*, the results are all out of proportion to the labor and time expended. When much higher magnifications than one thousand are desired, the only practical way is first to photograph the object with as high a power as will give a good, sharply defined image (say up to three thousand diameters), and then to enlarge the negative. In this way it is possible to attain magnification of ten or twelve thousand diameters. But again we are limited in this method, as when we attempt to enlarge a gelatin negative more than three or four diameters, the grain of the gelatin begins to become disagreeably apparent and to interfere with the sharpness of outline of the image. It should always be remembered that the magnification of the objective is the only magnification that resolves the details of the object. What further enlargement we may get by oculars of high power, by increased length of camera bellows, or by enlarging the negative, does not add any detail to that resolved by the objective originally; it simply spreads the image as given by the objective over a larger surface. It follows then that to magnify any object further than to make its details clear to the unaided eye is useless and to be condemned. *Edward Leaming.*

PHOTOTHERAPY. See *Roentgen Ray, etc.*

PHOTOXYLIN.—A nitro-cellulose, similar to pyroxylin, but prepared from wood pulp instead of cotton.

A three- to five-per-cent. solution in equal parts of alcohol and ether is recommended to replace collodion in plastic surgery and other conditions in which such an application is suggested. The solution forms a thick liquid, which upon evaporation leaves a firm, dense film, which is stronger than that of collodion. *Beaumont Small.*

PHRENIC NERVE.—ANATOMY.—The phrenic nerve, or the internal respiratory nerve of Bell, is the principal motor nerve of the diaphragm. The spinal origin in dogs and rabbits is located in the anterior horn of the spinal cord at the level of the fifth and sixth cervical vertebræ, and in man in the centre of the anterior horn, extending from the middle of the third to the sixth cervical segment. The superficial origin of the nerve is from the third, fourth, and fifth cervical nerves in the following proportions:

	Number of cases.	Fourth only.	Fourth and fifth.	Third, fourth, and fifth	Third and fourth.

When there is a single root, it is always from the fourth nerve.

COURSE.—The course of the nerve is as described in the standard text-books, there being but few variations. Passing over the anterior surface of the scalenus anticus, diagonally downward and outward, it passes in front of the first part of the subclavian artery and behind the subclavian vein. In about four per cent. of cases, however, the nerve passes in front of the vein, and so lies immediately behind the clavicle. Two cases are on record in which the nerve passed through the vein. Passing into the thorax it lies, on the right side, external to and slightly behind the right innominate vein and the superior vena cava; on the left side, in front of the arch of the aorta. On both sides it passes between the pleura and the pericardium, anteriorly to the roots of the lungs; on the right side being in close contact with the root, and on the left side passing out and to the left, in order to pass around the heart. The right nerve has an almost vertical direction, and passes to the upper surface of the diaphragm, where it divides into from three to six branches, which pierce the diaphragm externally to and in front of the opening for the inferior vena cava. The left nerve has a more circuitous route, and generally divides in the substance of the diaphragm.

Branches. 1. Communicating: (1) From the upper ganglion of the cervical sympathetic gangliated cord. (2) Occasionally, from the loop formed by the descendens and communicans hypoglossi. (3) From the nerve to the subclavius. (4) The right nerve, at its termination, sends branches to the right semilunar ganglion of the solar plexus. (5) The left communicates with the sympathetic plexus to the œsophagus above the diaphragm.

2. Distribution: (1) On the right side, to the superior vena cava. (2) Pleural branches, from one to three in number. (3) Branches to the pericardium, usually three. (4) Luschka has described twigs to the right auricle. (5) Terminal branches to the diaphragm. This is the main distribution of the nerve. It supplies the entire diaphragm except an area along the costal margin, about 3 cm. in width, which is supplied by the lower six intercostal nerves, and an indeterminate area on the crura,

Digitized by Microsoft®

probably supplied by the vagus. The exact area, supplied by the fibres from the various roots of origin, is as yet undetermined. A single case of a dog, in which Schroeder divided the upper roots of origin, and on post-mortem found degeneration of the anterior and middle portions of the muscular portion of the diaphragm, with the lateral and posterior portion intact, is the only case of the kind on record.

www.libtool.com.cn

Relations.—In the neck the nerve lies on the anterior surface of the scalenus anticus muscle, behind the great vessels and the sterno-cleido-mastoid muscle, the omo-hyoid muscle and the transversalis colli vein. In crossing the subclavian artery the nerve generally lies external to the origin of the internal mammary, but internal to the course of the artery in its course in the thorax. The other relations have been noted.

The physiological function of the nerve is that of the principal motor nerve supply to the diaphragm.

Pathology.—1. Paralysis of half of the diaphragm, as a result of inflammation or degeneration of the phrenic nerve, on the corresponding side, as a result of exposure, lead poisoning, or compression, may occasionally occur. The condition generally comes on slowly and is characterized by inversion of the type of respiration, which reduces intra-abdominal pressure, causing difficulty in defecation, etc. Respiration is usually affected only during exertion, when dyspnœa results.

2. Neuralgia. Some authorities describe a form of neuralgia characterized by pain in the lower and anterior part of the thorax, along the line of diaphragmatic attachment, extending up into the neck and along the inside of the arm, with painful areas at the points where the nerve becomes superficial. This condition is said to complicate angina pectoris, Graves' disease, and some forms of cardiac disease.

3. Surgical Pathology. Injury to or division of the nerve may occur in gunshot wounds or stab wounds, or in the course of surgical operations. This complication has generally been regarded as fatal, and the statement has been generally made in the surgical literature that it was necessarily so. A careful review of the literature, however, shows only six cases on record in which the nerve was injured. In all other cases, usually reported as injuries of the phrenic nerve, an examination of the original article shows that some other adjacent structure had been injured instead of the phrenic. Of the six cases of actual injury to the nerve, in the first four (those reported by Schurmayer, Beck, Bardeleben, and Erichsen) there was also injury to some other important structure, which was alone sufficient to cause death. Of the two cases of injury to the nerve alone, the first (reported by Mackenzie) was instantly fatal. The second (reported by Schroeder in 1902) ended in recovery, with paralysis of the corresponding half of the diaphragm. Mackenzie's case was that of an Indian coolie, who suddenly fell dead, and on post-mortem examination the reporter was unable to find any sufficient cause of death, except a rupture of the right phrenic nerve. It hardly follows, however, that the rupture of the nerve was the cause of death.

Schroeder's case, then, is the only one on record in which the phrenic was injured without injury to surrounding structures, and in which the exact extent of the injury was known. In removing a fibroma, which was attached to the borders of the foramen formed by the third and fourth cervical vertebræ, the upper root of the phrenic, coming from the third cervical, was found traversing the upper and outer part of the tumor, while the lower root came from below. As the tumor was thought to be malignant, an attempt was made to dissect the nerve from the tumor; but in doing so, the roots of the nerve were torn off. There was no material change in the patient except an increase of respirations to 32. The nerve was united by sutures, and on being pinched below the suture, the diaphragm responded. There was no cough or hiccough nor any other symptom, either during the operation or afterward, except that the respirations remained at 24 to 32 for four or five days, and then came down to 20. Examination after recovery showed the left half of the diaphragm stationary and two and one-half inches above its normal position. The patient left the hospital completely recovered, and resumed his former occupation.

Experimental Researches.—1. On the Human Being. In eighteen cases of tuberculous glands of the neck, the nerve was pinched during operation with the following results: Contraction of the corresponding half of the diaphragm, with sudden rising of the anterior abdominal surface below the costal arch. In ten cases the right nerve was pinched and the left in eight. In one case on each side there was some pain in the region of the diaphragm, but it subsided in forty-eight hours. The symptoms usually attributed to irritation of the diaphragm (*i.e.*, sneezing, coughing, and hiccoughing) were not observed in a single instance.

2. Experimental Researches on Dogs. In the course of an extended series of experiments on dogs, the following results were obtained: After resecting as much as possible of the cervical portion of the nerve, it was found that after resection of one nerve only, there was an increased thoracic expansion and a slight abdominal retraction, changes which were more evident on the divided side than on the normal side. In case of a double resection there occurred an inverted type of respiration, *i.e.*, decided retraction on inspiration and increased thoracic expansion, due to the action of the accessory respiratory muscles. In unilateral resection kymographic tracings showed that the normal half of the diaphragm rose half an inch on inspiration and fell the same distance on expiration, while the half of the diaphragm on the side on which the nerve had been resected moved only an eighth of an inch, as it was moved passively by the movements of the normal side. After division of the nerve, the diaphragm becomes relaxed and the muscle arches up into the thorax. The type of respiration becomes increasingly costal when one nerve is divided, and inverted when both nerves are cut. The accessory respiratory muscles become very active. There is no sneezing or coughing. In one case of double division the respiration became labored, but remained so for only a few days.

Post-mortem Findings.—In cases in which the dogs were killed in from seven to fourteen days after resection of the nerve, the atrophy of the diaphragm was not great and the color was reddish-yellow. When a longer time had elapsed, the atrophy was marked, the paralyzed part being thin and flabby, the color pale yellow, and in older cases translucent. In all cases there remained a margin from one-quarter to three-eighths of an inch in width at the costal border, which retained its normal color and thickness. This margin is supplied by the intercostal nerves.

Summary.—1. From clinical, experimental, and anatomical data it would seem that the diaphragm is not an essential muscle of respiration, and that the importance of injury to its principal nerve, the phrenic, has been exaggerated. Injury to the phrenic or division of one nerve is not necessarily fatal. It may, however, predispose to lung infection or be followed by diaphragmatic hernia.

2. While the diaphragm is supplied with branches from the lower six intercostal nerves, they are inferior to the phrenic in importance and unable to take the place of the phrenic after division of the latter.

lected, though much of the drug of commerce includes the large woody branches, or even the trunks, several inches in diameter. The branchlets are slender and crowded with leaves. The bark is ashy gray and finely roughened by minute, short, sharp, thickly set longitudinal ridges and minute gland-like protuberances, both of which exhibit, under the lens, a peculiar resinous structure. The bark of the trunk and larger branches scales off in ragged strips. The bark is rich in the resinous constituent, which exists also, to a much smaller extent, in the young wood, but is practically wanting from the old wood. The leaves are broadly ovate and thick, about a line long, bluish or whitish green by reason of the resinous exudation, which is profusely deposited at their bases and edges. Toward the ends of the branches are numerous very short branchlets, each terminating in a persistent white or bluish flower, which is funnel shaped and from a third to a half-inch long. These flowers are rarely seen in the drug. Five unequal, included stamens are borne upon the constricted portion of the corolla. The style is slender, the stigma small and two-lobed. The fruit is a two-celled capsule, about one-fifth of an inch long, and contains several brown seeds.

www.libtool.com.cn

The important constituent of pichi is a large and variable amount of a bitter resin. Associated with this is a little volatile oil, the important constituent of which is *fabianol*, and to which the peculiar odor of the drug is due. A fractional amount of the alkaloid *fabianine* and a fluorescent glucoside, occurring in bitter crystals and resembling aesculin, also occur, together with gum, an inert crystalline resin, and ordinary plant constituents.

Pichi is a highly valued drug, both with the laity and with the profession, in Chile and other South American countries, and was introduced into use in the United States by the present writer (*Ther. Gaz.*, 1885, p. 810). Its special repute is for the treatment of vesical and renal troubles arising from the uric-acid diathesis and for the expulsion of gravel and small calculi. It also acts as a sedative to the irritable mucous membrane, modifying the secretion and subduing the pain. The following account of its action and uses, by Beaumont Small, in the preceding edition of this work, can scarcely be improved upon:

"Its use has been extended to all forms of acute and chronic inflammation of the urinary organs, and numerous reports of cases in which it has been employed tell of its beneficial action, not only in cystitis and vesical irritation due to simple causes, but also when these have arisen from gonorrhœal and prostatic disease. A special indication for its use is said to be the presence of pus in the urine. Dr. Reginald Harrison, after using the drug for four years in private and hospital practice, stated that he obtained considerable benefit from it, particularly under the following conditions: (1) In renal colic and the passing of calculi through the kidneys and along the ureters attended with hæmaturia; though not exercising any solvent power, it seems by its action on the tissues in some way to favor the escape of the stone, and thus to suppress the bleeding. (2) In the hemorrhage which frequently accompanies cancer of the bladder. (3) The sedative action of the drug on the mucous membrane of the bladder has proved beneficial in many instances of irritability connected with an enlarged prostate.

"In addition to its employment in urinary disorders, it is recommended for the relief of the headache, dyspepsia, and other symptoms arising from a condition of lithiasis, and has been used as an hepatic stimulant for jaundice and dropsy due to hepatic disease. Given in small doses, preceding the meal, it has been found to be an excellent stomachic.

"The drug is generally administered in the form of a decoction or fluid extract. The decoction is prepared by adding one ounce to twenty ounces of water, the whole to be given in four portions during the day. The dose of the fluid extract varies between ten minims and two drachms. The average dose is from half a drachm to one drachm. The effects of the drug are usually experienced after a few doses have been given. The extract is not miscible with water, and the appearance of the mixture is made more pleasant by rendering it alkaline. Glycerin is recommended as the best vehicle for its administration; it is a fairly good solvent, and maintains the drug in suspension in fine particles. Salines should not be combined with it, as they cause the separation of the resin in dense curds. Fluid extracts of hyoscyamus, hydrangea, buchu, and other remedies may be combined when they are indicated. A solid extract allows of its administration in powder in capsules. The dose is from two to ten grains." *Henry H. Rusby.*

PICRIC ACID.—(*Carbazotic Acid, Trinitrophenol*). $C_6H_2(NO_2)_3OH$. Picric acid may be formed by adding carbolic acid to fuming nitric acid and heating. It crystallizes in yellow, glistening, laminar or acicular scales. It is soluble in 95 parts of water, and in 16 parts of alcohol. It readily combines with alkalies to form salts, of which ammonium picrate is preferred as a therapeutic agent. Picric acid and its salts form powerful explosives, and many accidents have been due to their careless handling.

Ammonium picrate forms in yellow crystals, soluble in water and alcohol. It has a bitter taste, is odorless, and imparts a yellow color to everything with which it comes in contact.

Picric acid and its salts may produce toxic effects when administered internally, or when absorbed from the skin or abraded surface. It has caused weakness and depression, diarrhœa, colic, black urine, jaundice, convulsions, collapse, and death. It stains the tissues yellow and produces an alteration in the character of the blood. Many cases are reported in which it has given rise to unfavorable symptoms when applied externally in the treatment of burns and skin affections. It also discolors the skin and has produced a vesicular rash and an erythematous condition resembling scarlet fever.

Picric acid in the form of the ammoniate has been suggested as a substitute for quinine in the treatment of malaria and malarial neuralgias. It is given in doses of one-eighth to one and a half grains three or four times a day. Although it has been of service in the hands of some, it has not proved of sufficient value to warrant its continued use. On account of its property of staining the tissues it has also been suggested as a method of treating trichiniasis.

Picric acid is employed locally in the treatment of inflammatory affections of the skin, and for burns and scalds. In erysipelas the application of a saturated solution, which has a strength of nearly one per cent., has proved of value. It is to be applied from five to ten times a day and the solution allowed to dry upon the part. Its power of reducing the inflammation is supposed to be due to the fact that it penetrates the corneous cells of the skin, and by its astringent property acts as a protective to the Malpighian layer of cells; it also acts as a parisiticide upon the specific cause of the disease.

It is recommended in eczema when the inflammation is acute and superficial and accompanied by much itching. It is of less service in chronic forms accompanied by induration of the skin. A compress of the saturated solution is kept applied to the part for several days. It lessens the weeping and pain and promotes healing.

Of late years it has been particularly recommended for the treatment of burns and has been extensively employed for this purpose. It is most serviceable in burns of the first and second degree, as its special effect is to favor the growth of new epidermis. If there is a granulating surface it is of little value. A layer of absorbent cotton, saturated with the solution, is kept applied to the part. Under this treatment the heat and pains subside and the superficial lesions quickly heal. After which, if there are deeper burns and granulating surfaces, they may be treated by other means. Ointments of a strength up to five per cent. have been used, but it has been pointed out that where absorption and ill effects have occurred, these stronger preparations have been employed. The discoloration of the skin may be removed by washing with alcohol or with a solution of carbonate of lithium.

Digitized by Microsoft®

Picric acid has also been used in genito-urinary disorders, urethritis, ear and eye diseases, and many other conditions, but has not met with much favor.

Beaumont Small.

PICROL—di-iodo-resorcin monosulfonate of potassium, $C_6H_2(OH)_2SO_3K$—is a white, odorless, bitter crystalline powder which contains fifty-two per cent. of iodine, and is soluble in water, glycerin, and ether. It is a soluble substitute for iodoform. *W. A. Bastedo.*

www.ibtool.com.cn

PICROTOXIN.—*Picrotoxinum* (U. S. P.).—A neutral principle obtained from the seed of *Anamirta Cocculus* (L.) W. et A. (*Menispermum C.*, L.: *A. paniculata* Colebr. Fam. *Menispermaceæ*).

The origin of picrotoxin from fish-berries has been explained under *Cocculus Indicus.* The seed alone contains the active principle picrotoxin. This is extracted with boiling alcohol, the solution concentrated and cooled, the fat removed, and the residue treated with boiling water. The picrotoxin is crystallized out from the slightly acidulated decoction, and is afterward purified by the use of alcohol. Several associated alkaloids are liable to occur as impurities of picrotoxin. The substance is thus described by the Pharmacopœia:

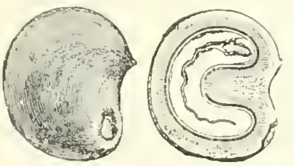

FIG. 3807.—Fruit of Cocculus Indicus. Whole and in section. (Baillon.)

Colorless, flexible, shining, prismatic crystals, or a micro-crystalline powder, odorless, and having a very bitter taste; permanent in the air.

Soluble, at 15° C. (59° F.), in 240 parts of water, and in 9 parts of alcohol; in 25 parts of boiling water, and in 3 parts of boiling alcohol; also soluble in solutions of the alkalies, and in acids. Very slightly soluble in ether or chloroform.

Picrotoxin is neutral to litmus paper.

When heated to 200° C. (392° F.) picrotoxin melts, forming a yellow liquid, and upon ignition it is consumed, leaving no residue.

Concentrated sulphuric acid dissolves picrotoxin with a golden-yellow color, very gradually changing to reddish-brown, and showing a brown fluorescence.

On mixing about 0.2 gm. of powdered sodium nitrate with three or four drops of sulphuric acid, in a small, flat-bottomed capsule, sprinkling a minute quantity of picrotoxin over it, and then adding, from a pipette, concentrated solution (1 in 4) of sodium hydrate, drop by drop, until it is in excess, the particles of picrotoxin will acquire a brick-red to deep red color which fades after some hours.

On diluting 2 c.c. of alkaline cupric tartrate V.S. with 10 c.c. of water, and adding a small portion of picrotoxin, red cuprous oxide will be separated within half an hour at ordinary temperatures, and much more rapidly upon the application of heat.

The aqueous solution of picrotoxin should remain unaffected by mercuric or platinic chloride T.S., tannic acid T.S., mercuric potassium iodide T.S., or other reagents for alkaloids (absence of *alkaloids*).

ACTION AND USES.—The most elaborate study of the action of picrotoxin was that made by Chirone and Testa, whose conclusions were as follows (*London Medical Record*): (1) Picrotoxin is capable of causing a true artificial epilepsy. (2) The epilepsy so induced is independent of the psychomotor centres, inasmuch as it is most intense after the removal of those centres. (3) Picrotoxin acts primarily on the bulb and on the commissural fibres between the cerebral and spinal centres, and secondarily on the spinal centres themselves. (4) It demonstrates the existence of a functional antagonism between the psychomotor and motor centres of the bulb and spinal cord. (5) The convulsive movements of the limbs induced by picrotoxin depend primarily upon the action of the drug on the bulb, which is thence propagated to the spinal marrow, and secondarily upon its direct action on the spinal centres. (6) In frogs the influence on the spinal functions is more marked than upon the cerebral, while in dogs and the higher animals the cerebral motor centres are the most acted upon. (7) By cinchonidine an epilepsy of cerebral, by picrotoxin an epilepsy of spinal origin, can be induced.

From the foregoing it is evident that the action of picrotoxin closely resembles that of strychnine. Besides the use of this substance for poisoning fish, it is said to be a constituent of some arrow poisons and to be employed for the poisoning of vermin. The flesh of fish poisoned by it is said to be dangerous unless early steps are taken to remove the poison from it.

The medicinal employment of picrotoxin is exceedingly limited. It has been recommended in paralysis, epilepsy, chorea, hystero-epilepsy, etc., but has not been very successful. As a retarder of the pulse it might be thought of, but we have already several safer remedies for this purpose. It has been used considerably for the prevention of the night sweats of phthisis; the hypodermic use of gr. $\frac{1}{100}$ to gr. $\frac{1}{50}$ proving very serviceable in many cases of this troublesome condition. It has been used locally in some cutaneous diseases, and as a parasiticide (in the form of an ointment); but it has no advantage for this purpose over less dangerous substances. "Convulsions and death have followed its application to the head" (Brunton); from one to two per cent. of picrotoxin in, say, petrolatum is of sufficient strength for pediculi, etc., if it is desired to use it. Dose, from 1 to 10 mgm. (gr. $\frac{1}{60}$ to gr. $\frac{1}{6}$). *Henry H. Rusby.*

PIEDMONT WHITE SULPHUR SPRINGS.—Alameda County, California. These springs are located three miles from Oakland, and have gained considerable local reputation in the treatment of rheumatism, jaundice, liver and kidney troubles, and disorders of the stomach. There is a well-kept hotel with pleasant grounds at the place, and its nearness to San Francisco makes it available for residents of that city as a day resort. The situation on the western slope of the Berkeley Hills commands a most picturesque view over San Francisco Bay and the Golden Gate The following analysis by Winslow Anderson shows the mineral ingredients of two of the springs:

ONE UNITED STATES GALLON CONTAINS:

Solids.	The Iron Spring. Grams.	The Sulphur Spring. Grams.
Sodium chloride	5.10	7.91
Sodium bicarbonate	11.70	9.40
Sodium carbonate	.52	6.20
Potassium carbonate	3.15	.76
Potassium iodide	Trace.	Trace.
Magnesium carbonate	6.37	3.17
Magnesium sulphate	1.03	17.80
Calcium carbonate	2.13	3.32
Calcium sulphate	1.60	7.09
Ferrous carbonate	1.73	Trace.
Alumina	.45	Trace.
Borates	5.23	1.90
Silicates	4.19	5.06
Organic matter	Trace.	Trace.
Total solids	43.20	62.61
Gases.	**Cubic inches.**	**Cubic inches.**
Carbonic acid gas	7.25	4.60
Sulphureted hydrogen	Trace.	9.25
Temperature of water	58°	60°

These analyses show that the waters are valuable as a tonic, antacid, diuretic, and aperient; they are useful in dyspepsia, constipation, anæmia, rheumatism, and liver and kidney troubles. *James K. Crook.*

PIEDRA.—(Synonym: Trichomycosis nodosa.)

This is a parasitic disease that occurs on the long hairs, especially those of the scalp. It may affect the beard,

Digitized by Microsoft®

It was first described as occurring only in Cauca, one of the United States of Columbia. A few cases have been reported in Germany and one in this country. It is characterized by the appearance of from one to ten small, dark-colored, very hard and gritty nodes along a hair. When the hair affected by the disease is combed or shaken, the nodes rattle together like stones. This gave the disease its name, which in the Spanish language means stone. The hair itself is unaffected, the nodes being simply attached to it. Women are most commonly affected, men only exceptionally so, and then it is their beards.

www.libtool.com.cn

ETIOLOGY.—It occurs in warm countries and is a fungous growth. Microscopical examination shows that the nodes are composed of a mass of pigmented spore-like bodies arising from one cell that sends out columns radially in all directions.

DIAGNOSIS.—It differs from the other diseases of the hair in which nodes form, such as trichorrhexis nodosa, in that the hair itself is unaffected. Its nodes differ from the nits of pediculi in their dark color, and in their not being placed on one side of the hair.

TREATMENT.—The nodes can be readily removed by soaking them with a hot solution of bichloride of mercury 1 to 1,000. They can be combed off or pulled off when softened. *George T. Jackson.*

PIGMENT. (PATHOLOGICAL.)—The pigments found in the human body, either under normal or under pathological conditions, are formed either by the body cells themselves (*intrinsic or autochthonous pigment*), or are derived from the bile (*hepatogenous pigment*) or the blood (*hæmatogenous pigment*), or are foreign pigments which are deposited within the body from without (*extrinsic pigment*). The last named may enter the body through the respiratory or the gastro-intestinal tract, or through wounds; or, as in the case of malarial pigment, they may be formed inside the body by the activity of the cells of parasites.

Pigment.

  - 1. Carbon.
  - 2. Silver.
  - 3. Lead.
  - 4. Tattoo.
  - 5. Malarial pigment.
  - 6. Various dusts.

1. AUTOCHTHONOUS PIGMENTS.—*Melanin* is found normally in the cells of the rete and in the choroid. It is believed by the majority of writers to be a product of specialized connective-tissue cells (chromatophores), which in the skin lie just beneath the cells of the rete, in the upper layers of the tissue of the dermis. These cells contain fine yellow or brownish granules of melanin, or their protoplasm may be diffusely stained with the pigment. Protoplasmic processes containing the pigment extend from the chromatophores into the epidermis, between the epithelial cells of the rete, and it is believed that the pigment is transferred to the epithelium by means of these processes. The chromatophores are most numerous normally in the skin of the flexor surfaces, about the nipples, external genitals, and anus. They are more abundant in dark-skinned individuals than in those having a light skin. The chemical nature of melanin is not known; it is a nitrogenous body rich in sulphur, and is believed to be a product of the combination of certain split products of albumin that contain sulphur. It does not give a reaction for iron. It is not a derivative of hæmoglobin, but is either built up by cell activity from the end products of albumins circulating in the blood or is formed by the cell from its own albumin.

A physiological increase of melanin occurs during pregnancy, particularly about the nipples, external genitals, and in the median line of the abdomen (linea fusca, chloasma uterinum). This pigmentation is especially pronounced in brunettes. In freckles, tan, lentigines, pigmented moles and warts, etc., the pigmentation is due to an increased formation of melanin by the chromatophores. In various cachexias, but particularly in Addison's disease, there is a greatly increased production of melanin, to such an extent that the individual may become very dark. Melanin may also be formed in excess in or about scars of the skin caused by various skin lesions or eruptions. From an abnormal proliferation of the chromatophores a pigmented sarcoma (melanotic sarcoma) may arise. The cells of these growths produce melanin in great excess, so that their color is usually brown or black. Their metastases, wherever produced, likewise form melanin. Such metastases occur most frequently in the liver; and they often overshadow the primary tumor, which may be of insignificant size, often originating in a small pigmented mole. The excessive production of melanin by sarcoma cells is of the nature of a degeneration; with the formation of the melanin the cells die.

Lipochrome is the coloring matter of fat tissue, corpora lutea, ganglion cells, epithelium of the seminal vesicles, and of the greenish-colored sarcomata known as chloromata. Its chemical nature is not known. It does not contain iron, and is colored black by osmic acid.

Hæmofuscin is the yellow or brownish granular pigment found in heart muscle, striped muscle, and in the unstriped muscle of the gastro-intestinal tract, vas deferens, seminal vesicles, etc. The pigment found in the cells of the glands of the stomach and intestine, as well as in the cells of the lachrymal, mucous, and sweat glands, is by some writers regarded as identical with hæmofuscin, by others as belonging to the melanin group. Its sulphur content favors the latter theory. Hæmofuscin does not give the iron reaction. In atrophic conditions of muscle particularly when following hypertrophy, the amount of hæmofuscin is either relatively or absolutely increased. The color of such muscle may become a deep brown. This is not infrequently seen in the case of atrophy of heart muscle in failure of compensation for valvular disease (brown atrophy of the heart). Microscopically, the pigment is found to consist of fine yellow granules arranged at the poles of the nuclei, in the form of a cone, the base of the cone toward the nucleus. In all cases the presence of a notable amount of hæmofuscin in muscle cells is to be taken as an evidence of degeneration (pigment atrophy).

HEPATOGENOUS PIGMENT.—*Bilirubin* is found as a pathological pigment in the tissues in icterus. As a result of the appearance of bile pigment in the blood, the skin, conjunctivæ, the internal organs, serous membranes, subcutaneous tissue, blood plasma, urine, etc., are stained yellow in mild or recent cases; but in jaundice of long standing the color may be an olive-green or a deep bronze. The bile pigment gains entrance to the circulation as a result of obstruction to the outflow of bile through the biliary vessels, or through changed conditions of the liver cells brought about by intoxication, infection, or through nerve influences, whereby the secretion of the liver cell, instead of passing into the bile capillaries, passes into the blood. Carried through the body by the circulating blood, the bilirubin gives to all of the tissues a diffuse yellow color. After a time granules of bilirubin collect in the lymph spaces and in the tissue cells themselves, and particularly in the lymph glands, spleen, and bone marrow. In the cells of the connective tissue, liver, and kidney, rhombic plates and needles of bilirubin may sometimes be found. In the kidneys the cells of the convoluted tubules are stained with bile pigment, and in the collecting tubules yellow, brown, or greenish casts are found. The presence of the casts is due to the degenerative processes set up in the cells secreting the bile pigment. In icterus there constantly occurs a deposit of hæmosiderin in connection with the bilirubin, as a result of the destruction of red blood cells by the bile acids.

Digitized by Microsoft®

HÆMATOGENOUS PIGMENTS.—The pigments arising from the destruction of the red blood cells may be classed in two groups: one containing iron, *hæmosiderin*, and one not giving the iron reaction, *hæmatoidin*. The exact chemical nature of these pigments is not known, and the terms *hæmatoidin* and *hæmosiderin* represent groups of related pigments rather than individual pigments. The deposit of derivatives of blood pigment is known as *hæmachromatosis*, that of *hæmosiderin* alone, as *hæmosiderosis*. Hæmatoidin and hæmosiderin in all cases are derived from the destruction of hæmoglobin, either in extravasates or in the circulating blood. *Hæmatoidin* is regarded as identical with bilirubin. It is a ruby-red or reddish-yellow granular or crystalline pigment, soluble in absolute ether, chloroform and carbon disulphide, and insoluble in water and alcohol. With potassium ferrocyanide and hydrochloric acid it gives no reaction for iron. Hæmosiderin occurs in yellowish or brownish granules, which when treated with potassium ferrocyanide and hydrochloric acid give the Prussian blue reaction. With ammonium sulphide it forms a black sulphide of iron. After a time hæmosiderin may lose its iron reaction and become changed to hæmatoidin.

www.libtool.com.cn

Hæmatoidin is formed when the blood pigment is but little exposed to the action of living cells, as in the central portions of thrombi, or in large extravasates in the tissues, or in extravasates lying in the body cavities. It may be produced artificially by enclosing blood clots in capsules which admit the tissue juices but not the wandering cells, and by introducing such capsules into the peritoneal cavity or beneath the skin.

Hæmosiderin is formed in extravasates, in those portions exposed to the action of living cells, and is usually found around the periphery of thrombi and extravasates, in the area of organization. The pigment may lie free in the tissue, or may be contained within cells. The free pigment and that contained within phagocytes give rise to a pigmentation of the tissue about the extravasate, varying from a light yellow to a deep brown. After hemorrhage into the lung alveoli both hæmatoidin and hæmosiderin granules may be found in the sputum, either free or in phagocytes (pigment cells).

Both *hæmatoidin* and *hæmosiderin* may be carried from the seat of extravasation to the lymph glands and there deposited. Soluble blood pigment in the circulation is deposited partly as hæmatoidin and partly as hæmosiderin, in the spleen, bone marrow, lymph glands, liver cells, and kidney cells; and under certain conditions in the parenchymatous cells of various organs. The greater part of the pigment thus deposited gives the iron reaction, and therefore is to be classed with hæmosiderin. Such deposits of iron-containing pigment occur in pernicious anæmia and pernicious malaria, in poisoning with arsenic, toluylendiamin, potassium chlorate, mushrooms, etc., in overheating of the body, etc. As a result of the destruction of the red cells there occurs a hæmoglobinæmia; an increased amount of bile is formed, and there is an increased excretion of urinary pigment. In the kidneys the hæmosiderin is found chiefly in the cells of the convoluted tubules. In pernicious anæmia the hæmosiderin is found in greatest abundance in the liver cells of the peripheral portion of the liver lobules. Around the central vein the liver cells may contain hæmatoidin. The endothelial cells of the liver capillaries also contain the pigment; in the early stages of the process the pigment may be found only in these, later it is transferred to the liver cells.

If hæmosiderin comes into contact with hydrogen sulphide it becomes changed into a black hæmosiderin hydrogen sulphide. This condition is known as *pseudomelanosis*. It is usually seen after death in the intestinal canal, peritoneum, and suppurating wounds, but its production is dependent upon a formation of hæmosiderin in the tissues before death. It may take place in the living body as the result of hydrogen sulphide produced by bacteria. The green color seen in the early stages of the decomposition of the cadaver is due to a sulphur compound of methæmoglobin, produced by the action of H_2S on oxyhæmoglobin.

A peculiar brown or black pigmentation of cartilage, tendons, and the capsules of the joints occurs in old people, and occasionally in younger individuals. The condition is known as *ochronosis*. By some the pigment is regarded as allied to melanin, by others as a derivative of blood pigment. Neither its chemical nature nor its mode of formation is known. A similar pigmentation of cartilage may be produced by formalin.

EXTRINSIC PIGMENTS.—*Silver* taken into the body as a soluble salt (silver nitrate) is reduced by the cells of the blood-vessels and deposited as free silver or a low oxide in the connective tissue of the kidneys, intestine, skin, intima of large arteries, adventitia of the smaller ones, choroid plexus, etc. The epithelial structures and nervous tissue are alone spared. The pigment appears in the tissues in the form of fine black granules, lying in or between the connective-tissue cells. The condition is known as *argyria*. (See *Argyria*.) *Lead* may be deposited as a grayish-black discoloration of the gums, consisting of granules of sulphide of lead. *Iron* may be taken into the body in excess and deposited in the bone marrow, spleen, and lymph glands (*siderosis*), but this is rarely of a noticeable extent. In iron workers the lungs may acquire a reddish tinge from the deposit of iron-oxide dust. *Carbon* is the most common of the extrinsic pigments. It is usually taken into the body through the respiratory tract and deposited in the connective tissue of the lungs and in the peribronchial lymph glands (*anthracosis*). Under certain conditions, such as softening or tuberculous caseation of the bronchial glands, the carbon pigment gets into the general circulation and is deposited in the spleen, bone marrow, lymph glands, liver, etc. It occurs in the tissues as a deep grayish-black, coarsely granular pigment. *Colored dusts* from pottery clays, pigments, etc., may be found in the respiratory tract of individuals following certain trades. Various *pigments* may be introduced into the body in tattooing. Cinnabar and India ink are most commonly used. The pigment occurs in the connective tissue of the dermis as coarse black granules. The greater part of the pigment introduced into the wound of the skin is carried to the lymph glands, the remaining portion lies in the spaces of the scar tissue formed. As the pigment is constantly removed by wandering cells the outlines of tattoo marks slowly become indistinct. Carbon may enter the body through wounds of the skin: powder marks, cinders rubbed into cuts, etc. Silver particles may also enter the body through the skin or respiratory tract. *Malarial pigment* is a brownish-black pigment formed by the cell activity of the malarial plasmodium. It does not give an iron reaction. By some writers it is incorrectly called melanin. Its chemical nature is wholly unknown. It collects in the small capillaries of the body and is taken out of the circulation by the endothelium and also by wandering cells, and transferred to the tissue cells, chiefly in the spleen and bone marrow.

PATHOLOGICAL ABSENCE OF PIGMENT.—A failure of melanin production leads to the conditions known as *albinism* or *vitiligo*. The absence of pigment may be congenital or acquired. A lack of pigment throughout the skin of the entire body is known as *albinismus universalis*; in certain regions only as *albinismus partialis*. The hair may also be destitute of pigment (*leucotrichia*); and in universal albinism the pigment of the choroid and iris is also wanting. Acquired *vitiligo* is a condition characterized by a loss of pigment over certain portions of the skin, following scarlet fever, typhoid, or recurrent fever; or occurring as an epidemic disease without known cause. Idiopathic cases also occur. With the loss of the skin pigment may be associated a *leucotrichia acquisita*. Vitiligo appears to depend upon an atrophy of the chromatophores; its exact nature is unknown. It may depend upon a disturbance of adrenal function, or of the sympathetic system. A third form of absence of pigment follows infectious inflammations of the skin, leprosy, syphilis, etc.; and is known as *leucoderma*. The

Digitized by Microsoft®

skin covering the scars produced by these diseases loses the power to produce pigment. This may be explained by a disappearance of the chromatophores, or by the inability of the epithelium to take up the pigment. The non-pigmented portions are not infrequently surrounded by a heavy pigmented border. See *Coloring Matter, Argyria, Vitiligo, etc.*) *Aldred Scott Warthin.*

PILOCARPUS. See *Jaborandi.*

PINEHURST AND SOUTHERN PINES, N. C.—Pinehurst, six hundred and thirty feet above sea level, is situated in the "Pine Belt" of North Carolina, not far from the centre of the State, about seventy-five miles southwest of Raleigh. It is a comparatively recent creation, an attempt by one person to establish a model health resort in a favorable climate.

It embraces about five thousand acres, privately owned, and under the absolute control of the owner. Much labor and expense have been bestowed upon this enterprise; the grounds have been carefully laid out by landscape architects, and every attention has been paid to the sanitary conditions, sewerage, water supply, plumbing, etc., so that one is assured of finding here most wholesome hygienic surroundings and excellent accommodations. Consumptives, however, are not received, the desire evidently being to provide a winter resort for the large number of persons who, though not ill, desire to spend the winter in a comparatively mild and equable climate where they can remain for the greater part of the time out of doors.

Invalids are also received here, according to the writer's understanding, suffering from diseases other than tuberculosis. The soil of all this upland region is sandy, quite resembling the dry sand on the edge of the seashore, in which soil the long-leafed pine flourishes. Pines and sand comprise the scenery, but this lack of variety has its compensation in the abundant sunshine and bracing air. Moreover, the peacefulness of such surroundings must be restful to tired nerves.

The average winter temperature ranges from about 44° to 65° or 70° F., said to be about that of Southern France. In January, 1902, the maximum temperature was 72° and the minimum 20°, while in Philadelphia it was 54° and 15° respectively, and in Boston 54° and 4° F.

There is a large amount of sunshine, and one can generally spend most of the time out of doors. In the Piedmont Plateau which embraces this region, the annual average rainfall is 49.85 inches, and for the winter 12.28 inches. Snow is said to appear about once in two years, but remains only for a few hours. January is the coldest month; there may then be frosts at night and thin ice may coat the ponds. Spring begins by the middle of February. Protection is afforded from the cold northwest winds by the Apalachian range and by the pine forests. Naturally there is little to attract the visitor in this monotony of sand and silent, dark pines, but art has done much to make life attractive here. There are extensive golf links and a club house; shooting preserves for quail; horseback riding, tennis, croquet, etc. There are several hotels of varying prices, and furnished cottages for rent. The water is obtained from artesian wells and is pure and good. All the conditions of modern living are found here, and every attention seems to have been given to the maintenance of a high standard of sanitary excellence. Pinehurst has electric railroad connection with Southern Pines, six miles distant, which is on the Seaboard Air Line Railroad. It is a journey of eighteen hours from New York to Pinehurst.

Southern Pines, about six hundred feet above sea-level, is six miles distant from Pinehurst, and possesses similar conditions of climate, soil, and vegetation. It is situated upon a large sand bank, and is surrounded by the characteristic pine.

It is a comparatively new town of about one thousand inhabitants, and is essentially a winter health resort largely made up of Northern inhabitants or visitors. It has more of the features of a town than Pinehurst, there being several churches, shops, a graded school, library, electric lights, a trolley line, good water supply, and a sewerage system. There are several hotels of varying accommodations and prices, furnished cottages, apartments, and boarding-houses. Tuberculous patients are generally received here, although at the largest and most pretentious hotel, the "Piney Woods Inn," the statement is made that "confirmed consumptives will not be cared for."

Opportunities are afforded for various outdoor diversions, such as golf, tennis, driving, bicycling, and small-game shooting.

It is said that several thousand visitors frequent this resort during the winter season, and it can be recommended, especially for those of moderate means and requirements who desire to live with their families in one of the many small cottages which can be obtained at a moderate rental.

Several miles south of Southern Pines is Pinebluff, which is being developed as a health resort.

The air in all this pine-belt region is pure and dry, and impregnated with the balsamic emanations of the pines. It affords favorable conditions for many cases of tuberculosis and bronchitis, for convalescents from acute diseases, and for those suffering from chronic nephritis. This region is also a convenient halting place for those going to or returning from the lower South.

The season is from November to April.

Edward O. Otis.

PINE LAWN SPRING.—Bergen County, New Jersey.
—Post-Office.—Hohokus.

The Pine Lawn Spring water, recently introduced into the markets, is obtained from an artesian spring at Hohokus, twenty-three miles from New York City. The place is not used as a resort, but we are informed that residents of the neighborhood attach considerable medicinal value to the water and use it in large quantities. The following analysis was made in 1897 by Messrs. Smith and De Roode, chemists of New York:

One United States gallon contains: Potassium sulphate, gr. 0.06; sodium chloride, gr. 0.43; sodium sulphate, gr. 0.32; calcium sulphate, gr. 0.49; calcium nitrate, gr. 0.66; calcium carbonate, gr. 2.04; magnesium carbonate, gr. 0.72; alumina, a trace; silica, gr. 0.57. Total, 5.29 grains.

The water is exceptionally free from organic matter, and presents no evidence of surface pollution. It is clear, palatable, and sparkling, and well adapted for the table. *James K. Crook.*

PINGUECULA. See *Conjunctiva, etc.*

PINKROOT.—*Spigelia* (U. S. P.). The dried rhizome and roots of *Spigelia marilandica* L. (fam. *Loganiaceæ*).

This is a perennial herb, with a horizontal, twisted rhizome, and several erect, simple, somewhat quadrangular stems. Leaves opposite, sessile, ovate-lanceolate, smooth. Inflorescence terminal in a one-sided (scorpioid) spike, of half a dozen or more showy flowers. Calyx small, five-parted; corolla tubular, trumpet-shaped, with five acute, spreading lobes; bright scarlet outside, bright yellow within. Stamens five, inserted on the corolla; pistil single; ovary two-celled, several-seeded, superior. Pinkroot is a native of the Middle and Southern States, where large quantities are annually collected. Its medicinal properties have been known for upward of a century.

The description of the drug is as follows:

The rhizome is of oblique and sharply tortuous growth, somewhat branched, mostly 2.5–5 cm. (1–2 in.) long and 2–4 mm. ($\frac{1}{12}$–$\frac{1}{6}$ in.) thick, knotty from the approximate stem bases of the upper surface, which bear cup-shaped scars, dark brown or blackish, thickly clothed underneath and at the sides with long, rather coarse, finely branched, lighter brown roots, which are usually broken shortly, not leaving a long, bare, woody central portion; brittle, showing a whitish wood and a dark or decayed

Digitized by Microsoft®

pith; somewhat aromatic; taste sweetish, bitter, and somewhat pungent.

The larger, lighter-colored rhizome of *Ruellia*, sp., with fewer coarse roots, from which the bark readily separates, is frequently substituted or admixed.

But little is known of the constituents of this drug. Starch, resin, gum, tannin, fat, volatile oil, and other ordinary plant substances exist, together with a small

www.tibtool.com.cn

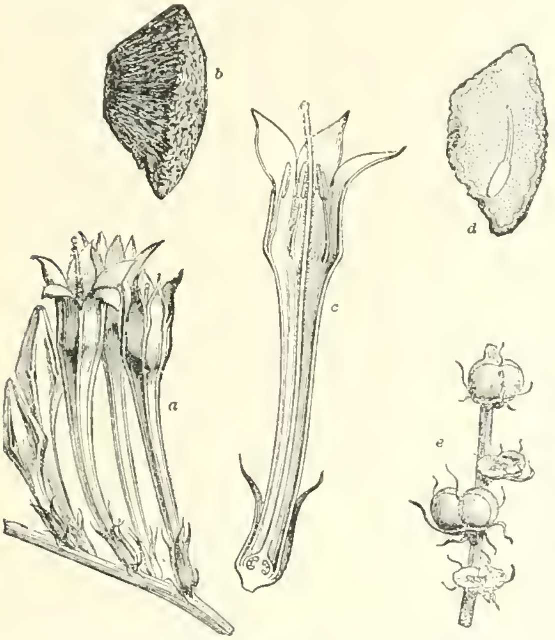

FIG. 3808.—Pinkroot. *a*, Twig with blossom; *b*, grain centre; *c*, section of flower; *d*, section of grain; *e*, fruit. (Baillon.)

amount of the volatile alkaloid *spigeline*, which is soluble in alcohol and water, and is probably the active constituent.

ACTION AND USE.—In overdoses spigelia is a narcotic poison. Quickening of the pulse, dryness of the throat, flushing and heat of the skin, uneasiness and delirium have followed its use. There is little doubt that in the cases in which it is most employed,—cases of *lumbrici* or round worms,—it is of considerable value. A fluid extract (*Extractum Spigeliæ Fluidum*, U. S. P.) is a good preparation, and the one generally prescribed. It is frequently combined with senna or some other cathartic. Dose of the fluid extract, for an adult, 2–8 c.c. (fl. ʒ ss.–ij.); for small children, from 1 to 4 c.c. (fl. ʒ ¼ to i.).

Allied Plants.—Another Spigelia, *S. anthelmia* L., growing in South America and the West Indies, has, as its name implies, similar properties and uses. Although used chiefly in its home, it has also been introduced into Europe. It is regarded, probably correctly, as more active than our own. *Henry H. Rusby.*

PINTA.—(Synonyms: Carat, Carate, Carathe, *Mal de los pintos.*)

Pinta is a parasitic disease characterized by the appearance on the skin of spots and patches of various sizes and colors.

Until recent times the disease had been observed only in Central America, Mexico, and South America, but lately reports have been published of its occurrence in Africa. It is said to be most common in the Mexican States of Tabasco and Chiapas, but it is also quite prevalent in Peru, Bolivia, and Brazil. In Venezuela and Colombia, along the low-lying banks of the rivers Zulia and Magdalena, the affection is quite in evidence. The half-breeds, mulattoes, and mestizos that make up the bulk of the laborers and crews of vessels plying these waters seem to have a peculiar susceptibility to the disease, or perhaps their skins offer less resistance to its inroads than the skins of the pure whites or pure negroes. I have often seen on these river boats as many as a half-dozen cases on a single vessel. So common is the trouble that it soon ceases to awaken interest in the average passenger.

The dorsal surfaces of the hands and feet, the anterior aspect of the legs, and the surface of the chest are the parts most often affected. The disease attacks both sexes and all ages, although it is seldom seen in children under six years of age. Like other diseases of a similar nature, it seems to have a preference for people of unclean habits, filth apparently having a direct bearing not only on the persistence but perhaps on the very existence of the affection. For this reason it is rare in the better class of mestizos and native whites.

The color of the patches may be red, blue, black, or white; hence the Spanish names rojo, azul, negro, blanca, etc. The size of the individual patches is quite variable. The disease first appears in one or two small spots which tend to increase along their periphery and merge into one another; it also extends by auto-inoculation in the act of scratching.

Some observers claim that the victims of this disease emit an offensive odor. One compares it to the odor exhaled by a mangy dog, another compares it to that of dirty linen. Personally I have never been able to detect this peculiar smell apart and distinct from the naturally offensive emanations from a body and clothes that have never been subjected to the action of soap and water.

SYMPTOMS.—The general health is not affected in this disease. Dr. Freites, of Venezuela, states that he has observed as prodromal symptoms chills, headache, anorexia, etc., but, so far as I know, no other observer has had a similar experience. The eruption appears suddenly as one or two small spots, at first slightly elevated above the surrounding surface. It progresses slowly and may even remain stationary for a variable period—the quiescent stage. This may be followed by a period of activity when the patches extend peripherally or appear on other parts of the surface, being the result of auto-inoculation, in the act of scratching. Pruritus may be excessive, even to the point of interference with sleep, or it may cause little or no annoyance. Desquamation is as a rule of a furfuraceous character, varying in quantity from almost *nil* in the white to a relative abundance in the red and black forms of the disease; in some cases of the latter variety it occurs in thick crusts. Suppuration and bleeding are due to the injuries inflicted by scratching. After a period of variable duration some of the spots merge into one another, giving the patient the characteristic piebald appearance.

The above symptoms are common to all forms of the disease. A few additional words regarding each variety of the disease would perhaps make the matter clearer.

White Form.—This looks very much like an ordinary leucodermic patch. The color is like that of yellowish-white wax, and the surface of the patch is smooth and shiny. When this form attacks the hairy portions of the body the hairs become thin, like lanugo, and lose their pigment.

Red Form.—This at first looks as if the surface had been scalded; later the affected portions become bright red and smooth. As the pruritus in this form is usually more intense, it is the one most liable to suppuration and other accidents due to traumatism.

Blue Form.—The eruption appears first as a group of small blue spots, like those made in tattooing; sooner or later these spots extend and merge into one another, the whole patch then having a peculiar blue color, which I would compare to the blue shell of a duck's egg. These patches are covered by a thin layer of dust-like grayish-blue scales.

Black Form.—In this form the spots are at first of a dirty gray color, which gradually becomes darker as the spots themselves grow older and larger. Eventually, the area affected resembles nothing so much as a surface

Digitized by Microsoft ®

spread with a layer of blue ointment. Another division that has been made recognizes a superficial form, including the blue and the black forms, and a deep form, embracing the white and the red varieties, in which there is destruction of the deeper underlying tissues. Several of these forms may and do occur together in the same individual.

www.libtool.com.cn

PATHOLOGY.—"The scales contain a white, highly refracting mycelium, and black spores which are round or oval in shape. The spores contain a yellow fluid in which abundant pigment is found. The mycelial filaments are short, non-branching, and taper from a broad base to a blunt point, by which each filament is attached to a single spore" (Manson).

DIAGNOSIS.—Pinta may be distinguished from anæsthetic leprosy by the facts that the sensibility of the patches is not impaired, and that the mucous membranes are not attacked; from acquired leucodermia or vitiligo by the fact that in the latter there are no changes of structure or of sensibility in the affected skin. From chromophytosis, ringworm, and erythrasma pinta may be distinguished by the history of the disease and the color and localization of the lesions.

PROGNOSIS.—As to life the prognosis is very good, but the disease is very rebellious to treatment; and in spite of all treatment it usually lasts a long time.

TREATMENT.—Absolute cleanliness and the local applications of chrysophanic acid, sulphur, iodine, the salts of mercury; in fact, all the stronger parasiticides are indicated.

N. J. Ponce de León.

PIPERAZIN (*Diethylene-Diamin. Ethlenimin*).—A synthetical compound primarily intended to replace spermin, but found to be a different body, both in chemical and in physiological characters. It is now utilized only as a solvent for uric-acid deposits in the place of lithia salts.

It is formed from the action of ammonia on ethylene bromide, which produces a mixture of compounds from which diethylene-diamin is separated by fractional distillation at a temperature between 130° and 180° C. When separated by a patented process it is supplied to the profession under the name of piperazin. It is a solid which melts at 104° to 107° C., and boils at 145°. It forms in bright, lustrous tables. When exposed to the air it absorbs water and carbonic acid gas, and becomes liquefied. It is very soluble in water, and forms a tasteless, alkaline solution without being in the least corrosive.

Experiments with solution of piperazin upon uric acid and upon calculi formed either of uric acid or of uric acid with phosphate of lime, prove that it exerts a powerful solvent action. When placed in a one-per-cent. solution at a temperature of 90° F., the stones are rapidly acted upon, the sharp edges are removed, and the surface becomes smooth and slippery; within twenty-four hours the mineral portion is dissolved and a soft mucoid skeleton only remains. All forms of urinary deposits are said to be more or less acted upon. Compared with carbonate of lithium it dissolves twelve times as much uric acid. Tests have been made of the relative solubility of fragments of a stone in one-per-cent. solutions of piperazin, lithia carbonate, borax, and sodium carbonate. In the piperazin solution the fragment was dissolved in six hours, the lithia solution did not dissolve the fragment until after forty-eight hours, the borax dissolved only a very small portion in forty-eight hours, and the sodium solution had no effect whatever after the lapse of the same period of time. In each case the residue was placed in the piperazin solution, when it entirely disappeared.

The action of the drug when administered to a person in health is perfectly harmless. It does not disturb the digestive, circulatory, or respiratory organs. After its administration and absorption it is not decomposed or acted upon, but passes through the system and is excreted by the kidneys unchanged. Piperazin may be detected in the urine two hours after its administration, and it continues to be excreted for a prolonged period. The urine is not rendered alkaline, nor in any way altered by its prolonged use.

Piperazin is theoretically a very valuable drug for the treatment of all conditions in which uric acid is formed in excess. Numerous cases are reported in which it has been used with very marked success—in gout in all its forms, in lithiasis, renal calculi, and vesical calculi, and in many forms of rheumatism of a gouty character. In these conditions it is supposed first to saturate the uric acid that remains dissolved in the organism, and then to attack all deposits of uric acid. The soluble urate of piperazin that is formed is readily excreted with the urine. The piperazin that is not neutralized in the system comes in contact with calculi and deposits in the kidney and bladder and there exerts its specific properties. On account of its freedom from any irritating action on the mucous membrane, it may be made to act directly upon the deposits in the bladder, by injecting a one-per-cent. solution, which assists in the decomposition of the larger calculi that would otherwise require operative treatment.

The results of its use have not always been so favorable. Prof. H. A. Hare reports having employed it in some cases of well-marked gout and in gouty rheumatism without any beneficial effects. He administered it internally and by hypodermic injection in the usual doses without relief. Sir William Roberts, in the "Croonian Lectures for 1892," on the treatment of the uric-acid diathesis, states that piperazin in blood serum or synovia had not the slightest effect in adding to the solvent powers of these media on sodium biurate, nor the slightest effect in retarding its precipitation from serum and synovia artificially impregnated with uric acid. He concludes that if piperazin has any beneficial action in gout it is not due to its solvent powers on the material of gouty concretions.

On account of its hygroscopic properties it must never be prescribed in powder or pill form. It is supplied in bottles containing 5 gm., which is sufficient for five days' use. This is to be dissolved in a definite quantity of water, and one-fifth given each day in divided doses. The quantity employed by all observers has been 1 gm. daily, in solution, well diluted. The effects of the drug are rapidly manifested. After the subsidence of the attacks a smaller dose of eight to fifteen grains may be given every third day, and continued for months. When administered hypodermically, fifteen minims of a ten-per-cent. solution may be used. The injections are to be made in the neighborhood of the affected joints. The drug is to be given internally at the same time. The effects of this method are reported to be very gratifying; the swelling and pain subside and the deposits are absorbed and greatly reduced in size. In some cases it is reported that deposits of gouty material in the pinnæ of the ears and in the eyelids were removed by two or three injections. The following solution is also prepared for local application to the affected joints: Piperazin, gr. xv.–xxx.; alcohol, ʒ v.; water, ℥ iiss.

Beaumont Small.

PIPERONAL—heliotropin, methylene ether, protocatechuic aldehyde, $C_6H_3COH.O_2CH_2$—occurs in small white crystals with a strong odor of heliotrope, and is soluble in alcohol and ether and insoluble in water. In dose of 0.5–1 gm. (gr. viij.–xv.) it is antiseptic and antipyretic. It is also used in perfumery.

W. A. Bastedo.

PIPSISSEWA. *Chimaphila. Bitter* or *False Wintergreen, Prince's Pine.* "The dried leaves of *Chimaphila umbellata* (L.) Nutt. (*Pyrola u.* L.; *C. corymbosa* Pursh. —fam. *Pyrolaceæ*)."

This very pretty little plant, native of dry woods throughout the cooler regions of almost the entire North Temperate Zone, is an herb-like undershrub, having an erect stem a few inches in height, arising from a short, prostrate portion. The leaves are crowded near the ground and the scape bears several very pretty, five-

Digitized by Microsoft®

merous, wax-like, white, subpendulous flowers, about a half an inch broad. The leaves are from 2.5 to 5 cm. (1 to 2 in.) long and 1 to 1.5 cm. (⅜ to ⅝ in.) broad, oblanceolate, the lower half cuneate and entire, the upper coarsely and sharply serrate, acute or obtusish, thick and rigid, brittle, above dark-green or brownish-green, and slightly shining, the veins strongly impressed, underneath paler, the veins very prominent; odor very slight, tea-like; taste astringent and bitterish.

www.libtool.com.cn

Their constituents are almost identical (as are the properties and uses) with those of *Uva Ursi.* There is between four and five per cent. of tannin, arbutin, sugar, gum, etc., and a small amount of the yellow, crystalline, neutral substance, *Chimaphilin,* which is inodorous and tasteless, soluble in alcohol, ether, and chloroform, but only slightly soluble in water. For its mildly astringent and diuretic properties and uses, see *Uva Ursi.* The Pharmacopœia provides a fluid extract, the dose of which is 2 to 4 c.c. (fl. ʒ ss. to i.). *Henry H. Rusby.*

PITCH, BLACK.—Common pitch. See *Turpentine.*

PITCH, BURGUNDY.—*Pix Burgundica* (U. S. P., B. P.); *Poix de Bourgogne, Poix des Vosges, Poix jaune* (*Codex Med.*). This opaque resin is nominally, and properly, obtained in Europe from the Norway spruce, *Abies Abies* (L.) Rusby (*Pinus* A., L.: *P. Picea* Du Roi—fam. *Pinaceæ*), a magnificent evergreen with a pyramidal head reaching 40 metres or more in height, and having branches even down to the very ground. Its cones are large and pendent, its foliage is close, and of a brilliant green color. It is an abundant forest tree of Northern Europe and Asia, and a frequent ornamental one here.

Burgundy pitch is not an empyreumatic product like common black pitch, but a turpentine which has been exposed to hot water or steam, and has in consequence taken up enough of it to become opaque. It is collected by making rather deep incisions in the trunks of the trees, scraping off the resinous sap that flows out, boiling it in water, and straining it through cloths. The collection is carried on in Austria and Switzerland, but not to a very great extent, and is diminishing. In the place of this genuine article, the turpentine of other European Pinaceæ, prepared in the same way, is frequently substituted, and is sanctioned in most countries; and besides this, an entirely spurious preparation of common American rosin, mixed with oil or fat and water, is the common (false) Burgundy pitch of the market. That sold in this country is said to be almost never genuine. The following is the official description:

Hard, yet gradually taking the form of the vessel in which it is kept; brittle, with a shining, conchoidal fracture, opaque or translucent, reddish-brown or yellowish-brown; odor agreeably terebinthinate; taste aromatic, sweetish, not bitter.

It is almost entirely soluble in glacial acetic acid, or in boiling alcohol, and partly soluble in cold alcohol.

The principal portion of this substance—eighty per cent. or more—is *resin,* amorphous and opaque until the water is evaporated off, then clear; from three to five per cent. of *essential oils* is also present, and from five to ten of *water.*

It is a mildly stimulating substance when applied to the skin; taken internally it has the properties of common rosin, or, in a mild degree, those of turpentine; stimulating in small doses, irritating in large ones; but it is milder in its taste and action than common turpentine. Its very limited medicinal use is almost entirely confined to its presence in a few plasters, of which the following are official here: Burgundy pitch plaster (*Emplastrum Picis Burgundicæ,* U. S. P.). Burgundy pitch, 80 parts; yellow wax, 15 parts; olive oil, 5 parts, melted together. It may be used as it is, or as the basis for other more active medicaments. The pitch plaster with cantharides is more stimulating; it consists of: Burgundy pitch, 92 parts; cerate of cantharides (thirty-two per cent.), 8 parts, melted together after straining the cantharidal cerate through a very fine strainer. *W. P. Bolles.*

PITCH, HEMLOCK.—*Pix Canadensis* (U. S.), *Canada Pitch.* This is a product of the *Hemlock Spruce, Tsuga Canadensis* (L.) Carr. (*Pinus C.* L.: *Abies C.* Mx.—fam. *Pinaceæ*), collected and prepared in much the same way as the preceding. It appears often to have been boiled for a greater length of time, and is frequently very dark, almost black in consequence. It is described as follows: "Hard, yet gradually taking the form of the vessel in which it is kept; brittle, with a shining conchoidal fracture, opaque or translucent; dark reddish-brown; having a weak, somewhat terebinthinate odor." Canada pitch has essentially the same composition and properties as the preceding, and is used for the same purposes. A plaster is made of it in exactly the same way as the Burgundy pitch plaster (see above). *W. P. Bolles.*

PITUITARY GLAND.—(*Hypophysis Cerebri*: Ger., *Hypophyse*: Fr., *Gland* or *Corps Pituitaire*: Ital., *Glandula Pituitaria*; Span., *Ghiandola Pituitaria.*) Vesalius was the first to describe this organ, and in his "De Corporis Humani Fabrica" (1553) he calls it the "glans pituitam excipiens," due to the mistaken idea that this organ secreted the nasal mucus (pituita). Soemmering (1778) described it more fully and called it "hypophysis cerebri." Both thought that the pituitary was a gland, but as they could not find any duct, they considered it a part of the nervous system. Rathka (1838) pointed out the significant fact that the organ is developed from two *Anlagen,* one arising from that part of the fore-gut which later forms the pharynx, the other arising from the base of the third ventricle. These views were disputed for some time, but Mihalkovichs (1874) agreed with Rathka, and his proofs were so conclusive that but few have disputed them since that time. Pathological changes were noticed by many of the early observers. Wepfer, Bonnet (1679), and Morgagni found colloid cysts; Greding (1771) and Melcarne (cited by Mechel) found "enlargements of the pituitary gland"; and Wenzel claimed that diseases of the pituitary caused epilepsy. The physiology of this organ has been neglected much, and it is only recently that its physiological action has been given much attention.

Anatomy.—The pituitary body is an oval, glandular organ, consisting of two lobes and a connecting part. It rests in the sella turcica, and is enveloped by a layer of dense connective tissue, which is a prolongation of the basal dura. The average weight of the pituitary is 0.5 gm. In a series of one hundred cases Schönemann found that the average weight was 0.63 gm. between the ages of twenty and thirty, but that the weight diminished after that time until the average at fifty was 0.6 gm. Boyce and Beadles examined the pituitary glands from fifty female insane and found that the weight varied from 0.384 to 0.896 gm., the average being 0.6 gm. In fifty male insane the weight varied from 0.712 to 1.302, with an average of 0.453 gm. The ages of these cases varied from twenty-two to seventy-eight, none having presented symptoms referable to the pituitary. According to these authors the weight of the pituitary has no definite relation to that of the brain or to the age of the patient. The organ measures about 14 mm. in its lateral diameter, 7 mm. in its antero-posterior, and 6 to 7 mm. in thickness. The color of the pituitary is a dark brown or a bluish-red. The consistency of the organ is about that of the normal liver.

Histology.—The microscopical structures of the two lobes differ markedly, the anterior being made up of glandular elements, and the posterior of a tissue resembling, with ordinary stains, a modified glia. From the connective tissue surrounding the gland, fine trabeculæ carrying the blood-vessels run into the interior and separate the cords of epithelial cells. These epithelial cells are rather hexagonal in shape and are of two kinds. One contains a round or oval, deeply staining nucleus embedded in a large amount of granular protoplasm which stains deeply with eosin ("eosinophilic cells"). The other cells are somewhat smaller, more granular, and they do not stain with the acid dyes ("cyanophilic cells").

Digitized by Microsoft®

www.libtool.com.cn

The posterior lobe is enveloped by a capsule of connective tissue from which the fine septa carrying the blood-vessels enter the lobe. Immediately beneath the capsule are several layers of cells, which, according to Gemelli, react with certain stains like glio-epithelium. Beneath these is an indefinite layer of secretory cells of the epithelial type, which are often arranged into distinct alveoli separated by the fine connective-tissue septa. The central zone of this lobe contains small round, polygonal, and few pear-shaped cells together with a small amount of connective tissue. The pear shaped or nerve cells possess either one or two neuraxons. These cells are of two types, the large and the small pear-shaped cells. The large cells have many branching dendrites ending in feathery tufts. The neuraxons of these cells come off close to the cell bodies, have few collateral branches, and end by breaking up into fine threads, some of which are lost near the cell, while others end in networks among the epithelial cells along the border of the lobe. The other type of nerve cell or the small pear-shaped cell has dendrites, all of which are short, except one which is covered with hair-like processes. All the dendrites come off close to the cell body and terminate as clubbed ends.

The cells which possess more than one neuraxon are flask shaped. Each cell has three or four dendrites which gradually grow finer and terminate free, and from two to four neuraxons which apparently terminate about similar cells. Most of the neuraxons run toward the infundibulum, but Berkley, who has worked much on this subject, has been unable to trace them into the infundibulum. Gemelli has described nerve fibres in the pedicle; they enter the posterior lobe and branch in the shape of a fan under the glio-epithelium. From there he was unable to trace them to any cell in this lobe which he could call a nerve cell.

The infundibulum or the pedicle consists of a loose connective tissue which is composed of anastomosing stellate and spindle shaped cells, and which holds in its meshes blood vessels and nerve fibres and encloses small blind spaces lined by cubical epithelium, the remains of the neural central canal.

Embryology.—The pituitary gland is developed from two *Anlagen*, one coming from the midbrain ectoderm and the other from the entoderm of the posterior pharynx. At the angle formed by the pharynx and mouth a solid bud of cells is given off from the median area of the upper wall of the posterior pharynx. These cells grow out into the thin layer of mesoblast separating the brain from the pharynx, and the bud as a whole becomes hollowed out to form a duct like communication with the pharyngeal cavity. About the time when the pharyngeal bud begins to develop the brain sends another bud downward until the two *Anlagen* come to lie side by side. About this time the mesoblastic cells surrounding the *Anlage* from the pharynx grow into this hollow flask-shaped mass, and the wall of the once smooth cavity becomes folded inward upon itself. These papillæ become divided and interlaced to form the mature gland. While this has been taking place the canal communicating with the pharynx has become occluded and absorbed, and the base of the sella turcica has ossified.

When the *Anlage* for the posterior part of the gland is given off, it contains few embryonic ganglion cells, which are found as cells less developed than their corresponding cells in the base of the third ventricle. Along with these cells glia cells are found, some of which disappear and others remain as the cells described by Berkley.

Pathological Anatomy.—Because of the location of the pituitary body pathological conditions at the base of the brain are apt to cause secondary changes in it. These secondary changes may or may not be marked enough to produce symptoms. Usually before symptoms on the part of the pituitary appear, the primary condition at the base of the brain has produced its effects, which have either killed the patient or have masked the symptoms caused by the pituitary lesion.

Circulatory Disturbances.—General *congestion* of the brain, either active or passive, produces a similar condition in the pituitary. Anæmia of this organ occurs in general cachectic conditions such as result from malignant neoplasms, tuberculosis, general arteriosclerosis, etc.

Two instances of hemorrhage into the organ have been reported, one by Bailey, in which the lesion was due to endarteritis, and a second one by Anders and Cattell, which occurred in a case of pernicious anæmia.

Infarct of the pituitary has not been reported as yet.

Retrograde Changes.—Atrophy of the pituitary body results from the cachexias of malignant tumors, tuberculosis, syphilis, and pernicious anæmia. Senile atrophy occurs physiologically in every individual over fifty.

Necrosis. Necrosis of any form involving the whole organ has not been reported, but localized simple, liquefaction, and coagulation necrosis may be present under certain conditions. General infection may produce a simple necrosis of the gland cells of the anterior lobe of the pituitary body. Liquefaction necrosis may follow infection of the organ by the pus-producing germs, and coagulation necrosis may be present under similar conditions.

Degenerations.—General cloudy swelling and fatty degeneration may result from the general intoxications of infections or from inflammations of the tissues surrounding the pituitary. By far the most common retrograde change in the pituitary is colloid degeneration, which is, up to a certain degree, a physiological condition, similar to that of the thyroid. Accompanying an overproduction of colloid, there are often formed cysts, which are due to the inability of the organ to excrete the colloid. These cyst walls are lined by the cuboidal cells which are the remains of the parenchymatous cells.

Progressive Changes.—Hypertrophy. The most common progressive change, if not the most common change of any form, is hypertrophy. This change is confined usually to the glandular portion of the organ, and occurs in a large number of cases of acromegaly. The parenchymatous cells of the anterior lobe are increased both in size and in number, the connective tissue being relatively increased also.

Inflammations. Inflammation of the pituitary gland is usually secondary to a meningitis and, in pyæmia, secondary abscess may develop in the organ. Secondary inflammation may in rare cases result from an abscess of the pharyngeal vault.

Chronic Inflammations (Granulomata); Tuberculosis. In 1901 Baldwin reported tuberculosis of the pituitary gland in a case of general miliary tuberculosis; that this was a true case of tuberculosis cannot be doubted since the germs were found in stained sections. A careful study of the literature at that time failed to give another case of true tuberculosis of the pituitary. Weigert had reported a case of "tuberculous like granuloma" of the pituitary, but he was not positive as to its identity since he could find no germs in this granuloma, and he could find no tubercles in any other part of the body. Boyce and Beadles, and Wagner have reported cases similar to that of Weigert, but were unable to demonstrate germs.

Syphilis. Lancereaux says that the hypophysis may be enlarged in hereditary syphilis, such enlargement being due to increase of the connective tissue. Weigert, Barabacci, Birch Hirschfeld, Hunter, Sokoloff, Frasier, and Hektoen have reported gummata of this organ which resembled in structure gummata found elsewhere in the brain.

Tumors. The only mature connective-tissue tumors which have been reported are two cases of lipoma, and one of fibroma. The lipoma in both cases arose from the fat tissue about the organ, and not from the gland proper. Chiara published the case of a woman, aged sixty-three, in whom a fibroma the size of a bean was found in the pituitary.

Many of the tumors of the pituitary gland which have been reported have been called large, round-celled alveolar sarcoma or endothelioma, other varieties of the sarcomata being very uncommon. However, when the structure of the normal pituitary body is borne in mind, it is probable that many of the so-called round-cell sarcomata

Digitized by Microsoft®

Pituitary Gland.

were adenomata. One case of lymphosarcoma of the pituitary, and another of spindle-cell sarcoma have been published, the former by Heusser and the latter by Hoffmann. Of the mixed sarcomata and those showing degenerations or deposits some of the large round-cell sarcomata have been alveolar and consequently mixed. To these may be added the angiosarcoma of Walton, the myxosarcoma reported by Whitwell, and the gliosarcoma of the posterior lobe published by von Graefe.

www.libtool.com.cn

Of the epithelial tumors various forms have been described. As stated before, small retention cysts are common in the anterior lobe and in the infundibulum of the pituitary. These may become very large and may replace the greater part of the organ. They may be lined by a single smooth layer of rather flattened cuboidal cells or the inner surface may be folded slightly. In every case these cysts contain a substance very similar to the colloid of thyroid, if not identical with it. Unless the retention cysts are classed as tumors, adenomata of the pituitary are the most common variety of epithelial tumor. It is possible, however, that many of the so-called adenomata have been examples of hypertrophy. In both hypertrophy of the pituitary and in adenomata the anterior lobe is the only part of the organ which is affected, and it becomes often a matter of personal opinion whether a given case represents a condition of hypertrophy or one of adenoma. In those cases which are genuine instances of adenoma all the elements of the anterior lobe are increased in number and many of the epithelial cells are enlarged. The lymph spaces between the cords of cells are broader and in many the colloid secretion may be slightly increased. These tumors are malignant only by position. Cases of carcinoma of the pituitary have been described.

The possibilities of inclusions of foreign embryonic cells into the *Anlage* of the pituitary and the subsequent formation of dermoid cysts from these cells are great. Nevertheless, very few of these tumors have been reported. Engel (1839), Rippermann (1864), Arnold (1875), Baart de la Faille (1875), Wasserthal (1875), Beck (1885), White (1885), Sanisburg (1886), and Beadles have described teratomata of the pituitary gland.

Most of these teratomata have been composed of small cysts containing semi-solid pultaceous material. The connective tissue surrounding these cysts contained small pieces of bone. Many of these tumors have been found accidentally at autopsy and have produced no symptoms during life. Others have been found in a fœtus, and these have shown a more complicated structure. Some have contained cortex, ganglion cells, liver, parts of the intestinal tract, hair, teeth, and bone, and they may have represented a parasite engrafted upon an autocyte; others of these teratomata have arisen from the remains of the pharyngeal diverticulum.

Of the parasites found in man Sömmering has reported a case of echinococcus cyst of the pituitary gland.

Physiology.—The physiology of the pituitary is not fully known. Before 1886 this organ was supposed to represent some evolutionary remains. In 1886 Marie found that it showed marked changes in so many cases of acromegaly that the old idea that it was non-functional was reconsidered.

Oliver and Shäfer have injected into animals intravenously a saline extract of the pituitary, and have found that it produced a rise in blood pressure. Howell confirmed this work, and found further that a second dose did not have so marked an effect as the first, unless considerable time had elapsed between the two injections. Shäfer and Vincent were able to extract from the pituitary one substance which depressed and one which increased the blood pressure. The substance which possessed the power of increasing the pressure was found to be soluble in salt solution and insoluble in absolute alcohol and ether. The other substance, however, was soluble in all three of these reagents. The experimenters injected the salt-solution extract and found that the blood pressure rose, but soon fell. They explained this by the fact that the depressive substance acted more slowly than the stimulating one. Osborne and Vincent extracted from the infundibular lobe a depressive substance which resembled that obtained from the cortex of the brain, and consequently they are not sure that the depression effects may not be due to the nerve elements of the infundibular lobe.

That the pituitary gland is similar in structure to the thyroid had been known for some time. Michel (1860) and Peremeschko (1866) were among the first if not the first to note the similarity and, in describing the pituitary gland, they compared it to the thyroid. It remained for Rogowitsch, in 1886, to prove that this supposed similarity was a fact. Since this time many workers have observed in diseases such as myxœdema, cachexia thyreopriva, and cretinismus, that the hypophysis is increased in size. The cells of the glandular lobe are larger than normal, and the amount of colloid material found in the organ is increased. Hence these writers have assumed that when the thyroid is diseased, the hypophysis attempts to assume the function of the thyroid. On the other hand, cases have been reported in which the hypophysis has been abnormal either in structure or in function, the thyroids and in some cases the parathyroids have been increased in size. In such cases it has been assumed that the thyroids and parathyroids attempt to compensate for the diseased pituitary bodies.

The experimental evidence on this subject is not uniform at present. Casseli has been able to produce a condition exactly analogous to cachexia thyreopriva by removal of the pituitary; and he states that arrest in development of the pituitary retards the growth of the organism as a whole. Freedmann and Maas removed the pituitary bodies from cats, and could not obtain the same results. Nevertheless, the great weight of clinical evidence and the larger part of the experimental study tend to show that the relation is very close between the pituitary body and the thyroid and the parathyroid glands.

Pathological Anatomy of Acromegaly.—In all the cases studied, Israel says (1901) that Virchow was able to find only five cases in which the pituitary was not enlarged. In sixty-nine cases which the writer has had the opportunity of analyzing the pituitary is found "not enlarged" in only one case. In all other cases this organ shows some pathological change.

The following shows the changes found as they were diagnosed:

Colloid degeneration and hemorrhage	2
Hypertrophy (anterior lobe)	22
Hypertrophy (posterior lobe)	1
Vascular hypertrophy	2
Fibrosis with atrophy of follicles	1
Tumor	4
Hypertrophy (?) or sarcoma (?)	1
Glioma	1
Glioma (?) sarcoma (?)	1
Neurogliomic sarcoma	1
Adenoma	10
Adenoma (?)	3
Sarcoma, round cell	19
Sarcoma (?) or lymphadenoma (?)	1
	69

In 29 of these cases the thyroid was examined, and in only 5 was this organ reported normal.

The conditions found in this organ are as follows

Normal	5
Atrophy	1
Atrophy with interstitial fibrosis	2
"Chalk-like" deposits	1
Colloid degeneration	3
Cystic degeneration	1
Hypertrophy	11
Hypertrophy with colloid cyst	2
Hypertrophy with interstitial fibrosis	2
Interstitial fibrosis	1
	29

In this connection it may be well to note that in 18 cases in which the thymus region was examined, the thymus was reported absent in 7; persistent in 7; both lobes were enlarged in 3, and in 1 case only the left lobe was enlarged.

The relations of the pituitary to the thyroid and thy-

Digitized by Microsoft®

mus glands in acromegaly have not been demonstrated. That pathological changes of the pituitary occur in almost every case of acromegaly is true, but pathological changes are also found in this body in cases in which there has been no overgrowth of the bones or any other symptom or signs of acromegaly.

Frederick A. Baldwin.

PITYRIASIS.—Pityriasis is an affection of the skin in which there is slight redness accompanied by a branny desquamation. The term was formerly used to describe many scaly conditions of the skin, but it is gradually passing out of use, as the conditions are now described under other headings.

Pityriasis of the scalp is described in the article on *Eczema;* it is the dry form of dandruff in which the scales do not adhere, but fall whenever the hair is brushed.

Pityriasis of the face and neck is usually found as ill-defined slightly scaly patches with very little redness. This condition is described by most authors under seborrhœa or seborrhœic eczema. (See article on *Seborrhœa.*)

Pityriasis rosea, Pityriasis rubra, Pityriasis rubra pilaris, and Pityriasis versicolor are described elsewhere. (See the articles on *Pityriasis Rosea, P. Rubra,* and *P. Rubra Pilaris,* in THE APPENDIX, and that on *Tinea* in Vol. VII.)

Howard Morrow.

PIXOL is a cheap substitute for lysol made by mixing one pound of green soap with three pounds of liquid tar (Pix liquida) and slowly adding a solution of three and one-half ounces of potash in three pints of water. The resulting liquid is miscible with water, and is used, in five-per-cent. dilution, for disinfecting the hands, linen, etc. It is claimed to be about as strong as carbolic acid.

W. A. Bastedo.

PLACENTA, ANATOMY OF.—The placenta (ὁ πλακοῦς, a cake) is a discoid, spongy body attached during pregnancy to a portion of the inner wall of the uterus. It is connected by means of the umbilical cord with the fœtus, and forms for it the organ of respiration, nutrition, and excretion. After the expulsion of the child, it becomes separated from its area of attachment, and together with the fœtal membranes is cast off as the so-

FIG. 3810.—Decidua Vera, Fourth Month. × 16. (From J. Whitridge Williams' "Text-book of Obstetrics," Appleton & Co., New York, 1903.)

called *after-birth* (Nachgeburt, l'arrière-faix). The portion of the placenta which is attached to the uterine wall is rough and irregular and is known as the maternal surface, while that facing the fœtus is smooth and covered by the thin glistening amnion, which overlies the smooth surface of the chorion and is closely applied to it.

The recently delivered placenta at term is smaller, but at the same time somewhat thicker than it is when in utero, the change resulting partially from the compression to which the organ has been subjected during labor, and partially from the escape of the greater part of the blood contained in its interior. The organ is spongy in consistence, and varies considerably in shape, size, and color. In single pregnancies,

FIG. 3809.—Maternal Surface of Mature Placenta, Showing Cotyledons; Membranes Turned Back. × 2/3. (From J. Whitridge Williams.)

Digitized by Microsoft ®

as a rule, it is more or less rounded, though it may be ovoid or oval, reniform, crescentic or lobulated. It measures from 15 to 20 cm. in diameter, and from 2 to 4 cm. in thickness, generally thinning gradually toward

www.libtool.com.cn

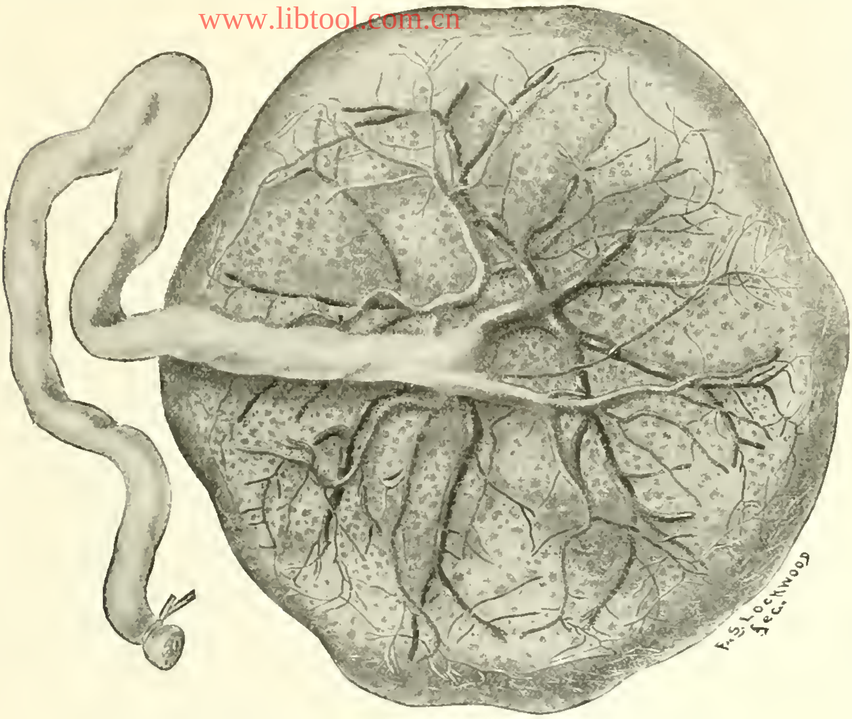

FIG. 3811.—Fœtal Surface of Mature Placenta. × ⅔. (From J. Whitridge Williams.)

the edges, which fade away into the thin fœtal membranes. Sometimes, however, the thickness is fairly uniform up to the very margin. Its weight varies from 500 to 600 gm., being usually about one-sixth of that of the child, though in syphilis, nephritis, and some other conditions it may be relatively heavier.

The placenta presents two surfaces for examination, the *maternal* and the *fœtal* (Figs. 3809 and 3811). The former varies considerably in appearance, but is usually dark red in color, varying according to the amount of blood contained in its substance and the density of its structure. It is divided into a number of irregularly shaped areas, the *cotyledons*, which are separated from one another by shallow fissures. They vary considerably in number, sometimes as many as thirty being observed, and may measure from 1 to 8 cm. in diameter. The cotyledons are not primary divisions of the placenta, but appear first at the fourth or fifth month (Minot). The outer layer of the entire maternal surface consists of a thin investment of *decidua*, which dips down to form the cotyledonary divisions, and at the edges of the placenta is continuous with the inner coating of the membranes. The decidua is transformed uterine mucosa; while the placenta is in utero, it constitutes the boundary between the chorionic villi of the placenta and the uterine muscle, and separates in the final stage of labor, so that its outer or compact portion is carried off as part of the placenta and membranes, the spongy or glandular portion remaining attached to the muscle wall (Figs. 3810 and 3816). Scattered over the maternal surface are numbers of minute yellowish-white patches of varying size. Some of these have undergone calcareous degeneration, and impart to the palpating finger a sensation as of coarse sand paper. Close inspection of this surface reveals the torn openings of many blood-vessels. Thus Klein was able to count one hundred and five of these on a single specimen, fifty-one being arteries and fifty-four veins.

As opposed to the rougher maternal surface, the fœtal side presents a smooth and glistening surface, and is of a purplish-gray color, mottled with minute yellowish patches, and marked by irregular yellowish-white areas of varying size (white infarcts) (Fig. 3811). It is covered by the thin glistening *amnion* which is loosely attached to it, but which may be separated as far as the insertion of the cord. Beneath the amnion lies the smooth *chorion*, from the lower surface of which the villi extend, giving rise to the mottled appearance of the surface.

The *umbilical cord* terminates upon the fœtal surface of the placenta, and presents a dull white translucent appearance. It varies from 1 to 2.5 cm. in diameter, and averages 55 cm. in length, the extreme variations being 0.5 and 198 cm. When unusually short it may give rise to dystocia at the time of labor. As the blood-vessels are usually longer than the cord, they grow in a spiral manner, and are frequently folded upon themselves, giving rise to projections which are termed *false knots*. On the other hand, *true knots* are sometimes noted. These may be most complicated in form, and are believed to be due to fœtal activity. Contrary to the usual statements, the cord is not enclosed in an amniotic sheath, but is covered by stratified epithelium,

FIG. 3812.—Umbilical Cord, Fœtal End. × 5½. *U.A.*, Umbilical artery; *U.S.*, remnant of umbilical stalk; *U.V.*, umbilical vein. (From J. Whitridge Williams.)

Digitized by Microsoft®

which is continuous with that of the abdomen of the fœtus. Its interior is made up of mucoid connective tissue—*Whartonian jelly*, in which are embedded two arteries, a vein, the umbilical stalk, and a remnant of the allantois (Fig. 3812). The latter is seen only at the fœtal end. The cord is rarely inserted centrally, being usually somewhat eccentrically placed, although occasionally it may terminate at the margin of the placenta (*battledore placenta*). Less frequently the blood-vessels separate before reaching the fœtal surface, and make their way to the placenta in a fold of amnion—*velamentous insertion*. The arteries come down together from the cord, and are usually but not always connected by a transverse vessel, just before reaching the placenta. The vessels then spread in all directions in the superficial part of the chorion, each branch producing a ridge upon its surface, by which its course can easily be followed. The veins lie beneath the level of the arteries, are larger in calibre, and distended with blood. Both arteries and veins branch repeatedly, each set following in a general way the course of the other, but they do not anastomose upon the placental surface. Generally they can be traced in their ramifications until they disappear as fine branches, turning at right angles into the placental tissue,

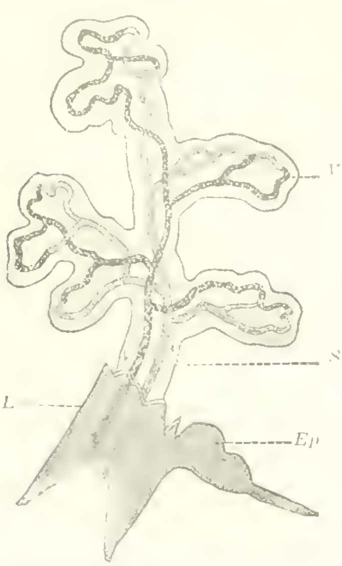

FIG. 3813. Chorionic Villus from Full-Term Placenta. Highly magnified. (After Kollmann.) *Ep*, Epithelial covering; *S*, stroma of villus; *V*, vascular loop.

in order to supply the chorionic villi. Occasionally, however, a large vessel, more often a vein, dips down abruptly. The greatest possible variation is noted in the arrangement of the placental vessels. When the cord is inserted near the margin they are arranged much more symmetrically than when the insertion is nearer the centre. There are no signs of a distinct cotyledonary circulation, but corrosion specimens of injected placentæ show that the terminal arteries communicate with veins by means of capillaries, at the free extremities of the chorionic villi.

In nearly all cases, as shown by Schultze, the *umbilical vesicle* and stalk may be found between the amnion and

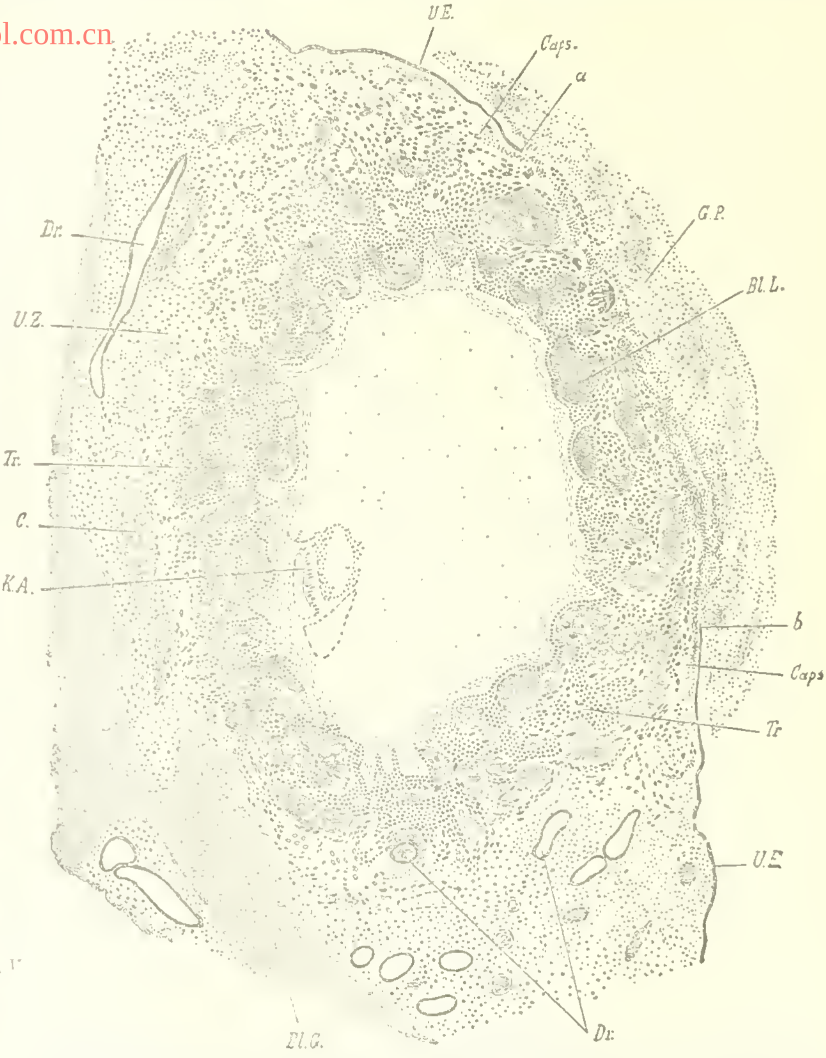

FIG. 3814.—Peters' Early Ovum. (From J. the chorion, and near the placental margin. When the membranes are separated it usually lies upon the inner surface of the amnion. The vesicle itself is a minute rounded sac 2–4 mm. in diameter, which usually contains in its interior a calcific point. It is attached to a thread-like stalk which extends to the cord, and frequently can be traced throughout its entire length. These may rarely be accompanied by omphalo-mesenteric vessels which have remained persistent.

The decidual and chorionic layers of the placenta are each less than a millimetre in thickness, save where the latter is thickened by blood-vessels or infarcts. On section the placenta presents a sponge-like structure, whose meshes are filled with blood, while the imperfect partition walls are formed by chorionic villi, which occupy the space enclosed between the decidual and the chorionic membranes. Some idea of the complexity of the villi may be obtained by floating a small piece of placenta in decinor-

Digitized by Microsoft®

mal salt solution, and washing it free from blood, when one can distinguish a number of arborescent structures, consisting of a primary stalk, which divides and subdivides like the branches of a tree. The larger stalks arise from the maternal side of the chorionic membrane and extend a varying distance through the placenta, some ending freely, while others are firmly attached to the decidual portion. Under the microscope, the arborescent branching is readily appreciated, and it will be found that a great part of the interior of the terminal branches is occupied by blood-vessels, which break up into capillaries, just before reaching their free ends (Fig. 3813).

www.libtool.com.cn

Development of the Placenta.—All early human ova thus far described have presented, upon their outer or chorionic surface, branching villi each of which consists of a core of chorionic mesoderm covered by two layers of epithelial cells. For many years the origin of the latter has been a source of dispute, due in great part to the fact that much of our knowledge of human embryology is purely hypothetical, and is based upon observations made upon the lower mammals. During the last few years, however, considerable light has been thrown on this question by the study of the early human embryos of Peters, Leopold, and Spee, and by the work of Selenka upon the anthropoid apes, and of Hubrecht upon hedgehogs. Peters' specimen is the earliest human ovum thus far described, and was believed by him to be from three to four days old (Fig. 3814). Many writers, however, consider it to be somewhat older, probably at the end of the first week. The ovum was embedded in the depths of the endometrium, and was surrounded by a thin layer of mesoderm, surmounted by a capsule of many layers of fœtal ectoderm. To this latter Peters applied the term *trophoblasts.* He advocated the view that the trophoblasts proliferate rapidly, and invade the capillaries of the surrounding decidual tissue, with the consequent formation of pools of maternal blood of varying size. These are situated in the trophoblastic capsule, but are bounded externally by decidua, and represent the earliest stages in the formation of the *intervillous spaces.* As a result of the opening of the maternal vessels the trophoblasts soon present a sieve-like appearance, and the cells become compressed into masses of irregular form, some of which extend from the ovum to the surrounding tissue, while the majority never reach it. Into these the mesoderm soon makes its way, thus giving rise to the primary villi. Those reaching the decidua are known as *fastening,* or *anchoring villi,* and become firmly attached to it by the proliferation of the ectodermal cells at their extremities, giving rise to masses of cells, which may be seen throughout the first half of pregnancy and are designated as *cell nodes.*

FIG. 3815.—Reichert's Ovum. Magnified six times. (From J. Whitridge Williams.)

During the first weeks of pregnancy branching villi project from the entire periphery of the ovum (Fig. 3815), and come in contact not only with the decidua upon which it rests (serotina), but also with the layer which separates it from the uterine cavity (reflexa). During this period, the villi are devoid of blood-vessels,

and the ovum is nourished by osmosis from the maternal blood. Probably as a result of contact with the maternal blood, the outermost cells of trophoblasts early undergo marked changes, becoming converted into a layer of

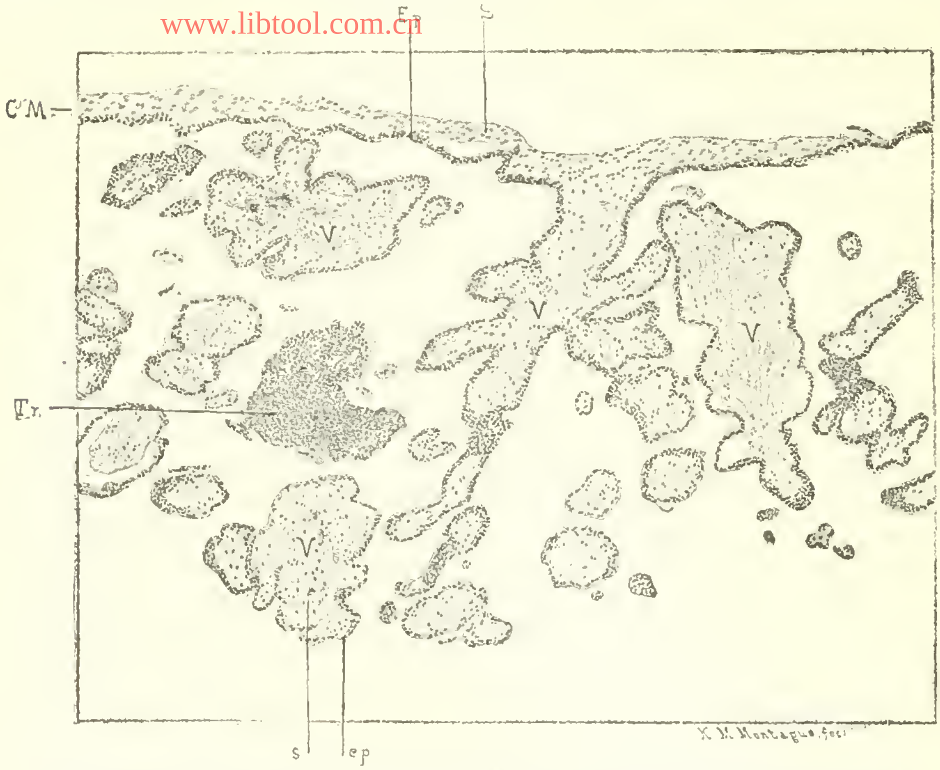

FIG. 3817.—Section through Chorionic Membrane and Villi of a Two-Weeks Ovum. Magnified 33 times. (From J. Whitridge Williams.) *C.M.*, chorionic membrane; *Ep*, epithelium of chorionic membrane; *S*, connective-tissue layer of chorionic membrane; *V*, villi; *s*, stroma of villus; *ep.*, epithelium of villus; *Tr*, decidual island (remnant of trophoblast).

coarsely granular, vacuolated protoplasm, with no sign of division into individual cells, and through it are scattered irregularly shaped, darkly staining nuclei. This tissue is known as *syncytium*, a term introduced in 1893 by Kossmann, although its characteristics had been recognized many years before by Kastschenko, who described it as plasmodium. Beneath the syncytium, and in contact with the chorionic connective tissue, develops a layer of sharply outlined, polygonal cells, with clear protoplasm and large vesicular nuclei, which is designated the *cell layer*, or *Zellschicht of Langhans*.

With the advance of pregnancy, the blood supply of the decidua serotina becomes more and more abundant, while that of the reflexa gradually disappears; as a consequence the villi in contact with the former are better nourished, and grow more rapidly than elsewhere, thus giving rise to the formation of the *chorion frondosum*. At the same time the villi covering the rest of the ovum develop less rapidly, and eventually undergo atrophic changes, so that this portion becomes known as the *chorion læve*. As the ovum increases in size, the intervillous spaces in the chorion læve diminish in size and gradually become obliterated, and by the fourth month, when the reflexa has come in contact with the decidua vera, the villi become atrophied, lose their epithelium, and eventually appear as round or oblong hyaline bodies. On the other hand, the villi of the chorion frondosum proliferate, and together with the decidua serotina form the placenta, which assumes its distinctive characteristics about the third or fourth month. It is probable that the primary villi do not increase in number with the advance of pregnancy, but their branches rapidly increase in complexity, so that their growth has been aptly compared to the development of a forest from a number of young trees.

Cross sections of chorionic villi differ markedly in appearance at the various periods of pregnancy, and De Loos has shown that their age may be roughly estimated according to their structure. Thus, in the early weeks, they consist of a more or less mucoid stroma with a few branching cells, the proliferation of which gives rise to the fibrillar structure observed in older villi. After the first few weeks the stroma is invaded by blood-vessels of fœtal origin, which come down by the cord, and which follow the villi in all their ramifications. The epithelial structures also differ in appearances according to the stage of development. During the first few months the distinction between the syncytium and Langhans' cell layer is sharply marked. As pregnancy advances, Langhans' layer gradually disappears, so that in the last months the villi are covered only by a thin layer of flattened syncytium.

Projecting from the surface of the villi are occasional buds of syncytium, which when cut across tangentially appear as *giant cells*, lying free in the intervillous blood spaces. They consist of a protoplasmic mass, which presents no distinct cellular division, and contain a large number of darkly staining nuclei. These represent the first stage in the development of new villous branches, and, as might be expected, when one bears in mind the development of villous processes, are seen less frequently in more mature placentæ.

Here and there, in the spaces between villi, may be seen masses of small clear cells with vesicular nuclei—*decidual islands*. These are usually surrounded by a layer of syncytium, rarely, if ever, contain blood-vessels, and appear to consist of decidual tissue, which frequently presents areas of degeneration. They are usually interpreted as cross sections through the so-called *decidual septa*, which are supposed to extend toward the chorionic membrane. Formerly they were regarded as being maternal in origin, but in the light of more recent investigation, it seems better to consider that they arise from fœtal tissue, and represent areas of trophoblasts that were not concerned in the formation of the chorionic villi.

The decidua is uterine mucosa which under the influence of pregnancy has been transformed to fit it for the reception and development of the ovum. It is composed of large branching cells of an epithelioid character, with round vesicular nuclei, containing a rather scanty chromatin network. In the upper portion of the decidua serotina is a thin layer of homogeneous tissue, staining deeply

Digitized by Microsoft®

with eosin, and containing many vacuolated areas. This, the so-called *layer of canalized fibrin*, results from the degeneration of the trophoblastic cells forming the cell nodes. It was first described by Raissa Nitabuch, who showed distinctly that it marked the boundary between fœtal and maternal tissue; the cells which lie above it, in spite of their resemblance to decidual tissue, are of fœtal origin, and result from the proliferation of the trophoblasts, while those below it are of maternal origin and have developed from the stroma of the uterine mucosa. Interspersed between the latter are giant cells of syncytial origin, which invade the depths of the decidua serotina, and may even extend into the uterine muscle.

The intervillous spaces are lined throughout by syncytium, save where it has undergone degeneration in the decidua serotina and forms part of Nitabuch's fibrin layer. They contain maternal blood, as has been definitely proven by the work of Waldeyer, Farre, Turner, and others. The portion of the intervillous spaces which lies at the periphery of the placenta, between the edge of the decidua serotina and chorion, has been termed the circular sinus. It is not a continuous channel, although the villi here are less abundant than elsewhere. The blood gains access to the cavities by branches of the uterine arteries, which pursue a convoluted course through the decidua serotina, and after their walls have been reduced to a single layer of endothelium, open from the sides of the decidual septa. The blood escapes through widemouth veins upon the decidual surface, and makes its way to the large venous sinuses, underlying the placental site. It would consequently appear that the intervillous circulation is necessarily of a sluggish character, thereby facilitating the interchange of substances with the fœtal blood in the vessels of the chorionic villi.

FIG. 3818.—Section through a Three-Months Placenta, Showing Structure of Chorionic Villi. Magnified 110 times. (From J. Whitridge Williams' "Text-book of Obstetrics," Appleton & Co., New York, 1903.) *S*, Stroma of villus; *Sy*, syncytium; *Z*, Zellschicht; *S.B.*, syncytial bud; *G.C.*, so-called placental giant cells.

contain branches of the umbilical arteries which break up into capillaries in the terminal ramifications. As direct communication between the fœtal and maternal circu-

FIG. 3819.—Cross Section of Seven-Months Placenta Showing Beginning Infarct Formation. (From J. Whitridge Williams.)

lation has been disproven, it is evident that the fœtus is nourished by substances derived from the maternal blood, by osmosis and by the selective power of the syncytium. These must traverse the layers of the chorionic villi which separate the two circulations. In the early and middle months of pregnancy there are four such layers—syncytium, Langhans' cell layer, the connective tissue of the villi, and the endothelium of the villous capillaries. Later, this number is reduced to three by the disappearance of the Langhans layer. These act as a barrier to the passage of formed substances. While the evidence concerning this question has been conflicting, it seems probable, in the light of recent investigations, that bacteria at least are not transmitted from the mother to the child unless the placenta presents definite lesions, which may constitute portals of entry.

The full-term placenta contains many infarcts, which if of moderate size cannot be regarded as a disease, but rather as a sign of senility of the placenta, analogous to the changes which are observed in the villi of the chorion læve at an earlier period of pregnancy. These begin as a rule in an obliterating endarteritis. At the same time changes may be seen in the portion of the villi which corresponds to the position occupied by Langhans' cell layer in the early months. This progresses and the tissue becomes converted by coagulation necrosis into canalized fibrin. If the process continues, numbers of villi become fused together and are eventually converted into a fibroid material, which in its final stages is indistinguishable from fibrin derived from the blood. Such structures are known as white infarcts, and are constantly present in varying size in every normal placenta, as has been shown by Ackermann, Eden, and Williams. The primary change in the production of infarcts occurs most frequently in the villi, although it may be initiated in the so-called decidual septa, which, as we have seen, are prone to degeneration, owing to the absence of blood-vessels. The frequency of infarcts has been emphasized by Williams, who found white surface infarcts of at least 1 cm. diameter in 243 of 500 placentæ, and marginal infarcts which extended throughout at least one-third of the placental periphery in 184 cases of the same series.

Anomalies in Form.—As already indicated, the placenta may present many varieties in size and form. We have seen that it becomes discoid in shape by atrophy of the villi of the chorion læve, and develops from the chorion frondosum, which is attached to the most highly vascularized portions of the decidua. Abnormalities in the blood supply of the decidua cause most of the anomalies of the placenta. If the vascularization, instead of being limited to the single area of the chorion frondosum, develops in several portions of the decidua, certain villi of the chorion læve, corresponding to the seat of vascularization, persist, and the resulting placenta may present one or more lobes, separated from each other by normal membranes. When it is incompletely divided into two lobes and the vessels extend from one to the other to form the umbilical cord, we term it *placenta dimidiata*, or *bipartita*. Ahlfeld noted this condition once in six hundred cases. If it consist of two separate lobes, the vessels of which are perfectly distinct, and do not unite until just before entering the cord, it is known as *placenta duplex*. The insertion of the cord in such cases is generally marginal, and at the periphery between the two lobes. Occasionally the organ may be made up of three distinct lobes—*placenta triplex*, while in very rare instances it may consist of a number of small lobes, Hyrtl having described as many as seven—*placenta septuplex*.

One or more accessory lobules are frequently noted in the membranes at some distance from the periphery of the main placenta. Ordinarily they are united to the latter by vascular connections and constitute the *placenta succenturiata*. When these are lacking and the accessory lobules are functionless, they constitute the *placenta spuria*.

Failure of the chorion læve to atrophy results in the formation of a thin placenta, which covers more or less of the entire inner surface of the uterus with functioning villi. This constitutes the *placenta membranacea*, which is frequently adherent, and may give rise to serious complications in the third stage of labor. Atrophy of the central primary villi of the chorion frondosum gives rise

Digitized by Microsoft®

to the so-called *placenta fenestrata* in which there is an aperture of varying size in the central portion of the placenta, covered only by normal membranes. Other anomalies may occur, and as reported by Taurin the human placenta may be a broad annular organ which encircles the uterine cavity like those of the carnivorous animals.

www.libtool.com.cn

The outlines of the placentas in the case of twins varies accordingly as development occurs from the ova of two Graafian follicles (double-ovum twins), or from one ovum whose nucleus has undergone cell division (single-ovum twins). In the former instance there are two distinct placentas. In the latter, there is but one placenta, with a single chorion which contains two separate amnions, so that each child lies separated from the other by two amniotic walls. This septum may be ruptured by unusual pressure of the amniotic fluid or by excessive fœtal activity and atrophy of the partition may result.

The placenta in utero is generally attached either to the upper portion of the anterior or posterior wall, and extends for some distance upward and upon the fundus. If the insertion be low, it may cover the internal os of the cervix, which condition is known as *placenta prævia* and constitutes a most dangerous complication of pregnancy. Schroeder has drawn attention to the fact that the direction of the round ligaments may indicate whether the placenta is anteriorly or posteriorly placed. If the placenta develops upon the anterior uterine wall, the increased blood supply will cause a more rapid growth in this region and the resulting increased breadth of the uterus will cause the ligaments to run more or less parallel. If the placenta be posteriorly situated the reverse will be true, and the ligaments will be found to diverge in their course downward. The distance between the internal os and the edge of the placenta may be estimated by measuring the length of the membranes of the shed placenta from their point of rupture to the placental margin. As rupture occurs over the internal os, we can by this method frequently reconstruct the position of the placenta in utero, having first determined by palpation of the round ligaments as to whether the placenta was anteriorly or posteriorly placed.

PLACENTA, PATHOLOGY OF.—The chief part of the pathology of the placenta has been discussed under the heads of *Chorion, Pathology of the*, and *Decidua, Pathology of the*. This article will treat only of the general pathological conditions of the organ considered as a whole; namely, anomalies of development, size, and location, general disturbances of circulation, inflammation, etc.

Anomalies of Development.—These are of not infrequent occurrence. Instead of the usual round or oval form, the placenta may exhibit the greatest diversity of shape, such as crescentic, horseshoe, elliptical, etc. (*Pl. biloba, triloba, multiloba, reniformis, fenestrata, panduræformis, etc.*). Besides the main organ there may be found completely separated cotyledons appearing as smaller accessory placentas (*Pl. succenturiata*). The smaller accessory placentas owe their origin to a localized failure of placental development in certain areas corresponding to an endometritic thickening of the decidua with fibrin formation, leading to an obliteration of the intervillous sinuses at the point of separation between the main mass and the accessory cotyledons. Following the obliteration of the intervillous spaces the villi of the intervening areas undergo atrophy or fibroid change. Not infrequently the accessory placentas may suffer a similar change from obliteration of the intervillous spaces and appear in the mature placenta as thickened, bloodless areas separated from the main organ (*placenta spuria*). If the placenta becomes divided in similar manner by atrophy or non-development of a portion of the chorion, into two portions of approximately equal size, the phenomenon of an apparently double placenta with one child is presented (*Pl. duplex, dimidiata, bipartita*). Smaller accessory placentas may also be associated with this condition. The cord may be inserted marginally upon one half, or there may be a velamentous insertion between the two halves. It is also possible that a double placenta may be formed by the changes that occur in the placenta following the original implantation of the ovum in one of the uterine horns. Under such conditions the placenta finds proper nourishment for its development upon the anterior and posterior walls of the uterus, but not in the horn itself where the decidua is developed but slightly. As the result of the non-development of the chorion over the poorly developed

Digitized by Microsoft®

decidua of the horn the portions of placenta developing on the anterior and posterior walls become separated from each other and appear as a double organ. According to some writers a double placenta may be formed through a secondary implantation of a placenta reflexa upon the opposite uterine wall; but by the majority of authorities this is considered doubtful. The peculiarities in development of the placenta mentioned above have been regarded as examples of an atavistic reversion to the placental type of some of the lower animals; but it is very likely that they represent the sequelæ of inflammatory conditions of the endometrium, or are secondary to a localized obliteration of the intervillous spaces and atrophy of the chorion analogous to infarct formation. Such atrophy may be due to the fact that the affected portions of the chorion do not find a favorable location for development. The various anomalies of development may have a practical importance, in that portions of the placenta may be retained after delivery; this is particularly likely to occur in the case of double placenta or when accessory placentas are present.

Placenta marginata. This term is applied to the placenta when the chorion læve is given off, not from the edge of the placenta, but from its surface, so that there is produced beyond the attachment of the fœtal membranes an edge or margin which does not stand in direct connection with the main mass of the chorion. From this margin the membranes are easily stripped; its surface is covered with a thick, firm, yellowish fibrin layer which is elevated 1–2 cm. above the general surface of the chorion. On microscopical examination the fibrin ring or margin is found to consist of atrophic and necrotic villi with obliterated blood spaces. Its structure is therefore the same as that of the placental infarct. If, on the inner side of the fibrin ring, there is developed a ring-formed elevation of the chorion, the variety known as the *placenta circumvallata* is produced. Both of these anomalies develop as the result of an abnormal proliferation of the *reflexa* with a subsequent infarction of the same and of the enclosed villi. In this way there is formed on the surface of the placenta a stiff and inelastic ring of fibrin at a time when the placenta has not yet attained its full size. The fibrin ring hinders the peripheral growth of the villi, but these are able to penetrate the decidua outside of the ring, where they give rise to masses of villi lying outside of the firm attachment of the membranes to the placenta. As the result of the formation of the placenta marginata, portions of the membranes are likely to be retained after delivery; and in those cases in which the condition develops very early the growth of the placenta may be so limited that the fœtus will probably be insufficiently nourished and abortion may occur.

The *placenta membranacea* is a rare form in which the organ is thin and flat, and extends over a large surface, either the whole or a large part of the chorion bearing permanent villi. It has been variously explained, but the most plausible theory is that the persistence of the villi over such a large part of the chorion is due to the fact that the villi penetrating the original serotina did not obtain sufficient nourishment. The *placenta membranacea* may give rise to clinical symptoms of *placenta prævia*, hemorrhages, retention, etc. Separation in the case of this form of placenta is much more serious than that of the normal form of organ.

Abnormalities of Site.—The *placenta prævia* is the most important form of abnormal location of the placenta. The placenta may completely cover the os (placenta prævia centralis), or extend into the lower uterine segment without reaching the inner os (placenta prævia lateralis). The etiology of the condition is obscure; and many theories have been offered in explanation. As a result of previous endometritis the cavity of the uterus may become so enlarged that its walls are no longer in contact with each other; so that when the ovum enters the uterus it drops downward and becomes attached to the lower portion of the uterus. In some cases the placenta prævia may be a normally situated placenta, which is so large that it extends into the lower uterine segment. It is also probable that the placenta prævia may owe its origin to a development of a portion of the chorionic villi in the decidua reflexa, instead of those implanted in the serotina. The clinical importance of placenta prævia lies in the fact that in the later months of pregnancy the enlargement of the lower pole of the uterus gives rise to detachment of the placenta with consequent hemorrhage.

Anomalies in the insertion of the cord are not infrequent; the usual attachment is the centre of the organ; not rarely it is eccentric, or even at the margin (*battledore placenta*). When the cord is inserted into the membranes some distance outside of the placental margin the condition is known as *velamentous insertion*. The vessels bifurcate at the point of insertion, their divisions running between the amnion and chorion to the placenta.

Circulatory Changes.—Œdema of the placenta occurs rarely. It is usually associated with general œdema of the fœtus; more rarely with maternal dropsy. Disturbances of fœtal circulation, thrombosis of umbilical or hypogastric arteries, antenatal closure of the foramen ovale, etc., have been regarded as the exciting causes. The placenta of acardiac monsters is usually œdematous. The number of leucocytes in the blood of the fœtus may show a great increase in these cases. The œdematous placenta is larger and heavier than normal, pale, friable, and soft. Microscopically the villi are found to be greatly enlarged and closely packed together; the intervillous spaces are reduced in size and contain but little blood. The stroma of the villi is separated by fluid, the cells being pushed far apart. The fœtus usually dies in utero as the result of the conditions causing the œdema.

Hemorrhage.—True apoplexies of the placenta are rare. They may occur either in the maternal or in the fœtal portion, and are usually the result of inflammatory changes. In the fœtal portion the mass of blood becomes encapsulated by a dense layer of fibrin. The neighboring villi are compressed and become atrophic or necrotic. The nutrition of the fœtus may be impaired and abortion result. Very rarely the hemorrhage may occur upon the surface beneath the amnion, or the blood may burst through the serotina and escape externally. In such cases the fœtus is usually born dead. In some of the reported cases the hemorrhage was regarded as due to a rupture of a branch of the umbilical vein or artery following thrombosis, twisting, or laceration. The causes of these hemorrhages are unknown and their pathology is doubtful. It is probable that some of the cases described were not true placental apoplexies. The small dark red areas frequently seen throughout the placenta, and regarded by many as interstitial hemorrhages, are not true hemorrhages, but represent local congestions of the intervillous spaces. Inasmuch as the blood is contained within the normal blood spaces the condition cannot be considered to be hemorrhage.

Hemorrhage into or from the placenta as the result of trauma or of attempts at abortion are of frequent occurrence. Hemorrhage from partial separation of the organ occurs in placenta prævia. In inflammatory conditions of the maternal portion of the placenta, degenerative changes in the serotina, etc., partial separations of the fœtal placenta may occur. Such hemorrhages are of frequent occurrence in the acute infections, syphilis, nephritis, Basedow's disease, chronic endometritis of gonorrhœal origin, etc. In all these cases the hemorrhage is from the maternal vessels and not from the fœtal. They represent decidual changes rather than placental. The escaped blood fills up the cavity caused by the separation of the chorion or outer layer of the decidua, or may break through the fœtal membranes or escape externally. The serotina may be completely destroyed and a large cavity formed between the muscle of the uterine wall and the placenta. The chorionic villi and fœtus may be compressed; the latter suffering from disturbances of nutrition may die, or may present abnormalities of development.

Retrograde Changes.—As has been mentioned in the articles treating of the pathology of the chorion and decidua, the retrograde changes which are constantly found

Digitized by Microsoft®

in the mature placenta must be regarded as the expression of a physiological decay of the organ. The great majority of the older observations on inflammation, fatty degeneration, amyloid change, etc., were most probably nothing more at foundation than the various appearances produced by the physiological processes of infarction found constantly in the ripe placenta.

www.libtool.com.cn

Atrophy of the placenta may follow extensive hemorrhages, or inflammation, or atrophy of the decidua.

Necrosis.—Simple necrosis of the chorionic villi occurs in placental infarction. An abnormal degree of this change may be caused by nephritis of the mother, by syphilis, tuberculosis, etc.

Placental Infarction (see *Chorion, Pathology of*).

Fatty Degeneration.—The cases described in the literature by Barnes and others were undoubtedly placental infarcts. Fatty degeneration of the chorionic villi is extremely rare except as a sequela of other changes, retained placenta, placental infarction, etc. A small amount of fat is almost constantly present in the normal ripe placenta, and is to be regarded as physiological.

Calcification within certain limits is almost constantly found in the mature placenta, and is to be regarded as physiological. Only in marked degree is it of pathological significance. In the latter case it follows excessive infarction, fatty degeneration, etc., in nephritis, syphilis, acute infections, etc.

Amyloid has been described as occurring in the placenta; but the appearances taken for amyloid were probably those of infarcted areas.

Myxomatous degeneration of the stroma of the chorionic villi occurs in retained placentas and in hydatid moles.

Pigmentation.—Deposits of blood pigment may be found in both the normal and the diseased placenta, resulting from the disintegration of red blood cells contained in the clots found between the villi. Rarely this pigment may be taken up by the villi and be found deposited in the stroma of the latter.

Hyaline degeneration of the villi occurs to a certain extent in the ripe placenta as an evidence of physiological atrophy. When it occurs prematurely, or to a marked degree, it is to be regarded as of pathological significance. It may follow the changes produced in the villi by the acute infections and certain intoxications, but is most often due to syphilis.

Hypertrophy.—An enlargement of the placenta may be due to œdema or degenerative conditions of the villi. Fibrous hyperplasia occurs in syphilis, nephritis, etc. A true hypertrophy—that is, an enlargement of the organ with preservation of normal structure—is of rare occurrence in association with abnormal development of the fœtus.

Inflammation (see *Chorion, Pathology of*).

Tuberculosis of the placenta has been described but a few times (Lehmann, Schmorl, and Kockel, Auché and Chambrelente, Warthin). It is not improbable that the disease is of more frequent occurrence than the few published reports would indicate. Inasmuch as there are no gross changes in the placenta by which the condition can be recognized without microscopical examination, it is probable that cases escape diagnosis. In all cases of maternal tuberculosis of advanced degree, in miliary tuberculosis, and in all cases of maternal tuberculosis in which the tubercle bacilli gain entrance to the blood, the bacilli will undoubtedly be found in the blood contained within the intervillous spaces. The conditions would therefore favor the development of tubercles in this location. On the other hand, it may be argued that the syncytium and fœtal tissues possess a certain degree of immunity toward the tubercle bacillus. This view is supported by the fact that in placental tuberculosis large masses of fibrin containing great numbers of tubercle bacilli may be found resting upon an apparently normal syncytium; and in a case seen by the writer the syncytium had even grown around and enclosed such a fibrin mass containing tubercle bacilli.

Syphilis may affect either the fœtal or the maternal portion of the placenta. In both cases the changes are those of inflammation and premature degeneration. Gummatous proliferations have been observed in the serotina; but it is not improbable that some of the changes described as such were in reality fibrin masses and not gummata. The most characteristic and constant change in the placenta due to syphilis is that which occurs when the infection takes place at the time of conception or during the early stages of pregnancy. In such cases the chorionic villi not infrequently show a fibroblastic proliferation (interstitial placentitis) of the villus stroma with resulting obliteration of the chorionic vessels. If the fœtus survives, the affected villi undergo a fibroid change. In the great majority of cases, however, the condition results in abortion. Infection during the later months may produce little change in the placenta; or the physiological phenomena of obliteration of the chorionic vessels and infarction may be much more extensive than normally. The interstitial placentitis occurring in the early months of pregnancy is characteristic of syphilitic infection only in the involvement of large areas. A similar change is also found in the neighborhood of placental tubercles.

Gonorrhœal placentitis has been regarded clinically as a cause of abortion. Two cases have been reported in which the gonococcus was found; but neither the bacteriology nor the pathology was established beyond a doubt. The etiological rôle of the gonococcus has, however, been clearly shown in cases of interstitial decidual endometritis.

Placental adhesions with the uterine wall are of much more rare occurrence than is usually believed. In rare cases the serotina may fail of development and the chorionic villi penetrate directly into the uterine wall. In cases of decidual endometritis fibrous connective tissue may develop in the serotina and give rise to firm connections between uterus and placenta. As a result of such adhesions portions of the placenta may be retained, and this may lead to severe hemorrhages or to secondary infection. Putrefactive processes may take place in such retained placental tissue, as well as in that retained after abortion.

Detachments of the margin of the placenta of slight degree are relatively frequent, and possess no significance. Their occurrence is revealed by masses of fibrin or blood clot lying between the decidua vera and the reflexa. More extensive detachments may endanger the life of both mother and fœtus. Such detachments are usually associated with hemorrhage; the blood may collect in the space formed by separation of the placenta from the serotina or burrow between the layers of decidua and escape externally. In rare cases the blood may rupture into the amniotic cavity. Only exceptionally, when the detachment occurs in the central part of the placenta while the edges remain attached, is the hemorrhage unimportant. In such cases death of the fœtus occurs, however, as the result of disturbed nutrition. The detachment of the placenta during birth is of rare occurrence. Such premature loosening of the organ is due to sudden diminution in the volume of the uterus following the loss of large amounts of amniotic fluid. The weight of the placenta causes it to descend into the lower segment of the uterus, where it may present before the fœtus, and may be expelled first. In such cases the child is usually lost.

Changes in the Placenta after Intra-uterine Death of the Fœtus or Abortion.—After death of the fœtus in the early weeks of pregnancy the retained chorion may continue to grow. Hemorrhages occur repeatedly, forming thick layers of blood clot, which gradually loosen the placenta remains. These together with the blood clot are discharged as a *fibrin* or *fleshy mole*. A deposit of calcium salts in the fibrin mass gives rise to a *stone mole*; myxomatous or hydropic degeneration of the stroma of the villi to a *hydatid* or *grape mole* (see *Chorion, Pathology of*). Through continued growth of the villi with successive deposits of fibrin, polypoid tumors (*placental polyps*) may be formed. These may be discharged spontaneously or may become gangrenous or purulent as the result of in-

Digitized by Microsoft®

fection. A penetration of the uterine wall by proliferating villi gives rise to the condition known as *malignant* or *destructive placental polyp* (see *Syncytioma*).

Placental Cysts.—Cystic formations have been frequently described as occurring in the placenta. The majority of these are probably degeneration cysts, arising either from a myxomatous or hydropic degeneration of the stroma of portions of the chorion, or from the liquefaction of areas of infarction. Less frequently small cysts may arise in the placenta as the result of the liquefaction of small encapsulated hemorrhages. The cysts arising from the degeneration of infarcted areas may reach a very large size, and in rare cases may be mistaken for a second amniotic sac. They are found usually on the fœtal side, beneath the connective tissue of the chorion. Their walls are lined by large epithelioid cells, in part syncytial and in part decidual. Small cysts lined with epithelial cells (so-called dermoids) have been observed in the placenta. These have been interpreted as representing remains of the allantois.

Tumors.—New growths of the placenta belonging to the connective-tissue group are extremely rare. Alin collected twenty-three cases from the literature, and twenty additional cases have been reported up to 1902. The diagnoses given were myxofibroma, fibroma, angioma, fibromyoma, and sarcoma. The majority of these cases are very doubtful. The so-called myxoma fibrosum is the most common form; it is found usually on the fœtal surface, and is rarely embedded in the placental mass, and still more rarely it reaches the maternal side. These growths present a varied appearance, but are usually encapsulated, firm, and homogeneous on section. Microscopically they show an alveolar structure, the tissue resembling that of the umbilical cord, sometimes very rich in cells, at other times containing but few. It is very doubtful indeed if these formations are to be regarded as true neoplasms.

Of much more frequent occurrence are the growths arising from the syncytium, the *benign chorio-epithelioma* or *hydatid mole*, and the malignant chorio-epithelioma (*syncytioma malignum*). (See *Syncytioma*, and *Chorion, Pathology of the*.) Such growths arise from retained chorion after abortion or delivery, usually after the former during the early weeks of pregnancy. From the decidual cells a sarcoma may arise (*sarcoma deciduocellulare*). Confusion, however, exists with regard to this variety; in many cases syncytioma has undoubtedly been regarded as a sarcoma of decidual origin. (See also *Chorion, Pathology of*, and *Decidua, Pathology of*; and *Syncytioma*.) *Aldred Scott Warthin.*

PLACENTA PRÆVIA. CLINICAL.—When the placenta is attached in whole or in part to that portion of the uterus which is dilated during labor for the passage of the child, it is called "prævia."

Dr. Robert Barnes, in a paper read by him in 1892 before the International Congress of Diseases of Women and Obstetrics in Brussels, divided the uterus into three zones—the fundal or superior zone, the equatorial zone, and the inferior zone. The inferior zone is separated from the equatorial by Barnes' boundary line, which has also been called the "internal os of Braune," the "ring of Bandl" and "Schroeder's contraction ring." It is this inferior zone which is dilated during labor for the passage of the child.

Varieties of Placenta Prævia.—Some writers make four divisions of placenta prævia:

1. Lateral, in which the placenta is attached toward the upper part of the inferior zone.

2. Marginal, in which the placental edge comes down to, but does not cover, the internal os.

3. Partial, in which the internal os is partially covered by the edge of the placenta. And

4. Complete, in which the internal os is completely covered by the placenta.

The nomenclature of Schroeder, Bodin, Parvin, and others who make but two divisions is more practical and less confusing. They condense the first three varieties under one head, lateral placenta prævia, which includes all cases not complete. Lateral placenta prævia occurs more frequently than complete, probably in the ratio of two or three to one.

Frequency.—Placenta prævia occurs about once in one thousand cases of labor, though the figures as to its relative frequency are widely divergent. Thus, Winckel gives 1 to 1,500; Kaltenbach, 1 to 1,500 or 1,600; Jewett, 1 to 1,000; while Townsend, at the Boston Lying-In Hospital, found 1 case in 239 labors, and White, at the New York Lying-In Hospital, reports a frequency of 1 to 322. These latter figures, however, are much higher than is usually found, as a great many abnormal cases are referred to lying-in hospitals by midwives and physicians.

Etiology.—The cause of the faulty attachment is still unknown. Predisposing causes are endometritis, relaxation of the uterine walls, anomalies of the uterus, as uterus bicornis and unicornis. Ingleby reported two cases in which there was a low opening of the oviducts. Webster says: "Three different sets of conditions explain the occurrence of placenta prævia: 1. Low implantation of the ovum. 2. Development of chorionic villi on the decidua reflexa, forming a reflexal placenta. 3. Low implantation of the ovum with a reflexal placenta."

Complications.—Faulty presentations are common, owing to the placenta filling the lower zone of the uterus which is usually occupied by the presenting part.

Anomalies of the placenta are frequently found in conjunction with the faulty attachment. It is usually thinner and spread out over a larger area than that occupied by the normally attached placenta; it is apt to be irregular in form, and "placenta succenturiata" is not uncommon. There are frequently abnormal adhesions between the placenta and the uterine wall.

Prognosis.—This is one of the gravest of the complications of pregnancy. The more nearly completely the internal os is covered and the earlier the hemorrhage the greater the danger to both mother and child. The prognosis is affected by the time at which the case is first seen and by the skill of the operator. The figures for maternal mortality range from five or ten per cent. (Winckel) to twenty-three per cent. From fifty to seventy per cent. of the children are lost. Lateral placenta prævia is less dangerous than complete.

Symptoms.—The cardinal symptom of placenta prævia is hemorrhage. This may occur at any time after the formation of the placenta, but is rare before the twenty-eighth week. In the complete variety it occurs earlier and is more profuse than in the lateral. Winckel states that the first hemorrhage in lateral placenta prævia occurs usually after the thirty-second week; in complete, between the twenty-eighth and the thirty-second. Hemorrhage occurring in the latter months of pregnancy without obvious cause is strong presumptive evidence of the presence of a prævial placenta. The diagnosis can be made certain only by feeling the placenta through the os with the examining finger. Before the os is sufficiently dilated to admit the passage of the finger, the failure to find the placenta by abdominal palpation, a faulty presentation of the fœtus, and on vaginal examination inability to recognize the presenting part through the vaginal vault and uterine wall, are suggestive symptoms.

The first hemorrhage, if it occurs before labor, comes on without warning. It may be profuse, or there may be only a slight flow which ceases spontaneously, to recur after a few hours or days. Rarely it is so profuse as to cause death. Sometimes there is constant oozing.

Treatment.—The treatment to be adopted depends on the period of pregnancy at which hemorrhage occurs, the extent of the bleeding, and the ability to control it by simple measures.

When the first hemorrhage occurs before the child is viable, when it is slight and controlled by rest in bed, if there are no contractions of the uterus, we are justified in temporizing, in the hope of getting a living child.

Digitized by Microsoft®

Such a course being determined upon, the patient should be kept in bed and as quiet as possible until labor comes on spontaneously or is induced with the expectation of delivering a living child. She should be meanwhile on a nutritious and non-stimulating diet, and should be watched with unremitting care for a recurrence of the bleeding.

www.libtool.com.cn

Should, now, the hemorrhage be profuse, whether labor be present or not, there is no condition of pregnancy in which danger to life is more imminent or in which judicious interference is more essential. We have before us then the problem of how best (1) to check the hemorrhage, (2) to expedite labor. No single method of treatment can apply to all cases.

Should the hemorrhage occur first after the onset of labor, with lateral implantation of the placenta and a normal presentation, if the os is fully dilated or easily dilatable, simply rupturing the membranes and allowing the presenting part to engage will often stop the hemorrhage. Should this fail to check the bleeding, the head may be brought down with the forceps, or, if the breech present, a foot may be grasped and the os plugged with the thigh and buttocks. Should the presentation be a transverse one, podalic version is indicated.

When, on the other hand, we have a brisk hemorrhage coming on during pregnancy or labor, with a rigid os barely admitting one finger, rupture of the membranes would be a very doubtful procedure. In such a case most obstetricians advise the use of the tampon. To be of use, it must be applied with thoroughness and care, and, needless to say, with all aseptic precautions. The best material with which to tampon is gauze. It may be either sterile or medicated, and should be folded in strips about one inch wide and two or three yards long. A Sims speculum of large size facilitates its introduction. The patient should be placed on her side or in the lithotomy position. The cervix should first be plugged if possible, and then the vagina should be firmly packed throughout, the tighter the better. We accomplish two things by this procedure: check the hemorrhage and stimulate uterine contraction. The tampon may be left in place, provided there is no oozing through or alongside it, until the cervix is fully dilated or is easily dilatable. It should be remembered that the tampon is simply a preparatory measure. Its usefulness ceases with dilatation of the os. Some physicians allow it to remain until it is expelled by the advancing head. It is better not to allow it to remain for a longer time than ten or twelve hours, should no indication arise for its removal sooner. When it is removed, if the cervix is found to be dilated or nearly so, and the presenting part shows a tendency to engage, the membranes should be ruptured and the labor terminated by forceps or version. Should the cervix be partially dilated—two fingers or more—we have to choose between the use of some of the rubber dilators, such as Barnes' bags, the *ballon* of Champetier de Ribes, Braune's colpeurynter, etc., and version, either external, or the combined external and internal or bipolar version of Braxton Hicks.

Of the rubber dilators, the *ballon* of Champetier de Ribes is probably the best. Its conical form and moderate elasticity adapt it thoroughly to the purpose of a uterine dilator, and acting from within it closely simulates the action of the membranes in normal cases. It is urged against it that it sometimes fails to stop hemorrhage, that it adds to the danger of sepsis, and that it displaces the presenting part. It is applicable to the same class of cases as bipolar version, over which it has the advantages that it can be applied without anæsthesia and that it takes less time. But, like the tampon, its use is only a preparatory measure, and its expulsion or extraction must be followed in most cases by the use of the forceps or version.

External version is practicable only before the presenting part sinks into the pelvis and before rupture of the membranes occurs. As soon as it is accomplished the membranes should be ruptured, a foot brought down, and the os plugged with the thigh and buttocks. There is little danger of concealed hemorrhage, as the presenting breech makes firm pressure on the placental site.

The conditions necessary for the performance of bipolar version are: that the liquor amnii should be present, that the cervix should admit two fingers, and that the vagina should admit the rest of the hand if necessary. The operator should use, in the vagina, the hand corresponding to the position, *i.e.*, the left hand in left positions, and the right hand in right. Two fingers are slipped up through the cervix and push the head to that side upon which the dorsal plane lies, while with the other hand the breech is pushed to the opposite side. As soon as the head is pushed up out of the pelvis, the breech is crowded down with the outside hand upon the fingers inside the cervix, and a knee is grasped and brought down. The version is completed by drawing down the leg into the vagina, while the head goes up into the fundus, and the breech engages. The advantages of bipolar version over internal version are that it can be done earlier and that in bipolar version only two fingers enter the uterine cavity, thus causing less shock and less danger of sepsis.

Internal version, or ordinary podalic version, is one of the oldest and, when it is applicable, one of the best of the methods of treating placenta prævia. When there has been little blood lost in the earlier part of labor, when the os is fully dilated or is soft and sufficiently dilated to admit the hand, it is the most practical and direct method of effecting delivery. The hand and arm, during their introduction into the uterus, make pressure upon the bleeding surfaces, and thus check the hemorrhage, while, later on, the same office is performed by the thigh and breech of the child.

Whatever the method of version, after the foot is brought down and the os is plugged by the thigh, the further delivery may be left to the natural forces, provided there is no imperative indication for rapid extraction.

When the hemorrhage continues after the birth of the child, the placenta should be extracted manually at once, and the uterine cavity packed with sterile gauze, if necessary.

There is another class of cases in which the cervix is rigid and undilated, in which the tampon fails to stop the hemorrhage, or in which if the hemorrhage is checked the cervix fails to dilate and recurrence of the hemorrhage is imminent. In such a case, when the surroundings are not prohibitive, Cæsarean section would seem to offer much. With the improved technique of recent years, the mortality after this operation has steadily fallen, and as between it and "accouchement forcé"—by which is meant forcible manual dilatation of a rigid and oftentimes friable os, followed by internal version and delivery—Cæsarean section in competent hands should give a lesser mortality. *Richard Ewell Brown.*

PLAGUE, THE. See *Bubonic Plague*.

PLANTAIN—Codex Med. The flowering plant of *Plantago major* L., *P. media* L., and *P. lanceolata* L., three common European weeds, of which the first and last have made themselves pretty well at home in our fields and door-yards. They are very slightly acrid and bitter, somewhat astringent, and quite mucilaginous; containing a little of some sort of *tannin*, some *resin*, some "*bitter extractive*," and considerable *mucilage*, but no more active substances. They are almost obsolete as medicines, but were formerly esteemed as astringents, hæmostatics, and even antispasmodics, and were used locally in leucorrhœa, hemorrhoids, conjunctivitis, and scrofulous eruptions.

The order *Plantaginaceæ* is a large one of several hundred species, but none having active properties. The seeds of one, *P. Psyllium* L., have an abundant mucilage, like that of flaxseed, and are employed in the arts for sizing cloths, etc., and occasionally in medicine as collyria or demulcent washes. *W. P. Bolles.*

PLASMA CELLS.—In 1891 Unna described the elements which he called "plasma cells," believing them to correspond with certain granular connective-tissue cells to which Waldeyer had previously given the same name. Later studies indicated that the two were not identical, and Waldeyer advised the restriction of the term "plasma cell" to that of Unna, thinking that the structures named by himself (Waldeyer) corresponded, at least in large part, with the "mast cells" of Ehrlich. Various papers on plasma cells have appeared since Unna's earlier publications, while their nature and properties have been the subject of numerous discussions, often lengthy and occasionally acrimonious. From this it appears that our knowledge of them is still far from definite. There is even some difference of opinion as to what a plasma cell is in fact. It has received its name on account of having *protoplasm* that may be stained by basic aniline dyes. This property is by no means peculiar to it, however, and is shared by several other varieties of cells; for instance, ganglion cells, lymphocytes, osteoblasts, certain giant cells, and mast cells. (In the case of mast cells, large granules contained in the body of the cell are the part stained, and they assume a different shade of color from that of the pure stain itself—metachromism.)

MORPHOLOGY.—With Unna's polychrome methylene blue (described hereafter) the protoplasm of the plasma cells is stained blue-violet, while the nuclei become blue. The outer part of the protoplasm stains more deeply than the inner part, leaving a pale zone around the nucleus. The nucleus is round or oval, and is usually placed eccentrically. Five to eight deeply stained masses of chromatin occur in the nucleus, chiefly around its border. Some observers have described a nucleolus. Two or more nuclei are occasionally present. In size the plasma cells vary from being of the dimensions of a leucocyte to objects of a much larger size—average diameters, 6 to 7 μ by 8 to 10 μ. In shape they are round, oval, roughly cubical, or elongated, according to whether or not they are confined by connective-tissue fibres or by the pressure of other cells. Evidences of both mitotic and amitotic division have been witnessed in plasma cells.

The above account is, in all essential respects, in accord with the views of von Marschalkó, which have been adopted by the majority of workers. It differs somewhat from the one originally given by Unna. According to Unna, the plasma cells have protoplasm that contains numerous granules capable of being stained. Such granules have not been seen by most other observers. It is not uncommon, however, to find plasma cells whose protoplasm is not homogeneous, but which contain small clumps and particles that stain unequally and irregularly. Cells having the metachromatic granules characteristic of mast cells, but otherwise like ordinary plasma cells, have been seen—plasma mast cells. These are unusual. Furthermore, according to Unna, the nuclei of plasma cells give up their stain much more easily than does the protoplasm, and in a preparation properly made the nuclei appear as unstained spots. Some have even maintained that two kinds of plasma cells exist, those of Unna and those of von Marschalkó. However, it is certain that the staining of the nucleus depends much on the technique employed.

OCCURRENCE.—Although they were at first supposed to belong only to pathological conditions, plasma cells have been reported as occurring in lymph nodes, in the lymphoid tissues of the spleen, and in the bone marrow, both in man and in the lower animals, in ligaments, in the framework of mucous glands of the tongue, and in the mucosa of the stomach and intestine in man. Information as to their distribution in normal tissues is not very full or exact.

On the other hand, so much has been written on their occurrence in diseased conditions that a mere enumeration of these conditions is impracticable. Unna's first accounts of plasma cells were based on sections of lupus. He directed attention to tumor-like collections of these cells. Such a collection he called a "plasmoma." It has since been learned that plasma cells are abundant in the lesions of tuberculosis wherever situated, in those of syphilis, leprosy, actinomycosis, and rhinoscleroma—*i.e.*, the so-called "infectious granulomata." They are also frequently seen in the stroma of carcinoma. In the main they are characteristic of rather chronic processes, where they constitute an important part of what is often termed round-cell infiltration. They are said to collect especially around small arteries. Their relations with the epithelioid cells of granulation tissue are in dispute. In acute inflammatory conditions, and especially in acute suppuration, they appear in smaller numbers. Plasma cells have, however, been demonstrated in acute inflammatory lesions, bacterial or otherwise, in keratitis in the rabbit, in recent granulating wounds in man and in the dog, in the lesions of typhoid fever, in the cell infiltration of acute interstitial nephritis, and in the stroma of the lung and even in the exudate late in lobar pneumonia. Further work is needed on their relations to the cells of sarcomata, and it may possibly yield information of use in diagnosis. The study of the plasma cells in diseases of the skin has been carried on by Unna with great energy; the results may be found in his "Histopathology of the Skin."

ORIGIN AND FUNCTIONS.—Unna held that the plasma cells were derived from connective-tissue cells, stating that he was able to detect all the necessary transitional forms between the two. This theory has obtained a few adherents. Most observers, however, believe that plasma cells are derived from the lymphocytes, and chiefly from the small lymphocytes. It is claimed by some, furthermore, that plasma cells may become connective-tissue cells and thus aid in the formation of fibrous tissue. This latter hypothesis would make the production of connective tissue from lymphocytes possible under certain circumstances, the plasma cells being an intermediate stage. It would modify existing ideas considerably and convincing proofs will be demanded before it can be accepted.

Some writers take a middle ground, believing that the plasma cells come in part from lymphocytes and in part from connective-tissue cells.

The functions of plasma cells in other respects are equally uncertain. It is to be noted that they are not distinctive of any particular disease or class of diseases. Their relative absence in acute suppuration is remarkable. According to Councilman and Mallory, they have the power of ameboid movement, they may occur inside the blood-vessels, and may be seen in the act of emigrating from the blood-vessels. It is doubtful if they possess phagocytic properties, and if so these are probably not energetic.

Other ideas that have been proposed as to their functions are purely speculative. It has been suggested that their peculiar staining property is the expression of diminished activity or degenerative changes, that it indicates an increase of activity, that it is due to their having taken up chromatin from other and degenerated cells, that they have some protective function, and that they serve to eliminate some unknown substance.

TECHNIQUE.—Fixation of tissues may be secured with alcohol, corrosive sublimate, Zenker's fluid, formaldehyde, or Müller-formol. Either paraffin or celloidin embedding may be used. Various methods for staining plasma cells have been proposed. Unna's alkaline or polychrome methylene blue gives satisfactory results; thionin or toluidin blue serves equally well. The plasma cells may sometimes be stained with hæmatoxylin. The following formula, which is one of many given by Unna, will be found serviceable: Methylene blue, 1 part; potassium carbonate, 1 part; distilled water, 100 parts. The solution must stand for periods varying from weeks to months before it is fit for use.

Stain in the methylene blue solution, which may or may not be diluted, fifteen minutes or longer. The sections will be overstained.

Rinse in water.

www.libtool.com.cn
Digitized by Microsoft®

Decolorize in water to which a few drops of "glycerin-ether" have been added, for a quarter of a minute or several minutes, as required, till differentiation of the structure begins to appear (one-per-cent. acetic acid, or alcohol alone serves nearly as well).

Rinse in water.

www.libtool.com.cn

Complete the decolorization with alcohol.

Clear in oil of bergamot or xylol.

By this process the plasma cells are stained blue-violet, their nuclei and other nuclei and bacteria blue, the granules of mast cells violet to red. Epithelial cells take the blue stain, sometimes intensely, especially the horny layers of the epidermis; giant cells are frequently stained as well: also the products of certain degenerations, as amyloid and mucoid, which may show varying degrees of metachromism. *Herbert U. Williams.*

PLASMODIUM MALARIÆ.—The protozoan parasite which Laveran discovered in 1880 was designated by Marchiafava and Celli Plasmodium malariæ. The organism which is classified with the sporozoa has little resemblance to the multinucleated amœboid bodies to which the term plasmodium has been given by zoologists; but even though unsuitable the binomial name, in virtue of its priority, is applicable to the species to which it was originally given. Observations inaugurated by Golgi have shown the existence of three readily distinguishable varieties of parasite, each of which is capable of producing malarial fever. The organism discovered by Laveran and later studied by Marchiafava and Celli is the æstivo-autumnal parasite which causes the most severe type of intermittent fever, characterized by irregular periodicity and occurring most commonly during the late summer and fall. That type of malarial fever which recurs at regular intervals of two days is caused by a closely related parasite which, nevertheless, presents such well-marked peculiarities that it is usually regarded as a distinct species. A third parasite causes the quartan type of malarial fever, distinguished by paroxysms recurring at intervals of three days. If, in accordance with the opinion of a few observers, it should be shown that the three parasites associated with these various types of fever are varieties of a single species, the name Plasmodium malariæ is applicable to this variable organism. In the present article, however, the organisms associated with tertian, quartan, and æstivo-autumnal malaria will be described as separate species.

The parasites of the malarial fevers multiply within the red blood corpuscles of their human host. Recent research has demonstrated that they are capable of development within the body of certain suctorial insects, which have fed upon the blood of an individual suffering with malarial fever. A second individual is infected by the bite of such an insect, which thus acts as an intermediary host.

Geographical Distribution of the Malarial Parasite.—The general and local conditions which favor the occurrence and spread of malaria are such as conduce to the extracorporeal existence of the parasite. The presence of mosquitos capable of transmitting the organism is essential to the endemic occurrence of the disease, so that the geographical distribution of malaria is in great part dependent upon factors which aid the multiplication of certain species of mosquitos.

In Africa, malaria prevails in its most pernicious form on the west coast, especially in the neighborhood of the Congo and Niger rivers. South of the Congo malarial fevers become infrequent and disappear in the most southern part of the continent. Upper Egypt is free from the disease, which occurs with great severity elsewhere upon the Mediterranean coast.

In Asia malaria is prevalent upon the coast of Asia Minor, Arabia, and near the Persian Gulf. Endemic malaria abounds not only in the basins of the Indus and of the Ganges, but upon the tableland of the Deccan. In many of the East India islands severe malaria prevails, but in the Philippine Islands, though the disease is widely distributed, it is not particularly severe. Pernicious malaria occurs in places near the coast and along the rivers of China, but in Japan the disease is mild and infrequent. Of interest is the almost complete immunity enjoyed by Australia, New Zealand, and the islands of the Pacific.

In Europe malaria prevails in the southern part of Russia, particularly upon the shores of the Black and of the Caspian seas, along the shores of the Danube, and upon the peninsulas bordering the Mediterranean Sea. In Italy well-known seats of endemic infection are the plains and marshes of the western coast, including the Roman Campagna and the Pontine marshes. Here the disease is so prevalent that it has been designated Roman fever, and its frequency and severity in Italy have stimulated much of the investigation which, since the discovery of the malarial parasites, has explained the complicated life history of these organisms. Northern Europe, including the British Isles, is in great part free from malaria, though there is evidence that at an earlier period, particularly in England and in Denmark, it has occurred with severity in regions where it is now almost wholly absent.

In the West Indies, along the northern and eastern coasts of tropical South America, and in Central America malaria exists in its worst form. The disease is common in the southern part of the United States near the Gulf of Mexico and along the Mississippi and its tributaries. It occurs near the Atlantic coast with gradually diminished severity as far north as New York. Elsewhere are a few scattered localities where the disease is of mild type.

Malaria is pre-eminently a disease of tropical and subtropical countries, but prevails with diminished severity in many parts of the temperate zone. It is endemic in certain localities, particularly near the mouths and along the banks of rivers. In such localities are found the pernicious types of fever caused by the æstivo-autumnal parasite, while where the disease is less prevalent milder types, the regularly intermittent tertian and quartan fevers, are more common.

Conditions which Favor the Occurrence of Malaria.—The influence of temperature upon the occurrence of the malarial fevers is well illustrated by the preceding account of its distribution. In the endemic foci of the tropical and subtropical countries where malaria occurs in its severest form the disease prevails throughout the year. In the temperate zone as the poles are approached its frequency and severity progressively diminish with the temperature, and, according to Hirsch, malarial fever does not occur in localities where the mean summer temperature is below 15° or 16° C. Even in tropical countries its prevalence increases during the summer and reaches a maximum about the beginning of autumn. In temperate regions the disease may be limited to the warmer months of the year. The incidence of the disease in Baltimore, as described by Thayer, illustrates this condition. During January and February malarial fevers are almost absent, but the gradually increasing number of cases which occur during the spring and early summer are of the milder tertian and quartan type. Double tertian and triple quartan infections occur later in the summer, and the æstivo-autumnal parasite makes its appearance. Cases of æstivo-autumnal infection now increasing in number form a very large proportion of those which occur during September and October, and then,

Digitized by Microsoft®

gradually diminishing in number, finally disappear completely during the winter.

Conformation of the soil and its saturation with water have an importance little inferior to that of heat in determining the local incidence of malaria. Standing water associated with a warm climate is always suggestive of a malarious region, and the name paludal or marsh fever illustrates the well recognized relationship between the disease and marshy regions. The geological character of the soil does not influence directly the occurrence of malaria, but is of importance only in so far as it determines the saturation of the ground. Hence a clay soil is favorable to the disease, while a more porous, chalky, or sandy soil is less able to retain water; an impervious subsoil is especially capable of fulfilling this condition.

www.libtool.com.cn

Since saturation of the soil has such an important influence upon the existence of the disease, the most malarious regions are the low lying coasts and the marshy banks of rivers and lakes. Land which is submerged during a part of the year is believed to be particularly subject to endemic infection. The amount of rainfall has an important influence, and in tropical regions the disease usually reaches a maximum about the end of the rainy season.

Altitude, with its influence upon drainage and upon temperature, affects the local occurrence of malaria so that the severity of the disease tends to diminish as one ascends above the sea level. Nevertheless, severe malaria may be endemic upon high plateaus and even in mountainous regions, but here, according to Hirsch, it is the basin like depressions that are most markedly infected.

Cultivation and drainage of malarial regions have in numberless instances been followed by the disappearance of the disease, but occasionally an opposite result is produced and epidemics of severe malaria have followed the clearing of such lands. Moreover, outbreaks or exacerbations of the disease have followed extensive excavations of soil in making canals, railroads, and fortifications but careful examination of the attendant circumstances have not infrequently shown that such disturbances have in various ways interfered with surface drainage.

Recent observations having shown that the malarial parasites pass a part of their life within the body of the mosquito, it has become obvious that the previously described conditions under which the disease occurs are such as favor the multiplication of these insects. Since the development of the larval mosquito occurs in stagnant water, poorly drained lowlands and marshes afford most suitable conditions, and heat and abundant atmospheric moisture are favoring circumstances. No malarious region has been found to be free from these insects, but on the other hand it is not surprising that malaria does not always occur where mosquitos abound, for in the first place, as will be pointed out later, only mosquitos of the genus Anopheles have been found to transmit the disease; and in the second place, the malarial parasite may not have found its way into a locality where mosquitos of this genus prevail. A correspondence exists between the habits of the mosquito and the seasonal incidence of the disease in temperate climates. With the beginning of winter many mosquitos are killed while a few hibernate. In the spring those that survive lay their eggs upon stagnant ponds and continue to multiply during the warm season. Marchiafava and Bignami state that during the fall mosquitos, many of which are infected, seek shelter within the houses, thus explaining the frequency of infection at this time and the occasional occurrence of house epidemics.

Even should mosquitos of the genus Anopheles and malarial parasites coexist in the same locality, external conditions will determine the prevalence of the disease. Investigations of the Italian observers have shown that the parasites within the mosquito develop best at a temperature between 20° and 30° C., but at 14° to 15° C. development does not occur. This fact accords with the observation previously mentioned, that malarial fever does not occur as one passes from the equator beyond an isotherm at which the mean summer temperature is below 15° to 16° C. (59° to 60.8° Fahr.).

Method by which the Malarial Parasite Enters the Body.—Before the discovery of the malarial parasite, two theories explaining the mode of malarial infection were much discussed. It was believed that the contagium causing the disease entered by one of two possible paths; either (1) by the digestive tract, being ingested with water, in which the infectious agent was thought to have its natural habitat; or (2) by the respiratory tract, being breathed in with the air.

Clinical evidence has been adduced to show that the disease is a water-borne infection. Supporters of this theory cited instances in which, of two neighboring communities, each using a different water supply, one was subject to malarial fever while the other escaped. It was believed that boiling of drinking-water was an efficient prophylactic measure. Such claims are found to have been based upon insufficient evidence, and in individual instances the difficulties of diagnosis between typhoid and malarial fevers were not clearly recognized. In recent years Italian observers have attempted to infect individuals with drinking-water obtained from localities well known to be malarious. Celli failed to infect individuals in Rome by the repeated administration of water brought from the Pontine marshes, and Zeri obtained similar results in a considerable number of experiments in which water from malarious regions was administered in large quantity to healthy subjects.

Certain clinical facts favor the alternate theory of air infection; for example, the well-known danger of infection after exposure to the night air in a malarious district may be cited. The contagium was believed to have its home in the water and in the soil of marshy malarious districts, whence it found its way into the air and was inspired by those exposed. Since the discovery of the malarial parasites numerous efforts to discover some phase of these micro organisms in water or in the soil have proved futile, while the hypothetical means by which such bodies might reach the overlying air was difficult to conceive. Moreover, certain well-known facts are incompatible with this theory; for example, prevailing winds have little influence upon the spread of infection from an endemic focus, and the fact is frequently cited that upon vessels anchored off a malarial coast only those individuals become infected whose duties carry them ashore. This theory of air infection, unsupported by any convincing evidence, is now abandoned since accumulating evidence has demonstrated that the malarial parasite is transferred from one individual to another by a suctorial insect, within which the micro-organism passes one stage in its life history.

Manson, in 1878, showed that Filaria bancrofti is carried from one human host to a second by the mosquito; Theobald Smith has shown that Texas fever of cattle is inoculated by a species of tic. These important discoveries have pointed the way to a clear recognition of the method by which the malarial parasites enter the human body and have helped to explain its life history outside. The solution of these difficult problems has received much aid from the studies of parasites which, occurring within the red blood corpuscles of birds, are so closely related to the malarial parasites that by some observers they have been regarded, doubtless erroneously, as identical species.

The possibility that malaria might be transmitted by the mosquito had been suggested long before the malarial parasites were discovered and the fact had been recognized that localities and conditions favorable to the disease are such as further the multiplication of this insect. Manson, in 1896, brought this theory into prominence. Bignami subsequently published a considerable amount of evidence to show that malarial infection occurs under conditions which favor the attack of mosquitos. When the wind blows on the Roman Campagna, he says, mosquitos hide close to the ground or beneath the trees and are transported little if at all from the locality in which

Digitized by Microsoft®

their larvæ develop. When the wind goes down at sunset, the insects rise in great numbers and attack men and beasts. The well-recognized danger of infection during the night is due to the nocturnal habits of the mosquito and is increased by sleeping in the open air. Many of the precautions which are taken by the inhabitants of malarious districts to ward off the fever are such as protect them from the attacks of insects. On the Pontine marshes relative protection is afforded by elevating dwellings on platforms six or eight feet high, for the insect tends to fly close to the ground.

www.libtool.com.cn

Ross, working in India, has shown that the parasite of birds which is closely related to the malarial organism undergoes a series of developmental changes within the body of the mosquito, and subsequently found that mosquitos which had bitten infected birds were capable of transmitting the parasite to others which repeated examination had proved to be healthy.

Grassi, in 1898, undertook a laborious investigation of the species of mosquitos found in malarious regions of Italy, and came to the conclusion that certain species are constantly present in districts of endemic infection. Where malaria prevails Anopheles claviger and other species of the genus Anopheles are abundant, while in non-malarial regions, though species of the genus Culex abound, he found the genus Anopheles unrepresented.

Direct proof of the agency of suctorial insects was finally brought by experiments of other Italian observers. Bignami brought to Rome mosquitos belonging to the genera Culex and Anopheles, obtained from a marshy region characterized by the severity of its malarial fever. An individual who had never suffered with malaria slept in the room in which these insects were liberated, and was exposed to their attack during more than a month. At the end of this time he became ill, suffered with chills and fever, and in his blood was found the parasite of æstivo-autumnal fever. In three subsequent experiments performed upon individuals who had never suffered with malaria, fever caused by the tertian or æstivo-autumnal parasite was produced by the sting of Anopheles claviger obtained from malarious districts. In every case recovery followed the administration of quinine.

In one of these experiments, insects, obtained, to be sure, from a malarious region, were allowed to sting a patient suffering with æstivo-autumnal fever. Subsequent examination of some of these mosquitos showed those developmental phases of the parasite which will be described later. Three such mosquitos, of which two were later found to be infected, were allowed to sting a healthy man. After an incubation period of from nine to twelve days, uncertainty being due to repeated exposure, fever of an irregular type ensued and the æstivo-autumnal parasite was demonstrated in the blood of the infected individual. It has been urged that these experiments were conducted in Rome, where malarial fevers are not uncommon. In order to meet this objection, Bignami sent to England where malaria rarely occurs, mosquitos infected with the parasite of tertian fever. P. Manson, Jr., who exposed himself to the sting of these insects, suffered a mild attack of tertian fever.

Demonstration that the parasites of malarial fever and the related organisms of birds undergo a peculiar process of development within the body of the mosquito, amplifies and confirms the experimental results just cited.

Parasites of the Malarial Fevers.—The micro-organisms which cause malarial fevers belong to the group of sporozoa known as Hæmosporidia. Recent observers have shown that they undergo two cycles of development: (1) One occurs within the human body where the organism, developing within the red blood corpuscles and multiplying by an asexual process, causes malarial fever; (2) parasites ingested by the mosquito when it attacks an individual suffering with the disease undergo a second cycle of development in the body of the insect. This second stage in the life history of the organism is preceded by a process of fertilization which occurs in the stomach of the insect and terminates by division of the parasite into a great number of reproductive bodies.

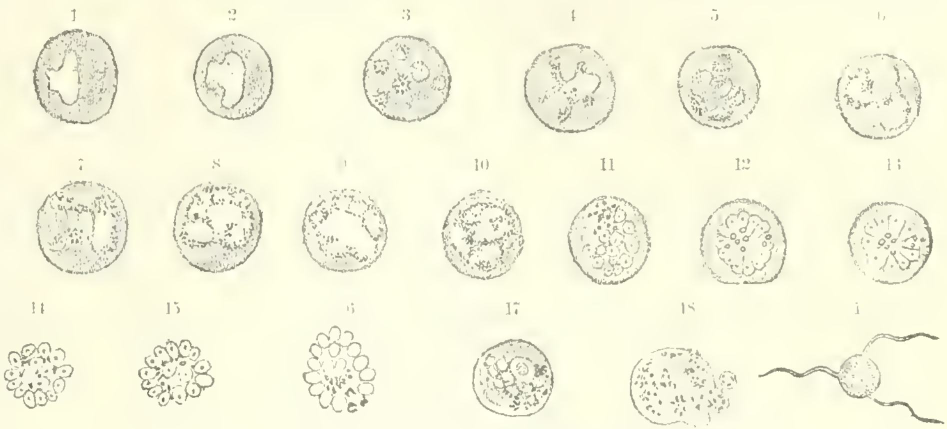

FIG. 3820.—Parasite of Tertian Fever. (After Marchiafava and Bignami.)

Golgi showed that the parasite which causes regularly intermittent fever of the quartan type differs morphologically from that associated with tertian fever. Both the tertian and the quartan organism within the human body develops in great groups, all members of which are at any given time in the same phase of development. The parasite of quartan fever completes its cycle in seventy-two hours, while the parasite of tertian fever repeats its cycle every forty-eight hours. It was subsequently shown that the organism present in those severer forms of malarial fever which prevail in the late summer and in the autumn months have distinctive peculiarities. In harmony with the irregularly intermittent course of the fever the parasite does not present the regular periodicity which characterizes the development of the other two varieties. Some observers have claimed that even among the parasites producing the irregular or æstivo-autumnal type of fever two varieties may be distinguished, but the distinctions which they emphasize are not sufficiently marked to establish the existence of more than one æstivo-autumnal parasite. Most observers recognize the existence of three distinct species of parasite; not only are differences observable within the human body, but during their development within the mosquito as well, morphological characteristics serve to identify the three varieties.

For the purpose of clinical diagnosis the malarial parasite is best observed in thin films of freshly drawn blood. Much attention has been given to the study of the parasite fixed and stained by a variety of methods, in great part modifications of that used by Romanowsky, who employed a mixture of eosin and methylene blue. The body of the organism stains blue, while its chromatin substance takes a lilac color. Wright has recently so modified this method that it may be used for the purpose of clinical diagnosis.

The Parasite of Tertian Fever.—The earliest phase of

Digitized by Microsoft®

the parasite, Fig. 3820 (1 and 2), found within the red blood cell is represented by a minute clear body, often circular in outline, with a diameter about one-fourth that of the corpuscle. Active amœboid movements are readily observed, and the processes which are protruded often give the body a very irregular outline. The hyaline organism may temporarily assume the appearance of a ring. This phenomenon is apparently due to the fact that the centre of the disc-shaped body, becoming for a time thinner than the periphery, is lost to view.

As the organism becomes larger one or more particles of yellowish-brown pigment formed from the hæmoglobin of the containing corpuscle appear within its substance, Fig. 3820 (3 to 10). These granules, which have an active dancing movement, increase in number and size as the organism grows. At the end of twenty-four hours the parasite fills from one-third to one-half the red corpuscle, the latter showing certain changes as the result of its presence, being larger and paler than the neighboring unaffected corpuscles. The young forms exhibit active amœboid movements, which with further growth become less conspicuous. At the end of about forty-eight hours the organism has reached its full size, about that of a normal red corpuscle, and is ready to undergo the process of segmentation. The parasite, Fig. 3820 (12 and 13), having assumed a circular outline, the pigment granules collect into a clump, often a solid block, which usually lies in the centre of the body. The organism acquires a dense opaque appearance not observable in the amœboid stage. Refractive dots may be seen near the periphery, occasionally in the more central portion, and radial striations extending inward from corresponding indentations at the margin appear between the refractive points. The striations represent lines of separation which divide the body into segments corresponding in number with the refractive dots; very frequently there is formed a peripheral circle of segments, within which, nearer to the central pigment, is a second group. These bodies, numbering twelve to twenty or even thirty, assume a circular outline, the aggregation being still surrounded by a pale, very inconspicuous yellowish rim, the remains of the much-enlarged and decolorized corpuscle, Fig. 3820 (11). Finally, this ruptures and sets the bodies free in the plasma, Fig. 3820 (14 to 16).

As previously mentioned, all the members of a group segment at approximately the same time. During a period of about three hours before the chill, the temperature rises gradually and segmenting bodies can be found in the blood. During the chill and with the beginning of the hot stage, they are present in greatest number. It seems probable that a toxic material is set free when the parasite segments and that this toxin causes a febrile reaction. Occasionally two groups of parasites are present in the same blood and double tertian fever results. The two groups undergo segmentation on alternate days, and at any given time parasites in two phases of development are discoverable in the blood.

In addition to the full-grown parasites which undergo segmentation are even larger bodies situated within enlarged pale corpuscles. Since they do not divide to form reproductive segments, they were at one time regarded, in part at least, as degenerate forms. Some of them exhibit the remarkable phenomenon known as flagellation, Fig. 3820 (19), and their significance will be subsequently explained in describing this process.

FIG. 3821.—Parasite of Quartan Fever. (After Marchiafava and Bignami.)

Certain details of internal structure not observable in the living organism may be studied in stained specimens. In preparations treated with eosin and methylene blue according to the method of Romanowsky, the existence of nuclear material may be demonstrated. In such specimens young hyaline forms exhibit an external zone of blue color, the central part remaining unstained. Situated near the periphery of the body, at times encroaching upon the unstained area, more rarely wholly surrounded by it, is a compact round or oval body which takes a deep lilac stain. As the parasite grows the chromatin becomes less compact and, according to Ziemann, takes on the appearance of a collection of fine filaments. When the organism has attained its full growth, this mass of material divides to form a variable number of irregular chromatin bodies, and when division is complete each mass assumes a round compact outline and is surrounded by an achromatic zone. Changes now take place in the cell protoplasm and result in the separation of the body into a corresponding number of segments.

The Parasite of Quartan Fever.—The quartan, like the tertian parasite, pursuing its development in great groups, all members of which are in the same phase at any given time, repeats its cycle in seventy-two hours. As with the tertian organism, the malarial paroxysm is simultaneous with the process of segmentation, and, when the result of an infection with a single group, occurs every fourth day. When more than one group are present, they reach maturity on different days, the members of two groups never undergoing segmentation on the same day. When the blood is infected with three groups paroxysms occur daily.

The quartan parasite resembles closely the organism of tertian fever; nevertheless, certain differential peculiarities can be noted. The amœboid hyaline bodies Fig. 3821 (1 and 2) are indistinguishable from those of the tertian parasite, but with increase of size and the acquisition of pigment Fig. 3821 (3 to 9) the characteristic features become evident. The pigment of the quartan organism occurs in coarser granules having a deeper brown color. The body of the parasite has a more refractive appearance and its outline within the corpuscle is much more distinct; the amœboid movements are much less active, and as early as the second day they almost or completely cease. The changes produced in the containing red corpuscle differ from those caused by the tertian organism; the corpuscle is not swollen and decolorized, but becomes somewhat shrivelled and assumes a deeper color of a greenish copper-like hue. As the parasite increases in size the surrounding rim of the corpuscle becomes smaller, and at the beginning of segmentation, about ten hours before the paroxysm, though present, it is almost imperceptible. The pigment Fig. 3821 (10) collects toward the centre of the body, and in doing so usually assumes a radial arrangement not seen in the tertian organism. The segments are fewer in number, often not more than from six to ten, and are arranged regularly in a single row about the central pigment mass. In stained specimens the details of structure previously described for the tertian parasite are observed and the same division of the chromatin substance is found to precede segmentation.

The Parasite of Æstivo-autumnal Fever.—The severer forms of malarial infection, including those presenting pernicious symptoms, are caused by an organism which differs in several important particulars from those pre-

www.libtool.com.cn
Digitized by Microsoft®

viously described. Since, as already mentioned, its development, unlike that of the tertian and quartan parasites, does not take place in great groups, of which the members mature at approximately the same time, its cycle cannot be followed with the same readiness. And in accordance with this irregularity of development the symptoms of the disease do not present the same periodically paroxysmal character observed in the other two types. Moreover, the parasite of the irregular fever does not undergo its whole development within the circulating blood, and all stages of growth cannot be observed in specimens obtained in the ordinary way. In the blood from the peripheral circulation only the youngest forms are found, the subsequent development taking place in the internal organs. The more mature organisms tend to accumulate in the spleen and bone marrow, possibly because, as suggested by Bastianelli and Bignami, the red corpuscles being profoundly injured by the contained parasite act as foreign bodies and are taken up by the cells of these organs. The absence of definite groups and the difficulty of following in the peripheral circulation the process of maturation through all its stages have made it impossible to determine as yet the duration of the cycle of development. Certain observers believe that it lasts two or three days, or even longer.

The youngest intracorpuscular form of the parasite, Fig. 3822 (1 to 7), is represented by an amœboid organism resembling the hyaline bodies of tertian and quartan fever; it is, however, somewhat smaller and has a greater tendency to assume a ring-like form. Such a parasite may be seen to assume alternately a ring shape and an amœboid form. With further growth pigment granules are acquired, and occasionally one sees in the blood from the peripheral circulation a small body, one-fifth the diameter of the red corpuscle, containing one or two minute granules of dark brown pigment. Larger pigmented forms are only very rarely found in the peripheral circulation, so that the later stages have been studied mainly in specimens of blood aspirated from the spleen. As the parasite grows the pigment increases in amount, but does not become so abundant as in the tertian and quartan organisms. Indeed, Marchiafava and Celli have described instances in which the parasite attained its full growth and underwent segmentation without any formation of pigment. The invaded corpuscle takes on a greenish brassy color, and wrinkling and crenation may be observed in corpuscles containing even the smallest hyaline bodies. The full-grown forms, Fig. 3822 (17 to 19), vary considerably in size, often exceeding in diameter one-half that of the containing red cell. The pigment collects into a clump, Fig. 3822 (Fig. 21 to 23), and is finally caked into a solid block, usually situated near the centre of the body. The organism acquires a refractive waxy appearance and divides, in a manner similar to that exhibited by the tertian organism, into from eight to sixteen segments, Fig. 3822 (24), which are finally set free in the plasma by the rupture of the containing rim of the corpuscle. In stained specimens the existence of chromatin resembling that of a tertian parasite can be demonstrated; it undergoes the same division and arrangement previous to segmentation.

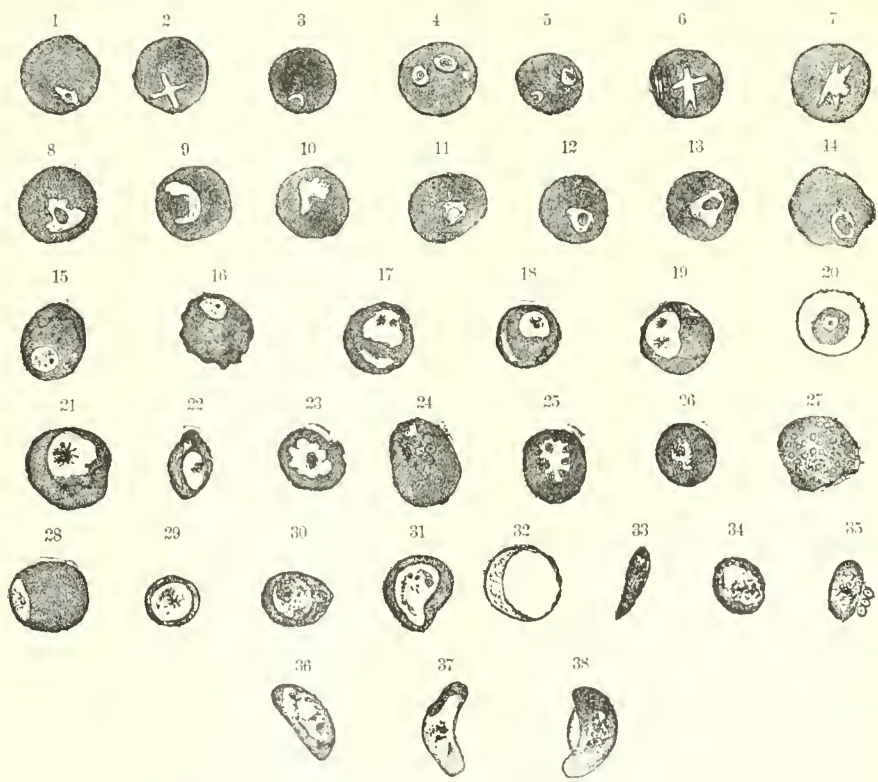

FIG. 3822.—Parasite of Æstivo-Autumnal Fever. (After Marchiafava and Bignami.)

In the blood of patients suffering with æstivo-autumnal malaria are found bodies not present with the regularly intermittent types—the crescents and ovoid bodies described by Laveran. The crescentic bodies, Fig. 3822 (36 to 38), present in the blood after the fever has lasted a week or more are longer than the red blood corpuscles, somewhat more than half their diameter across, and with very refractive protoplasm. A pale yellow rim projecting in bib-like form (38) from the concave side of the crescent surrounds the organism; this represents the remains of the corpuscle in which the body developed. Pigment, usually present in considerable quantity, is either distributed throughout or collected into a mass situated near the centre. The ovoid bodies, Fig. 3822 (34 and 35), differ from the crescents only in shape. Early stages, Fig. 3822 (28), in the formation of these bodies are found, and they represent transitions from the youngest forms of the ordinary cycle. Becoming fusiform, they develop in the red cells, and, as they exceed in length the diameter of the corpuscle, become bowed in order to accommodate themselves to its shape. Their significance has been much disputed, but, now understood, will be explained in describing the process of flagellation.

Flagellation.—The very remarkable phenomenon of flagellation is observable in freshly drawn blood. With tertian infection, within a week after onset of the disease, large spherical bodies, which do not segment, are present in the blood. The periphery of such a body in a specimen of fresh blood now unsurrounded by a rim of corpuscle is seen to undergo violent undulation, when suddenly there appear one or more thread-like filaments which lash about so actively that their outline is distin-

www.jtbtool.com.cn
Digitized by Microsoft®

guished with difficulty. Fig. 3820 (19). A flagellum with a club-like enlargement at one end not infrequently separates from the parent body and floats away in the plasma with an active undulatory motion. It has been shown that the flagella contain part of the chromatin substance. All the extracellular bodies observable in freshly drawn blood do not undergo [illegible]

www.libtool.com.cn

With the quartan infection a similar process is observable. Flagellate bodies, however are encountered with much less frequency than in cases of tertian fever.

In cases of æstivo-autumnal fever it is the crescents

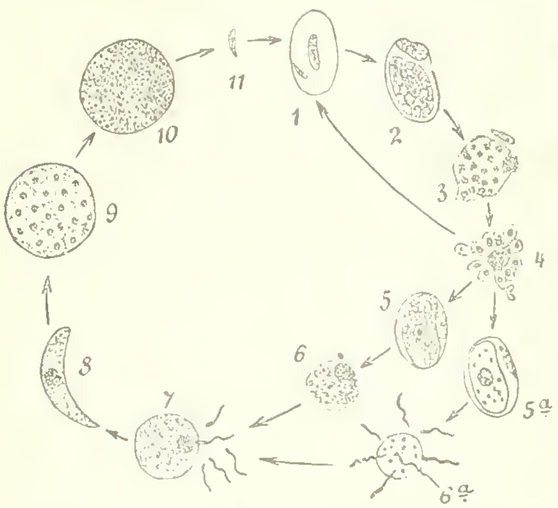

FIG. 3823. Diagram Showing the Life History of the Avian Parasite, Proteosoma. 1 to 4, Development of the parasite within the blood of the bird; 4, merozoites; 5 and 6, macrogamete; 5a and 6a, microgametocyte; 7, fertilization; 8 to 10, formation and maturation of oöcysts; 11, sporozoite. (After Grassi from Lühe, *Cent. f. Bakt.*, 1904, xxxvii.)

which undergo flagellation. In a specimen of fresh blood some of these bodies remain unchanged or merely assume a round or oval form; but others, after becoming spherical, extrude actively motile filaments which may become detached from the parent body.

The significance of this phenomenon has been explained by the study of a closely related parasite, Halteridium danilewsky, which occurs in the blood of many birds. This organism, which develops within the red blood corpuscles as a semilunar or halter shaped body curved alongside the nucleus of the containing corpuscle, like the malarial parasites forms pigment granules from the hæmoglobin. Opie showed that the parasite may assume two distinct forms, either of which when fully grown becomes free in the plasma after the blood is drawn. With one form the protoplasm is granular and stains deep blue by the method of Romanowsky; the nucleus is small. The other form, somewhat larger than the first, is characterized by the possession of a very large nucleus and scant protoplasm which stains with difficulty. The supposition that this form alone undergoes flagellation has been confirmed by MacCallum, who has demonstrated the occurrence of a remarkable phenomenon. Flagella break from the parent body and make their way to the granular bodies which have become extracellular. Several flagella may collect about such a body and beat against it with active lashing movements. One flagellum finally projects itself into the substance of the body, with which it becomes merged. The process is to be regarded as one of fertilization; the granular body with small nucleus is the female element, or, according to zoological nomenclature, the macrogamete, the flagellum is the male element, or microgamete, its parent body being designated by the term microgametocyte. The fertilized body remains quiescent for from fifteen to twenty minutes, when it assumes an elongated form and becomes capable of very active progressive movement, constituting the pseudo-vermiculus described by Danilewsky.

Flagella-formation observable with the three varieties of malarial parasite doubtless represents a similar process of fertilization, though only in the case of the æstivo-autumnal parasite has the phenomenon been actually observed. With both the tertian and the æstivo-autumnal forms morphological differences have been established between the microgametocyte from which arise flagella or microgametes and the macrogamete which undergoes fertilization. With the æstivo-autumnal parasite those crescents which do not flagellate, like the analogous macrogamete of the halteridium, stain more deeply and are granular. The formation of a body similar to the pseudo-vermiculus of birds has not been observed.

Life History of the Malarial Parasites in the Body of the Mosquito.—Study of the parasites in birds has here again pointed the way to an understanding of the life history of the malarial organisms outside the human body. Ross, working in India, directed his attention to the extracorporeal development of the avian parasite, Proteosoma grassi, because at the time cases of malarial fever were not available. Observations of Manson upon the development of filaria in the body of the mosquito suggested the agency of these insects. Ross proved that the mosquito can act as an intermediary host in transferring infection from one bird to another, and showed that the parasite develops within the body of the insect. The process of flagellation occurs with much activity in the middle intestine of an insect which has fed upon the blood of an infected bird. The flagellum or macrogamete unites with the microgamete, and the so-called pseudo-vermiculus which results, endowed with active motility, makes its way into the wall of the mosquito's intestine, where it becomes encapsulated and divides into a great number of minute bodies designated sporozoites. The latter, after rupture of the containing capsule, finally reach the salivary glands of the insect and hence may be injected into a second bird, there to undergo asexual multiplication.

In mosquitos which had fed upon the blood of individuals infected with tertian and æstivo-autumnal malaria, Ross found pigmented bodies similar to those which he had discovered in mosquitos. Bignami, Bastianelli, and Grassi have extended these observations and have shown that the tertian, quartan, and æstivo-autumnal parasites pass through similar changes within the body of mosquitos of the genus Anopheles.

An insect of this genus confined in glass test tubes is allowed to feed upon the blood of patients infected with malarial fever. The mosquito is so voracious that it stings when the mouth of the tube is applied to the skin of the patient. It is then kept confined in a larger vessel at a temperature of 20°–30° C., and is supplied with abundant moisture and vegetable matter for food. The parasite in the insect is studied after varying periods, in the intestinal wall and in the salivary glands, prepared by delicate teasing and examined in salt solution. Sections of the insect hardened and stained for microscopic examination give additional information.

With the tertian parasite fertilization of a macrogamete by a flagellum (microgamete) doubtless occurs, though the process has not been actually observed. During the second day after the insect has fed on malarial blood pigmented bodies can be found in the muscular walls of the intestine. Grown to twice the size of a red blood corpuscle, they are sharply outlined and possess homogeneous or vacuolated protoplasm. In stained specimens the chromatin substance is found to have increased in amount and may have undergone division into several small masses. Increasing in size, the parasite acquires a refractive capsule, and on the third day its contents have divided into a varying number of small bodies, each containing a part of the chromatin substance; between these lie the pigment and a small amount of undivided cytoplasm. This cyst-like body

Digitized by Microsoft®

increases in size and within it is formed an increasing number of small bodies. Finally, on the sixth day, the parasite, which has grown to such size that it projects into the body cavity of the insect (compare Fig. 3825 showing Proteosoma of birds), contains a great number of slender bodies www.libtool.com.cn sporozoites, Fig. 3825 (*C*) each containing a particle of nuclear substance demonstrable only in stained specimens; they are arranged in groups side by side. The containing capsule ruptures and the sporozoites are set free in the body cavity, whence they make their way to the salivary glands of the insect. Should a mosquito so infected sting a human being, parasites are injected with the irritant fluid secreted by the gland. Developing within the red blood corpuscles, the organism now begins in its new human host the asexual cycle of development with which is associated tertian malarial fever.

A few observations have shown that the quartan parasite passes through a series of phases corresponding to those just described, but when mosquitos are allowed to sting patients suffering with quartan fever, in only a small proportion of the experiments are developmental stages of the parasite obtained. The small number of flagellate forms observable in the blood of patients suffering with quartan infection may explain this fact as well as the relative infrequency of this type of malarial fever.

The development of the æstivo-autumnal parasite in the mosquito may be readily observed. On the seventh day after the mosquito has stung a patient infected with the disease, cyst-like bodies project into the body cavity of the insect and are filled with sporozoites, which, though more numerous, resemble those of the tertian parasite. Even before sporozoites are formed, the æstivo-autumnal parasite is recognizable by the character of its pigment and by the high refraction of its cytoplasm.

Terms in general use by zoologists have been introduced to designate various phases of the asexual generation of the malarial parasite in man and of its sexual generation in the intermediate host, the mosquito. Some of these have been mentioned. The microgamete or flagellum, derived from the microgametocyte or flagellate body, unites with the more granular macrogamete, and as the result an oöcyst is formed within the stomach wall of the mosquito. Division of cytoplasm preceded by nuclear division gives rise to a great number of nucleated bodies known as sporozoites. The latter, injected by the mosquito, are capable of transmitting malarial infection, since they are capable of development within the red blood corpuscles of their human host. Reaching a certain size, the intracorpuscular parasites divide without preceding fertilization into a variable number of bodies, which may be termed merozoites, each capable of re-entering a red blood corpuscle and undergoing the same process of multiplication. A certain number of merozoites, however, are not destined to multiply by such asexual division, but give rise to macrogamete or microgametocyte as already described. By union of the male and female elements within the stomach of the mosquito is formed a body which is capable of development in the intermediary host. An analogous alternation of asexual and sexual generation occurs with other protozoan micro-organisms, notably those belonging to the order Coccidia. Asexual reproduction is the means by which a few parasites which have gained entrance multiply in the new host. In the case of the malarial parasite, relatively few organisms injected by the mosquito multiply to form the great number characteristic of the malarial fevers.

PLASMOLYSIS is the term used in a general sense to denote the disorganization of the achromatic part of the cell, in opposition to *karyolysis*, which is applied to the complete disorganization of the nucleus. *Achromatolysis* is, accordingly, used as a synonym for plasmolysis. The word plasmolysis, having been introduced by a number of investigators working along special lines, is frequently used in a more narrow sense to indicate the destruction or degeneration of the protoplasm of certain forms of cells. Thus, for example, plasmolysis is by a large number of writers applied only to such changes in the red blood cells, and is used interchangeably with *erythrocytolysis*. In this condition the soluble substances of the red cell escape into the plasma so that the red cells become smaller (microcytes) or come to consist only of the outer envelope (red cell shadows). Through the imbibition of fluids such cells may become swollen. Grawitz uses the term to indicate solution of the red blood cells and the production of hæmoglobinæmia. In the case of nerve cells, plasmolysis is applied to the simplest disorganizing changes in the achromatic part of the cell. In the case of bacteria, plasmolysis is used to indicate the formation of clear spaces beneath the capsule, due to the shrinking of the plasma, as may be observed in bacteria held in a salt solution. *Aldred Scott Warthin.*

PLASMORRHEXIS is the term applied to processes of disorganization in the protoplasm of the cell, in opposition to *karyorrhexis*, which is used to denote similar processes in the nucleus. By the majority of writers plasmorrhexis is applied to these changes as occurring in the red blood cells alone, and the word is used as a synonym for *erythrocytorrhexis*. The process is characterized by the formation of small granules or globules in the protoplasm of the red cell, and the escape of these from the cell; or the formation of minute prickles or globules over the surface of the cell, giving it an appearance of a gooseberry or mulberry; or the formation of variously shaped

Digitized by Microsoft®

processes. Plasmorrhexis may be regarded as the stage immediately preceding plasmoschisis.

Aldred Scott Warthin.

PLASMOSCHISIS.—The partial or total disorganization of the cell through fragmentation or splitting of its protoplasm. It is characterized by the snaring off of the processes developed through plasmorrhexis, and the formation of round, oval, disc-like, angular, or thready bodies, which may be homogeneous or granular; or by the separation of the protoplasm from the nucleus. The term is used, particularly with reference to the disintegration of the red blood cells, as a synonym for *erythrocytoschisis*. It is believed by many investigators that the blood plates are nothing more than specially formed products of the plasmorrhexis and plasmoschisis of the red blood cells.

Aldred Scott Warthin.

PLASTIC SURGERY. See *Reparative Surgery*.

PLETHORA. See *Circulation, Pathology of*.

PLEURISY.—The pleura may be the seat of various forms of inflammation, some of which are only a part of a general inflammation involving the tissue of the lung, as in pneumonia, tuberculosis of the lung, and emphysema of the lungs, and some of which involve the pleura without disease of the lung.

A pleurisy may be primary, or it may be secondary to disease of the lung, or to some general disease, as chronic nephritis or rheumatism.

The different forms of pleurisy may be conveniently classified as follows:

1. Pleurisy with the production of fibrin, or acute pleurisy, or dry pleurisy.
2. Pleurisy with the production of fibrin and serum, or sero-fibrinous pleurisy, or pleurisy with effusion, or subacute pleurisy.
3. Pleurisy with an excessive production of fibrin.
4. Pleurisy with the production of fibrin, serum, and pus, or empyema, or suppurative pleurisy.
5. Chronic pleurisy with adhesions.
6. Tuberculous pleurisy.
7. Cancerous pleurisy.
8. Traumatic pleurisy.

Etiology.—Pleurisy occurs at all ages and in both sexes. Pleurisy may be *primary* or *secondary*, but there is at the present time considerable difference in opinion as to the relative frequency of true primary pleurisy, as well as to the frequency of tuberculous infection as the essential factor in the production of so-called primary pleurisies. Thus Strümpell states that we know positively of but two forms which may be regarded as primary, viz., the traumatic and the rheumatic; while others regard exposure to cold and wet and individual predisposition as frequent exciting causes. Of late years, under the lead of the French and German writers, the tendency of a large number of the profession has been to regard the majority, if not all, of acute and subacute pleurisies as tuberculous. There seems, however, good reason to reject so sweeping an assumption. That the tubercle bacillus is a frequent cause of pleurisy is, of course, well known, but many cases of pleurisy with effusion have been observed in which no tubercle bacilli have been found in the exudate, and in which tuberculosis has not subsequently developed. Moreover, an exactly similar pleurisy with effusion has been produced experimentally in the lower animals by chemical agents, as is shown by Delafield. By injecting a saturated solution of chloride of zinc with a hypodermic syringe into the pleural cavity of the dog he was enabled to excite a pleurisy exactly resembling that which is seen in the human subject. By varying the amount of fluid injected he was able to obtain pleurisies of different degrees of intensity, and with different amounts of products of inflammation.

Pleurisy may be secondary to changes in the lungs, notably tuberculosis of the lungs and lobar pneumonia, or to the infectious diseases, especially la grippe, to rheumatism, to peritonitis, to abscess of the liver, to carcinoma of the stomach, liver, or chest wall, or to nephritis.

Bacteriology.—Cultivations from the exudate give in the larger proportion of cases negative results, but, as stated by Netter, we may recognize three groups of acute or subacute pleurisy, caused by the tubercle bacillus, the pneumococcus, and the streptococcus respectively.

The tubercle bacillus is very difficult to find in the exudate. It has been demonstrated that a large amount of the exudate must be taken to make the test complete, either in cultures or in the inoculation of animals.

The pneumococcus pleurisy is almost always secondary to a focus of inflammation in the lung. It may, however, be primary. The exudate is usually purulent, but the prognosis of this form is very favorable. The streptococcus pleurisy is the typical septic form which may occur either from direct infection of the pleura through the lung in bronchopneumonia or in cases of streptococcus pneumonia; in other instances it follows infection of more distant parts. This is the most serious and fatal of all forms. The exudate is usually purulent.

These, then, are the important groups, but other bacteria have been found, as the staphylococcus, the typhoid bacillus, the bacillus coli communis, the gonococcus, the pneumobacillus of Friedländer, and the influenza bacillus.

Pleurisy with the Production of Fibrin (Dry Pleurisy).—*Morbid Anatomy.*—The inflammation may begin on the pulmonary, costal, or diaphragmatic pleura according to the cause which produces it. That beginning in the pulmonary pleura is always secondary to changes in the lungs. That which begins in the costal pleura is often independent of any inflammation of the lung. Usually only a circumscribed portion of the pulmonary, costal, mediastinal, or diaphragmatic pleura is involved, but the entire pleura of one side of the chest may be inflamed. The inflammation always extends to the portion of the pleura opposite to it. The inflamed pleura is coated with a more or less thick layer of fibrin, and bands of fibrin extend between the opposite pleural surfaces. As most persons recover from dry pleurisy, but little is known of its bacteriology.

This form of pleurisy is regularly seen with lobar pneumonia, less frequently with bronchopneumonia. It is very frequently associated with tuberculosis of the lungs, and may be the first or only sign of such tuberculosis. It is frequently found in connection with la grippe, and it may develop at any time in the course of this disease. It may develop simply from exposure to cold.

Symptoms.—The rational symptoms are usually few and not well marked. There may be more or less pain over the affected side, a slight dry cough, a little fever, and some malaise. Often these symptoms are absent. Though the pain is usually referred to the seat of inflammation, it must be remembered that this pain may be referred to a distant point, and thus the error may be made of regarding the case as one of lumbago or of appendicitis, of renal colic, or, in cases of diaphragmatic pleurisy, of peritonitis.

The physical signs are characteristic. Over the inflamed area are heard crepitant or subcrepitant râles. With these there may be a little dulness on percussion and some little diminution in the intensity of the breathing, but the essential sign is the presence of fine pleuritic râles. These râles may be scanty or very abundant. Sometimes they may be so faint as to be heard with the greatest difficulty. They are usually brought out best by causing the patient to cough. It must be remembered that these râles—contrary to the usual impression—are not necessarily constant; they may come and go in the same manner as a bronchial râle. If the pleurisy be diaphragmatic or mediastinal, no râles may be heard.

With acute or subacute miliary tuberculosis of the lung a dry pleurisy may either mark the invasion of the tuberculous inflammation of the lungs or it may be repeated from time to time as the tuberculosis goes on. Recent

www.libtool.com.cn
Digitized by Microsoft ®

pleuritic râles, pain in the chest, and a rise of temperature regularly accompany these attacks.

So well is it recognized that fine pleuritic râles may be the only symptom of a beginning tuberculosis that such evidence of localized dry pleurisy, especially if primarily at the apex of the lung and attended with afternoon fever, is always a source of great anxiety to the physician, unless he can be sure that he has to do with an acute pleurisy due to other cause than tuberculosis, as, for example, one occurring in the course of an attack of influenza. In primary dry pleurisies involving the costal pleura there is a great variation in the extent of pleura involved. The inflammation may involve only a small area of the pleura; there are râles heard over a circumscribed area only, the patient has but little fever, and the pleurisy runs its course in a week. In other cases the pleuritic râles are heard all over the front or back of the chest, the pain is quite severe, there is considerable fever, and the patient may be confined to bed or to the house for two weeks.

The *prognosis* is good. Most cases end in recovery after a short time, but the patient is often left with permanent thickenings and adhesions of the pleura. Such adhesions may give no further trouble, or they may form the starting-point for a chronic pleurisy with adhesions, or the process may go further and cause chronic interstitial pneumonia and chronic bronchitis.

Rarely, dry pleurisy is succeeded after several days by a pleurisy with effusion.

In a moderate number of cases one or more attacks of dry pleurisy are followed by pulmonary tuberculosis.

Treatment.—Many of the milder cases are never seen by the physician and need no treatment, although it would seem wise to keep them in the house till the pleuritic râles have disappeared. The more severe cases should stay in the house or go to bed till the attack has run its course. There is no especial drug treatment. The pain in the chest may be relieved by poultices, strapping the chest, opium, phenacetin, or the like. Most physicians either paint the affected chest with iodine or employ wet or dry cups, but it is doubtful if anything is gained by these counter-irritants.

PLEURISY WITH THE PRODUCTION OF FIBRIN AND SERUM (PLEURISY WITH EFFUSION).—This is a much more serious form of pleurisy, and is the type which is most commonly seen by the general practitioner, since many persons with acute dry pleurisy never consult a physician.

Morbid Anatomy.—The essential lesion is the inflammation of the greater part of the costal and pulmonary pleuræ on one side, and the accumulation of a considerable or large amount of serous fluid in the pleural cavity. Sometimes, however, the extent of the inflamed pleura is small, and the serum is shut in by adhesions (sacculated pleurisy).

Rarely, the pleuræ of both sides of the chest are inflamed, and when this is the case there is apt to be *pericarditis* also.

The surface of the inflamed pleura is coated with fibrin, and bands of fibrin join together its opposed surfaces. In the pleural cavity is found clear or turbid serum of a straw or amber color, containing a few leucocytes. Red blood cells are so rarely found that a bloody effusion is usually regarded as a sign of a tuberculous or a cancerous pleurisy. The blood, however, may be due to an injury. There are, moreover, a few cases which do not differ from ordinary cases except that the fluid is bloody. Thus bloody fluid may be found in pleurisy in connection with cirrhosis of the liver and with infectious diseases. The quantity of fluid varies from a few ounces to a quantity sufficient completely to fill and distend the pleural cavity. The fluid is, of course, found in the most dependent part of the pleural cavity, unless shut in by adhesions, in which case it may be found anywhere, but most commonly at the base of the lung and in the neighborhood of the axillary region. If the effusion be of any considerable quantity the lung is compressed upward and backward against the vertebræ, the degree of compression of the lung depending upon the amount of fluid. In extreme and long-continued cases the lung is almost unaërated. If the amount of fluid be great the adjacent viscera may be displaced. After the inflammation has subsided the serum and fibrin are absorbed and the pleura is left thickened by connective tissue and with connective-tissue bands between the two layers. The compressed lung expands again either completely or partially; if the latter, more or less retraction of the affected side of the chest is left.

The causes of pleurisy with effusion have been already stated.

The behavior of the acute cases is such as to make it probable that infection by the pneumococcus is the cause of the inflammation; and this belief has been confirmed in a considerable number of cases, but, as before stated, in a large number of cases the fluid is found to be sterile.

The *diagnosis* is made by the symptoms and physical signs.

The essential symptoms are *pain* in the chest, *cough* with little or no expectoration, *dyspnœa*, and *fever*.

The essential physical signs are *absent*, or greatly diminished, *vocal fremitus*, *flatness* on percussion, *feeble* or *absent breathing*, *feeble* or *absent voice*.

With this combination of symptoms and physical signs the diagnosis is one of the simplest problems in medicine, but there are so many variations from these conditions of the problem that a more extensive discussion of the subject is advisable.

First, as regards the symptoms and course of the disease. We may conveniently divide the symptoms of pleurisy with effusion into three groups:

1. Pleurisy with an acute invasion.
2. Pleurisy with an insidious invasion.
3. Pleurisy with a subacute invasion.

In the first group the symptoms may very closely resemble the invasion of lobar pneumonia.

In the second group the pleurisy may be entirely overlooked by the unwary, and "malaria" or some equally indefinite diagnosis may be made.

In the third group the conditions are more regular and the diagnosis more simple.

First Group.—In pleurisy with an acute invasion the patient is suddenly taken ill with the symptoms of an acute infection. Sometimes there is an initial chill, as in pneumonia; more often there are chilly feelings, and then the patient is taken with a sudden pain in the chest, with a high fever, 103°–104° F., a dry cough and immediate prostration. The pulse is full, 100–120, and the face is flushed. In a few hours dyspnœa appears, and this may increase so greatly that the patient cannot lie down in bed. The breathing is from 28 to 35. The pain is apt to be very great and referred to the affected side, but it may be also felt throughout the muscles of the body. The pain, on the other hand, may be very slight over the inflamed pleura, but is referred to the opposite side of the chest, or to the abdomen. In the latter case, if it be on the right side, the rigidity of the abdominal muscles and the situation of the pain may lead to the erroneous diagnosis of appendicitis, an error which of course would be corrected by a proper physical examination of the chest. As the fluid accumulates in the pleural cavity this pain becomes much less.

While the constitutional symptoms are going on the fluid accumulates rapidly, and within two days it may fill the pleural cavity; but the quantity of fluid varies greatly in different cases.

The patient continues to have a high temperature and all the appearances of a severe illness for about two weeks; then the temperature subsides, leaving only a moderate afternoon fever, which continues as long as the fluid remains in the chest. These cases make us think of an infection of the pleura by the pneumococcus.

The prognosis is usually good, but sometimes death occurs, and some of these patients die suddenly.

In the *second group*, that of insidious invasion, we have a picture which is just the opposite. The disease begins so gradually that the patient hardly knows when

Digitized by Microsoft®

he began to be ill. He has a little fever, he feels weak, has but little appetite, and he may feel short of breath on exertion, but the dyspnœa is not urgent. He may have no cough and no pain in the side, and he may go about his business for weeks suffering from fever and loss of flesh before the disease is recognized. For example, a gentleman coming from the South told me that he had suffered for three months from "malaria and an enlarged spleen." His dyspnœa was obvious to me at once, but he had hardly noticed it. His left chest was completely filled with fluid. The term "silent pleurisy" has been applied to this group of cases, and they are not infrequently tuberculous in their origin.

The duration depends entirely upon the length of time the fluid is left in the chest. If the fluid is removed recovery, as a rule, ensues at once—but tuberculosis of the lungs sometimes follows later; the interval may be weeks or months or years.

The *third group* is perhaps the most common. The invasion is of moderate severity; the temperature is about 101° F. in the morning and not usually above 103° F. in the afternoon; the respiration is about 30 and the pulse about 100; pain in the side, dry cough, and dyspnœa are prominent symptoms. The patients usually feel ill enough to go to bed, though they do not always do so. The fluid accumulates in the chest fairly quickly at first; then it continues to increase slowly, and if treatment is not instituted it will go on slowly increasing for several weeks.

The prognosis is good; these patients rarely die, and they usually make a perfect recovery.

The duration depends upon the treatment. Twenty years ago, when I was a hospital interne, the regular treatment was rest in bed, blisters to the chest and diuretics, and the regular duration was six weeks in bed and two months in hospital. Now the duration is often not more than two or three days in bed, and perhaps two weeks in hospital.

After recovery from this pleurisy changes in the chest may be left behind, which changes are in proportion to the quantity of fluid and the length of time it remains in the pleural cavity. The expansion of the lung may be complete, and no evidence of the former pleurisy remains. More often bands of connective-tissue adhesions are left between the opposing surfaces of the pleura, and the expansion of the lung is not complete. As a result there remains more or less retraction of the affected side of the chest, and the adhesions of the pleura may cause pain in the chest for several months; or, less frequently, these adhesions may be the starting-point of a chronic pleurisy with adhesions, of an interstitial pneumonia, or of a chronic bronchitis.

The *physical signs* of pleurisy with effusion depend largely upon the amount of the effusion and upon its situation. The rule is that we find the fluid in the lower part of the pleural cavity, and the lung more or less compressed upward and backward against the vertebral column. It is customary to describe the physical signs as in three groups, those above the level of the fluid, at the level of the fluid, and below the level of the fluid, but for the purposes of this article it will be sufficient to give the physical signs found above the level of the fluid and below the level of the fluid, as these are sufficient for all practical purposes.

Inspection may or may not show a fulness of the chest upon the affected side, and there is usually limitation of motion on the affected side. In children there may be bulging of the intercostal spaces below the level of the fluid. If the effusion be large there may be displacement of the heart or of the liver, but this displacement is not seen in cases of moderate effusion. There may be evident dyspnœa, and the patient usually lies upon the affected side.

The vocal fremitus is usually absent below the level of the fluid, but it may be only diminished even in large effusions.

Percussion, above the level of the fluid, may give exaggerated resonance, or skodaic resonance, or normal resonance. The percussion note over the opposite chest may be exaggerated or tympanitic. Below the level of the fluid the percussion note is usually absolutely flat, and this flatness together with the feeling of marked resistance to the finger used as a pleximeter is so constant a sign of fluid in the pleural cavity as to suggest at once the diagnosis without further physical signs, though it is not, of course, pathognomonic. In many cases, however, we do not get absolutely flatness, but only more or less marked dulness, even when the amount of fluid is considerable; this is notably the case in children. If the amount of fluid be small we get dulness on percussion of varying degrees of intensity.

Upon *auscultation* of the breathing, *above* the level of the fluid, the breathing is usually normal; it may be of a blowing character (cavernous or broncho-cavernous), or it may be feeble; *below* the level of the fluid it is generally stated that the breathing is *absent*, but this has not seemed to be the case to me. I should prefer to say that below the level of the fluid the breathing is quite feeble in most cases; exceptionally it is absent. There is another and most important exception to the character of the breathing heard all the way down the chest, below the level of the fluid, viz., distinctly *bronchial breathing*. This characteristic of the breathing in many cases of pleural effusion is now quite generally recognized, but it is necessary to emphasize it on account of the danger of mistaking this breathing for that of consolidation of the lung. It is usually noted in cases of large pleural effusion; but this condition is by no means essential.

If the effusion be slight, the breathing is only slightly diminished in intensity or is normal.

The *voice* above the level of the fluid is usually normal; it may be exaggerated or it may be slightly diminished in intensity. Below the level of the fluid the voice is very greatly diminished or absent. If there be bronchial breathing there is usually bronchial voice also, and this bronchial voice often seems distant from the ear. If the effusion be moderate in amount, there may be only slightly diminished voice or there may be ægophony.

Râles may be heard over the affected side if one see the case before the effusion of serum has taken place. After the two layers of the pleura are separated by the effusion it is only rarely that one hears râles below the level of the fluid. The important exception must, however, be noted that fine râles may be heard below the level of the fluid. This is not the place to speculate as to the explanation of this phenomenon, but it must be borne in mind that râles may be heard below the level of the fluid, or else the error of excluding pleurisy with effusion will inevitably be made.

Râles may, of course, be heard above the level of the fluid if there be fibrin on the pleura, or bands of adhesions at that point.

If the fluid be shut in by adhesions (sacculated), we get irregular physical signs, dulness or flatness, changes in the breathing and voice, and râles, corresponding to the situation of the fluid and the compression of the lung. In many cases there may be doubt as to the presence of fluid in the pleural cavity, and this applies to fluid free in the pleural cavity as well as to sacculated pleurisy. Here the diagnosis may be made by the introduction of an exploring needle attached to a hypodermic syringe. This little procedure is attended with such slight risk to the patient that its use is to be recommended in all cases of uncertainty of diagnosis. It must be remembered that a "dry tap" does not exclude the presence of fluid, which may be shut into numerous compartments by adhesions, and therefore introductions of the needle at several different points may be required before the fluid is found. Cases of sudden death *have* followed exploratory puncture, but fortunately these cases are rare.

As recovery takes place and the fluid is absorbed, the breathing and voice can be heard more and more distinctly, and lower and lower down, until recovery is complete. The flatness changes slowly into marked dulness, and this dulness persists for some time after all the fluid is removed. When there is doubt as to the exact height

www.libtool.com.cn
Digitized by Microsoft ®

of the fluid which remains, the point at which the voice becomes distinctly muffled is the most reliable test.

The *treatment* of pleurisy with effusion is a matter of great importance both as regards the duration of the illness and as affecting the future of the patient. Personally I believe that there should be but one recognized form of treatment, and that is the mechanical removal of the fluid by aspiration of the chest, and that the sooner the fluid is removed the shorter the duration of the disease and the less the risk of the formation of permanent pleuritic adhesions. Aspiration, which was first advocated by Bowditch and Wyman many years ago, is now extensively adopted by physicians, but many still adhere to the practice of depending upon the lymphatics for the removal of the exudate, and wait two or more weeks before resorting to aspiration. There are many who seek to restrain the exudation by the use of the dry diet, and who give sodium chloride in considerable doses. If the effusion be at all considerable it has been an almost universal custom to administer diuretics, even though aspiration were resorted to quite early. After aspiration the use of diuretics is really unnecessary, and its use before aspiration is of doubtful value.

www.libtool.com.cn

The method I would advocate is that in the cases with high temperature and other symptoms of acute and severe invasion the patient be put to bed and on a fluid diet. His restlessness should be quieted by the use of some of the coal-tar antipyretics; and if the pain in the chest be severe, relief may be obtained by the application of poultices to the chest, or by the administration of morphine. After two or three days of this treatment, if the fluid has accumulated it should be removed at once by aspiration. The temperature usually falls on the day following aspiration, and the acute symptoms subside also, and in a few days the patient feels well enough to sit up. In the cases of insidious and of subacute invasion the removal of the fluid seems to be all the treatment necessary. The patient may be put on a normal diet at once, and may be gotten out of bed as soon as the fluid is removed. Before aspiration the skin of the chest should be disinfected, just as for a major surgical operation, and the aspirating needle and the operator's hands also rendered aseptic. With these precautions purulent infection of the pleura does not ensue.

The amount of fluid removed at one sitting varies. If the amount be not very great, it may be all removed at once; but if the chest be entirely filled, it is not safe to remove it all till the following day. In ordinary cases it is a good rule to remove all one can get, but to stop if the patient feels faint or if he begins to cough. If a little fluid be left it will usually take care of itself. In cases in which the fluid re-accumulates two or more aspirations may be required to effect a cure. The subacute cases in which removal of the fluid is not attended by a fall of temperature are apt to prove to be tuberculous. Sudden death has followed aspiration of the chest, but this is a very rare accident. It must be also borne in mind that when a chest is completely filled with fluid sudden death may occur if aspiration is delayed, and that it is imperative to remove a portion of the fluid as soon as possible.

The *differential diagnosis* of pleurisy with effusion must be made from empyema, pneumonia, pleurisy with excessive production of fibrin, pericarditis, abscess of the liver, or other enlargements of the liver, and new growths of the pleura. Of course the question of the fluid in the pleura being an hydrothorax, or of the pleurisy being a part of a tuberculous process in the lung, or of a lobar pneumonia, must also be considered. A due consideration of the associated symptoms will usually lead to a correct diagnosis, but where there is doubt the introduction of the exploring needle is the most important aid to diagnosis. It must also be remembered that the leucocytosis in all cases of inflammation of the pleura, except empyema, is usually moderate in amount, about ten to fourteen thousand per cubic millimetre, but the leucocytosis may be low in pneumonia or high in a pleurisy, so that the blood count is not a certain means of differentiation between these two diseases. Where there is the slightest element of doubt the importance of the introduction of the exploring needle cannot be too forcibly emphasized. Frequently pus will be found by the exploring needle when the physical signs would suggest consolidated lung or only a thickened pleura.

Among the infants which we see at Bellevue Hospital, many of whom are half starved or badly nourished, it is not so uncommon to find pus in the pleural cavity when the only reason for the introduction of the needle is a febrile condition and a little dulness over one chest.

Pleurisy with an Excessive Production of Fibrin is a much more uncommon condition. We find the pleura on one side, both costal and pulmonary, greatly thickened by a deposit of fibrin, which may be even an inch or more in thickness; there may be a little fluid in the pleural cavity or there may be none.

This pleurisy may be seen in connection with an acute articular rheumatism, or with tuberculosis of the lung, or with epidemic influenza, or without known cause.

The *symptoms* are very similar to those of pleurisy with effusion with acute invasion, or to those of lobar pneumonia.

The physical signs are usually diminished or absent vocal fremitus, flatness on percussion, distant bronchial breathing, distant bronchial voice, or, more commonly, ægophony, and abundant fine and coarse pleuritic râles. The physical signs may resemble those of a pneumonia or of pleurisy with effusion.

Exploration of the chest shows that little or no fluid is present, and the absence of the rusty sputum, of the high leucocytosis, and of the flushed cheeks, which are so characteristic of pneumonia, may point to the correct diagnosis.

Unless the inflammation is tuberculous the prognosis is good.

The *treatment* is symptomatic only.

Empyema.—The inflammation usually involves the whole of the pleura on one side of the chest; occasionally it involves a circumscribed portion of the pleura only.

When we examine the pleura we find two different conditions:

(1) We see that it is coated with fibrin and pus, and that the pleural cavity contains purulent serum. This form is most common in children.

(2) In other cases we find the conditions as above, and in addition the pleura itself is much changed. It is split up by a great number of new cells, so that it resembles granulation tissue. In old cases the pleura becomes much thickened and may be infiltrated with the salts of lime.

As in pleurisy with effusion the fluid usually accumulates in the lower part of the pleural cavity, or it may be sacculated in any part of the pleural cavity; or it may be sacculated between the lobes (interlobular empyema), and this is said to occur most commonly between the middle and the upper lobe of the right lung. The suppurative process may extend from the pulmonary pleura to the lung, and the pus will then escape at intervals from the bronchi, or the pus may escape through the chest wall, or the pus may travel down and simulate a psoas abscess. In a few cases the inflammatory products and the superficial layers of the pleura become gangrenous. The purulent fluid is either thin and consists of a considerable number of pus cells in an ordinary sero-fibrinous effusion, or it is thicker and contains a large number of pus cells, or it is a thick and creamy fluid, nearly all pus cells. This latter is usually pneumococcus empyema.

The micro-organisms found are either streptococci or pneumococci in the great majority of cases. In 109 cases of empyema examined by Netter, he found the streptococcus alone in 48 cases, the pneumococcus alone in 29 cases, the pneumococcus with streptococcus in 3 cases. Staphylococci were found in 2 cases. Of 12 tuberculous cases the tubercle bacillus was found in 6.

Of 15 cases of fœtid effusion saprophytic organisms were found in all.

Netter points out the much greater benignity of the

Digitized by Microsoft ®

pneumococcus, and explains by this fact the more frequent recovery of children; for of 28 cases in children the pneumococcus was present alone or with the other two cocci in 15—a ratio of 53 per cent., which is exactly that of the streptococcus in adults.

www.libtool.com.cn

The micro-organisms of infrequent occurrence are the typhoid bacillus, the colon bacillus, the gonococcus, and the influenza bacillus.

The inflammation may be primary or secondary. If primary it may follow exposure to cold or to heat, or be without discoverable cause, or it may be only a part of a general streptococcus or pneumococcus poisoning.

It may be secondary to an abscess in the wall of the thorax, in the liver, in the abdominal cavity, or in the lung, any of which may rupture into the pleural cavity.

Empyema not uncommonly follows a lobar pneumonia or a grippe pneumonia. It may follow a simple pleurisy with effusion, but it is a question if this does not depend upon the imperfect precautions taken in aspiration. In the primary cases the rational symptoms are the same as those of the first group of pleurisy with effusion, only they are much more severe. The temperature is higher and may be of the pus type; there are chills and sweating and marked prostration. The symptoms may continue acutely and the patient die in a short time, or they may subside and the inflammation pass into a chronic course. When empyema follows a pneumonia it regularly develops as the pneumonia is subsiding, or a few days after defervescence. The temperature rises again and the patient feels ill again. In the secondary cases the larger number pursue a subacute course, with afternoon exacerbations of fever, dyspnœa, cough, and gradual loss of flesh and strength.

Recovery with absorption or with perforation is very rare. But in some patients there is a partial recovery, most of the pus is absorbed, but there is set up an interstitial pneumonia, with more or less bronchitis, which goes on indefinitely.

The physical signs are essentially the same as those of pleurisy with effusion, and subject to the same modifications, the only exception being that sacculation and irregular and indefinite physical signs are more common in empyema. In many cases the diagnosis can be made only by the exploring needle.

The diseases from which differential diagnosis must be made are pleurisy with effusion, pneumonia, abscess of the liver, subphrenic abscess, tuberculosis of the lungs, and malignant endocarditis; the last two being thought of only where the physical signs in the lungs are unsatisfactory.

The duration of empyema, when no operation is performed, may be from a few days to many years, the patients in the latter case finally dying, emaciated and with waxy degeneration of liver, spleen, and kidneys.

The *prognosis* without operation is bad; with a proper surgical operation it is very good. Recovery is almost the rule.

Treatment.—The essential point in the treatment is to remember that we have to do with an abscess, and that we must follow the ordinary surgical rule, viz., to open the abscess and evacuate the pus. This should be done just as soon as the presence of the pus is shown by the exploring needle, and nothing but the removal of the pus should be thought of. No matter how weak the patient may be he will gain by the evacuation of the pus.

The method of procedure varies according as we have to do with children or with adults.

In children aspiration should first be resorted to, and in a majority of cases this will effect a cure. If the temperature does not fall, and the pus reaccumulates, then the chest may be opened and a drainage tube inserted.

In adults it is a waste of time to aspirate. The chest wall should be opened at once, under the strictest antiseptic precautions, and a drainage tube inserted.

There is some difference of opinion as to whether it is better to incise an intercostal space or to remove a portion of one or more ribs. Personally, I prefer to remove a large piece of one rib, as the indications are twofold: to make an opening large enough to permit of the insertion of the hand and the breaking up of pleuritic adhesions, so as to permit of thorough drainage, and to favor the closure of the abscess cavity by the collapse of the chest wall. It is not necessary to wash out the pleural cavity unless the contents be fœtid. A good-sized drainage tube is inserted, absorbent dressings are applied, and the whole chest is wrapped in bandages. The wound is dressed only when the discharge comes through the dressing. The patient is gotten out of bed as soon as possible, and at the end of a month, at the latest, the drainage tube should be removed. The principal danger after operation is that of reinfection of the pleura, and the success of the operation depends upon the antiseptic precautions taken during the operation and in the subsequent dressings.

If one can be sure that there is only a small sacculated collection of pus, as may be the case in an empyema following pneumonia, aspiration is all that is necessary to effect a cure.

Chronic Pleurisy with Adhesions is a condition which is of interest chiefly because of its resemblance to chronic miliary tuberculosis of the lungs, and of the importance of discriminating between the two diseases.

By chronic pleurisy with adhesions we mean a chronic productive inflammation of the pleura, and *not* the old adhesions which are found at so many autopsies.

It is an inflammation which is chronic from the beginning and results in the production of new connective tissue only. We find thickenings of the pleura and adhesions between the costal and pulmonary pleuræ. One pleura may be involved, or both, or only part of one pleura. The natural tendency is for the inflammation to extend, until finally both lungs are completely adherent to the walls of the chest. There develops more or less inflammation of the larger bronchi, and the heart becomes smaller.

The disease usually originates in the adhesions which have been left by previous attacks of dry or of subacute pleurisy, but sometimes no history of previous pleurisy can be obtained. It may be associated with emphysema or chronic phthisis.

The *symptoms* are slight or well marked, according to the extent of the lesion. There may be only some pain over the chest and a slight dry cough, or there may be considerable pain, cough with expectoration, dyspnœa, and loss of flesh and strength.

The physical signs depend upon the extent of the lesion. If this be slight there are only a little dulness over the affected chest and pleuritic râles. If the lesion be extensive, we have more marked physical signs. The chest is flattened or retracted, expansion is diminished over the affected area, vocal fremitus is sometimes normal, sometimes increased, and sometimes diminished. The latter is perhaps the most common condition. There is more or less well-marked dulness on percussion; the breathing is diminished, or it may be changed in character, resembling bronchial breathing or broncho-vesicular breathing; the voice is usually diminished, but it may be increased in intensity. Over the affected area are usually heard numerous pleuritic râles, some the creaking sounds of old adhesions, others the crepitant and subcrepitant sounds of more recent adhesions. It must be remembered that if the pleuræ are tightly adherent there will be no râles at all. These patients usually die from some intercurrent disease, but occasionally the pleurisy is the only discoverable cause of death.

The *treatment* is to expand the lungs as much as possible, and to live an outdoor life as much as possible. I am in the habit of advising such a patient to take the deepest possible breaths at each street crossing, and to practise mild chest gymnastics night and morning. The pneumatic cabinet is of service in these cases. Cod-liver oil and general tonics also help.

Tuberculous Pleurisy is usually secondary to tuberculous inflammation elsewhere in the body; most com-

Digitized by Microsoft®

monly, for example, in the lungs, next in the bronchial lymph nodes, then in the peritoneum, bones, etc.; or the tuberculous pleurisy forms simply a part of a general miliary tuberculosis. In some cases, however, no tuberculous focus can be found elsewhere in the body, and these must be regarded as cases of primary tuberculosis of the pleura.

www.libtool.com.cn

The inflammation regularly involves the whole of the pleura on one side. It may be confined to the costal pleura or may involve also the diaphragmatic or pulmonary pleura.

There may be localized, or widely disseminated, miliary tubercles upon or beneath the pleural surfaces, either in direct association with lesions beneath the pulmonary pleura, or apart from them, or upon the costal pleura.

According to Delafield the gross appearance varies as follows:

1. The pleura is thickened, its surface is bare of fibrin, it is of a bright red color from the congestion of the blood-vessels, and this red surface is mottled with white dots—the miliary tubercles. In the pleural cavity is bloody serum.

2. The pleura is thickened, it is thickly coated with fibrin, no tubercles are visible to the naked eye; the pleural cavity contains clear serum.

3. The pleura is thickened and the pleural cavity contains purulent serum.

In all these cases the changes in the pleura itself are essentially the same—the thickened pleura is infiltrated with new connective-tissue cells. Scattered through its entire thickness are tubercle granula, either singly or joined together by diffuse tubercle tissue. The smaller blood-vessels show a growth of their endothelial cells.

In the serum of tuberculous pleurisy the tubercle bacillus may be occasionally demonstrated by staining, especially if the centrifugal machine is used, but it requires long and careful search, and often all one's efforts are unrewarded. The tubercle bacillus may be associated with other bacteria, most often with the staphylococcus pyogenes in the purulent exudate.

Many cases of pleurisy with sero-fibrinous exudate, giving no growth of bacteria on the ordinary culture media, are found to be tuberculous by the inoculation of guinea-pigs with the fluid.

The *symptoms* and physical signs are the same as those of pleurisy with effusion, or of empyema, or of pleurisy with an excessive production of fibrin. Of course the only positive diagnosis lies in the finding of the tubercle bacilli in fluid withdrawn from the pleura, but this is a procedure which is rarely successful. A fairly positive diagnosis can, however, be made in a majority of the cases by the consideration of associated conditions. Thus a bloody serum is more likely to indicate tuberculous pleurisy than anything else. A "silent pleurisy" is very apt to prove to be tuberculous. When the temperature remains high after the serum has been removed, and when the serum reaccumulates rapidly after each aspiration, the case is usually tuberculous. When the family history and the patient's history point to tuberculosis, the diagnosis can usually be correctly made. When there is empyema and the opening of the chest is followed by little or no improvement, the case is usually tuberculous. When the empyema is sterile it is usually tuberculous.

The *treatment* is unsatisfactory. We remove the fluid or we open the chest for the empyema; and then, if the diagnosis is certain and the patients are well enough, we treat them as we would any case of tuberculosis by out-of-door life, change of air, creosote and cod-liver oil, and good food.

Cancerous Pleurisy is rare; it may be primary or secondary. Fibroma, sarcoma, and endothelioma may occur as primary tumors of the pleura. Fibroma and lipoma formed in the subpleural tissue may encroach upon the pleural cavity.

Endothelioma usually occurs in the form of larger or smaller, flat or projecting, irregular nodular masses frequently most marked and extensive upon the costal pleura. Carcinoma may invade the pleura by extension, or sarcoma or carcinoma may be secondary to distant growths of the same nature. Small white, slightly projecting, often pigmented elevations of the pleura, either single or multiple, are common. These were formerly regarded as mostly miliary fibromata, but Hodenpyl has shown that they are mostly fibrous masses which replace or enclose miliary tubercles.

The tumors may be associated with an exudative pleuritis, and with either primary or secondary cancer of the pleura the exudate is frequently bloody. It must be remembered that though bloody fluid suggests either tuberculous pleurisy or cancerous pleurisy, and is due to one of these causes in the great majority of cases, it is possible to have a hemorrhagic pleurisy from other causes:

1. A perfectly simple pleurisy may be hemorrhagic.

2. A bloody fluid is met with in the pleurisy of the asthenic states, such as cancer, nephritis, and cirrhosis, in the malignant fevers, and in severe infections.

3. There may be a hæmatothorax due to the rupture of an aneurism, or to the pressure of a tumor on the thoracic veins.

4. The chest wall or the lung may be wounded by the aspirating needle, and blood in this way may get mixed with the sero-fibrinous exudate.

5. Wounds of the walls of the chest, fractures of the ribs, and blows on the chest may cause hemorrhagic pleurisy.

The *symptoms* of a cancerous pleurisy are those of the original new growth plus the signs of a pleuritis. If it be a primary new growth of the pleura, the diagnosis may present very great difficulties.

The subject of Traumatic Pleurisy need not detain us. If there be perforation of the costal or pulmonary pleura there will usually be a sero-fibrinous pleurisy, which may become purulent. Fracture of the ribs or blows upon the chest may cause a dry pleurisy or a sero-fibrinous pleurisy.

Pneumothorax.—By this we mean *air in the pleural cavity*, and also pyopneumothorax, *air and pus* in the pleural cavity, and hydropneumothorax, *air and serum* in the pleural cavity.

Air alone in the pleural cavity, a pure pneumothorax, is an extremely rare condition, for a pneumothorax usually becomes a pyopneumothorax, or, more rarely, an hydropneumothorax. We, therefore, speak of these three conditions under the term pneumothorax.

Pneumothorax occurs chiefly in adults, although we see it occasionally in very young children. It is more frequently met with in males than in females, and most commonly on the left side. It is caused by anything that perforates the pleura and allows air to enter the pleural cavity; but in ninety per cent. of the cases this cause is the rupture into the pleural cavity of a softened tuberculous nodule, or of a tuberculous cavity.

Other causes are: Perforating wounds of the chest; perforation of the diaphragmatic pleura from malignant disease of the stomach or colon, or ulcer of the stomach; perforation of the pleura by cancer of the œsophagus; perforation of the pleura, in the normal lung, from rupture of the air vesicles during straining; septic bronchopneumonia; gangrene of the lung; abscess of the lung; perforation of the lung from the pleural cavity by an empyema; the development, in a pleural exudate, of the gas bacillus (B. aërogenes capsulatus).

Osler has seen pneumothorax caused by the rupture into the pleura of an hemorrhagic infarct in chronic heart disease.

Pneumothorax has occasionally followed the introduction of an exploring needle into the lung. The number of cases of pneumothorax due to these exceptional causes is so small that practically pneumothorax is regarded as of tuberculous origin until it is proved that it is not.

Pathology.—If it be a pure pneumothorax we find the air in one of the pleural cavities under considerable pressure. The lung is compressed against the vertebral

Digitized by Microsoft®

column, and it may be small, dense, and unaërated. If there be old pleuritic adhesions the lung may not be compressed against the vertebral column, but irregularly compressed, being held against the chest wall by the adhesions. The mediastinum and the pericardium are displaced, being www.libtool.com.cn side, and the liver or spleen may be displaced downward. If there be a pyopneumothorax, or an hydropneumothorax, there is in addition fluid in the pleural cavity, purulent or serous, and the pleura is inflamed.

Symptoms.—In the tuberculous cases we have first the ordinary history of tuberculosis of the lungs, then during some severe muscular exertion, or during a paroxysm of coughing, the rupture of the pleura suddenly takes place and the patient experiences a severe pain in the chest accompanied by intense dyspnœa and a feeling of weakness or faintness. He may even become completely unconscious, and he may die without recovering consciousness. If he does not die at once he rallies from the shock caused by the rupture of the lung, but he is much sicker than he was before. He has constant and very severe dyspnœa, and he is usually confined to his bed. He may remain in this condition for two or three weeks and then die, either with or without, though more commonly with, the development of pyopneumothorax, or he may grow stronger and be able to get out of bed and go about a little, but if pyopneumothorax has not already developed it usually supervenes. Then the symptoms of pyopneumothorax are developed, which are, of course, simply an intensification of the symptoms of tuberculosis of the lung with mixed infection. The patient loses flesh rapidly, he has a high fever at night, he sweats profusely, and he may expectorate a great deal of foul-smelling material—the pus from the pleural cavity. He finally dies of exhaustion. It must be remembered, however, that there may be no urgent symptoms of pneumothorax in cases of long standing tuberculosis of the lungs. There has been found post mortem a pneumothorax which was unsuspected during life. West states that even in healthy adults this latent pneumothorax may occasionally occur.

The *diagnosis* of pneumothorax is usually made with ease by the physical signs. The rule is that the affected side is larger than the other, and it moves but little with respiration. The heart is displaced, and the liver or spleen, or both, may be displaced downward. The vocal fremitus is usually absent.

Percussion gives tympanitic resonance or exaggerated resonance, or amphoric resonance. Auscultation gives amphoric breathing or absence of breathing. Auscultation of the voice gives amphoric whisper or very feeble voice.

If the lung be adherent to the chest wall, there may be pleuritic adhesion râles. There may be the metallic tinkle, even though no fluid be present.

The coin sound, Trousseau's "bruit d'airain," is characteristic. To obtain this sound the auscultator should put one ear on the back of the chest while an assistant taps one coin on another placed on the front of the chest. The metallic-echoing sound which is produced in this way is one of the most constant and characteristic signs of pneumothorax.

Certain exceptions to these physical signs must be noted:

1. There may be but little displacement of the viscera.
2. Vocal fremitus may persist.
3. Percussion may give nearly normal resonance, or *flatness*, or *dulness*, signs which may very well deceive us greatly.
4. The breathing may be normal over most of the chest, or it may be bronchial.

The physical signs of pyopneumothorax or hydropneumothorax are usually those of pneumothorax above the level of the fluid, and of pleurisy with effusion below the level of the fluid, to which is added the characteristic sign of air and fluid in the pleural cavity, viz., the *Hippocratic succussion*. This sign is obtained by placing the auscultator's ear upon the chest, and then shaking the patient's body. A splashing sound is produced which may be audible even at a distance. The patient can often feel and hear this fluid splashing in his chest.

Pneumothorax must be differentiated from large phthisical cavities; from total excavation of one lung; from diaphragmatic hernia following a crush or other accident; from pleurisy with effusion. In most cases the differential diagnosis does not present serious difficulties. The total excavation of one lung in which only a thin shred of lung tissue remains attached to the chest wall presents the physical condition which exactly resembles a pneumothorax and therefore presents unusual difficulties in diagnosis. This is, however, a very rare condition, and the patient does not develop a pyopneumothorax.

The *prognosis* is usually bad. According to West, the mortality is seventy per cent. The tuberculous cases usually end fatally within a few weeks. According to West, of thirty-nine patients, twenty-nine died within a fortnight, ten died on the first day, and two of these within twenty and thirty minutes, respectively, of the attack.

Pneumothorax developing in a healthy individual, it is said, often ends in recovery. There are tuberculous cases in which the pneumothorax, if occurring early, seems to arrest the progress of the tuberculosis.

The question of *treatment* is a difficult one to decide. As a rule, little can be done for the unfortunate victim. An operation for empyema does little good, since we have in the advanced tuberculosis of the lung the main cause of the inflammation of the pleura. In cases which develop early the fluid may, of course, be removed by aspiration, if serous, or a rib may be excised and permanent drainage obtained if the fluid be purulent. If the patient suffers from dyspnœa due to the pressure of the air, this may be relieved by the insertion of a fine trocar and allowing the air to escape. The aspirator should not be used. *Frank W. Jackson.*

PLEURISY ROOT.—*Asclepias* (U. S. P.). *Butterfly Weed.* "The root of *Asclepias tuberosa* L. (fam. *Asclepiadaceæ*)" (U. S. P.).

Asclepias L. is a genus of some sixty species, occurring chiefly in North America, a few in Central and South America, and in the tropics of the Old World. A number of these have been found to possess the composition and properties of the official one, and it is probable that the same properties are general in the genus.

The species in question is very abundant in sandy soil from New England southward and southwestward. It is a perennial, hairy herb, sending up a cluster of erect or ascending stems a foot or two long, as thick as a goose-quill, densely leafy, and bearing at the summit several branches terminating in handsome large umbels of orange-colored flowers. It is the only species of the northeastern United States with orange-colored flowers. The commercial root is irregularly or interruptedly fusiform, 10–20 cm. (4–8 in.) long, 1–5 cm. (½–2 in.), rarely more, in thickness, usually cut transversely or longitudinally into irregular pieces; externally light orange-brown, becoming gray on keeping, coarsely annular at the crown, bearing numerous fine longitudinal and transverse furrows, imparting a finely tuberculate appearance and feeling; fracture tough, uneven, granular, whitish, the thin bark yellowish in the outer layer, the wood bundles pale yellow; almost inodorous, taste bitterish, slightly acrid and nauseous.

Besides two resins, gum, and a large amount of starch, pleurisy root contains the bitter glucoside asclepiadin, to which its properties are chiefly due. Asclepiadin is a yellow amorphous substance, soluble in alcohol, ether, and hot water, becoming of a deeper yellow, then green, with concentrated sulphuric acid.

Pleurisy root is diaphoretic and expectorant, and in domestic and country practice it has been used extensively in lung affections and catarrh of the air passages. In large doses it is emetico-cathartic. If desired, it can be given in decoction. Dose from 1–3 gm. (gr. xv. to xlv.). The fluid extract is official. *Henry H. Rusby.*

PLOMBIÈRES.—Plombières has been called, not without reason, "the Queen of Watering-places of the Vosges." It is charmingly situated, and its surroundings are so attractive that it is a favorite summer resort with many who have not been ordered there for a course of the waters. The little town has only about two thousand inhabitants. It is situated in a narrow valley, with mountains rising steeply up on either side. The climate is invigorating, and, while the days in summer are often hot, the nights are invariably cool.

ANALYSIS.—One thousand parts of the water contain in parts:

	Source Vauquelin.	Source No. 1, Du Thalweg.	Source Des Dames.	Source Du Crucifix.	Source No. 5, Savonneuse.

A special feature at Plombières is the long time (from half an hour to an hour and a half) during which patients remain in the water. Mr. Wolff ("The Watering-Places of the Vosges") says that only four springs out of the twenty-seven which are now in use at Plombières are drunk at all. The first is the chalybeate, which is very mild, and is employed mainly as a table water and as an adjunct to bathing in cases of anæmia and chlorosis. Another spring used for drinking, and also for bathing, the "Source Savonneuse," is mildly laxative. Besides these, the "Source des Dames" and the "Source du Crucifix" are employed for what little drinking there is. Apart from the chalybeate and the Savonneuse, the Plombières waters all belong to one category. Dr. Constantin James calls them alkaline; Dr. Bottentuit, "*arséniatées sodiques, sulfatées et silicatées sodiques*"; M. Jacquot, "*bicarbonatées sodiques silicatées*"; and Dr. Macpherson, "indifferent." The latter designation is most in keeping with their slight degree of mineralization.

The same author states that, "in addition to the baths, a very effective remedy in some cases applied at Plombières are the *étuves*, also called *étuves de l'Enfer*. These are hot vapor baths, for which the heat and vapor are supplied by the running springs. There are two such establishments, both of course underground, and both, at their hottest points, very hot indeed. But for people who cannot stand excessive heat, there is the convenient institution of *étuves en boîte*, which are taken in a closed box, with a hole left in the top for the head." Energetic massage is also much employed at this spa; so that the patient's time, what with drinking, bathing, walking, douching, massaging, and dieting, is quite fully occupied. Most of the visitors are women, although it is by no means an exclusively "female watering-place."

The place is rich in mineral springs, but the proportion of solids in the waters is rather insignificant. Over twenty-five springs are used at Plombières, and the water of most of them is collected into a single conduit and conveyed to the different thermal establishments. Only three of the latter are perfectly modern and satisfactory, viz., the *Nouveaux Thermes*, the *Bain Romain*, and the *Bain Stanislas*. Although so slightly mineralized, the varying temperature of the baths (65° to 160° F.) admits of a certain amount of variety in treatment. The waters are easily borne when taken internally, and do not produce any constitutional disturbance.

A course of Plombières is useful in many nervous states, especially those associated with hyperæsthesia, as well as in those depending upon lithæmia. Many symptomatic neuralgias and paretic conditions derive benefit from a course of treatment at Plombières. Stiff joints may be limbered up, lumbago cured, gouty manifestations alleviated, diseases of women improved. The place also has quite a reputation for the cure of sterility, though on what grounds does not specifically appear. The waters are also applicable to cases of gastralgia, dyspepsia, catarrhal conditions of the bowels, especially when accompanied by chronic diarrhœa. Some skin diseases, such as eczema and psoriasis, are likewise said to be greatly benefited by these waters. The chalybeate springs are, of course, useful in anæmia and chlorosis. In phthisis the place is said to be contraindicated.

Plombières is a decidedly international watering-place, although English and Americans form but a small contingent of the six thousand annual visitors of the spa. With reference to accommodation, Mr. Wolff is authority for the following: "The better hotels and villa-pensions seem intended for people altogether of the better classes. They are good, but dear. Of course, there are less pretentious ones, down to the lowest point of the scale; for the spa is much visited. The following are among the best: The Grands Hôtels, Hôtel de la Paix, Hôtel Stanislas, Villa Mocquard, Le Chalet Rose, and Maison Rossignol. There are as many as about a hundred private hotels, many of them with a regular table-d'hôte." Altogether, it is quite true that Plombières should be better known in our country than is now the case, especially as it is more convenient of access than Wildbad Gastein, Teplitz, and the other spas of that order, which Americans are wont to visit. *Edmund C. Wendt.*

PLYMOUTH ROCK MINERAL WELL.—Wayne County, Michigan. POST-OFFICE.—Plymouth.

Plymouth is a handsome village of about eighteen hundred inhabitants, twenty-three miles west of Detroit, from whence it is reached by both the Flint and Père Marquette and the Grand Rapids and Western railroads. The well is situated in a picturesque spot on the farm of Dr. M. V. B. Saunders. It was bored several years since, and the following analysis was made by Prof. John E. Clark, of Detroit, in 1893:

One United States gallon contains: Sodium chloride, gr. 14.38; sodium sulphate, gr. 0.37; sodium bicarbonate, gr. 5.27; potassium bicarbonate, gr. 1.73; calcium bicarbonate, gr. 5.47; magnesium carbonate, gr. 2.90; alumina and iron carbonate, gr. 1.73; silica, gr. 0.50; organic and volatile matter, gr. 1.29. Total, 33.64 grains. Lithium carbonate and carbonic-acid gas not estimated.

No accommodations have so far been prepared for visitors, but the water is widely sold. It is a good example of the alkaline-saline carbonated variety of water, and is useful in conditions to which this class is applicable. Its best effects have been observed in disordered states of the stomach, especially when accompanied by hyperacidity. It is also highly recommended in irritable states of the bladder and kidneys as a diuretic and diluent of the urine. It is said to have produced excellent results in gout, rheumatism, gravel, and other affections.

James K. Crook.

PNEUMATIC CABINET, THE.—The pneumatic cabinet, as distinguished from the pneumatic chamber of European countries, is an air-tight box of sufficient size to contain only a single patient.

By means of an attached bellows the contained air may be rarefied or compressed, and by means of a tube and stopcock in one wall of the cabinet the patient's lungs may be instantly connected with, or cut off from, the out-

Digitized by Microsoft®

side air. The cabinet is designed for the application of differential atmospheric pressures, the differentiation being between the cutaneous and pulmonary circulations. Coincidently it may be advantageously employed in the administration of the various inhalations. It has no relation to, and is in no way comparable with altitude, but is properly classed with apparatus for the use of compressed and rarefied air. It differs, however, from all other apparatus of this class in that the differential pressure is applied to the systemic as well as the pulmonary circulation. As this differentiation is always negative, the effects upon vascular tension and blood flow are directly the opposite of those from compressed and rarefied air.

Physics.—The available variations of atmospheric pressure to which the patient may be subjected and under which respiration may take place are:

1. Diminished pressure on both cutaneous and pulmonary surfaces, the patient being in and breathing the rarefied air of the cabinet, called negative pressure.
2. Increased pressure on both surfaces, called positive pressure (rarely if ever used).
3. Barometric pressure on the pulmonary, with diminished pressure on the cutaneous surface, the patient being in rarefied air while breathing from without, called negative differentiation.
4. Barometric pressure on the pulmonary, with increased pressure on the cutaneous surface, called positive differentiation.

Respiration may be continuous under either of the above conditions or the differentiation may be shifted between inspiration and expiration, giving the following combinations:

COMBINATIONS.

Inspiration.	Combined with expiration.	Called.
Under No. 3	Under No. 1	Forced inspiration.
Under No. 3	Under No. 4	Forced respiration.
Under No. 2	Under No. 4	Forced expiration.
Under No. 4	Under No. 3	Obstructed respiration.

Clinical experience has shown that negative differentiation, and its combination with negative pressure in the form of forced inspiration, are the most effective and, essentially, the only desirable methods of application. The physical demonstration is, therefore, limited to these two motions.

Negative Differentiation.—In this motion respiration is carried on under a constant differential pressure, that upon the pulmonary circulation being barometric, and that upon the cutaneous and abdominal circulations being less by the amount of rarefaction in the cabinet. The mechanical effects are identical with those from compressed air aside from the circulation; but as they can be obtained in larger degree by forced inspiration with an increased instead of retarded circulation, this motion is never employed for the purpose of expanding and clearing the lung. Because the respiratory effort is shifted from inspiration to expiration, respiration under these conditions has been thought to be of benefit as a form of pulmonary gymnastics, and in developing the expiratory muscles. But the results are of little clinical value as it is the voluntary muscles which are increased, not the normal expiratory forces of pulmonary and thoracic elasticity.

The value of this form of pneumatic differentiation depends solely upon its action on the circulation. Respiration under negative differentiation results in:

1. Reduction of vascular tension in both the systemic and the pulmonary circulations.
2. Depletion of the pulmonary vessels with venous hyperæmia of the systemic circulation.
3. Slowing of the entire circulation, both systemic and pulmonary.
4. Mild anæmia of the cerebro-spinal vessels.

The manner in which these conditions are developed is obvious. While the barometric pressure of the respired air offers no increased resistance to the pulmonary circulation, and hence no impediment to right heart action, the lower pressure on the cutaneous surface becomes essentially a suction force influencing all the systemic circulation, save that of the brain and cord, which are protected by their bony envelope. As the result all the systemic vessels, and particularly the capillaries, are dilated, vascular tension is lowered, and for a moment the circulation is hastened as the blood is drawn from the lung. But with the continuance of the differentiation the contracting arteries gradually force a relative excess of blood into the veins, from whence it passes more slowly to the pulmonic vessels which are under the higher barometric pressure. The coincident slowing of circulation and pulmonary anæmia are such that a strong man can hardly breathe five minutes under a negative differentiation of one inch of mercury without marked dyspnœa. Clinically, therefore, this motion must be alternated with negative pressure, which increases the pulmonary circulation.

The pathic conditions to which negative differentiation is applicable are: (*a*) pulmonary hemorrhage. There is no measure at our command which so quickly arrests bronchial hemorrhages. It is an almost universal impression that pneumatic differentiation of necessity causes abnormal expansion of the lung, and is therefore dangerous in all cases of hemorrhage, or where there is softening of pulmonary tissue. Such is not the case, and negative differentiation may be applied with even less than normal expansion of the chest. It is, therefore, of value (*b*) in all forms of acute inflammatory hyperæmia of the lung or pleura. It affords immediate relief in (*c*) pulmonary congestion from any form of cardiac disease, except mitral obstruction, and is the proper motion with which to begin the treatment of any organic cardiac or arterial disease, with the above exception. In all of the above conditions after the acute processes have been relieved, negative differentiation should be supplemented or replaced by forced inspiration.

Forced Inspiration.—The effects of this motion are of two distinct forms, mechanical and circulatory. The pulmonary expansion, the opening and clearing of collapsed and plugged alveoli, and the stretching of pulmonary and pleuritic fibroses attained by means of the pneumatic cabinet do not differ in themselves from the corresponding effects of compressed air. The clinical results, however, are very greatly superior by reason of the coincident effect of the cabinet upon the attendant pathic processes through its control of the circulation. In this motion, during inspiration, which takes place under negative differentiation, the action upon the circulation is the same as with negative differentiation alone. It is greater in degree since a higher differentiation can be employed when the patient is to expire into rarefied air. With the decrease in cutaneous pressure the vessels are dilated and the blood is drawn from the lungs through the heart and arteries into the veins with a quickened flow and lowered tension. Before this action reaches the point of slowed circulation inspiration is ended and the differentiation instantly changed to negative pressure, under which, although the absolute pressure on the cutaneous and pulmonary circulations is the same, there is, nevertheless, a relative negative differentiation in favor of the pulmonary vessels due to their weaker anatomical protection and support. A pulmonary suction is thus developed which draws the blood from the hyperæmic veins into the depleted pulmonary vessels, again with quickened flow and under lowered tension. Thus during each respiratory cycle a double negative differentiation is developed alternately in favor of the systemic and the pulmonary circulations.

Continuance of this process results in increase of both circulations with all which that implies of increased absorption and improved nutrition, and this, too, under decreased vascular strain.

It is this power of the cabinet to hasten circulation and diminish arterial strain which distinguishes it from all

Digitized by Microsoft®

other forms of apparatus for the use of pneumatic differentiation, and which renders it the most potential measure for the relief of very varied conditions. All the mechanical effects of compressed air may be attained by forced inspiration, with the addition of improved tissue nutrition. This motion is valuable in all forms of inflammatory pulmonary disease after the acute stage. All pulmonary and pleuritic fibroses are loosened and absorbed much more quickly than by any other means. The effect of forced inspiration upon all forms of organic heart disease, with the exception noted under negative differentiation, is more immediate, satisfactory, and prolonged than that from any other method of treatment. Cardiac angina and dyspnœa are speedily relieved, often within a few minutes, and in young subjects this relief often becomes permanent after a few treatments. Cases of aortic regurgitation give especially brilliant results.

In all conditions producing high arterial tension also, this measure affords very marked relief, the extent and duration of which depend, of course, upon the nature and continuance of the primary cause. The treatment does not cure Bright's disease, but it does relieve and delay the secondary arterial and tissue changes.

Charles E. Quimby.

PNEUMOGASTRIC NERVE, RESPIRATORY FUNCTION OF. See *Respiration*.

PNEUMONIA, BRONCHIAL.—(Synonyms: Bronchopneumonia, catarrhal pneumonia, lobular pneumonia, capillary bronchitis, etc.) The name bronchopneumonia is growing in favor, especially in this country, and is preferable. The condition is marked by the presence of bronchitis with areas of pneumonia. The latter are as a rule peribronchial, being confined to the immediate vicinity of the small bronchi, the bronchioles and their atria, the cells adjacent to which are filled with exudate.

Etiology.—The disease is most common in the extremes of life, that is, in the aged and in children under five years old. Of the cases occurring in children, about one-third are primary, the others being secondary most often to the diseases of childhood. Of these, measles is most frequently complicated by bronchopneumonia, and after this come pertussis, diphtheria, scarlet fever, influenza, and chickenpox. It will be noticed that these are diseases in which bronchitis is regularly present, or in which the upper air passages are involved in the morbid process. In older children and adults the disease may occur as a complication of any long-continued, severe illness, especially in those cases in which the mucous membrane of the mouth and pharynx becomes foul and the laryngeal reflexes are less effective than normally.

The predisposing causes in primary cases are old age or infancy, bad hygienic surroundings, the impure air of overcrowded, poorly ventilated rooms, bad feeding, and institutional life. We must also include among the predisposing causes the frequent presence of the diplococcus pneumoniæ and other pathogenic micro-organisms in the healthy air passages.

The exciting causes are sometimes difficult to discover. Exposure to cold and wet is one cause, and this accounts for the greater frequency of the disease in the cold months. The predisposing causes of secondary bronchopneumonia are the same as those of the primary form of the disease, plus dorsal decubitus and the weakened condition due to the original disease. The exciting causes are again hard to determine. Exposure is one, but there is a something in addition which favors the growth and multiplication of the micro-organisms usually present, even in health. In cases of deglutition-pneumonia the exciting cause is manifest.

The development of bronchopneumonia in old people is favored by the diminished powers of resistance and the less perfect expectoration.

Bacteriology.—In studying the flora of bronchopneumonia we have again to distinguish between primary and secondary cases. The micro-organisms most commonly found are the diplococcus pneumoniæ, streptococcus, staphylococcus aureus and albus, Friedländer's bacillus, and Loeffler's bacillus.

In nearly all of the primary cases the diplococcus pneumoniæ is present, and in about half of these it exists alone. When not alone, it is most often associated with the streptococcus and much less frequently with the staphylococcus and the other organisms just mentioned. Infrequently the streptococcus is found alone.

In secondary cases it is the rule to find a mixed infection. The diplococcus pneumoniæ appears in about seventy-five per cent. of the cases, but seems less potent in giving character to the disease than the streptococcus. The diplococcus pneumoniæ, the streptococcus, the staphylococcus, and Friedländer's bacillus may each be present alone, unassociated with other bacteria, but in the case of Friedländer's bacillus, at least, this happens only rarely. Although, generally speaking, the streptococcus plays the most important part in bronchopneumonia complicating measles, it is precisely in this form that the diplococcus pneumoniæ is more often found in pure culture than in other secondary cases.

Holt reports six tuberculous cases which were studied by Wollstein, and in all of which the diplococcus pneumoniæ was also found; indeed, this organism gave the character to the disease in these cases, as clinically they were indistinguishable from those of an ordinary bronchopneumonia, the post-mortem examination alone revealing their tuberculous nature.

Bronchopneumonia has in rare instances been found to be due to forms of streptothrix, and French investigators have reported the finding of the colon bacillus.

In deglutition-pneumonia the streptococcus and staphylococcus are most commonly found, and then, as a rule, in virulent form.

Pathological Anatomy.—In about eighty per cent. of the cases coming to autopsy, lesions have been found in both lungs. These lesions consist essentially of those of bronchitis and of pneumonia.

When the chest is opened the pleural cavities are seen usually to contain little or no excess of fluid. The parietal and pulmonary pleural surfaces may be normal or the seat of a fibrinous pleurisy. The lesions of the latter consist of patches of fibrin which vary considerably both in extent and in character. At times they are almost invisible lustreless spots, and then again they may be quite large and thick (as much as half a centimetre thick) and more or less discolored. Such patches correspond closely to areas of superficial pulmonary consolidation.

The lungs do not collapse as completely as they normally should, though crepitation is found quite generally when the lungs are handled in the search for nodules of consolidation. The latter are most often found in the lower lobes posteriorly. There may be found collapsed areas, bluish or bluish-brown in color, set in a lighter background. These are areas of simple atelectasis, and will yield to gentle inflation through a tube inserted in a bronchus. The bronchial nodes are invariably congested and enlarged. The heart—the right side more commonly—may be dilated.

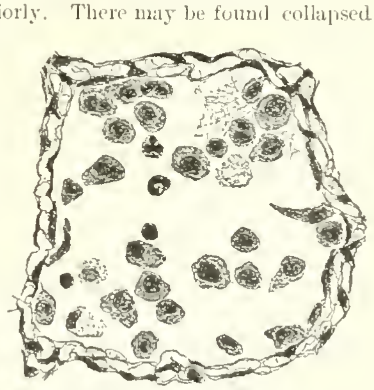

Fig. 3826.—Bronchopneumonia. Exudate in an air cell, consisting of exfoliated epithelium, a few pus cells, and a little fibrin. (From Delafield and Prudden.)

On section, the pneumonic areas stand out a little, are of a dark mahogany color, or more or less marbled with gray, smooth or finely granular, and moderately wet; only a small amount of dark blood escapes from the

Digitized by Microsoft®

vessels. Such areas vary greatly in size, and may be close together or widely separated. Near the centre of each a bronchus is seen, white or gray, because of the exudate which it contains. The unconsolidated lung tissue may

www.libtool.com.cn

FIG. 3827.—Bronchopneumonia in a Child, Showing Single Lobular Pneumonic Area, with Bronchus in its Centre. The thickened wall of the latter merges into the surrounding zone of pneumonia. Near the corners the accompanying emphysema is shown. (From Delafield and Prudden.)

be normal, but more often it is congested and œdematous, particularly behind. An emphysema, usually vesicular, is often present, being most pronounced anteriorly. Upon section of the areas of atelectasis, dark fluid blood escapes; the cut surface is seen to be smooth, with occasional lobules projecting above it. Creamy pus can be pressed from the smallest bronchi; portions carefully removed are found to contain no air and they sink in water.

With the aid of the microscope we see that the exudate within the bronchi of the consolidated areas is composed of leucocytes, mucus, desquamated epithelium in various stages of disintegration, a few red blood cells, and the micro-organisms responsible for the condition. The walls of the bronchioles and bronchi are swollen and infiltrated with new small round cells with more or less indistinct contours and having large nuclei. (See Plate XLIX.)

Northrup mentions a mechanical dilatation of the smaller bronchi. These dilatations, which are for the most part fusiform in shape, are found with especial frequency in the lower lobes. They are associated, according to this authority, with three conditions: (1) Weakened bronchial walls; (2) abundant secretion within the bronchi; and (3) impermeable tissue surrounding them. The dilatation is due to the secretion being forced by each inspiratory impulse from larger to smaller bronchi. The process, which is observed in children between three and five years of age, occurs more often after the fifth day of the disease. The dilatations disappear entirely on the recovery of the patient.

As the walls of the bronchioles are swollen and infiltrated with new cells, so also are those of the atria and of the air sacs, including the partitions between the air cells. The capillaries are engorged with blood and small hemorrhages may be noted here and there. The air cells, air sacs, and atria are filled with leucocytes, swollen desquamated epithelium, occasionally a few red blood cells, and sometimes also a little fibrin.

In deglutition- or aspiration-bronchopneumonia the process is more intense, the infiltration with leucocytes often resulting in suppuration and gangrene.

In the areas of atelectasis the bronchi are seen to be filled with pus and swollen and detached epithelia, and the walls of the bronchioles are infiltrated; the air cells and sacs are partially collapsed, the diminished lumen being filled with swollen and proliferating epithelia and pus cells. The blood-vessels are tortuous and gorged with blood. Here and there are hepatized lobules. In some cases the emphysema is very marked (see Fig. 3828).

The bronchial lymph nodes may or may not show a cellular infiltration. They are always congested.

SYMPTOMS.—The symptoms may be most obscure, even misleading, making it almost impossible, for a period of several days, to reach a correct diagnosis.

Prodromal Symptoms.—In primary cases, as in acute bronchitis, the early signs are a general malaise with more or less anorexia, slight elevation of temperature, acceleration of pulse and respiration, and cough, dry or with mucous expectoration in patients old enough to perform that important act. The invasion may resemble that of lobar pneumonia, being marked by a chill or convulsion and by rapid rise of temperature to 103° or 104° F. or over; or the invasion may present no characteristic features, the symptoms resembling those of typhoid fever or meningitis. In the cerebral cases there may be repeated convulsions, apathy, photophobia, retraction of the head with rigidity of the neck, and an absence of physical signs of consolidation.

In *secondary* cases, the prodromal symptoms and the invasion are masked by the symptoms of the primary disease. The invasion is gradual, seldom marked by a chill or convulsion, the child becomes restless, the temperature rises, and the pulse-respiration ratio diminishes. If there was a cough before, it becomes worse, or one develops if there was none previously. If there is any expectoration it is muco-purulent in character. An early symptom may be the cough,—painful, frequent, and hacking,—and it often continues after resolution has taken place.

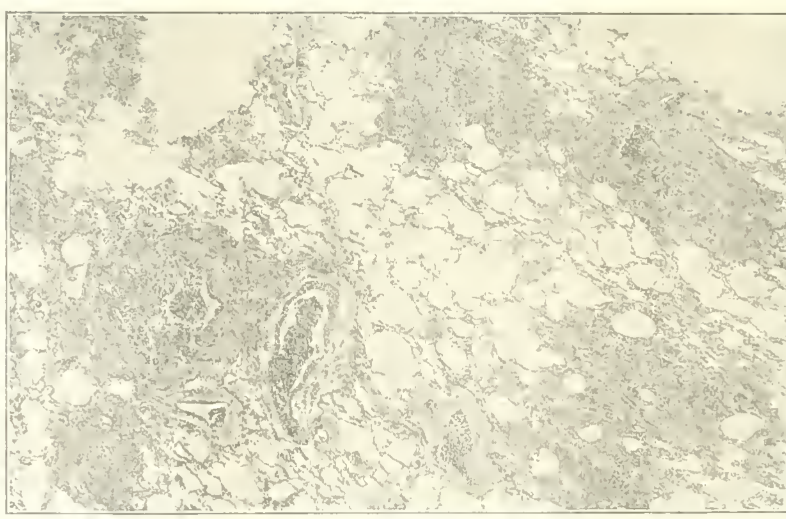

FIG. 3828.—Bronchopneumonia in an Adult, Showing Several Areas of Consolidation, with the Central Bronchus Filled with Exudate. Marked emphysema may also be seen in parts of the section. (From Delafield and Prudden.)

The temperature varies according to the extent of the

lesions, the virulence of the infection, and the general condition of the patient; apparently also it is influenced by the variety of micro-organism present. It may rise slowly or very suddenly, as a rule to 103° or 104° F., and it averages moderately high, with sharp elevations, most often in the afternoon, but at times in the early morning. The variations in the temperature curve gradually become less and less; in favorable cases the general trend is downward, restoration to the normal being by lysis. In unfavorable cases the trend of the curve is constantly upward, the temperature sometimes going as high as 107° F. The temperature may be of a high, continued type, this usually portending a fatal issue. On the other hand, in greatly debilitated subjects the temperature may rise little if at all above 100° F. The usual termination of such cases also is death.

www.libtool.com.cn

Pain is not a constant symptom, and as a rule it occasions little trouble.

Cyanosis is quite common, but there is little or no dyspnœa. When it is caused by atelectasis the temperature remains unaffected or falls a little. The skin is often cold and clammy. These symptoms disappear upon the removal of the cause of the atelectasis, and the patient is then about as well as before the attack. If the cyanosis persists for more than a day or two, however, the result is a fatal one.

In well-marked cases, the respiratory rhythm is changed. Instead of the inspiratory murmur being nearly continuous with the expiratory, the pause which in health was after expiration and before inspiration, is now transferred and is after inspiration and before expiration. The child quickly draws its breath, holds it, then with an explosive grunting sound expires and without pause inspires. The expiration is prolonged and loud. There may be Cheyne-Stokes respiration.

Gastro-enteric symptoms, such as loose green stools without vomiting, are frequent in infancy. The urine may become scanty, high colored, and with a trace of albumin, but casts are rare.

In cases ending in recovery amelioration of all symptoms may occur at any time from the fourth day to the third or fourth week. In mild cases it is looked for from the fourth to the eighth day.

Resolution takes from seven to fourteen days in favorable cases. Relapses are common.

Physical Signs.—It may be that for days no signs at all can be discovered within the chest, and it frequently happens that no signs of consolidation are found at any time during the course of the disease. In primary cases the first signs are due to congestion and bronchitis; they are either localized in one or more areas, or are generally distributed. The results of percussion may be negative, or there may be slight dulness. On auscultation we detect feeble breathing, which later has a higher pitch over the affected areas, and is associated with fine sibilant and coarse sonorous râles of the same or of wider distribution. These râles may disappear when the patient coughs. A little later, very fine moist râles are heard, as a rule, only over one or more areas, usually in the lower lobes behind. The vocal fremitus is unaltered. In such cases the pneumonic areas are deeply seated, small, and scattered.

The signs of consolidation, when present, vary according to the degree of consolidation, the area involved, and its proximity to the chest wall. In well-marked cases percussion reveals the existence of dulness in varying degree, associated at times with a sense of resistance. The vocal fremitus is increased only over areas of fairly complete consolidation. Auscultation reveals the presence of the râles above mentioned, only they are more marked and apparently closer to the examining ear; the breathing is bronchovesicular or diminished; the voice sounds approach the bronchial in character. In the cases in which there is a considerable area of complete consolidation, the signs more nearly approach those of lobar pneumonia, a disease which occurs in young children more often than was formerly believed. The dulness and vocal fremitus, however, are less than one would expect to find with voice and breathing of such a bronchial character. The signs of bronchitis are rarely general, and are most numerous in and near the edges of the consolidated areas. Friction sounds are infrequently present, usually only in cases of complete consolidation extending to the pleura.

It may be necessary to make the patient cough in order to develop the sounds of bronchitis, or crying may bring out, in an area of diminished voice and breathing, a marked bronchial quality. In extreme cases the breathing becomes shallow and very rapid, 80 or more to the minute, with retraction of the xiphoid and ribs and playing of the alæ nasi. The right ventricle of the heart may be found increased in size.

When resolution begins the signs of consolidation, which were the last to come, are the first to go. They may disappear very rapidly or they may persist for days or weeks. The signs of bronchitis subside less rapidly, often being found as late as from two to four weeks after resolution has begun. The blood count, as a rule, reveals a decided leucocytosis; in influenza pneumonia, however, it is only in exceptional cases high.

Complications.—We rarely find any pleurisy, except when there is marked pulmonary consolidation that reaches to the pleura. The simple fibrinous pleurisy is the most common.

The possibility of empyema must always be borne in mind. Abscess of the lung complicating bronchopneumonia is found in about seven per cent. of the cases that come to autopsy; these abscesses are usually minute and multiple, and not clinically discoverable. Gangrene is less frequent. Tuberculosis may complicate any bronchopneumonia, and in fatal cases cannot be diagnosed before death.

As in lobar pneumonia, so in bronchopneumonia, a purulent meningitis may occur, and may mask the symptoms of the primary disease.

Pericarditis is found at times, almost always in cases in which there is marked consolidation in the left lung. The rarity of endocarditis makes it hardly worth mentioning.

It is common to find functional derangement of the gastro-intestinal tract, as shown by vomiting and diarrhœa, which are serious, not in themselves, but in that they reduce the patient's chances of recovery in the other fight.

Nephritis is not a common complication, and when it does occur it is usually of an acute exudative type and does not much affect the course of the original disease.

Diagnosis.—The diagnosis of primary bronchopneumonia from lobar pneumonia is at times very difficult. It must be made on the age, history, and mode of invasion, on the character of the temperature, on the sputum (when there is any), and on the physical signs; the latter alone furnish positive evidence.

The diagnosis from pleurisy with effusion or from empyema must be settled by an exploratory puncture, several dry taps with a large-calibre needle being necessary to establish the absence of fluid.

As an aid to diagnosis in uncertain cases, in children two years of age or under, Northrup gives the three following points:

1. The pulse-respiration ratio tends to depart from the normal, which is as four is to one, and approximates or exceeds three to one. For instance, instead of being 80 to 20, it approximates the ratio of 120 to 40.

2. Fever; persistent elevated temperature, whether remittent, intermittent, or uniform.

3. Râles; subcrepitant and crepitant over a circumscribed area or areas, and especially if these râles are found on one side only.

Malaria is excluded by the absence of malarial organisms, by normal spleen, and by no history of exposure in malarious regions; the presence of leucocytosis also argues against malaria.

Treatment.—No treatment directly influences the pneumonic process. Much, however, can be done to prevent the development of the disease and to help

Digitized by Microsoft®

the patient pass safely through it, when once it is established.

I would outline the treatment under the following heads: (1) Prophylaxis. (2) General management of the disease. (3) Diet and feeding. (4) Special treatment: (*a*) by drugs; (*b*) by serum therapy. (5) Symptomatic treatment: (*a*) ... (*b*) to lower the temperature and moderate the nervous symptoms; (*c*) to stimulate the heart, in order to prevent cardiac failure or to overcome it if present; (*d*) to stimulate respiration.

Prophylactic treatment is very important. Care must be taken to see that children are sufficiently clothed yet not overclothed; that they are much out of doors, and that while indoors they are in well-ventilated rooms, with a temperature not over 68° or 70° F. during the day and a few degrees lower at night. Children ill with any diseases, particularly those that are most likely to be complicated by bronchopneumonia, should be turned often in bed, now on one side, then on the other, now on the back and then on the abdomen. Bronchitis in an infant should be most carefully treated, as such cases, especially if neglected, are very prone to develop bronchopneumonia. In all cases the mouth should be carefully washed at least once daily, preferably with some alkaline antiseptic solution; and antiseptic nasal sprays are advisable as preventive measures.

General Treatment.—Infants are better for being much held in the nurse's arms; older patients are to be put to bed at once and the bowels moved by calomel, in doses of one tenth of a grain every half hour or every hour for ten doses, or until the desired effect is obtained. The sick room should be large, light, and well aired; there should be a steady renewal of the supply of fresh air, and—if it is deemed advisable—additional moisture should be imparted to it. A change of rooms several times in the twenty-four hours is the best arrangement, provided all of the windows of the one which the patient leaves be opened wide so that it may be in the best condition upon his return. An open fireplace is an excellent ventilator. When the patient's temperature is high the temperature of the room may be at from 65° to 68° F.; when the patient's temperature is normal, the room temperature should be 70° F. The chest had better be protected by an oiled-silk jacket throughout the attack, and the skin of the chest may advantageously be kept red by some light application of mustard. Thick hot poultices should not be used.

It is well to establish a more or less strict isolation, and to disinfect the patient's rooms and their contents before they are used by another person. Especially should this be done in secondary cases.

Great care should be exercised in the management of the diet, as the turning of the tide one way or the other often depends upon it. Plenty of cool water, not iced, should be at hand, and the patient should be encouraged to drink it.

Special Treatment.—Drugs can often be given to advantage by inhalation. The child should be placed under a tent and some kind of a vaporizer employed. A variety of drugs may be added to the water or it may be used by itself. The addition of creosote gives particularly good results. Turpentine, compound tincture of benzoin, and terebene may also do good service when exhibited in this way. The inhalations should be given for from eight to fifteen minutes at a time, every two to six hours. The cough is often greatly relieved by such inhalations. The administration of drugs which, it is believed, can make the blood a less favorable medium for bacterial life, is not to be considered in the case of infants and young children.

For accomplishing this purpose we must look to the better preparation and use of serum therapy, which is now only in its incipiency.

Symptomatic Treatment.—Pain severe enough to demand the administration of some form of opium is unusual. When such a condition does exist, small doses of Dover's powder are quite efficient. Ordinary temperatures, say those under 104° F. rectal, do not in themselves call for special treatment. However, it may be advisable to apply cold, when this degree of temperature is reached, in order to control the nervous symptoms, such as sleeplessness, restlessness, or delirium. In some cases Holt gives for this purpose one grain of phenacetin every two hours to an infant of six months.

The cold is best applied by cool or tepid sponging, or by packs. The spongings are to be frequently repeated until the symptoms for which they are given are controlled. Both cardiac and respiratory stimulants may be needed. Of the first class we will mention alcohol in the form of brandy or whiskey, strychnine, nitroglycerin, and caffeine. None of these is to be administered as a routine treatment. As a matter of fact, however, very many, indeed nearly all, patients with secondary bronchopneumonia need cardiac stimulation, the chief indication for such being a weak, rapid, irregular pulse. The physician should determine how much alcohol it is desirable to give in the twenty-four hours and have it administered in small divided doses, well diluted with at least from six to eight times its bulk of water. A child one year old may need only half an ounce of brandy during the day, or he may need as much as two ounces. The dose, whatever it is, should be reduced as soon as possible, and the alcohol should not be continued for too long a time. Nitroglycerin may be used to help the heart over a particularly hard strain. To a child of the age mentioned above, gr. $\frac{1}{600}$–$\frac{1}{300}$ can be given every hour for several doses, say five or six. Strychnine is not to be given so frequently as alcohol or nitroglycerin. To a child of the age mentioned gr. $\frac{1}{400}$ to gr. $\frac{1}{300}$ of strychnine may be given every three or four hours. It is often best to use two of these drugs, giving them alternately. The effect of caffeine is less certain and the drug is not so much used as the others for its effects upon the heart; as a respiratory stimulant it is better.

The seat of the disease being in the lungs, it is very natural that respiratory stimulants should be called for. Strychnine helps here just as it does in cases of cardiac failure, and in addition to it we can use atropine, caffeine, and oxygen, all of which may be necessary in cases of respiratory failure. We should not wait until the patient is *in extremis* before giving oxygen; when administered it should be considerably diluted with air.

After an attack of bronchopneumonia general tonics are indicated, and it is especially advisable for the patient to have a change of air, preferably to a warm, dry climate, where he should remain for several weeks.

PROGNOSIS.—This must always be guarded, for bronchopneumonia is a dangerous disease. The mortality of all cases, considered together, is between sixty and seventy per cent.

The mortality of primary cases varies greatly, viz., from ten to fifty per cent., depending upon the previous condition of the patient, upon the virulence of the infection, and upon whether the child is an inmate of an institution or not. In private practice the maximum mortality is about thirty per cent.

In secondary institutional cases the mortality of infants under one year of age is appalling. In certain diseases it reaches and stays at one hundred per cent. for months at a time.

The prognosis depends upon the child's age, surroundings, and previous condition, and upon the nature of the infection. Rachitic children developing bronchopneumonia are almost sure to succumb. Bronchopneumonia is most fatal when associated with pertussis, next with measles, and then with diphtheria. This order, however, is a matter about which statistics differ.

Holt says the shortest cases are the most fatal; that the only termination under ninety-six hours is a fatal one, and he says further that, in cases of over two weeks' duration, the prognosis grows worse with each day of continued temperature.

Patients having a low temperature, little or not at all above 100° F., are usually in a condition of low vitality, and consequently about seventy-five per cent. of them die. The mortality of cases in which the temperature

Digitized by Microsoft®

reaches 106° F. or over is about eighty-five per cent. The most favorable prognosis is in cases with a fairly even temperature curve, one that does not run to either extreme, and does not vary much one way or the other from 103° or 104° F., during the period of activity of the infection.

www.libtool.com.cn

A steeple chart with great rises and correspondingly great drops of temperature, simulating a pus temperature, usually indicates a mixed or a streptococcus infection, and the prognosis is worse than in the cases with a more even curve.

A convulsion or two at the onset of bronchopneumonia does not affect the prognosis unfavorably, but when convulsions come later in the course of the disease they do affect it, and that decidedly for the worse.

Bronchopneumonia may terminate in resolution, suppuration, gangrene, chronic bronchopneumonia, or death.

PNEUMONIA, CHRONIC.—(Synonyms: Interstitial Cirrhosis of the Lungs, Chronic Interstitial Pneumonia, Pulmonary Fibrosis, Fibroid Phthisis.)

Chronic pneumonia is not an independent morbid entity, but occurs as a sequel of one or more previous or coexisting pathological conditions of the lungs or pleura. It is a chronic productive inflammation which may occur wherever connective tissue is found. It is encountered in two chief forms, circumscribed and diffuse. The circumscribed form is associated with tuberculosis, gummata, tumors, infarctions, hemorrhages, abscesses, and every morbid growth, and really is the attempt of the part to wall off the pathological condition.

The diffuse variety is secondary to incompletely resolved lobar pneumonia or to acute or subacute bronchopneumonia and chronic bronchitis, spreading mostly from the bronchial walls. It may also be a result of pleurisy, and is then called by Charcot pleurogenous.

Interstitial pneumonia may invade the lung in great bands, which develop in the normal septa. A potent cause of interstitial pneumonia is the inhalation, for a considerable length of time, of dust, as necessitated by certain occupations; for example, coal-mining, stone-cutting, and some kinds of work in iron. Zenker calls this form pneumonokoniosis.

In general arteriosclerosis inflammation of the connective tissue of the arterial walls extends to that of the lung itself and results in a diffuse interstitial pneumonia.

Chronic pneumonia is, as a rule, unilateral, but in pneumonokoniosis it is always bilateral. The circumscribed variety is, as a matter of course, distributed according to the distribution of the lesions with which it is associated. When these lesions are close to the pleura this membrane becomes involved, its two layers being thickened and adherent. The zones of new connective tissue about the original lesion contain blood-vessels at first, but later these become more or less obliterated, although there is not the same tendency to death of tissue as is found in tuberculous lesions. About these zones there is usually present a certain amount of emphysema.

In well-marked cases of the diffuse variety more or less of the pleura is adherent and greatly thickened, and the affected lung is smaller than normal and cannot be separated from the chest wall without tearing. The lung feels firm and leathery. The heart may be drawn to the affected side, and its right half may be hypertrophied.

On section the pleura is seen to be tough, fibrous, and of a grayish color. There is often a creaking sound as the lung is cut. The cut surface is firm, shiny, and of a dull red or bluish color or marbled. Much pigment is often present throughout the lung tissue and in the bronchial nodes. The walls of the small bronchi are increased in thickness and in many places dilated. Some of the dilatations are large and often contain varying amounts of pus. The microscope shows the new tissue to be connective tissue of the small-celled variety; most of the cells are round, but some are fusiform. There are at first blood-vessels in this new tissue, but they tend to disappear later; there is, however, as before mentioned, but little tendency to tissue necrosis. The walls of the atria, air sacs, and air cells are infiltrated with the new connective-tissue cells, and the air cells may contain organized exudate.

In the unilateral cases the unaffected lung is enlarged because of the compensatory emphysema present.

SYMPTOMS.—In looking for the symptoms of chronic pneumonia we first get a history of one or more of the diseases which it follows, especially chronic bronchitis or protracted bronchopneumonia. In the early stages the patient may feel fairly well, complaining only of cough with sero- or muco-purulent expectoration. The cough is worse in the morning, and is paroxysmal when there is an accumulation of secretion in the lower lobes. As the process advances there is dyspnœa on exertion. Lying on the unaffected side may cause dyspnœa, as it restricts the action of the functioning lung; consequently patients with unilateral chronic pneumonia lie on the affected side. With the onset of ulceration a new order of symptoms is noted, all of them being worse during the winter season. The sputum changes its character and becomes a thin muco-purulent fluid, of a gray or black color and is often fetid. On standing it separates into layers; the lowest contains solid particles and is yellowish in color; the next above is a greenish fluid; and the top layer is thin and frothy and contains mucus and fat. Cavities are formed, allowing of accumulations of pus, and these in some instances are emptied by change of position. Fever, of a hectic type, and night sweats may be looked for early, and small, frequent hæmoptyses are common occurrences. With the conditions present giving such symptoms, it is no wonder that the patient's general condition becomes rapidly worse. The whole aspect of the case is that of chronic pulmonary tuberculosis, excepting that no tubercle bacilli can be found.

There is no elevation of temperature except during exacerbations of the bronchitis and after ulceration has begun, as noted above. Pain is by no means a constant symptom. It is present only when the pleura is involved, and then the diminution of respiratory movement on that side usually keeps it from being very severe.

For months we may be able to discover only the physical signs of previous or coexisting disease. Gradually there develop signs due to diminution of aërating surface, thickening of pleura, contraction of the new tissue giving lessened or absent respiratory movement, deformity of the chest, spinal curvature, and displacement of the heart. The cardiac pulsations are sometimes abnormally visible. The dilatations of the bronchi, with or without contained fluid, also give rise to special symptoms. In unilateral cases the unaffected side is increased in size, has increased respiratory movements, and shows the signs of compensatory emphysema.

TREATMENT.—In the management of these cases prophylaxis is of the utmost importance. All patients with persistent bronchitis, or with protracted or unresolved pneumonias, and those who have had several attacks of bronchopneumonia, should receive the very best tonic treatment with respiratory exercises; and above all, they should find the climate in which they do best and should, if possible, live there. When the trouble is due to the occupation, this must be abandoned. No treatment directly affects chronic pneumonia when once it is estab-

Digitized by Microsoft®

lished. The therapeutic endeavor is then to control the cough, overcome the fetor of the sputum, and keep up the general tone of the individual. The patients must avoid exposure to cold and wet. They must spend their winters, at least, in the South, and are better for living the year around in a dry, warm, equable climate. Moderate daily outdoor exercise and the best of food are very important.

www.libtool.com.cn

Diagnosis.—In aiming at a diagnosis of chronic pneumonia, we have to consider the possibility of pleurisy, cancer of the lung, pneumothorax, and pulmonary tuberculosis.

Prognosis.—The outlook for the future comfort and happiness of these patients depends largely upon their dispositions and their ability to get to a suitable climate. No hope of cure can be held out to them. The disease, however, is seldom in itself a cause of death. Some intercurrent malady usually terminates the scene.

Harry E. Hale.

PNEUMONIA, LOBAR.—(Synonyms: Croupous Pneumonia, Fibrinous Pneumonia, Pneumonitis, Lung Fever.) The lung differs from all other structures in having two separate circulations—the nutrient, supplied from the left side of the heart through the bronchial arteries, and the functional, supplied from the right side of the heart through the pulmonary artery. This double circulation underlies all the phenomena of pneumonia, and must be recognized in any definition of the disease, as without it the disease itself could not exist.

Definition.—Lobar pneumonia is an acute disease in which a specific parasite invades the air cells of one or more pulmonary lobes, where it grows in a fibrinous medium exuded from the functional capillaries, and generates a toxin that infects the system at large.

The local process causes consolidation of the affected area by filling the air cells with the effused material, which material is afterward removed, leaving the structure of the lung intact. The general infection is marked by fever, which in a typical case begins with a chill, and after a duration of from four to nine days ends abruptly by crisis.

In most cases a local dry pleurisy is excited, the phenomena of which are added to those of the pneumonia proper.

Death may take place from the virulence of the infection, from loss of respiratory surface, from exhaustion of the right heart, from consecutive asthenia, or from a combination of two or more of these causes.

Symptoms and Clinical Course.—The attack may be preceded by prodromes,[1] such as malaise, headache, anorexia, pain in the limbs and back, etc. But, as a rule, the first complaint of the patient is of pain in the chest, usually in the mammary region. This is sudden in its onset and often very severe, and by restricting the movements of the ribs renders the respiration superficial and rapid. In most cases a chill follows, or, it may be, precedes the pain. The chill varies from a mere creeping sensation to a heavy and prolonged rigor, as severe as in a case of intermittent fever. With the chill there is a rise of temperature. The thermometer shows from 3° to 4° F. of fever during the first twelve hours, rapidly rising until the temperature reaches from 103° to 105° F. or even more. Then there is a period during which the temperature is maintained with slight variations until from the fifth to the eighth day, when a crisis occurs and the temperature becomes normal, or often subnormal. Cough is an early symptom, but it is repressed as much as possible to avoid the severe pain which it causes. The expectoration is apt to be frothy at first and mixed with florid blood; later it becomes viscid and very tenacious, so that it is spat out with difficulty and adheres like thick mucilage to the vessel containing it. Its color at this stage varies in different cases. It may be a light yellow, a pale green, or a chocolate-brown, or a mixture of these colors. It is often likened to prune juice. Sputa of this kind may be considered pathognomonic. As resolution progresses the expectoration becomes less colored, less sticky in consistence, and more catarrhal or purulent in its character, and the quantity gradually diminishes until it ceases altogether.

The respirations are early increased in frequency, and this quite out of proportion to the pulse rate and temperature. In nearly every severe case the respirations will go up to 40 or 50 or more to the minute, and they not infrequently reach 60 or more when the consolidation is extensive, or pulmonary œdema takes place. This disproportionate frequency of respiration is very significant. The pulse is full and strong in the early stages, running from 90 to 100 when the temperature is 103° to 104° F., and becoming weaker and more frequent as the disease advances. When the respiration is greatly embarrassed the pulse is apt to be small and creeping.

The skin is hot and dry at first, later there is a tendency to perspiration, which may be profuse. The face is pale, with often a dusky red patch on each cheek. The lips are inclined to a bluish hue in proportion to the degree of pulmonary implication. They are often the seat of an herpetic eruption.

After the first forty-eight hours the chlorides in the urine are greatly diminished, or entirely absent. In severe cases a moderate degree of albuminuria is common during the height of the disease.

The physical signs begin to be appreciable, as a rule, within from twelve to twenty-four hours after the initial chill. Usually the first to be noticed is a fine crepitant râle, heard only with inspiration, though in some cases this is preceded by a diminished clearness of the respiratory murmur. Dulness on percussion succeeds, increasing in intensity as the consolidation becomes more complete. Ultimately the respiratory murmur is wholly replaced by a peculiar whiffling sound heard most distinctly toward the close of expiration, the so-called tubular breathing. If the pleura is involved there may be a rubbing or creaking sound in addition. There are increased vocal resonance and vocal fremitus. At the crisis, while the temperature falls and the pulse and respiration become less frequent, there is no immediate change in the physical signs, showing that the condition of the affected area remains the same.

In a large proportion of cases of pneumonia there is decided leucocytosis, the white cells numbering 20,000, 30,000, 40,000 or more to the cubic millimetre.

Variations from the above course are common. The pain may be entirely absent, or it may be felt at a point outside the chest, as for instance in the abdomen. The chill is absent in about one-third of all cases. The subsequent severity of the attack seems to be in some degree proportioned to that of the chill, but this rule has many exceptions, especially in advanced age. The temperature begins to rise from the moment of the attack, and increases with slight fluctuations until the maximum is reached. In cases that pass the crisis the highest point is usually a few hours before the decided fall takes place. When death takes place before the crisis, the highest point often immediately precedes dissolution, when it may reach 107°, 108°, or even 109° F.

When defervescence occurs by crisis, which is usually from the fifth to the eighth day, the temperature falls within a few hours almost or quite to normal. This is apt to occur during the night, and it often happens that the patient is left at the evening visit with no sign of an approaching decline of temperature, yet the next morning is found in an almost afebrile condition.

Within a day or two after the crisis the temperature very often becomes subnormal.

In a considerable proportion of cases instead of crisis there is a gradual fall of temperature until the normal line is reached. This defervescence by lysis may be complete at any time between the third and the fifteenth or twentieth day.

Delirium.—As the pyrexia increases, delirium is pretty frequently observed. Occurring early, and in persons having a tendency to cerebral disturbance in the presence of fever, it may have but little significance, but in other cases it is due directly to the infection, and it then points

Digitized by Microsoft®

to a condition of considerable gravity. Old persons are especially liable to a quiet delirium resembling that of typhoid fever.

Sleeplessness is not at all uncommon, and should always suggest an inquiry into the habits of the patient,

www.libtool.com.cn

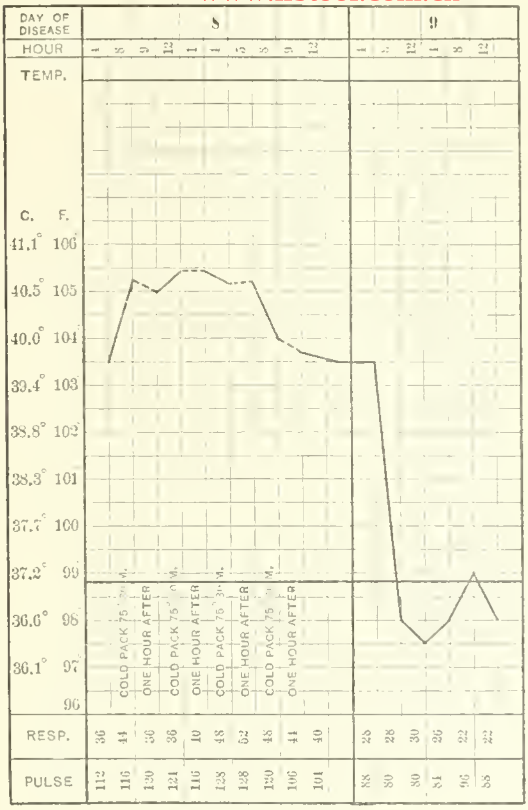

FIG. 3829.—Defervescence by Crisis.

for while it is not confined to those with alcoholic antecedents, it is much more frequent in such persons, and in the absence of delirium the key to the problem might be overlooked. In non-alcoholics the condition seems to be one of cerebral irritation at first, and later, perhaps, of cerebral exhaustion.

In children often, and very rarely in adults, convulsions take the place of the initial chill.

Causes of Death.—Death may occur in a variety of ways. The patient may be overwhelmed by the intense virulence of the infection, death occurring within from thirty-six to forty-eight hours after the chill. Apparently all the vital functions are overpowered by the toxæmia. There is extreme muscular and nervous prostration, the heart's action becomes rapid and feeble, digestion is suspended, the kidneys act imperfectly, delirium and coma supervene, and death occurs from acute asthenia.

In other cases death is caused by exhaustion of the right heart. The muscle, already enfeebled by the action of the poison, tires out from overwork, dilatation and over-distention follow, and finally, failure to contract.

Still another cause of death is loss of respiratory surface. This is rarely the result of simple pneumonic consolidation, but there are added to this, congestion and œdema of other portions of the lung. The lung fills up more and more, and death by asphyxia takes place.

Not infrequently death comes from exhaustion of the vital powers after a protracted struggle which the system is no longer able to endure. This is common in feeble and aged persons, and occurs usually after the febrile period.

Lastly, death may be caused by one or more of the complications of the disease.

In addition to the foregoing, sudden death may occur at any stage of the disease in a manner which, with our present knowledge, cannot be accounted for, and for which there is no anatomical explanation.

PATHOLOGY.—*Autopsical Findings.*—These correspond to a process extending from simple hyperæmia through extreme engorgement, fibrinous and cellular exudation into the air cells, complete consolidation, fatty degeneration of the exudate, and removal of the latter by absorption and expectoration. All of these stages may be represented at the same time in different portions of the lung.

The earliest lesion is simple congestion. When the chest is opened a portion of the lung may be found in this condition. It is not so fully collapsed as the surrounding normal lung, and to the touch it is slightly more resistant. On section the surfaces are bright red, and exude a bloody frothy serum. The physical sign corresponding to this condition is a slight localized feebleness of respiration, with more or less abundant moist râles. A few hours later the hyperæmia has passed into an extreme degree of vascular engorgement. The diseased part shrinks but little when the chest is opened. The pleural surface is of a deep red color, veiled by more or less of fibrinous exudate, which peels off readily in flakes. The resistance to touch is markedly increased,

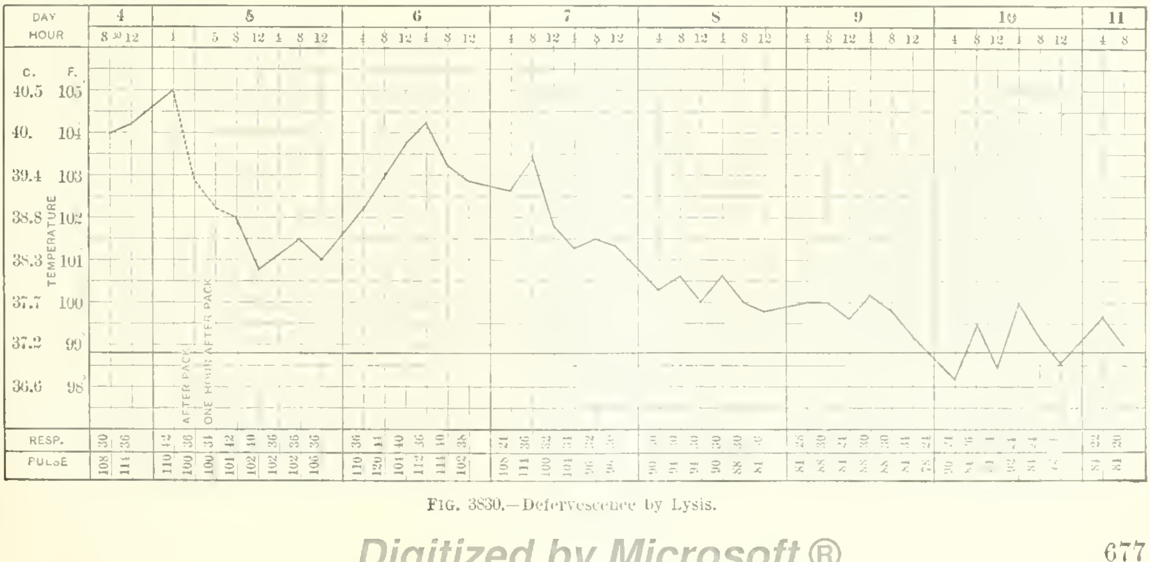

FIG. 3830.—Defervescence by Lysis.

Digitized by Microsoft®

and on section the tissue is more readily divided than in healthy lung. The cut surfaces are dark red, and dark blood mingled with air follows the knife. The appearance resembles closely that of an incised spleen, and the term splenization is applied to this stage of the local disease. Microscopically, the pulmonary capillaries are found distended with blood, more or less fluid occupying the air cells. But the lung still crepitates between the thumb and finger, and can be squeezed dry without breaking down. A piece of it thrown into water floats.

www.libtool.com.cn

The corresponding physical signs are diminished resonance on percussion, broncho-vesicular respiration, crepitant râles, and slightly increased vocal resonance. A pleural friction sound also is often present.

In the next stage the air cells are filled with a fibrinous exudate, by which the parenchyma is completely solidified. If a considerable area is involved, the lung is increased in volume, and pushes out into the intercostal spaces, so that furrows are imprinted on its surface by the ribs. The lung is usually covered by a dense layer of fibrin, which, if removed, shows a deep mottled red or purple color beneath. This layer is adherent to the costal pleura also, and the separation leaves both surfaces rough and irregular. When cut into, the solidified mass has much the consistence of liver, and is dark red or brownish-red in color, and for this reason the condition is known as *red hepatization*. A piece of lung in this condition will sink in water. The infiltrated tissue does not crepitate on pressure, is friable, and can be torn much more readily than normal lung structure. During this stage the weight of the lung may reach 2,500 or 3,000 gm., instead of 600 gm. which is the normal average.

Microscopically the contents of the alveoli consist

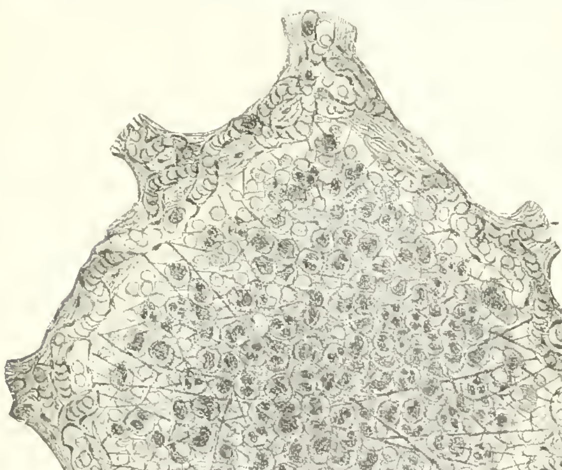

Fig. 3831. Air Cell Filled with Pneumonic Exudate. (Drawn by Dr. Louise Cordes from a specimen in the laboratory of the Presbyterian Hospital, New York.)

chiefly of fibrin in the form of a delicate mesh, red blood corpuscles, leucocytes, epithelial cells, and numerous diplococci pneumoniæ. Other organisms, such as streptococci, staphylococci, etc., are often found associated with the specific microbe.

In this stage the capillaries derived from the pulmonary artery are occluded, and the resulting thrombosis extends back into the larger vessels. The septa between the air cells are but little changed. The nutrient vessels remain pervious.

The physical signs of hepatization are dulness approaching to flatness, and increased resistance on percussion, with tubular breathing, or perhaps entire absence of respiratory sound and increase of vocal resonance and of vocal fremitus.

Succeeding the stage of red is that of *gray hepatization*. Much of the red coloring matter has been removed by absorption, white corpuscles have been added in great numbers, and the formed elements in the contents of the air cells have degenerated into a fatty, granular material. Hence the change in color. The tissue is softer than in the previous stages, so that the finger can be thrust into it, and the pit thus made fills with a dirty puriform fluid.

As resolution progresses, the infiltrated material is gradually removed, partly by absorption, partly by expectoration, and little by little the air regains access to the alveoli. It is several days, however, before the physical signs get to be entirely normal.

Often, besides the specific pneumonic lesion limited to a certain area, there is congestion in other parts of the same lung, and perhaps in its fellow. This may be so intense, and the resulting secretion so abundant, as to leave insufficient breathing surface, and thus be the immediate cause of death. The congestion may be hypostatic, when it will be limited to the dependent portion of the lung, or it may be due to cardiac weakness and affect all parts. Very frequently more or less pulmonary œdema is present.

Abscess of the lung as an event of pneumonia occurs in between one and two per cent. of all cases. The abscesses vary in size from that of a pea to the dimensions of the entire lobe.

After death from pneumonia the left cavities of the heart are usually found nearly or quite empty, while the right are distended by firm coagula that often extend into the branches of the pulmonary artery. The spleen is often enlarged and the liver congested. The cells of the renal tubes may be in the condition of cloudy swelling, and in a small proportion of cases there is fully developed "nephritis."

Pathology.—It is now very generally conceded that the essential phenomena of pneumonia are due to the action of one or more forms of bacilli. In nearly every case the diplococcus of Fränkel is found in the exudate. With this are sometimes associated other micro-organisms in such number as to suggest that they may play an important though subsidiary part in both the local process and the general infection.

As to the relation of the specific organism to the disease as a whole, we may note:

First, that no amount of traumatism inflicted upon the lung, be the methods ever so varied, produces pneumonia. We may cut, bruise, burn, or scald the lung; we may introduce mechanical or chemical irritants into the air passages, and while we get a certain kind of reaction as the result, we do not get pneumonia.

Second, we may have pneumococcic infection in several serous and synovial cavities at the same time, resulting in suppuration in each, and not have pneumonia.

Third, we may introduce the pneumococcus into any portion of the body save the lungs, and even into the blood itself, and not get pneumonia.

Fourth, but if we introduce active pneumococci into the parenchyma of the lung we get pneumonia as the result.

Fifth, in probably every case of pneumonia coming to autopsy during the active stage, if the search is properly conducted, the presence of pneumococci in the lung can be demonstrated.

Digitized by Microsoft®

The inference from these facts is that the one thing necessary for the development of pneumonia is the presence in the alveoli of pneumococci in a condition of active multiplication.

It is known that pneumococci exist in the upper air passages of a considerable proportion of persons in absolute health. It is necessary only that favoring conditions should result in the translation of some of these into the alveoli in order that pneumonia occur. Once in the air cell the specific organism produces its specific irritation, causing effusion of the specific exudate. In this exudate as in a culture medium the coccus grows and separates its specific toxin, which in turn is absorbed into the blood, and gives rise to the fever and other manifestations of toxæmia.

www.libtool.com.cn

So long as fresh supplies of toxin are being formed, or in other words, so long as the consolidation is spreading, so long the toxæmia will be maintained. But here again, as in artificial cultures, there is a limit beyond which the process cannot extend. A given quantity of culture medium can maintain the life of a given number of germs only for a certain time, beyond which the changes produced in it unfit it as a soil for the further growth of the organisms, and the death of the latter puts an end to the process. With the supply of toxin cut off, the temperature falls.

This does not exclude the theory of an antitoxin. Indeed, numerous observations, and especially those of the Klemperer brothers, go to show that a transient immunity is created by an attack of pneumonia, and that this immunity may be transferred to another subject by serum inoculation. This could scarcely be explained except on the theory of an antitoxin, and I can see no obstacle to accepting both theories in explanation of the phenomena in question.

The specific organism of lobar pneumonia is the *pneumococcus lanceolatus.* Discovered in 1880 by Sternberg, its causal relation to pneumonia was demonstrated by him a few years later. It is generally seen in pairs of oval or lancet-shaped elements surrounded by a capsule. In cultures, short chains of three or four members are common. Like other micrococci, it is non-motile. It grows in faintly alkaline media, and by transplanting every third or fourth day the growth may be continued indefinitely.

This organism is found, in all but a very small percentage of cases, in the expectorated material. Failure to find it is probably due to defective technique. When a pure culture is injected into the substance of the lung typical croupous pneumonia results.

When in a dry state the pneumococcus retains its virulence for long periods, especially when protected by being mixed with dried sputum. The disease has been communicated to newcomers in houses that had been closed for months.

Recent researches show that in fatal cases of pneumonia the specific diplococcus is quite commonly present in the blood, while in cases ending in recovery it is only exceptionally encountered.

Diagnosis.—A typical case of pneumonia seen from the beginning can scarcely be mistaken for any other disease. The abrupt onset, the pain, the chill, the fever, the respiration accelerated out of proportion to the temperature, pulse, and respiration, and, finally, the peculiar expectoration, will suffice to establish the diagnosis even without the aid of the physical signs. But when the latter are added, and we have fine crepitation with inspiration and a little later a blowing sound with expiration, while the vocal resonance and the vocal fremitus are exaggerated, and the percussion note becomes constantly duller until it approaches flatness, there is presented a picture which for vividness and individuality can hardly be surpassed.

But not all cases of pneumonia run a typical course. There is scarcely one of the classical symptoms or signs that may not sometimes be wanting. In about twenty per cent. of all cases the chill is absent. Pain is not a marked feature unless the pleura is involved, and in central pneumonia it is often not severe enough to excite complaint. In feeble or elderly persons the fever may be slight; indeed, even apart from these conditions, some of the worst cases that we meet show but a moderate temperature throughout. The pulse may not correspond with the temperature; and the respiration, usually the most characteristic of the symptoms, is sometimes not strikingly frequent. Cough and expectoration may be entirely absent, or the cough may bring up only a little frothy mucus from the bronchial tubes. Apart from the above, the diagnosis involves differentiation from quite a range of affections, such as bronchopneumonia, pulmonary œdema, pleurisy with effusion, pulmonary phthisis, cancer of the lung, atelectasis, engorgement in fever, typhoid fever, for which the reader is referred to the articles in which these affections are discussed.

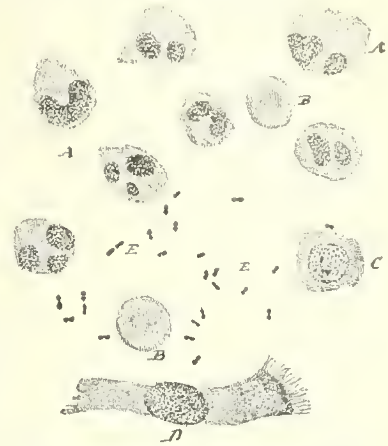

Fig. 3832.—The Micrococcus Lanceolatus in Pneumonia Sputum. *A A*, Leucocytes; *B B*, red blood cells; *C*, epithelial cell; *D*, ciliated epithelium; *E E*, pneumococci. × 1000.

Complications.—There are several affections that so often appear with pneumonia as to make it reasonably certain that there is a common influence at work, and this influence can often be found in the presence of the pneumococcus in the locality in question. The following tables show the complications observed at the Presbyterian Hospital, New York:

Complications of Pneumonia.

Out of 488 Cases.

	Number of cases.	Recovered.	Died.
Pleurisy with effusion	20	17	3
Pericarditis (acute)	6	1	5
Otitis media	6	6	
Thrombosis of femoral vein	3	3	
Bronchitis	13	9	4
Jaundice	2	1	1

Out of 304 Cases.

	Number of cases.	Recovered.	Died.
Gangrene of leg	1	1	
Delayed resolution	7	7	
Relapse	2	2	
Delirium tremens	11	5	6
Pyæmia	2	..	2
Abscess of lung	1	1	
Laryngitis	1	1	
Erysipelas	2	2	
Persistent bronchopneumonia	1	1	
Acute nephritis	3	2	1
Œdema of lungs	6	1	5
Empyema	10		

Prognosis.—This is modified by a number of preexisting conditions, the principal of which are sex, age, season of the year, habit as to the use of alcohol, and the presence or absence of certain chronic diseases.

While pneumonia is more frequent in men, it is more fatal in women. Of 223 patients in the Presbyterian Hospital 170 were males, with a mortality of 28.8 per cent., and 53 were females, with a mortality of 31.2 per cent. The mortality in reference to age is shown by the

Digitized by Microsoft®

following table taken also from the records of the Presbyterian Hospital:

www.libtool.com.cn

Pneumonia—434 Cases.

Relation to age.	Died.	Percentage dying.	Recovered.	Percentage recovered.
Below 5 years	0	0	13	100
Between 5 and 10 years	0	0	18	100
Between 10 and 15 years	1	9	11	91
Between 15 and 20 years	7	23 +	23	76 +
Between 20 and 30 years	28	22 +	95	77 —
Between 30 and 40 years	37	37 +	62	62 +
Between 40 and 50 years	31	42 +	42	57 +
Between 50 and 60 years	16	47 +	18	52 +
Between 60 and 70 years	16	66 +	8	33 +
Over 70 years	5	62 +	3	37 +
	141	32 +	293	67 +

As to seasons of the year, the spring months give the lowest mortality, the summer shows a slight increase, while in the autumn and winter the percentage of deaths is greatest.

The habitual abuse of alcohol unfits the system to bear up against pneumonia, as is shown by the following table:

Pneumonia—428 Cases.

Relation to alcoholism.	Died.	Percentage dying.	Recovered.	Percentage recovered.
Markedly alcoholic	36	70	15	29
Moderately alcoholic	52	32	109	67
Non-alcoholic	45	20	171	79

Among pre-existing conditions a rheumatic habit, diabetes, and chronic renal insufficiency, especially if associated with cardio-vascular changes, render the prognosis much more serious. The presence of advanced valvular disease leaves but little chance for recovery. Of the conditions arising in the course of the disease and affecting the prognosis, the first is the initial chill. This occurred in 144 out of a series of 223 cases, with a mortality of thirty-four per cent., while the remaining 79 cases in which the chill was absent gave a mortality of only nineteen per cent.

The prognosis depends largely upon the extent of the pneumonia. When both lungs are involved not half of the patients recover. Pneumonia occupying the whole of a lung is more dangerous than when only a part is involved. The right lung is more frequently implicated, and also gives a higher mortality.

A feeble pulse that is frequent in relation to the respiration and temperature is a disquieting element, as is also a very frequent respiration, especially when it occurs with a moderate temperature.

Up to 105° F. the danger does not seem to increase materially with the rise of the thermometer. A higher temperature, however, tells immediately upon the death rate.

A physical sign that has an important prognostic significance is accentuation of the pulmonary second sound. This is the result of increased tension in the pulmonary artery, and is a measure of the obstruction in the lung on the one hand, and of the power of the right ventricle on the other. If this accentuation becomes less marked it is either because the obstruction is diminished, which is a favorable sign, or because the right ventricle is becoming weaker, with all that this implies. Which of these two conditions is present is easily determined by the general symptoms.

A considerable increase in the number of the white blood cells is, as a rule, a favorable indication, while a low count is unfavorable. In anything like a severe case the prognosis is alarming if the leucocytosis remains below 12,000 or 14,000. On the other hand, a high leucocytosis persisting after the temperature falls indicates further trouble in store, probably some complication.

It is generally believed that the presence of herpes labialis is of good augury. If there is an absence of expectoration in the second and third stages, or if the expectoration becomes scanty and difficult, the outlook is grave. A sudden cessation of expectoration, if accompanied by tracheal râles, indicates the near approach of death. Late delirium is an unfavorable sign, as are also apathy and somnolence.

The mortality in pneumonia differs enormously under different conditions. It is much greater in hospitals than in private practice, and in civil than in military hospitals. In civil hospitals it runs from twenty-five to thirty per cent., while in private practice it is scarcely half so great. The death rate is much higher in some years and in some localities than in other years and in other places.

Etiology.—While the essential cause of pneumonia is the development of a specific germ in the pulmonary alveoli, there must be a contributing cause that in some way opens the system to attack. Among the predisposing causes are the following:

Sex. Males are more liable to attack than females.

Age. If the total number of persons living at any given age be considered, it is probable that the ratio of cases in successive decades is fairly uniform except during the most active period of life when exposure is greatest.

Race. In America, the negro race is decidedly more liable to pneumonia than the white.

Former Attacks. A person who has passed through one attack is more liable to another.

Unsanitary Living. Pneumonia occurs more frequently in dark, crowded, and ill ventilated dwellings than where the supply of light and air is ample.

The principal exciting causes include exposure to cold, exhaustion, the presence of some other infectious disease, and operations under the use of an anæsthetic.

Although not readily communicable, pneumonia may undoubtedly be transmitted from person to person. Indeed, it quite frequently assumes the form of a veritable epidemic. In addition to this, certain houses have been observed to furnish, year after year, an undue proportion of cases, which seems to indicate that the infecting principle lurked in the apartments.

As to the etiology of pneumonia in general, we are obliged to admit that in a large proportion of cases the attack appears to come on spontaneously.

Treatment.—A correct treatment of pneumonia must recognize that the disease is essentially a germ culture going on in the air cells of the affected part. The causal indication, therefore, is to inhibit this culture. The debatable question is whether such inhibition is practicable by any safe means within our reach. The writer is firmly convinced that it is; and observations sustaining this view are rapidly accumulating from many sources. The problem requires that we rid ourselves of the conception of an "inflammatory" process carrying on an independent work of its own, over and above the response of tissue to the irritation of the micro-organism. This irritation depends upon a specific vital property of the pneumococcus, as is shown by the fact that no other irritant whatsoever will produce a like result. If, therefore, we can so modify the bacterium that it loses its specific irritant property, the essentially pneumonic changes in the lung will be arrested. This then is the first indication for treatment, and it is as unwise to defer action upon it until the case becomes severe, as it would be to defer opening an abscess until the signs of pyæmia should appear.

It is clear that the material exuded into the air cells must contain its share of any substance circulating in the blood from which the exudate is derived. This makes it possible to impregnate the exudate with any desired medicament, including one inimical to the pneumococcus. It is not necessary to kill the germ; it is enough to inhibit its growth, a very much easier thing to do.

A considerable number of drugs seem to be capable of producing this effect. The salicylate of sodium or am-

Digitized by Microsoft®

monium has, up to the present time, been the most efficacious. It is given in doses of ten or fifteen grains every two hours. In a large proportion of cases, especially if given early, it will affect the temperature at the end of

www.libtool.com.cn

twenty-four hours, and bring about a defervescence by lysis in the course of the two or three days following. Recently Dr. George Peabody has substituted aspirin in doses of fifteen grains four times a day. Of twelve cases treated in this way all ended in recovery, and in every case defervescence was by lysis.

Creosote and its carbonate have also been employed successfully in a very considerable number of cases. Of the carbonate ten or fifteen minims are given every two hours, either in emulsion or in capsules.

The substitution of lysis for crisis in a large majority

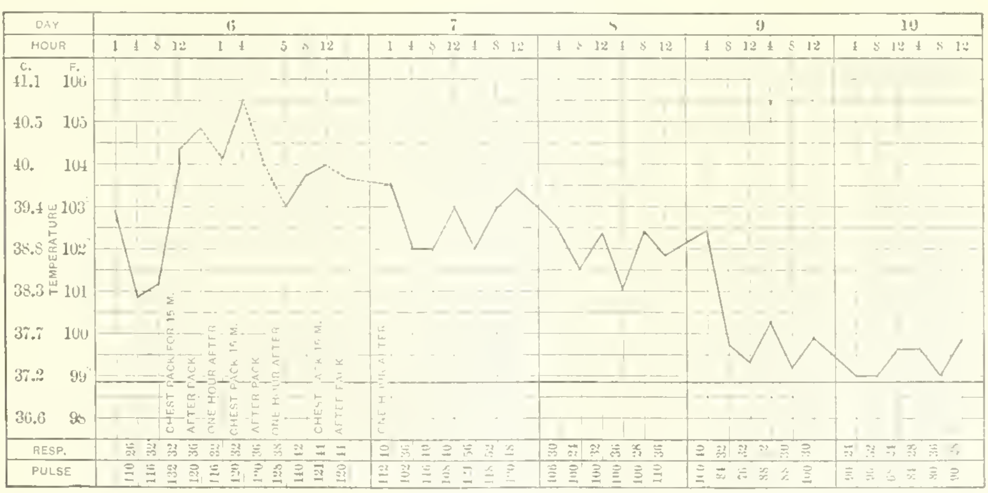

FIG. 3834.—Patient having Double Pneumonia who was Treated with Sodium Salicylate. Entered hospital on the third day of the disease with pneumonia of the lower right lobe. On the sixth day the left lower lobe became involved. Cold applied to the chest for temperature above 103.5° F., and twenty grains of sodium salicylate administered every four hours. Defervescence by lysis. Normal temperature on the tenth day.

of cases is a very remarkable result of remedies of this class, and demonstrates the power they possess to modify the usual course of the disease.

Specific medication of this kind is more efficient the earlier it is resorted to, but it is not without value at any stage of the disease. Many remedies besides those mentioned above have been employed with more or less success for their anti-bacterial effect, but have nothing especially to recommend them.

Aside from specific measures, the treatment of pneumonia will be in accordance with the following indications: Stimulation of the emunctories to throw off the poison as it forms; sustaining the vital powers and particularly the heart; relieving the pulmonary circulation; compensation for loss of respiratory surface by the inhalation of oxygen; reduction of excessive temperature; relief of incidental symptoms.

It is well at the outset to relieve the bowels by an efficient cathartic, and for this purpose nothing answers so well as calomel. Its operation is often followed by a considerable fall of temperature which may be permanent. If the urine is scanty a diuretic is called for, and the best of all is an abundance of cold soft water.

The vital powers must be sustained, and at the first evidence of flagging strychnine, strophanthus, caffeine, or other heart tonic is called for. Much harm is done by a routine use of digitalis. This drug increases the periph-

Digitized by Microsoft®

eral resistance and thus adds to the labor of the heart, while at the same time it favors venous congestion by lessening the capacity of the arterial system. Its use is admissible when cardiac arrhythmia is present, but it should always be guarded by an arterial dilator. Alcoholic stimulation may be required almost from the first, particularly in those patients who are addicted to its use. It is indicated when the pulse is small and thready, or when there is persistent delirium in an alcoholic subject. When under its use the temperature shows a reduction, and the pulse loses in frequency and gains in volume, we may be sure that the alcohol is doing good. It should not, however, be given in such quantity that its odor remains persistently in the breath.

www.libtool.com.cn

The pulmonary circulation may require to be relieved by dividing the blood more equally between the arteries and the veins. This is accomplished by the use of arterial dilators. Of these sodium nitrite in doses of two grains every two hours gives the most satisfactory and even result. It can be supplemented by nitroglycerin as occasion demands. The indication for arterial dilators is found in a small and creeping pulse with failing pulmonary second sound and a tendency to cyanosis. In cases presenting these conditions in an extreme degree venesection followed by saline infusion will sometimes prove singularly beneficial.

Compensation for loss of respiratory surface may be secured to some extent by inhalations of oxygen. These should be resorted to whenever the respirations exceed forty per minute, and they may be made continuous if the condition persists.

For the reduction of excessive temperature cold sponging and an ice-cap to the head are the most available means. When the fever produces extreme jactitation, tending to nervous exhaustion, the coal-tar preparations may be employed very cautiously and for brief periods.

For the relief of pain hypodermic injections of morphine are by far the best means at our command. They are efficient, and at the same time, by slowing and deepening the respiration, they improve the circulation in the affected part. They are to be used with care, however, and their frequent repetition is to be avoided. Hot poultices on the one hand, and ice bags on the other, are preferred by many, and are fairly efficient. In mild cases dry cups or sinapisms may suffice.

The feeding of the patient requires close attention. The tendency is to feed too highly. The conditions present are very unfavorable to digestion, and undigested food in the alimentary canal gives rise to flatulent distention and greater embarrassment of respiration, besides being a burden rather than a help to the vital power already overtaxed.

A concentrated fluid food that will not readily ferment is to be given, but in no greater quantity than can be easily digested and assimilated.

An abundance of fresh air from first to last is indispensable, and anxiety lest this should cause the patient to take cold should be dismissed. "Antiseptic precautions" should be adopted.

Serum therapy has not yet established its claim to be adopted, though the prospect for the future is somewhat encouraging. *Andrew Heermance Smith.*

PNEUMONIA OF INFANTS.—The acute pneumonia of infants may assume one of two distinct types—either that of an acute lobar pneumonia or that of an acute bronchopneumonia or lobular pneumonia. The former type, which is less common than the other, is caused by the pneumococcus, develops as a primary disease, has an acute onset, runs a short course, is characterized by a continuous high temperature, ends by crisis, and allows a good prognosis. The other type of pneumonia is the most common disease of infancy, is usually secondary, may be caused by one of several micro-organisms, is variable in onset, runs an indefinite course with irregular temperature, ends by lysis, and allows a less favorable prognosis—that is, one which depends largely on the disease to which it is secondary.

LOBAR PNEUMONIA.

Infantile lobar pneumonia—croupous pneumonia: Fr., *La pneumonie franche;* Ger., *Primäre genuine Pneumonie*—corresponds in some measure to the lobar pneumonia of adults, but it allows a more favorable prognosis. Lobar pneumonia is an acute disease of short duration, characterized by inflammation and hepatization of a certain area of lung tissue, and is caused by the pneumococcus.

ETIOLOGY.—The disease is almost always primary. Although it is less common before the third year, it may occur in early infancy. In fact, cases have been reported in which the disease developed before the birth of the child.

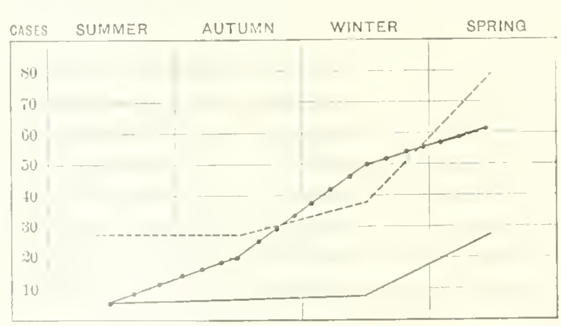

FIG. 3835. Chart Showing the Frequency of Lobar Pneumonia in Infants and Children at Different Seasons. - - - - - -, Cases reported by Dr. Comby; •—•—•, cases reported by Dr. Holt; ———, cases reported by Drs. Northrup and Freeman.

Digitized by Microsoft®

All statistics seem to agree that boys are more frequently affected with the disease than girls, the general ratio being 60 per cent. boys and 40 per cent. girls. Comby reports that in 172 cases seen by him 105 were in boys and 67 in girls. Of 44 cases reported by Henoch 24 were in boys and 20 in girls. Holt reports 60 per cent. of his cases as occurring in boys. Rilliet and Barthez, out of 408 cases, report 221 in boys and 187 in girls. Of 42 cases at the Foundling and Nursery and Child's hospitals in New York 25 were in boys and 17 in girls, or 60 per cent. in boys and 40 per cent. in girls.

Season.—This disease is seen most often in the spring. The accompanying chart (Fig. 3835), constructed from data by Comby and Holt and the authors of this paper, shows the frequency of lobar pneumonia, in children, in New York and Paris at different seasons. Exposure to cold, traumatism, contagion, and previous poor health have been mentioned as occasional etiological factors; but if they do play any part in the production of this disease, except by lowering the resistance, this must be true only in rare instances.

The micro-organism regularly found in the sputum and in the lesion, and occasionally in the blood, is the micrococcus lanceolatus or pneumococcus of Fränkel. Various other bacteria may be associated with the pneumococcus.

Pathology.—The focus of the disease may be located in various parts of the lung, but certain lobes are more often affected than others. Holt finds that the left lower lobe is the one most often affected, the next in order being the right upper and the right lower. Comby, on the other hand, finds that the right upper lobe is much more frequently affected, the next in order being the left upper and the left lower. Monti, who has had a large experience with the disease in Vienna, considers that the right upper lobe is much more often involved than the left, and the left lower much more often than the right. The cases collected by the present writers show that the right upper, the right lower, and the left lower lobes are about equally often affected, while the left upper lobe is the least apt to be involved. The exact figures of relative frequency are as follows:

	Right upper.	Right lower.	Left upper.	Left lower.
Holt	2	3	..	1
Comby	1	..	2	3
Ashby	2	..	..	1
Northrup and Freeman	2	3	..	1

So far as its general characters are concerned, the lesion of lobar pneumonia in children corresponds to that in adults. It will therefore not be necessary to describe them here in detail (see article on *Pneumonia, Lobar*, by Dr. A. H. Smith). The disease is an acute exudative inflammation of the lung, in the course of which the air spaces become filled with red and white blood cells, serum, and fibrin. At the same time there is developed a toxæmia from the absorption of the poisons which are produced in the lungs. The lesions are not usually in the same state of development in all parts of the involved lung tissue at the same time, for while one area is in the condition of red hepatization, a neighboring area may show gray hepatization.

Fig. 3836.—Temperature Chart of a Case of Lobar Pneumonia in a Baby of Nine Months.

Resolution does not always take place. The products may persist and become organized, or they may break down and form an abscess, or, finally, a necrotic process may ensue and gangrene manifest itself. In the lobar pneumonia of infants, however, these terminations are less often observed than they are in adults.

Pleurisy, with the development of fibrin only, or with a plastic exudate, or with pus, may accompany the pneumonia. A bronchitis is usually present. Pericarditis, endocarditis, and meningitis occasionally occur.

No sputum is, as a rule, expectorated by infants, all that is coughed up is swallowed. We have found that the sputum may best be obtained for microscopic examination by washing out the stomach half an hour after the child awakes and before food is given. Where this fails sometimes titillating the pharynx causes cough and ejection of small masses of muco-pus.

A leucocytosis appears at the beginning of the disease, and increases in intensity, disappearing as the temperature drops.

Symptoms.—There is no incubation stage in the lobar pneumonia of infancy. The baby becomes suddenly very severely ill. It usually vomits and has a rapid rise of temperature. Convulsions may occur with the onset, especially in infants that have rachitis. Chills are rarely seen with the onset of the pneumonia of infancy. The child becomes dull and apathetic. With the rise of temperature the pulse rate is increased, while the respiration is increased out of proportion to the pulse rate. Thus the ratio of respiration to pulse, which normally should be one to four, approximates that of one to three. The child develops a short dry cough, and is apt to have an expiratory grunt. The alæ nasi expand with each inspiration. The child's face is usually flushed and the skin dry. The severity of the attack may usually be judged from the degree of elevation of the temperature. Cerebral symptoms often accompany the disease. Convulsions are occasionally seen, while stiffness of the back of the neck, stupor, and delirium are often present.

The typical temperature chart of the lobar pneumonia of infancy shows a rapid rise of temperature to about 104° F., slight morning remissions and evening exacerbations continuing for less than a week, and the disease ending by crisis. Such a chart is shown in Fig. 3836; it

Digitized by Microsoft®

www.libtool.com.cn

represents the variations in temperature observed in a child nine months old while passing through an attack of lobar pneumonia. In other cases the remissions are more pronounced, the charts resembling more nearly those of bronchopneumonia, but differing in the fact that the disease now under consideration runs a short course and ends by crisis. The temperature continues to be elevated for about a week, and then usually falls somewhere between the fifth and the tenth days. It may fall on the second day or may persist for fully two weeks.

The pulse, which is at first full and strong, varying from 120 to 160 beats per minute, later becomes weaker, more rapid, and sometimes irregular or intermittent. The respirations are also increased in rapidity, even more so than the pulse; they may reach as high a rate as 40 or 60 or even 80 per minute. Usually, however, they bear to the pulse a ratio of one to three or at times one of even one to two and one half. The inspirations are short and the expirations long and accompanied often by a characteristic grunt or groan.

Physical Signs.—The physical signs of lobar pneumonia in infancy differ so materially from those usually found in adults that they should be especially emphasized. These physical signs are usually late in appearing and are less regular and well defined, while in some cases no physical signs at all can be elicited until after the temperature has dropped.

Many cases show, at the beginning of the attack, evidences of congestion; these being recognizable in the form of slight dulness on percussion and diminished respiratory murmur, at times quite pronounced. In many of the cases neither of these signs is present, but on carefully going over the chest there will be found a small area where subcrepitant or crepitant râles will appear at the end of a deep inspiration. In other cases the first sign will be a small area of high-pitched breathing, which may or may not have the true bronchial character. In whichever of these manners the signs first appear, other of the usual signs of lobar pneumonia in the adult are gradually added, so that in most cases, before the end of the week, the chest will present, in some particular area, a group of characteristic signs, the most important of which are dulness on percussion, bronchial breathing and bronchial voice sounds, and increased vocal fremitus. In some cases the disease manifests the characteristic onset and range of temperature, the ratio of the respiration to the pulse is as one to three, the alæ nasi are dilated, and the expiration groan is present, and yet no signs of consolidation can be made out in the chest. However, the signs in the chest are not essential for the establishment of the diagnosis in any given case provided there be present the group of symptoms just enumerated. In some cases the chest signs will first make their appearance at the time when the temperature falls. Again, in other cases, while there may be no definite signs of consolidation, percussion over the area situated below the clavicle may elicit an exaggerated or tympanitic percussion note, a sign which is believed by Comby to be of great value as indicating an involvement of the pleura or lung on that side.

Complications.—The most frequent complication is a general bronchitis, which may be the result of an infection with other micro-organisms than the pneumococcus. This complication may cause a greater daily variation in the temperature than is usually seen.

Next in point of frequency are the pleural lesions. At autopsies of these cases a dry pleurisy over the consolidated area—indicated by a lack of lustre in the pleural surface—is usually seen. In six or eight per cent. of these cases some exudate of a fluid or plastic character may form in the pleural cavity. When this is marked it forms a thick layer of fibro-purulent exudate of a yellowish color and shaggy appearance, accompanied by more or less purulent fluid. The character of this exudate in children is important, for in some cases it is thrown out in considerable amount, and yet only a small portion of it is free fluid. This small quantity, however, is sufficient to yield the physical signs of the presence of fluid in the pleural cavity and consequently to justify puncturing the chest wall with a needle. But the operation, under these circumstances, is very apt to prove unsuccessful, owing to the fact that the needle becomes occluded by the thick exudate.

Meningitis caused by the pneumococcus may occur as a complication, as may also pericarditis.

Diagnosis.—The diagnosis should be based on the history of an acute onset in the midst of good health, on the ratio which the respirations bear to the pulse rate, on the prolonged expiration, on the expiratory grunt, and on the dilatation of the alæ nasi. If the diagnosis can be confirmed by physical signs on examination so much the better, but the absence of these signs need not invalidate the diagnosis.

Prognosis.—The prognosis in primary uncomplicated lobar pneumonia in previously healthy infants is good, the mortality varying from three to five per cent. The prognosis is graver in children that have not been robust. The presence of only a slight leucocytosis is believed by Monti to render the prognosis worse.

Treatment.—On account of the possibility of communicating pneumonia to others, and for the good of the patient as well, a large, well-lighted and ventilated and quiet room should be obtained. But one person should be allowed in the room at a time. The number of cases which have presented at the onset the symptoms and physical signs of lobar pneumonia, but which have promptly recovered, is sufficiently large to warrant the belief that it is sometimes possible to abort the disease provided the efforts directed to the attainment of this object are made sufficiently early. Such treatment should consist in the administration of a single fairly large dose of calomel, the use of active counter-irritation by mustard paste, applied either over the whole thorax or simply over the suspected area, and the stimulation of the patient with strychnine. If no amelioration occurs within twenty-four hours after this treatment is begun, one may assume that the disease will run its course.

The medication, after the disease has once become established, should, as a rule, be directed either to the gastro-enteric tract or to the heart. Expectorants are rarely indicated. The tendency to constipation and tympanites, which is apt to embarrass the patient by interfering with the descent of the diaphragm, may usually be best treated by rhubarb or by a combination of rhubarb and soda. Heart stimulants are usually indicated early, and of these strychnine is the most valuable; it should be given in rather large doses, gr. $\frac{1}{100}$ to gr. $\frac{1}{50}$ every three or four hours. When the extremities are cold nitroglycerin is useful. Alcoholic stimulants should be reserved as a later resource. Among the antipyretics the use of water will be found to be most effective. Sponging with equal parts of alcohol and water has a moderate antipyretic action, and later, if it should be found necessary, a cold pack or a cool bath may be given. Of the antipyretic drugs only phenacetin should be given. In order to secure a sedative effect a very small dose (0.15 gm or gr. $\frac{1}{4}$) of codeine or from five to ten drops of paregoric may be administered. Oxygen (by inhalation) is one of the most valuable stimulants, especially in the treatment of very young babies who take medicine badly by the stomach.

Bronchopneumonia.

Bronchopneumonia—Lobular pneumonia; Capillary bronchitis; Fr., *Broncho-pneumonie*; Ger., *Bronchopneumonie*—is an acute disease of indefinite duration, which is characterized by a capillary bronchitis and by peribronchial areas of consolidation, and which may be caused by one or more of several micro-organisms.

Etiology.—This disease is the form of primary pneumonia most commonly found during the first two years of life, and at the same time it is the ordinary form of secondary pneumonia encountered throughout childhood. It is very common in infancy and early childhood; and at the autopsies in the New York Foundling Hospital it is a rare event not to find the evidences of more or less

Digitized by Microsoft®

www.libtool.com.cn

bronchopneumonia. The disease occurs most frequently during the first year of life and much less frequently with each succeeding year up to the fifth. After this age it is not a common disease. In the majority of cases the disease develops during the winter season; but this statement is more true of bronchopneumonia than of the lobar variety, for cases of the former disease in infants are seen also at other seasons of the year. Another important fact is, that bronchopneumonia rarely attacks infants who have previously been in good health. It often occurs in those who have had a preceding acute attack of chronic gastric or intestinal disorder. Rickets and hereditary syphilis predispose to the disease. The following acute diseases which are apt to precede bronchopneumonia are arranged in the order of frequency: measles, whooping-cough, diphtheria, influenza, ileocolitis, and scarlet fever. Furthermore, the environment has a good deal to do with the frequency of this disease. Thus, for example, it occurs with special frequency among the occupants of the tenements and hospitals, and among those who live in the crowded and poor sections of the cities, as has been well shown, so far as Boston is concerned, by Morrill.[8] Finally, exposure to cold, which is by the laity considered all-important, is undoubtedly occasionally an active factor, but the history of a sufficient exposure of this sort is rarely elicited. Experimental researches in the lower animals have shown that cooling of the body does predispose to infection with the pneumococcus.[2]

So far as the bacteriology of the disease is concerned, it has been distinctly determined that there are several varieties of micro-organisms which may be actively concerned in the production of bronchopneumonia. These bacteria are also often found in the upper air passages of healthy persons, and become active agents in the production of bronchopneumonia when the organism has become depressed by a previous disorder or by a severe exposure to cold or fatigue. One or several varieties of these bacteria may be present. The pneumococcus is the organism most frequently found, while the streptococcus and the staphylococcus are often present. Darrier,[3] in 1885, found in four cases of bronchopneumonia complicating diphtheria the streptococcus either alone or associated with the Loeffler bacillus. Prudden and Northrup,[4] in 1889, after an extensive study of the bronchopneumonia of diphtheria in infants, also found that the streptococcus was the usual cause. Netter[5] studied bacteriologically 42 cases of bronchopneumonia. In 25 only one organism was found, and in 17 more than one. As regards the 25 with only one variety of micro-organism, it was found that the pneumococcus was present in 10 cases, the streptococcus in 8 cases, the staphylococcus in 5 cases, and Friedländer's bacillus in 2 cases. As regards the 17 with more than one variety, it was found that the pneumococcus and the staphylococcus were present in 1 case; the pneumococcus and streptococcus in 3 cases; the pneumococcus, streptococcus, and staphylococcus in 2 cases; the streptococcus and staphylococcus in 5 cases; the streptococcus and Friedländer's bacillus in 3 cases; the pneumococcus, streptococcus, and staphylococcus in 2 cases; and the pneumococcus and Friedländer's bacillus in one case. Munier[6] in 10 cases, without any diagnostic signs of influenza, found the Pfeiffer bacillus alone or associated with other organisms. In 5 cases he found Pfeiffer's bacillus alone; in 2 cases with the pneumococcus; and in 3 cases with other undetermined organisms. Wollstein,[7] quoted by Holt, studied 33 cases, 19 of which were primary and 14 secondary. She found the pneumococcus alone in 17 of the primary cases, with the streptococcus in 7, and with the staphylococcus in 1. Holt found the streptococcus alone in 1, and the staphylococcus alone in 1. He found that the pneumococcus was present in 11 out of the 14 secondary cases. It was alone in two cases; it was associated with the streptococcus in 1 case; with the staphylococcus in 2 cases; with the tubercle bacillus in 2 cases; with the tubercle bacillus and the streptococcus in 2 cases; and with the tubercle bacillus and the staphylococcus in 2 cases. The streptococcus was alone in 1 case; it was associated with the staphylococcus in 1 case, and with the tubercle bacillus in 1 case.

Anatomical Characteristics of the Lung in Infancy.—Before we consider the pathology of the bronchopneumonia of infancy, it may be well to speak briefly of the anatomy of the lung in infancy, for this is undoubtedly a determining factor in the preponderance of the bronchial form of pneumonia at this age.

In infants the bronchi are larger and more numerous and thus form a much larger proportion of the lung tissue than is the case in adults. In infants, therefore, the alveoli represent a much smaller proportion of the lung as a whole. This is particularly marked during the first two years of life. The connective tissue is present in greater abundance and binds the different elements together very loosely. As a result the blood-vessels are loosely held and easily become distended and encroach on the alveoli. These characteristics of the lung of infancy persist to some extent until the fifth year, after which period it may be considered to have assumed the adult type.

Pathology.—The lesions of the bronchopneumonia of infancy are to be found most often in the posterior portions of both lungs, generally of the lower lobes, but extending frequently to the posterior portions of the upper lobes. In bronchopneumonia we have usually a tracheitis, a bronchitis, a capillary bronchitis, and a pneumonitis, the inflammation starting in the upper air passages and travelling downward until the lung tissue is involved. The inflammation may extend downward slowly, several days elapsing before the pneumonia is developed; or, in severe infections in subjects with little resistance, the disease may extend so rapidly that signs of pneumonia are noticed simultaneously with the indications of inflammation of the upper air passages. Upon examining, at the autopsy, the lungs of an infant who has had bronchopneumonia, one often finds evidence of some pleurisy over the pneumonic area; perhaps only a dull, lustreless appearance, or a little exudate on the surface, and, in rarer cases, a fibro-purulent exudate. On section of the lung, if it be an early case, the involved area will be found, usually in both lungs, to be dark red in color and resistant to the touch. Other areas of congestion will show the dark red color, but will offer little resistance. The cut surfaces will also have for the most part a dark red color. Small white areas, of the size of a pin's head, are due to the filling of small bronchi with muco-purulent material which may be pressed out. The larger white areas which are found at a later period of the disease, are due to lobules undergoing gray hepatization. In a section of a lung of a child where the bronchopneumonia has advanced still farther in its course, one often finds all stages of the process in different adjacent lobules, so that instead of having a general condition of red or gray hepatization one notices a mottled appearance. The exudate which forms the consolidation consists of serum, epithelial cells, red blood cells, fibrin, and polymorphonuclear leucocytes. There is, however, as a rule, less fibrin, and the leucocytes are fewer than in lobar pneumonia.

Among the other lesions which are sometimes observed in these cases may be mentioned the following: atelectasis, hemorrhages, emphysema, and gangrene. Atelectasis may occur in areas supplied by bronchi which have become plugged with mucus that forms a valve, allowing the air to pass out but not to enter. Hemorrhages may occur in other areas, so that, on examination with the microscope, the air passages are found filled with red blood corpuscles. A vesicular emphysema may also occur, especially in the anterior portions of the lungs. Both vesicular and interstitial pneumonia are frequently found associated with the bronchopneumonia of whooping-cough. Finally, gangrene of a portion of the involved lung is occasionally found at autopsy.

In addition to the pulmonary lesions already described, the bronchial lymph nodes are commonly found to be enlarged from cellular hyperplasia. Occasionally, on

Digitized by Microsoft®

www.libtool.com.cn

cutting such nodes, tuberculous lobules are discovered, although no tuberculosis is found elsewhere.

TERMINATIONS OF THE DISEASE.—Resolution may take place by cell degeneration and absorption at any stage in the process. This, however, takes place irregularly, and, while certain lobules may be undergoing resolution, others may show an advancing lesion. In the place of complete resolution, chronic bronchopneumonia may establish itself, especially in feeble babies, who will thus be left with patches of marked bronchopneumonia which may persist for weeks or months. These areas undergo interstitial changes with dilatation of the bronchi, and sometimes with the formation of cavities which are filled with muco-purulent material. At times these cavities represent veritable abscesses. Finally, death may occur at any stage of the bronchopneumonia.

SYMPTOMS.—In the bronchopneumonia of infants both the symptoms and the course vary greatly, as might be expected when the conditions are considered; for the term bronchopneumonia is applied to a disease that may be caused by any one or more of several micro-organisms, and that may develop either as a primary affection or as a secondary phenomenon in the course of some other severe disease. If, in addition, we take into consideration the varying resistance of the subjects, the extreme irregularity of the course of this disease will appear perfectly natural.

Of the different symptoms which accompany a bronchopneumonia *fever* is one of the earliest noticed, and it is very rarely preceded by a chill. This fever usually rises to 102° and sometimes to 104° F. and then falls, rising again as high as or higher than the highest point previously reached. Thus it continues with exacerbations, followed by marked remissions usually of from two to four degrees. The exacerbation of temperature usually occurs in the afternoon or evening. The temperature lasts one, two, or three weeks, or longer. Only twenty-five per cent. of the cases defervesce within the first week. When the disease runs a long course, there are often observed intervals during which the temperature, for a day or two, will run much lower, rising again with the invasion of new lung tissue. The fever usually ends by lysis.

A *cough* is commonly present from the first. It is ordinarily a dry, short, hacking cough, but at times it is paroxysmal in character and may be almost incessant. Later in the disease the cough may disappear, owing to a loss of reflex activity in the air passages. The cough often persists after the other symptoms of the pneumonia have disappeared. Inasmuch as babies swallow all the material which they cough up, we cannot examine the sputum unless we take special measures for obtaining it.

As the disease advances the *respirations* become rapid, rising usually to from 40 to 80 a minute, and sometimes higher. Respirations above 30 should make one suspicious of pulmonary complication, but usually they are over 40. They vary from 40 to 60 ordinarily, but may reach 100 or more in severe cases. The rhythm of the respiration is also disturbed. The pause, which normally takes place after expiration is completed, is done away with and a pause takes place after inspiration. The child quickly draws its breath, holds it and then with an explosive grunting sound, expires, and without pause again inspires. The expiration is prolonged and loud. The expiratory grunt is a very characteristic symptom of pneumonia in infancy. Another disturbance of rhythm is that known as Cheyne-Stokes respiration; this disturbance occurs in severe cases. Temporary suspension of respiration also occurs in the very sick. It may last as long as two minutes and be spontaneously resumed. Evidence of respiratory embarrassment is also found in the sinking in of the intercostal spaces and the dilatation of the alæ nasi with each inspiration, in severe capillary bronchitis. Cyanosis is another symptom which often develops in severe cases of capillary bronchitis.

The *pulse* is accelerated with the onset of the disease, and in an ordinary case will soon reach the rate of 150 a minute. It is usually full at first, but later, and especially in the severe cases, it becomes more rapid and weak.

A most important diagnostic sign of bronchopneumonia is to be found in the *ratio which the respirations bear to the pulse*. This is usually altered from the normal ratio of one to four to a ratio approximating one to three; that is, in an ordinary case the respirations will number about 40 or 50 and the pulse beats from 120 to 150 to the minute. Such a respiration-pulse ratio should at once direct attention to the thorax, which should be very carefully examined for evidence of pulmonary disease.

Pain is not a symptom of any importance in the bronchopneumonia of infancy. There is usually some soreness in the chest, but these little patients do not, commonly, suffer from acute pain.

So far as *cerebral symptoms* are concerned, the onset of bronchopneumonia in infancy is usually characterized by a condition of apathy. The patients are said to be "dopey"; they are markedly prostrated, indifferent to their surroundings, and want only to be left undisturbed. Convulsions at the onset are rare; they occur only in very severe cases, in children with marked rachitis, and in those of poor previous condition. Delirium and stupor often develop. The *tache cérébrale* and Kernig's sign may sometimes be elicited.

Various *gastro-enteric symptoms* are commonly associated with a bronchopneumonia. Thus, for example, anorexia usually occurs at the onset of the attack, while thirst may supervene at a later stage. The tongue is sure to become coated, and in a certain number of cases the disease begins with marked gastro-enteric symptoms, vomiting, abdominal pain, diarrhœa, and tympanites—symptoms which may lead to a false diagnosis, or at least to overlooking the pulmonary condition.

PHYSICAL SIGNS.—The physical signs vary as much as do the symptoms. Some cases, which in other respects are following a typical course, may at no time give physical signs; that is, the disease fails to produce marked changes in any part of the lungs adjacent to the thoracic wall. In other cases local physical signs will be elicited only when the temperature falls, while in still other cases one gets marked signs of consolidation from the beginning of the disease.

Inspection reveals the fact that the respiration is rapid, irregular, and variable in its rhythm; it also perhaps shows the existence of a certain degree of cyanosis.

Palpation is of less value in infants than it is in adults, owing in part to the fact that the lesion usually is bilateral and in part to the fact that it often fails to yield good evidence of the existence of consolidation.

Percussion also gives valuable information less often in infants than it does in adults. It must be practised with care and with the employment of very little force; one finger will suffice for the actual percussing, and the examiner should make a light, sharp stroke by quickly withdrawing the finger. The revelation, by means of percussion, of a very slight dulness, especially if it is associated with a sense of resistance, points to congestion and consolidation, while a marked degree of dulness should raise a suspicion that fluid is present, and this conjecture should lead to the employment of auscultation as a means of differentiating between these conditions.

It is by *auscultation* that the first evidence of local pulmonary involvement is usually elicited, and it is upon auscultation that one must especially rely for locating the bronchopneumonia in infancy. In these little subjects the ear should not be relied on alone, but a stethoscope with a small opening should also be used. If the baby is emaciated, a flexible rubber chest-piece may be necessary. Auscultation gives information as to the presence of râles, the duration of the expiration as compared with the inspiration, and the pitch of the breathing. Since in bronchopneumonia there is an inflammation of both large and small bronchi, and often a pleuritic inflammation as well, all varieties of râles may be heard. The coarse, low-pitched, sonorous râles, which have their origin in the large bronchi, are usually present.

Digitized by Microsoft®

Areas of subcrepitant or crepitant râles, audible at the end of an inspiratory effort, are carefully to be looked for, since they are usually the first physical sign found by which one can locate the bronchopneumonia in infancy. It is not sufficient to listen carefully over the chest of a sleeping or quiet child, for an effort must be made to secure deep inspiration. If the child cough, the coughing will be followed by satisfactory inspiration, but often it is necessary to make the baby cry. It is during crying that the most satisfactory examination of the baby's chest may be made, for it elicits both deep inspiration and voice sounds which may be difficult to get by other means. If the pneumonia is sufficiently developed one may get a prolongation of expiration, and high-pitched or bronchial breathing.

www.libtool.com.cn

In some cases the first local physical sign will be diminished breathing, which may be associated with dulness over the same area. Dulness and diminished breathing, although often due to congestion, should always suggest the possibility of fluid being present. If these signs are due to congestion, they should soon change to high-pitched breathing with râles; if they are due to fluid, they should persist and become more marked.

The location of the heart apex should always be definitely made out, as a displaced apex often determines the presence of fluid in cases in which other signs would seem to point to consolidation of the lungs.

Course of the Disease.—The bronchopneumonia of infancy usually begins with an abrupt onset, characterized by considerable fever and a condition of apathy. The child is evidently seriously ill. It coughs, breathes rapidly, and with each expiration is apt to groan or grunt. Dyspnœa develops, and sometimes cyanosis. The alæ nasi dilate with inspiration. The fever persists for from one to three weeks, finally ending by lysis. As the disease progresses, the prostration becomes more marked, the pulse more rapid, and the extremities, nose, and ears often become cold. The respirations become very rapid, and delirium or stupor may develop; gastric or intestinal symptoms also often occur.

The disease may manifest itself under one or the other of three different types: the acute congestive type (or capillary bronchitis), the latent type, and the persistent type. The first of these, *the acute congestive type*, may be primary or secondary, and occurs most often in young infants. They become suddenly severely ill, and breathe with great difficulty and very rapidly (70 to 80); there is high fever (104° to 106° F.); and the pulse is rapid (180 to 200). Death often occurs in from twelve hours to three days. Some of these cases will end in recovery in the course of a few days. By the expression *latent type* is meant a bronchopneumonia which is found in cachectic and marasmic infants, who may have neither fever, nor cough, nor dyspnœa. It is a hypostatic pneumonia, which gives little evidence of its presence during life, and is often first discovered at autopsy. The *persistent type* of bronchopneumonia is seen in children who are in poor condition at the time when they are taken ill; it also often develops after whooping-cough. In these cases the disease usually runs a moderately severe course for from two to three weeks, and then, instead of defervescing and undergoing resolution, it continues for some time to manifest a moderate degree of feverishness and the physical signs of persisting consolidation. These patients are apt gradually to become weaker and die, although some of them may recover after a long period.

In addition to the three types briefly outlined above, it is permissible to establish—in accordance with certain characteristics that belong to the secondary bronchopneumonias following the different acute infectious diseases—other less important groups. For example, one group may comprise those cases in which a *bronchopneumonia develops in the course of an attack of measles or scarlet fever*. In this group the pneumonia begins either when the eruption is at its height or not until after the temperature has fallen to normal. In the latter event the temperature does not remain at this low point but soon rises several degrees, and evidences of the pneumonia begin to manifest themselves. But whether the pulmonary complication develops at this later stage of the original disease or whether it develops at the time when the eruption is at its height, the prevailing character of the pneumonia is in either case likely to be severe; indeed, the disease often assumes a congestive character. *The bronchopneumonia of whooping-cough* constitutes another group. This develops usually during or at the end of the paroxysmal period. The onset is more gradual and less severe than it is in the preceding group, and the fever usually is moderate. The disease develops in children who are much depleted by the whooping-cough, and it runs a long, subacute course. Finally, in the third group may be placed *the bronchopneumonia of diphtheria*. In this group of cases the disease again manifests itself commonly in a severe form like that which characterizes the bronchopneumonia of measles and scarlet fever. It usually develops early in the attack of diphtheria.

Bronchopneumonia also develops in connection with other diseases. Thus, for example, it sometimes occurs in a fairly severe form in the course of an *influenza*. When it occurs in connection with an *ileo-colitis* it usually develops at a time when the baby has been much weakened by the primary disease, and it then assumes a type similar to that seen in whooping-cough.

Complications.—The one very common complication of bronchopneumonia—the one for which diligent search should be made daily, in order that it may not be overlooked—is *empyema*. This occurs in a considerable number of cases, and requires a prompt evacuation of the fluid whenever the baby suffers severely from its presence. Evidence of fluid is usually first found behind or in the post-axillary line; less frequently it is found in front. Diminished breathing sounds and marked dulness on percussion are usually the first local signs. Another occasional complication is *purulent meningitis*, which is caused by the same micro-organism that produces the lung consolidation. *Pericarditis* is also sometimes encountered, but usually in connection with empyema. On the other hand, in all the cases of bronchopneumonia which have been seen by the writers in the New York Foundling Hospital, the complication of an *endocarditis*, except when associated with pericarditis, has not once been observed. Finally, in a certain number of cases, *tuberculosis* may constitute a complication of the bronchopneumonia. In these cases the trouble may sometimes be attributed to the breaking down of an old cheesy bronchial lymph node.

Diagnosis.—The early diagnostic signs are the abrupt onset, the presence of fever and of a certain degree of apathy, the disturbed respiration-pulse ratio, and the discovery, by auscultation, of the existence of râles in the chest. To these signs may be added, at least for some of the cases, the following: some dulness on percussion, a high-pitched respiratory murmur, and broncho-vesicular respiration. Many of these signs may be absent, especially in the subacute form of the disease as it occurs in weak infants or as a complication of whooping-cough.

The differential diagnosis from lobar pneumonia is based on the following points: Most of the cases of bronchopneumonia are secondary, and when the disease is primary in its nature it occurs usually in infants under two years of age. The signs develop more gradually in this disease than in lobar pneumonia. Furthermore, the remissions of temperature are more marked than they are in the latter disease, and the return to normal takes place by lysis rather than by crisis. Finally, the course of the disease, unlike that of lobar pneumonia, is very irregular. In order to distinguish the disease from fluid in the chest, when there are signs pointing to the latter condition, it often becomes necessary to resort to an exploratory puncture in order to determine the truth. In making such a puncture it must be remembered that the fluid is often thick, so that a negative result from the use of a small needle means nothing. A large needle should always be introduced in an aseptic manner.

Prognosis.—The prognosis in the lobular form of pneumonia in infancy is always very serious. It is mod-

Digitized by Microsoft®

ified by several factors. In the first place, the younger the child the more serious the outlook. Pneumonia in an infant under one year justifies a very serious prognosis. The condition of the child's health before the attack is another important factor. The better the health of the baby when taken ill with the bronchopneumonia the better the prognosis. The environment of the child also modifies the prognosis. Usually cases do much better under good surroundings, with isolation, quiet, and plenty of air—*i.e.*, under such conditions as may be found among the wealthy classes—than they do in the tenements and hospitals.

Primary bronchopneumonia usually allows a much better prognosis than does that which develops in the course of some severe disease; for the outlook in secondary pneumonia varies with the disease which it complicates. Thus, in many of the cases of pneumonia complicating diphtheria the patients die, and the mortality of the disease, when it develops in the course of whooping-cough, is always very high (fifty to one hundred per cent.). The bronchopneumonia of measles is usually of a severe form, but, notwithstanding this fact, the mortality is somewhat lower than it is in the secondary pneumonias of diphtheria and whooping-cough (thirty-three to one hundred per cent.). In the influenza cases the mortality is more favorable.

TREATMENT.—A study of this disease emphasizes the importance of watching very carefully all children who are affected with colds, influenza, bronchitis, and the other primary diseases which bronchopneumonia is apt to complicate. Of still more importance is the careful watching of the digestion of babies and the prompt modification of the diet when necessary.

The direct treatment is entirely symptomatic, and the general hygiene, nursing, and feeding are usually of far more importance than the medicinal treatment. A baby with bronchopneumonia should be placed in a large quiet room with plenty of light and a southern exposure. The room should be ventilated from out of doors and not from other rooms in the house. Some moisture in the room will make the patient more comfortable, and this may be obtained by boiling water in a kettle. But one person should be allowed in the room at a time, and the same care should be observed to avoid disturbing the patient that is exercised in the case of a nervous adult.

The diet should consist of milk or modified milk, or milk with barley water, or oatmeal gruel. If the milk is not well digested, it may be given only after it has first been peptonized. If but little is taken at a time, the feeding may be done at intervals of one or two hours. With the onset three modes of treatment should be actively tried in an effort to abort the disease. These are: purgation, counter-irritation, and stimulation. For the attainment of the first of these objects, calomel is altogether the most satisfactory drug. For a baby under one year of age one-tenth of a grain may be given every half-hour until from four to ten doses shall have been given. If this medication fails to move the bowels, castor oil, in doses of one or two drachms, should be administered. Counter-irritation over the affected area, or, if this cannot be determined, over the whole chest in front and behind, may be made with mustard paste. The operation should be repeated at intervals until a marked redness of the skin is produced. Stimulation with strychnine in fairly large doses (from gr. $\frac{1}{100}$ to gr. $\frac{1}{60}$) every four to eight hours, according to the age of the child, may be resorted to temporarily. This treatment, which may be kept up until the physiological effects of the drug are obtained, will aid the organism in its effort to overcome the disease. Afterward the remedy may be administered with advantage in smaller doses throughout the entire course of the disease. The counter-irritation may also be repeated with benefit from time to time. Stimulation should be used when needed. Nitroglycerin is of especial value when the extremities become cold, and it should be given in a dose of gr. $\frac{1}{400}$ every four hours. At the same time hot-water bags should be applied to the feet. The administration of alcohol internally may usually be reserved for severe cases, since it is a drug that is often badly borne by babies. It may be given in the form of whiskey diluted with from eight to ten parts of water and sweetened; champagne and sweet wine may also be administered. Oxygen is a most valuable aid in the treatment of this disease, and it may be given at frequent intervals or constantly, and should be delivered from the pipe held close to the child's mouth.

The gastro-enteric tract must be carefully watched, as marked tympanites, which interferes with respiration by restricting the descent of the diaphragm, is a frequent and very serious complication in many cases. A mixture of rhubarb and soda, or of rhubarb and soda with bismuth, or an occasional dose of castor oil, will often relieve this symptom, but at times the introduction of a stomach tube or rectal tube is needed for evacuating the gas. Counter-irritation and hot fomentations applied to the abdomen are also useful. The employment of pneumonia jackets and of poultices, as a routine treatment of the bronchopneumonia of children, has been given up. Both of these tend to increase the temperature of a child already suffering from fever, and they limit the expansion of the chest. A woollen shirt provides a sufficient protection to the chest.

Antipyretic treatment is needed in the severe cases, and should be resorted to if the child is bearing the fever badly, even if the latter is not very high. Stupor, delirium, or great restlessness calls for antipyretic treatment. A temperature of over 103° F. is usually an indication for antipyretic treatment. There is no disease in which the thermometer is of so little service as a guide as it is in infantile bronchopneumonia. It is the child's general condition that furnishes the best indications for treatment.

Bathing furnishes the best means at our disposal for reducing temperature. Sponging with equal parts of warm water and alcohol may be used for slight fever and restlessness, but the most efficient and simplest method is to place the infant in a bath. The bath may have a temperature of from 80° to 90° F., and the baby may be kept in it for five or ten minutes. It is usually well to stimulate the baby before putting it in the bath. The bath may be repeated as often as indicated by the temperature.

The coal-tar derivatives should never be used as antipyretics for infants. Expectorants are very rarely needed in the treatment of this disease. Ipecac is probably the most efficient, but, if used, it should be given in small doses. Of sedatives, a warm bath is usually the only one needed. If the cough is constant and interferes with rest, and if it is not relieved by a bath, five-drop doses of paregoric may be given every three or four hours.

In protracted cases and during convalescence, the internal administration of creosote, or guaiacol and cod-liver oil, or of some iron preparation may be of advantage, while counter-irritation may be made by painting the chest with Churchill's tincture of iodine, or by the use of the Paquelin cautery. *William P. Northrup.*

PODOPHYLLUM.—U. S. P., *Mandrake, May-apple.* The dried rhizome of *Podophyllum peltatum* L. (fam. *Berberidaceæ*).

This striking and beautiful plant is found in the greatest abundance in rich soil throughout the eastern and central portions of North America, except the far north.

Digitized by Microsoft®

www.libtool.com.cn

The drug is mostly collected in the Ohio valley and the mountains southward. The very long and much branched rhizomes form a network a few inches beneath the surface of the soil, and produce large beds of the very peculiar foliage of the plant, which is herbaceous, about a foot high, and of the appearance shown in the accompanying illustration. The leaves are thin and somewhat shining, about a foot broad, the flower beautifully white and waxy, and about two inches broad. The sterile stems terminate in a circular, centrally attached leaf, which is similarly lobed, and presents the appearance of an umbrella, whence the plant is often called umbrella plant, whereas the form of those of the flowering stems have given it the name of duck's foot. The fruit is a yellow, sweet, and edible berry, about as large as a pigeon's egg, and is known as May, hog, Devil's, or Indian apple, also as wild or ground lemon.

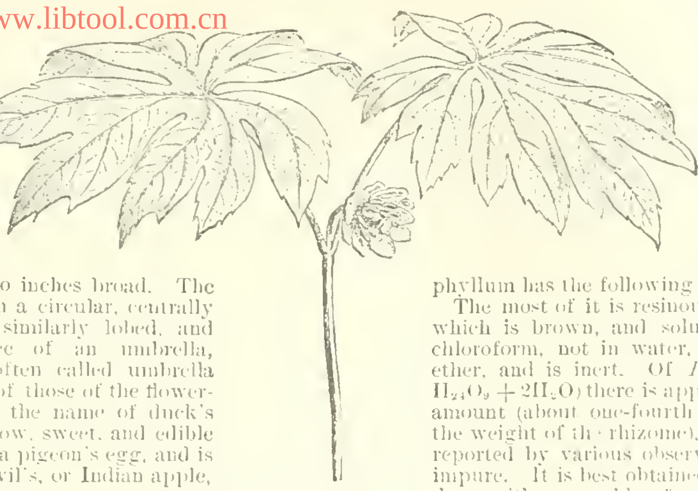

FIG. 3837.—Podophyllum: Flowering Plant. (Baillon.)

The younger portions of the rhizome, after being dried, are dark-colored, thin, and shrivelled, and are deficient in medicinal property. The drug is thus described:

Of horizontal growth and indefinite length, occurring in irregular pieces; cylindraceous, flattened from above, consisting of joints about 5–10 cm. (2–4 in.) long, the internodes 2–8 mm. ($\frac{1}{12}$–$\frac{1}{3}$ in.) thick, the nodes about twice as broad; yellowish brown to dark brown, the darker pieces usually longitudinally wrinkled, the lighter ones nearly smooth, the nodes marked above by broad cup-shaped scars and underneath by whitish, short stumps of the brittle roots; fracture short and sharp, whitish to pale brown, resinous in the best drug, marked by a loose circle of very short yellow wood wedges surrounding a large pith; nearly inodorous; taste sweetish and bitter, becoming acrid.

The active portion of the drug resides in its three to five per cent. of resinous matter, which is associated with much starch, a very little gallic acid, and small amounts of fixed oil, gum, etc. The resin is a somewhat complex mixture, but is an official substance and is very largely employed under the name *Podophyllin*. It is highly subject to adulteration, more than fifty per cent. of adulterant having been reported in it; hence, the official description should receive close attention. It is prepared by exhausting the powdered drug with alcohol, concentrating the filtrate by evaporation, and pouring it into water acidulated with a little hydrochloric acid, when the resin is precipitated. It is afterward dried and powdered. The resin is described as follows in the pharmacopœia:

"An amorphous powder, varying in color from grayish-white to pale greenish-yellow or yellowish-green, turning darker when exposed to a heat over 35° C. (95° F.); having a slight, peculiar odor, and a peculiar, faintly bitter taste. Permanent in the air."

FIG. 3838.—Rhizome and Bases of Roots of Podophyllum.

Its alcoholic solution has a faintly acid reaction.

Soluble in alcohol in all proportions; ether dissolves fifteen to twenty per cent. of it; boiling water dissolves about eighty per cent., and deposits most of it again on cooling, the remaining, clear aqueous solution having a bitter taste, and turning brown on the addition of ferric chloride T.S.

Resin of podophyllum is also soluble in potassium or sodium hydrate T.S., forming a deep yellow liquid which gradually becomes darker, and from which the resin is reprecipitated by acids.

It should yield not more than 0.5 per cent. of ash.

Resin of podophyllum has the following composition:

The most of it is resinous *Podophyllic Acid*, which is brown, and soluble in alcohol and chloroform, not in water, ether, or petroleum ether, and is inert. Of *Podophyllotoxin* ($C_{23}H_{24}O_9 + 2H_2O$) there is apparently a very small amount (about one-fourth of one per cent. of the weight of the rhizome), the larger amounts reported by various observers being probably impure. It is best obtained by extracting the drug with pure chloroform, and this extract with pure ether, then precipitating with petroleum benzin. Pure podophyllotoxin usually occurs as a white, amorphous, bitter, slightly acid powder, or in crystals soluble in ether, chloroform, hot water, and diluted alcohol. This pure substance is very difficult to obtain, being usually contaminated with the isomeric *Picropodophyllin*, which is readily formed from podophyllotoxin by the action of alkalies, and is much less active than the latter. Picropodophyllin occurs in bitter crystals, soluble in alcohol, not in water. Podophyllotoxin is also very apt to be contaminated with podophyllic acid, with the yellow coloring matter *podophylloquercetin*, and with fat.

ACTION AND USE.—Podophyllum or its resin is locally irritant, the dust occasioned by powdering the drug causing redness and smarting of the skin and inflammation of the conjunctivæ. It has also been known to produce, upon the perspiring skin, ulcers which have been mistaken for chancroids. It is an irritant cathartic, whether introduced into the bowels or stomach, given subcutaneously, or absorbed from a raw surface. It is a very slow-acting medicine, requiring from twelve to fifteen hours before its effects begin, but it is also rather persistent and thorough, and in full doses is followed by numerous watery stools. Griping pains are frequent accompaniments, and vomiting and persistent diarrhœa may follow if the dose is very large. After poisonous amounts the above symptoms are exaggerated, and inflammation and ulceration of the intestines, bloody stools, great prostration, stupor, and death may follow. The action upon man and the lower animals is essentially the same. It is supposed to stimulate the liver, and is very extensively given with a view to this effect, in the digestive disturbances called popularly "biliousness," but probably, as we now know of nearly all so-called cholagogues, it does not increase the production of bile, but merely favors its dejection.

Moderate doses of podophyllotoxin given to man produce the same effects as podophyllum itself, with perhaps less pain and less tendency to vomiting. Picropodophyllin acts like the above, but less violently, in consequence,

Digitized by Microsoft®

as is supposed, of its complete insolubility in water. Podophyllum and its preparations are, then, useful cathartics where action upon the whole intestine, or at least the small one, is desired and when the expulsion of bile is desirable. They are frequent ingredients of "antibilious" pills, both in regular and irregular practice, and are frequently given, too, in small doses in "after-dinner" and other mildly laxative pills.

www.libtool.com.cn

ADMINISTRATION.—The powdered crude drug may be given; dose from 0.5 to 1.5 gm. (gr. x. ad xx.). But, in view of the great compactness of the precipitated "resin" (*Resina Podophylli*, U. S. P., etc.), this is to be preferred. The following preparations are in the Pharmacopœia: Extract (*Extractum Podophylli*), strength about $\frac{1}{4}$; fluid extract (*Extractum Podophylli Fluidum*), strength 1, and the before-mentioned resin, strength about 3^{0}, dose from 1 to 3 cgm. (gr. $\frac{1}{6}$ ad $\frac{1}{2}$). Of these preparations only the latter need be remembered or used. *Podophyllotoxin* can be had in the larger cities, and should be more uniform than either of the above, though very commonly it is not.

The dose of the ordinary commercial article is about one-third that of the resin, but of the pure substance this would be about five times too much.

"Mandrake" of the ancients was *Mandragora officinarum* L., a solanaceous plant, containing mydriatic alkaloids of the atropine type. It is now obsolete as a medicine.

Henry H. Rusby.

POISONING, LEGAL ASPECTS OF.

—This paper does not discuss the general principles of toxicology. The reader's knowledge of these is taken for granted. The nature of poisons, the distinguishing characteristics of the various kinds, the different modes in which they may be administered and will operate, the appropriate methods of detection—these and other branches of the subject are elsewhere treated. The present purpose is to state very briefly those peculiar duties of the practitioner which are connected with the use or misuse of poisons.

LEGAL DEFINITION.—For the purpose of what may be called legal toxicology, there is little need of establishing a precise definition of the term "poison." Medical authorities on the subject agree that the word is one very difficult (some say impossible) of precise definition. The law, in general, either leaves the question "What is a poison?" to be determined by judges or juries, under the counsel of medical men and experts, in view of the particular case which brings it forward for decision; or relieves the doubts and obscurity which hang over the word by associating others with it which may enlarge its scope. Thus an English statute passed early in Queen Victoria's reign (1 Vic. c. 85, § 2), says that whoever shall administer, etc., to any person "any poison or other destructive thing" with intent to commit murder, shall be guilty of felony. A trial under such a statute as this would not call for any lengthy discussion of the meaning of "poison"; testimony of experts, that the thing administered was adapted, when administered in the way proved, to destroy life, would be sufficient on that point to sustain a conviction. On the other hand, if the experts doubted or disagreed, the judge would instruct the jury to give the accused the benefit of the doubt. Early American statutes use the simple word "poison," leaving the courts and juries to fix the meaning on the principles above stated. Thus in New York there are laws of long standing, punishing every person convicted of having "administered any poison to any human being," and every person who shall "wilfully poison any spring"; and every person who shall "wilfully administer any poison to cattle," etc., or shall "wilfully expose any poisonous substance to be taken by cattle"; etc. The actual administration of even such laws as these does not turn on chemical or medical discussions of the precise meaning of "poison" nor vary materially with changes in the exact idea attached to it by men of science. Statutes passed in recent years specify what are deemed poisons; thus the Act of Congress regulating sales of poisons in the District of Columbia names in two schedules the particular drugs intended; and of course, to sustain a conviction under such laws, there must be proof that one of the designated drugs was sold. Or, to put the idea in other words, the vital question in a trial at common law, as it is called, is not poisoning, but murder; did the accused kill the deceased by the drugs, etc., described in the indictment? In a prosecution under a statute punishing a particular form of poisoning the question is, Did the accused do the act prohibited by the language of the statute, in the manner alleged in the indictment? Experts called in cases involving poisoning are sometimes pressed to state by way of general definition, "What is a poison?" Such questions are unreasonable, except perhaps when put to test the witness' general knowledge and qualifications as an expert. The legitimate inquiry involved in the issue is this: Is the particular article or drug administered one within the class prohibited by the statute or rule of law on which the accusation is founded, as that is commonly understood? A physician may not be able to give an exact definition, or to enumerate all known poisons, yet be perfectly qualified to give an opinion on a question of poisoning by arsenic, by strychnine, by laudanum, etc., and such are the questions involved in all ordinary cases. Again, there is no important legal difference between the meaning of "poison" and that of "deadly poison." Drugs which prove speedily fatal when taken in small doses are characterized as deadly, but this is a mere matter of convenient classification. There is, however, a class of cases in which a general definition of "poison" may be important; they are such as arise under a statute which uses only "poison" to define the crime, without adding "destructive thing" or any similar term of enlargement; but the thing administered is not a poison in any correct sense, such as pins or needles, bits of sponge or wood, tufts of hair, orange seeds or peel, cherry stones, raw rice, pounded glass, boiling water, all of which have been effectively used with suicidal or murderous intent. In these cases, the objection that the accused had not administered a "poison" would prevail; at least the question of the extension of that term would be legitimately involved. And generally, in inquiries as to criminal poisoning, the intent with which the noxious substance was administered is quite as important an element as is the nature of the substance.

ADVERTISEMENT AND SALE OF POISONS.—The dissemination of advertisements of so-called remedies for procurement of abortion, framed in obscure, deceptive phraseology, has grown during the present generation to be a serious evil, and deserves to be mentioned as connected with the general subject of poisons. The regulation of the issuing of advertisements and circulars announcing such things rests wholly with the State legislatures and police. Congress has no power over that branch of the subject. Several of the States have enacted laws which, however, are not, as a general thing, very stringent or very efficiently enforced. The repression of the circulation of either the advertisements and the circulars, or the remedies themselves, devolves on Congress. The postal law, as in force at the beginning of September, 1887, and which operates, of course, over the whole country, excludes from the mails all poisons and every article or thing intended for the prevention of conception or procuring of abortion, or for any indecent or immoral use, and every written or printed card, circular, etc., advertisement or notice of any kind, giving information when or how such things can be obtained or made; and punishes by fine and imprisonment any person who shall deposit such things in the mails, or take them from the mails for the purpose of giving them circulation (Rev. Stat., § 3878, § 3893, as amended July 12th, 1876, 19 Stat., 90). The duty laws forbid and punish the importation from abroad (a matter wholly within the power of Congress) of all kinds of abortives, and advertisements of them (Rev. Stat. § 2491, as amended March 3d, 1883, 22 Stat., 489).

The selling of poisons, as distinguished from the mere advertisement of them as being for sale, does not belong to Congress (except as respects the Territories and the

Digitized by Microsoft®

www.libtool.com.cn

District of Columbia), but to the States. The laws are quite numerous and are varied in their provisions, but the general character of them is that they do not forbid, nor indeed restrain, the sale of poisons (in ordinary course of business of dealers), but prescribe a manner in which the vial or package containing a poisonous substance shall be labelled, and record made of the date of sale, name, residence, etc., of the purchaser. Independently of restrictions or penalties imposed by special statutes, the courts throughout the country hold dealers in drugs to a strict responsibility for sales of poisons made by mistake. A druggist who negligently sells a poison labelled as a harmless drug, and thereby causes the purchaser's death, is chargeable with manslaughter. That the error was merely carelessness is no justification; dealers in deadly drugs are held to a strict accountability for their sales. They must take the highest degree of care known among practical men, and are held to responsibility in dealing with poisons corresponding to the degree of knowledge required in the business. They are under a general implied obligation that what they sell is genuine, commercially pure, and fit for the use designed. A Kentucky druggist kept a mill for grinding drugs, and one day had need to grind some Spanish flies in it for a blister, and did so, not cleansing the mill properly afterward. Next day a customer brought a prescription calling for Peruvian bark, and the careless apothecary passed the bark through the same mill. It thus became mixed with a modicum of the dust of Spanish flies, and the unfortunate patient was made very sick. He recovered damages for the suffering and peril to which he had been exposed. The court said an apothecary is bound to know what he sells; and if Peruvian bark alone is called for, he must not sell bark mixed with cantharides (13 B. Mon., 219). More recently, another Kentucky druggist sold croton oil instead of linseed oil for a patient, who died in consequence of the mistake, whereupon his widow was adjudged to have a right to full damages (11 Bush, 380). And there is a memorable case in New York State in which some manufacturing druggists put up belladonna in jars labelled, through mistake, "extract of dandelion." These jars were sold to retailers at random, and one of them, a druggist in Cazenovia, filled a prescription calling for extract of dandelion from this belladonna jar. The patient, a married lady, was nearly killed. As the Cazenovia apothecary acted innocently he was not prosecuted; but the husband sued the manufacturers, and recovered (6 N. Y., 397).

Poisoning in Reference to the Distinction of Degrees in Murder.—In the legislation of many of the leading States during recent years murder has been divided into two degrees, the general purpose being to class the more aggravated, deliberate forms of homicide, in the first degree, and make them punishable with death; while those exhibiting an instantaneous intent only shall incur imprisonment for life. Murder by poisoning is eminently deliberate; in the statutes of several of the States—of Pennsylvania and New Hampshire, for instance—killing by poisoning is expressly declared murder in the first degree; under other statutes it falls into that class by force of general terms employed to define the class, such as "wilful, deliberate, and premeditated killing." Under such statutes there have been one or two convictions for the second degree, where poison was unquestionably the means used for the homicide; but such convictions do not imply that poisoning is not in the view of the law deliberate; they rather show a compromise among the jurors; those who hesitated to join in a conviction which would be capital induced the others to unite in a verdict of the second degree rather than have a disagreement. The intent to kill is, however, essential under all accusations of murder by poisoning. In an Indiana case the accused administered a dose of cantharides to a woman, not meaning to kill her, but to excite her passions, so as to induce her to consent to sexual intercourse; but the dose was excessive, and caused her death. The decision was that, for lack of intent to kill, the crime was not murder.

The Importance and Difficulty of the Physician's Duties in cases involving poisoning can scarcely be overstated. His task involves intimate knowledge of chemistry, and often of law, as well as of practical medicine. The recovery of the patient if alive, the honor of the dead in cases of suicide, the reputation of the living in cases of suspected murder, may depend on the acuteness and energy, or on the prudence and reserve, of his measures. He must work, not only with friends and nurses, but often with persons shuddering or smarting under suspicion, and with jealous detectives, and with suspicious police. If he is called while the sufferer is yet living, his duties are complicated by the primary effort to effect a cure. If death has taken place, he may probably be the first person to detect any fleeting indications that crime has been committed, and is above all others best fitted to register and preserve the evanescent evidences. Moreover, with the progress of chemical science, the list of means at the command of the well-instructed poisoner is constantly extending, while the rapidity with which the methods of detection at the command of the practitioner are increased in number and complexity renders his task steadily more difficult and responsible. Moreover, the number and variety of symptoms which poisons produce, many of which closely resemble those characteristic of natural disease and are easily mistaken for them, complicate and embarrass the examination. There are several diseases whose course and termination resemble the action of certain poisons. In short, of all crimes that of poisoning requires the most learning, acuteness, skill, and promptitude for its detection. The importance of the physician's part in the work is equalled only by its difficulty. In the capacity of medical jurist he needs a thorough knowledge of the physiological, therapeutical, and toxical actions of poisons and of the lesions which they may cause. As legal chemist he needs that wide knowledge of the kinds of poisons and of their distinguishing characteristics, and that practical experience and skill in chemical analysis and manipulation, which will enable him not only to detect a poison with certainty if it exists, but also to avoid all risk of obtaining evidence of it, or of confounding things similar but innocent.

Classification of Poisons for Legal Uses.—Dr Pugnet suggests ("Med.-Leg. Papers," 2d ser., rev. ed.) that the division of poisons into the organic and the inorganic, though acceptable to the chemist, is insufficient for the needs of the medical jurist. He suggests the following:

I. Corrosives.	*Strong Mineral Acids*		Sulphuric acid. Nitric acid. Muriatic acid.
	Vegetable Acid		Oxalic acid.
	Alkalies		Strong alkalies. Alkaline carbonates, etc.
II. Simple Irritants			The above diluted. Lime. Zinc. Silver, etc.
III. Specific Irritants			Arsenic. Mercury. Antimony. Phosphorus. Iodine.
IV. Neurotics.	*Narcotics*		Opium and its active principles.
	Sedatives	*Cerebro-spinal*	Hyoscyamus. Belladonna. Stramonium. Calabar bean.
		Spinal	Digitalis. Aconite. Prussic acid. Tobacco. Hemlock.
		Vaso-motor	Hellebores.
		Anæsthetics	Chloroform. Chloral. Bichloride of methylene. Ether. Nitrous oxide. Amylene.
	Convulsives.		Nux Vomica, Brucine, Strychnine.
V. Asphyxiants			Noxious gases.
VI. Abortives			Ergot, Savine, etc.

Digitized by Microsoft®

www.libtool.com.cn

The corrosives destroy the tissues with which they come in contact by chemical action, and are characterized by causing intense pain with a burning. The simple irritants cause primarily irritation; secondarily, inflammation, which may prove fatal. The specific irritants act primarily as local irritants but have a secondary specific action. These are the poisons with which the physician is most frequently called to deal in this country. In acute cases they cause lesions of the alimentary canal; but in cases of slow poisoning these are wanting. Of the neurotics, Dr. Pugnet says that they have not as yet occupied a prominent place in toxicology, but the day is not distant when the practitioner may be called upon to investigate cases of criminal poisoning by means of them.

The above classification is the most complete which the writer has seen. Others which have received wide approval are those of Orfila, Taylor, and Tardieu (the leading features of which are given in 2 Wharton and Stillé's "Med. Jur.," 4th ed.). What recommends it to the toxicologist is that the various poisons are classified according to their distinctive physiological action upon the living organism, and not upon their chemical organization and differences. Classifications by Christison and Foderé are also widely quoted.

Counsels and Cautions Relative to a Legal Inquiry.—The various works that discuss toxicology in its chemical and medical aspects contain numerous counsels and cautions to the practitioner as to the manner of carrying forward the scientific investigation necessary in cases of supposed poisoning. This paper will select and mention such as are particularly applicable where a suspicion of crime arises.

Remember that poisons may enter the system with fatal effect, not only by swallowing, but also by inhalation, by absorption through the skin, including the accessible mucous membranes, and by injection, subcutaneous or per anum. Swallowing is the mode best adapted for administering them with murderous intent, but in cases in which the symptoms are obscure and not explainable by a suspicion of a poison swallowed, the medical jurisprudent will do well to consider the possibility that one or the other modes may have been employed.

In particular persons, substances ordinarily poisonous may be rendered inert, or those not ordinarily unwholesome may be rendered poisonous, by some idiosyncrasy of the individual, by a habit of taking them, or by a condition of disease.

A poisonous compound may, by possibility, be formed within the body by two medicines innocently prescribed or taken, either of which alone would have been innocuous.

An organ may, by possibility, become impregnated with a poison after death, either accidentally, as where it has been laid in a soil in which are poisonous elements, or where such elements are introduced in the process of embalming; or feloniously, as where an attempt is made to introduce a poison in order to give ground for charging an innocent person with murder. The presence of substances introduced after death is scientifically distinguishable, no doubt, from those taken in life; but the two may be confounded if the distinction is forgotten.

The narrative of the symptoms attending the last illness is of less service than is usually supposed in determining the criminal character of the case. Modern experience is, that death cannot be safely attributed to poisoning from the symptoms alone; too many diseases resemble the action of poisons to allow of dispensing with an autopsy and a chemical examination, when poisoning is suspected. And still less light is thrown by the mere symptoms upon the question fundamental in the legal aspects of the subject—whether the poison was taken accidentally or ignorantly, or was taken with suicidal purpose, or was administered with felonious intent this question must be decided from the general attendant circumstances of the case.

The physician should never allow moral circumstances to prejudice his mind, neither should he neglect them. Indeed, he is the best judge concerning them. Let him ascertain whether an enmity exists between the sick person and any one who attends or visits him; whether any poisonous substances have lately been purchased; whether these are still in the house; whether the alarming circumstances came on immediately after taking a drink or any other substance of an innocent nature; and particularly, in case of a sick person, let him ascertain whether anything has been given without the orders of the physician or by a person ignorant of drugs; and then he should draw a comparison between the symptoms present and those that ordinarily accompany the supposed disease.

He should carefully examine and preserve samples of every article of a suspicious nature, such as vials, boxes or papers containing powders, remains of food or drink, linen, sponges, cooking utensils, etc., in use about the patient; and he may (if assured of the support of the persons interested to promote justice) safely exercise a good deal of assumed authority in taking such precautions as against anybody who may object or oppose. Often a careful search of the premises and of the dead body will bring to light some article which, coupled with peculiar circumstances, warrants suspicion.

To decide between the relative probability of suicide and murder is a difficult question. The following facts are considered to indicate suicide: that the deceased had recently met with great losses or disappointments, or was suffering under disgrace, or under some form of insanity or delirium; that the mode of poisoning was cunningly devised to avoid a suspicion of suicide while yet the deceased held a life insurance policy; that he left any recent writing expressing his last wishes. If death has not occurred, the circumstance that the patient does not complain, but declines medical aid and remedies, confirms a suspicion of suicide. On the other hand, such suspicion is partially excluded when the circumstances favor the presumption that the deceased was in the enjoyment of a prosperous and happy life; when the drug employed is rare and procurable only with great difficulty, or is one which needs the co-operation of a second person for its administration, or is known to be productive of long and severe suffering. Considerations like these, and the results of a skilful toxicological investigation, in which the means afforded by anatomical and microscopic science, chemistry, and spectral analysis are useful to be employed, are more important in determining that the death is attributable to poison, and that this may probably have been criminally administered than are the mere symptoms.

The examiners should observe perfect cleanliness at every step of their work; the organs removed from the cadaver for chemical examination should not be placed, for example, upon boards or in receptacles which have been cleaned with disinfecting solutions which may have had poisonous constituents, but should be placed in glass or porcelain-lined dishes previously cleansed. The prudent and judicious advice given by Wharton and Stillé (2 "Med. Jur.," § 11) is that whenever, in a case involving a suspicion of murder, "a chemical analysis for poison is to be made of any of the organs, these organs should be placed by the physician himself in perfectly clean glass jars; glass preserve jars with a glass or porcelain-lined cover are suitable for the purpose, and can always be obtained in the country or city. Each organ should be placed in a jar by itself—for instance, the stomach in one jar, its contents in another, the intestines in another, contents of intestines in a fourth, the liver in a fifth, the kidneys in a sixth, the brain in a seventh, etc. The organs which should be saved for chemical analysis are in order of their importance, as follows: stomach, contents of stomach, liver, intestines, contents of intestines, kidneys, brain, heart, spleen, and urine if there be any; in some cases, it is important to save portions of the muscular tissue, and in others a part of the lungs. In some cases it is wise for the physician making the examination to divide each of these substances into approximately two equal parts, each part to be kept in separate

Digitized by Microsoft®

jars, one to be given to one chemist for preliminary analysis, and the other to be retained by the physician himself, in case it may be necessary to have the analysis confirmed by another chemist, as is usually the case in trials for murder by poison. These jars containing the organs should be closed and sealed by the physician himself, the seal to be stamped with a private stamp. They should then be locked up until they are to be delivered to the chemist. It is better that the organs be placed under double lock, one key to be taken by one person and the other by another, so that neither one alone has access to the organs; this is, of course, not necessary if one person possesses the key and another has possession of the stamp with which the seals have been stamped. When the jars are to be sent to a chemist, they should be sent by messenger, preferably by two messengers, since, in the event of the investigation resulting in a trial for murder, the identity of the organs cannot be lost by the death of the messenger. The organs should never be sent by express since it is in that case impossible to preserve with absolute certainty the identity of the organs."

www.libtool.com.cn

Sending the organs or their contents to the chemist is often not enough, especially when crime is suspected. Thus, the reason why no poisonous substance is found in the stomach may be that all which was not absorbed was vomited; therefore all vomited matter which can be procured, including clothing, or carpet, or surface of floor which has received it, should have chemical examination. The vessel in which vomited matter has been contained will often furnish valuable evidence, since heavy mineral poisons fall to the bottom, adhere to the sides, or leave a sediment. The offender may have had the intelligence and opportunity to empty the basin, etc., but not have thought, or not have been able, to attend to the dress or the floor.

Formerly it was the practice to confine the analysis to the stomach and its contents. Experience has, however, shown that most if not all the viscera, including the bladder and urine, are required before anything like a satisfactory conclusion can be drawn as to the existence of poison.

The stomach, with its contents, should always be received by the analyst in its entire state, and not, as was formerly usual, sent to him slit, and the contents mixed in a jar with other fluids and organs—a practice which is highly objectionable, as it may lead to the ends of justice being defeated by the complication involved. A slight incision may suffice to inform those who perform the autopsy of the state of the organ and the nature of its contents, when it should be tied and handed to the analyst. If, in case of accident or dispute, a necessity arises to preserve a portion of the stomach and other organs, together with any fluids or solids, in bottles or otherwise, for further reference and confirmation, this may be done, but they should all be properly labelled and dated and kept in a cool place.

Besides receiving the matter to be analyzed or examined, the analyst should be thoroughly informed upon the history of the case, and the symptoms and effects, as a knowledge of these will aid his examination, enable him to avoid useless searches, and prevent his overlooking suspicious facts. He should even be informed of the exact time of the death, which is important in reference to the length of time usually taken for a fatal operation of the poison suspected; of the attitude of the body, etc., especially if there were any dying struggle; as certain poisons cause characteristic writhings or convulsions.

The analyst should never leave the vessel containing the suspected fluid in an exposed situation. He should keep it under lock and key, and, if interrupted in the course of the experiments, should restore it to such a place that he can positively affirm that no one could have meddled with it.

The notes of an autopsy or chemical examination should be promptly reduced to an orderly report; and greater care than is usually taken is desirable to avoid the use of medical or chemical terms, such as are not easily understood by judges and jurors.

When the chemist has completed his analysis, if he finds that the poisoning has been committed with an inorganic poison, such as arsenic, antimony, etc., he should bring the metal into court and present it to the jury; and there should be a sufficient quantity of it in order to submit it to all the tests necessary for its identification. With the organic poisons, the legal chemist would find this almost an impossibility, as the organic poisons are much more active, and are fatal in smaller doses. Their presence can be proved by various tests which are reliable; but their very nature would tend to prevent their complete isolation in sufficient quantities for presentation to the jury.

Benjamin Vaughan Abbott.

POISONOUS PLANTS.—It is generally agreed in toxicology that the term "poison" should not be applied to any substance which produces its injury through mechanical means. Following this terminology, we exclude from consideration in this article all such substances as cowhage, which produces intestinal injury chiefly by the piercing quality of its hairs, the sharp awns of the many grasses so fatal to grazing animals, the prickles and thorns of thistles, brambles, cactuses, and similar plants, which act mechanically, at least chiefly, notwithstanding that their presence often produces abscesses from which blood poisoning may result. From this article are excluded also all the ordinary disease germs. Although, strictly speaking, such diseases are the results of poisoning by these minute plants, growing within the system, their proper treatment pertains to bacteriology and pathology.

Since most of the more important poisonous plants are, by virtue of their activity, available for medicinal purposes, they are discussed elsewhere in that connection. Not only are their poisonous effects and the treatment there considered, but descriptions ample for their identification, in the condition of drugs, are provided. In many cases such drug descriptions have been supplemented by others, pertaining to the plants themselves, often with illustrations, in order to provide for their identification in cases of poisoning by the fresh material. The present article is intended to supplement the above by considering important poisonous plants not used as drugs. At the same time many of the latter will be referred to at the proper points in this system, and the other articles upon them will be duly cited.

General Recognition.—The question is frequently propounded, "Is there any general rule by which a poisonous plant can be recognized at sight?" To this question an emphatic negative must be returned. There are certain characteristics which frequently accompany poisonous properties, but this is not true in all cases; and, on the other hand, these characters may exist in the absence of such poisonous properties. Of such characters are the peculiar lurid purple color seen upon the stems of the castor oil, cicuta, conium, pokeberry, dogbane, and many other plants, though shown also by the harmless angelica. A narcotic odor is common to many of the most poisonous plants, but is wanting in many others. An acrid taste is probably the most common characteristic, and constitutes the best safeguard which we possess, since it is likely, especially in the fresh article, to furnish a warning before a dangerous quantity has been consumed. Thus the potato, though ordinarily quite bland, imparts, when poisonous, a peculiar bitter, nauseous, and slightly acrid taste. Even this taste-guide, however, fails in many notably poisonous substances. It may be added that milky-juiced plants are usually to be regarded with suspicion.

Principal Poisonous Families.

Of the two hundred and eighty or more families of plants, a number are recognized as being specially rich in poisonous species; but not all of the species of any family are poisonous, and important food plants are usually found closely related, in the same family, to violent

Digitized by Microsoft®

poisons. Thus the family *Solanaceæ* contains the deadly nightshade, stramonium, and henbane, yet yields the potato, the egg plant, and the tomato, and even the potato itself may at times be poisonous. In the *Euphorbiaceæ* we find the manchineel, croton, and euphorbium, together with the cassava; and we have indeed poisonous varieties of the latter. Many similar illustrations might be cited. It is, therefore, not deemed feasible to essay a classification based upon botanical or any other general relationship, although, as a matter of convenience, the characteristics of several highly poisonous families are given below. While only a practical botanist can be expected to utilize this method of recognition to the fullest extent, yet surgeons in the army and navy and other travellers may gain great assistance by recognizing suspected plants as pertaining to the following families:

Apocynaceæ (the Dogbane Family).—This large family, of more than a thousand species, chiefly tropical, is probably, all things considered, the most commonly and powerfully poisonous. Its members are mostly heart poisons, well illustrated by apocynum, strophanthus, and oleander. Its poisonous constituents are bitter and chiefly glucosidal, though many alkaloids are contained, and a number of them, or the extracts containing them, enter into the manufacture of arrow poisons, especially in the Old-World tropics. Poisoning accidents by members of this family are rather common in tropical regions, sometimes occurring through the use of the stems for spitting meat, stirring food, or in similar culinary operations. The botanical characters are as follows: Juice usually milky; leaves (in the poisonous species) opposite, simple, exstipulate. Flowers regular, perfect, 5-merous; calyx inferior, persistent, imbricated; corolla tubular, the limb usually rotate, convolute; stamens five, borne upon the corolla and alternating with its lobes, the anthers two-celled; pistil dicarpellary, the carpels distinct or united; the ovary 2-celled or with two parietal placentæ; styles united or divided up to the simple stigma; fruit usually of two follicles, occasionally drupaceous; seeds frequently plumose.

Araceæ (the Arum Family).—This monocotyledonous family is well illustrated by the calla and calamus. Its members are chiefly tropical, and produce thick, somewhat succulent stems, frequently climbing tree trunks, and usually large, somewhat succulent, cordate leaves similar to those of the calla. A great many species produce bulbous or tuberous stem bases, commonly regarded as roots. Some of these, as the taro (*Colocasia esculenta*), are important foods. Others would be so but for their poisonous constituents. In a few cases, where these poisonous properties are mild, they are destroyed by thorough cooking, while in others this method fails and attempts thus to use them may result disastrously. The injurious principles fall into three classes: First, as in the seeds of peltandra and skunk's cabbage, needle-shaped raphides of calcium oxalate, occurring in great abundance, and irritating mechanically; second, as in our common wild turnip, acrid juices which are partly destroyed by drying; third, powerful alkaloids, some of them, or the extracts containing them, used in the manufacture of arrow poisons. The flowers of the aroids occur densely massed upon a cylindrical (as in calla) or a globular (as in skunk's cabbage) spadix, enclosed or subtended by a spathe (the white portion of the calla), though this is sometimes obscure. The plants are diœcious, or the staminate flowers are on the upper, the pistillate on the lower portion of the spadix. Rarely the flowers are perfect. There is usually no perigone, though sometimes this exists in the form of a number of scales. The filaments are very short, their anthers two-celled, the cells separated by a broad connective and opening dorsally. The ovary is variable in structure, the stigma terminal, small, sessile, or on a very short style. Fruit usually a berry, occasionally inflated.

Cactaceæ (the Cactus Family). Beyond remarking that many leafless and spiny or succulent plants which do not pertain to this family are frequently mistaken for cactuses, little need be said of its characters. The juice is bland and never milky, the flowers are showy, polypetulous and polyandrous, and the inferior fruit is a many-seeded berry. In desert regions, in the absence of food, and more especially of drink, the flesh and juice of cactuses are often utilized. In such cases it should be borne in mind that while the spiny species are usually innocent, those which are unarmed, or nearly so, like the night-blooming cereus and the anhaloniums, are often narcotic or cardiac poisons.

Campanulaceæ (the Harebell Family), including *Lobeliaceæ* (the Lobelia Family).—The two divisions of this family here named have been regarded by many botanists as distinct families. Certainly there is a marked distinction between their properties, the former yielding roots rich in inulin and sometimes edible, whereas the Lobeliaceæ contend with the Apocynaceæ for first rank among poisonous families. The nature of the constituents and the character of the poisoning are pretty uniform and have been sufficiently detailed under Lobelia. Since the poisonous species are very widely distributed throughout both temperate and tropical regions and are quite showy and attractive, their recognition is unusually important; fortunately it is also quite easy. The juice is acrid and almost always milky; leaves alternate, exstipulate, simple, and commonly abundant; flowers perfect, mostly showy, usually 5-merous; calyx tube adherent, the limb mostly regular and persistent; corolla tubular, epigynous, irregular and oblique or two-lipped, its tube fissured on the upper side; stamens five, inserted upon or with the base of the corolla and alternate with its lobes, the filaments coherent for the most of their length, as well as the anthers.

Cucurbitaceæ (the Cucumber Family).—Notwithstanding that this family is rich in edible fruits, like the pumpkins, melons, and cucumbers, yet it contains also a very large number of poisonous species. The poisonous properties pertain usually to the roots or the fruits. The former class is typified in bryonia, and has been sufficiently considered under that title. The latter is illustrated in our accounts of colocynth and elaterium, and need not be further considered. No difficulty need be experienced in the identification of the *Cucurbitaceæ*, which are tendril-bearing vines, usually herbaceous, and the flowers of which are invariably constructed like those of the plants named above, though they are occasionally small or even minute.

Euphorbiaceæ (the Spurge Family).—The general and poisonous properties of this family have been considered in Vol. IV. The plants are readily recognized by their milky juices, in connection with the unisexual flowers, which are themselves inconspicuous, though often surrounded by showy modified leaves resembling a flower circle. The perigone and andrœcium are so extremely variable as to be difficult of any brief characterization. The ovary and fruit are almost uniformly three-celled and the latter few-seeded.

Iridaceæ (the Iris Family).—This monocotyledonous family almost uniformly contains irritant poisonous oleoresins, well illustrated by that of the official *Iris*. Owing to their acrid properties they are not very likely to cause poisoning, except through their medicinal employment. Nevertheless, owing to the fleshy and obviously nutritive character of their rhizomes or tubers, they are not infrequently resorted to as famine foods in some countries, and disastrous results have sometimes thus occurred. These plants are perennial herbs with narrow, distichous, often succulent leaves. The flowers are perfect, with an adherent six-parted convolute and marcescent perigone. The stamens are three and adherent to the outer perigone segments. The ovary and seed pod are commonly three-celled, with a three-parted style, and the ovules and anatropous albuminous seeds are numerous.

Leguminosæ (the Bean Family).—This family has already been briefly considered in Vol. V. as to the general nature and properties of its poisonous constituents. As poisons, its members present peculiar dangers, which, upon the whole, are not equalled by those of any other family. These dangers lie in the fact that, while the poi-

Digitized by Microsoft®

sonous constituents are very widely and irregularly distributed, and extremely subtle and uncertain, the family is at the same time the most highly nutritious as to albuminoid constituents in the vegetable kingdom. Even such edible articles as peas and beans are not entirely free from poisonous properties, which become apparent when they are fed in large quantities as stock foods. Although the poisonous properties pertain to all three of the sub-families, they are most common and conspicuous in the Papilionaceæ. The members of this family are rather easily recognized by their almost uniform habit of producing a legume for a fruit, and by their highly developed exalbuminous seeds. In the Papilionaceæ the leaves are alternate, stipulate, and usually compound, the flowers papilionaceous and nearly always perfect, the calyx more or less gamosepalous, the five or ten stamens almost always more or less coherent. In the two other sub-families the flowers, though often irregular, are not papilionaceous, and the stamens are commonly wholly or nearly distinct.

Liliaceæ (the Lily Family).—This very large monocotyledonous group is now, with good reason, divided into the Smilaceæ, Melanthaceæ, and Convallariaceæ as distinct families. Nevertheless, since they agree, excepting the Smilaceæ, as to their poisonous properties, the entire group is here considered. The plants are mostly herbs, growing from bulbs or fleshy rhizomes. The juices are usually bland, though sometimes, as in the onions, acrid. Indeed, the poisonous species have mostly acrid juices. The leaves are parallel-veined and usually sheathing at the base. The flowers are regular and possess a six-parted perigone in two circles. The family is distinguished from the *Iridaceæ* by its six stamens, which are usually free, or nearly so, and distinct. The ovary is three-celled and usually superior, the styles distinct or united. The pod is three-celled, the seeds are numerous and highly albuminous. This family, like the *Iridaceæ*, is very liable to cause poisoning accidents, owing to the succulent and nutritious properties of its underground portions and even of its herbage. The nature of its poisonous constituents, both chemically and physiologically, is too varied for any general description.

Loganiaceæ (the Nux Vomica Family).—This is here referred to as being a small family, closely related to *Apocynaceæ* and almost equally poisonous. It is closely similar to that family in its structural characters, but lacks the milky juice and the annular stigma. Accidental poisoning is scarcely likely to occur from its members, except through their medicinal employment, and those subjects are fully treated elsewhere.

Oxalidaceæ (the Oxalis Family).—This small family, for a long time regarded as part of the *Geraniaceæ*, is readily recognized by the close similarity of all its members in foliage and flower structure to the genus Oxalis, represented by the wood sorrel, the sheep or lady's sorrels, common garden weeds, and by many species cultivated in the conservatory. The herbage of these plants contains oxalic acid and, like the meadow, field, or kitchen sorrel (*Rumex Acetosella* L.) has, when eaten in excess, caused serious or even fatal results, both to children and to adults.

Papaveraceæ (the Opium Family).—This small family is almost uniformly narcotic-poisonous, very many of its species being also irritant. Its constituents are pre-eminently alkaloidal, and these alkaloids are very numerous and varied in their mode of action. Owing to their commonly irritant properties these plants are not likely to cause poisoning, except through their medicinal use. They have commonly milky or colored juices, mostly compound or lobed leaves, perfect flowers (usually regular), their parts free and, except as to the carpels, distinct. The seeds are numerous and small.

Pinaceæ or *Coniferæ* (the Pine Family).—The large family of cone-bearing evergreens is too well known to require description. Its constituents and properties have been sufficiently indicated in our accounts of *Juniper*, *Savin*, *Turpentine*, etc. Similar constituents exist generally throughout the family. Poisoning is not likely to occur, owing to the acrid and excessively disagreeable character of the tissues.

Ranunculaceæ (the Buttercup Family).—This large family is distinguished by its alternate, exstipulate leaves, flowers which show neither adhesion nor cohesion in any of their parts, innate anthers, anatropous ovules, and the small embryo in fleshy albumen, taken in connection with the acrid juices. These acrid juices are commonly cutaneous and internal irritant poisons. Attempts to utilize them for blistering purposes have been made, but the blister is not readily controlled. A great number of the species contain, in addition, principles which, upon absorption, act as cardiac paralyzants, of which aconitine may be taken as the type.

Simarubaceæ (the Quassia Family).—The constituents and properties of these plants have been sufficiently discussed in connection with quassia and simaruba. Their consumption so as to cause poisoning is almost impossible, owing to their very bitter taste. A curious case of poisoning by Ailanthus is recorded below under "Poisonous Leaves."

Solanaceæ (the Potato Family).—A description of the characters of this highly narcotic family is not called for, since pretty much all of the species likely to cause poisoning have been already considered in connection with the drugs, Belladonna, Henbane, Stramonium, etc., or below in connection with Solanum.

Umbelliferæ (the Parsley Family.)—This very large family, although it yields many important edible products (carrot, parsnip, parsley, celery, angelica, etc.), contributes also such violent poisons as conium, cicuta, and œnanthe. Its species are very readily identified. They usually possess, especially as to the poisonous species, hollow stems, petioles which are dilated and sheathing at the base, leaves pinnately compound, usually decompound, as seen in celery and parsely, flowers in (usually compound) umbels, these flowers usually minute, with five superior calyx teeth, five epigynous petals and stamens and fruits having the general structure of the well-known conium, anise, coriander, fennel, etc.

Violaceæ (the Violet Family).—Although not at all likely to be consumed in poisonous quantities, except as overdoses of medicine, the violets should be remembered as containing one or more emetico-cathartic poisonous constituents, very similar to emetine, and long mistaken for it. The violets are so well known that no description of them appears called for.

Local Cutaneous Poisons.

Poisonous plants can be conveniently divided into those locally poisonous to the skin and those internally poisonous. The first-mentioned class will be first considered.

They represent all grades of irritation, from a mild and brief itching to a severe corrosion or a dangerous or even fatal inflammation. The milder of these groups can be accorded but the briefest mention. A large number of them produce no effect upon most persons, but have been at times recorded as irritating to certain individuals with a highly sensitive skin, or who are subjects of idiosyncrasy. Illustrations of this class are seen in the fresh herbage of *Veratrum*, in various species of *Cypripedium*, *Catalpa*, *Rhododendron*, and *Kalmia*, and in *Vanilla*. In a number of cases the nature of the poison has not been ascertained, and it is possible that it is due to the presence of animal or vegetable parasites, or other foreign bodies. Others, like the various nettles (*Urtica*, *Urticastrum* [*Laportea*] *Urera*, etc.) are regularly irritating, but the irritation is temporary, though often very painful, and unless complicated does not call for treatment. In the last-mentioned genus of tropical American shrubs the stinging hairs of the ordinary nettle are magnified into needle-like prickles, several inches in length, intensely poisonous, and causing severe inflammation when contact with them is extensive and violent. The nature of this poison and its treatment have not been investigated, though doubtless much the same as in the nettles. Very similar to the nettles are the stinging hairs upon the various

Digitized by Microsoft®

Poisonous Plants.

species of *Jatropha*, *Tragia*, and others of the *Euphorbiaceæ*, *Sicyos* in the *Cucurbitaceæ*, *Echium*, and others in the *Boraginaceæ*. Those of the *Euphorbiaceæ* have also tropical relatives (*Hura*, etc.), in which the hairs are magnified into spines, the effects of which are severe.

The important poisonous plants, those requiring our attention, pertain chiefly to the families *Anacardiaceæ* and *Euphorbiaceæ*.

www.libtool.com.cn

The poisonous members of the *Anacardiaceæ* are numerous, and their effects are of extremely common occurrence and very severe. The poisonous constituents, their mode of action, symptoms, and treatment are in all cases either identical or so closely similar that they can be readily considered under the one subject of Rhus poisoning, the further consideration of the respective individuals being confined chiefly to their description and recognition.

Rhus Poisoning.—The principal agent concerned in this accident is the herbage of *Rhus radicans* L., the common Poison ivy or oak, Climbing or Three leaved ivy or sumach, Mercury, or Black mercury. There is considerable difference of opinion as to whether Linné's *R. toxicodendron* is identical with his *R. radicans*, but the title, as here used, includes both. The plant is a slender North American shrub, and occurs wild to some extent in Europe, where it has been introduced. It may lie prostrate upon the ground, though it prefers to climb shrubbery or trees, in sunny locations, or upon fences or walls, to which it clings by false or non-absorbing roots. Sometimes, especially southward, it grows with an erect, self-supporting stem. Having thus attained a support, its branches spread or droop outward to a considerable distance, being thus very apt to brush against the faces of those walking along country roadsides. Flower and fruit habit are well displayed in the accompanying cut (Fig. 3839). The trifoliolate, or occasionally quinquefoliolate leaves sometimes reach a foot and a half or even two feet, including the petiole, in length. The leaflets are very thin and present a peculiar satiny lustrous appearance. Although usually apparently smooth (sometimes conspicuously hairy on the lower surface), they in reality bear an infinite number of extremely fine and short hairs. The flowers are of a greenish-yellow and are followed by small drupaceous, pale green, smooth fruits, borne in loose bunches, quite unlike those of the ordinary red sumac.

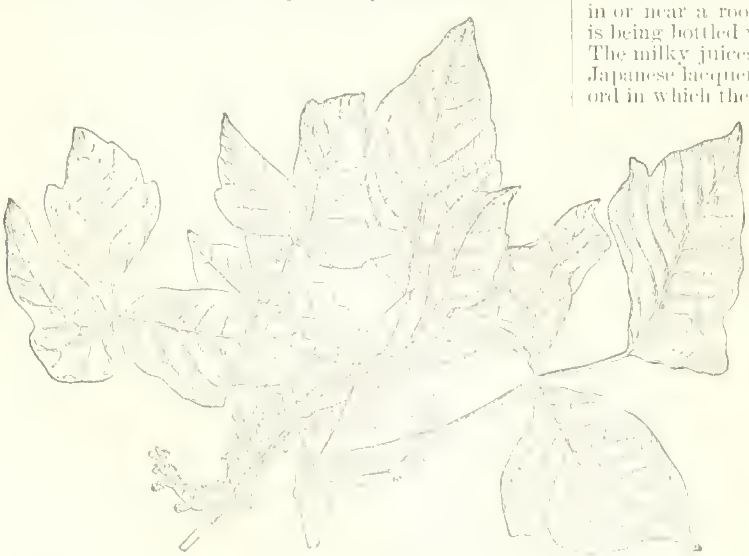

Fig. 3839. Rhus radicans. (Two-thirds natural size.)

Some of the conditions by which poisoning can occur from this plant are in dispute. On theoretical grounds, if what is known of the nature of the poisonous constituent be taken into consideration, actual contact in some form appears to be requisite; yet innumerable and well-authenticated experiences render this view quite untenable. There is the widest difference in the susceptibility of different individuals, some being apparently incapable of being poisoned by it under any circumstances. Others, who have been exposed to it frequently for many years without result may suddenly become severely poisoned. Others again are extremely sensitive to its action, the most serious, or even fatal, results ensuing from even a moderate contact. Finally, cases are of common occurrence in which poisoning occurs apparently without any contact whatever, a strong wind blowing over the plant from a short distance constituting a sufficient occasion. It has been suggested that in such cases the pollen grains constitute a medium of transportation, but such occurrences take place when no pollen grains are present. It seems hardly credible that the almost microscopical hairs can be active in these cases, notwithstanding that experiment has demonstrated their power, in very small number, to effect slight poisoning when directly applied to the skin of sensitive persons, under specially favorable conditions.

Much speculation has existed, and many conflicting statements have been published, as to the nature of the active constituent, but the laborious researches of Pfaff have gone far toward clearing up this subject. He has located the poison in the fat or fixed oil which exists in fractional percentage, and which has been called *toxicodendrol*. This is an alcohol-soluble fat, in which character it resembles croton oil and its relatives. Its chemical nature is very incompletely known. Reasoning by analogy, we should assume that the oil is not poisonous in its own form, but only through its freed fat acid. If, as originally claimed by Maisch, who called it *toxicodendric acid*, this decomposition product be volatile and active, all of the inconsistencies regarding its action would be removed. The same or similar fat existing underneath the bark acts similarly, and here again it is notable that many cases of poisoning have been recorded as occurring by contact with the smoke emanating from a smothered fire of the wood of the plant. It is also stated that certain very sensitive persons cannot remain in or near a room where the tincture of the fresh drug is being bottled without the certainty of being poisoned. The milky juices of other species of Rhus, especially the Japanese lacquer tree, act similarly, and a case is on record in which the emanations from a bottle of this lacquer poisoned the faces of those smelling it, though there was no contact. Poisoning did not result where the substance came into contact with the mucous membranes of the mouth and nose.

There exist in the leaves, besides toxicodendrol, a small amount of resin, some tannin, wax, and other unimportant constituents.

Poison ivy has been highly recommended by the homœopaths as a medicinal agent, purely upon the dogmatic assertion *similia similibus curantur*, and it has even found its way into the United States Pharmacopœia, though it is to be dropped from the forthcoming edition. Making the most liberal allowance, we are obliged to conclude from the evidence at our command that its medicinal activity is practically *nil*.

Ivy poisoning first appears as minute, clustered, itching papules, which soon become surrounded by a bright erythema, in part produced by the inevitable scratching. The papules have by the next day become minute, deep seated, eczematous blisters. For several days this appearance is not much changed, nor are the burning and itching diminished. Then the surface of the blisters gets rubbed

Digitized by Microsoft ®

off, the watery exudation moistens the surface affected, and often spreads the disease to other parts. The blisters finally become pustular, and then crusts and scabs cover the surface. The first appearance is always local, and if contracted in any of the usual ways is on either the hands or wrists or the face. In the latter situation the swelling is always great, the eyelids generally becoming completely closed by it. From the hands it easily extends to the breasts or male genitals, on the latter of which the burning is exceedingly hard to bear; occasionally it becomes general. The course of the affection in a single spot covers usually five or six days, but it may often spread over twice that time when different parts of the body are successively invaded. It heals without a scar, but is a little apt to return on successive summers.

www.libtool.com.cn

FIG. 3840.—Rhus vernix. (Two-fifths natural size.)

There is rarely any difficulty in establishing a diagnosis. The symptoms present some superficial resemblances to those of erysipelas, but in the latter disease the underlying tissues are swollen and hard, whereas in ivy poisoning the effects are superficial and the surface is soft and somewhat fluctuating.

Numerous remedies and specifics are in use against Rhus poisoning; still its course, when fairly begun, is not often really aborted. The measures for its treatment may be divided into the following classes: (1) The destruction of the poisonous constituent; (2) the prevention of friction due to scratching the affected surface, and the prevention of the spreading of the poisonous matter; (3) the relief or prevention of itching and pain from atmospheric irritation.

The first of these results can be fairly well accomplished if measures are taken very promptly after exposure and before the symptoms of poisoning have fairly presented themselves. Ordinary washing is inadequate, unless very thorough indeed; and it is, in fact, liable to spread the poisonous substance over a wider surface. Washing with a great abundance of common cheap laundry soap, or even the application of a thick layer of this soap to the surface, has yielded good results. Washing with a strong solution of sugar of lead is a favorite method with some, and lime water, black wash, and other alkaline applications are useful. The discovery of the fatty nature of the poison serves to explain to some extent the principles of this line of treatment, the alkali probably saponifying the fat and destroying its activity. The second-named object is attained by the use of vaseline or some similar application, and this also accomplishes part of the third object, protection against the effects of the atmosphere. These applications should be made as lightly as possible, though thickly, and not by means of plasters or similar coverings. Excellent results have been attained by applying the fluid extracts of Grindelia, Eriodictyon, and similar resinous substances, as well as collodion. In these cases the effect is probably due to the deposit upon the surface of a thin protective coating resulting from the evaporation of the alcohol. Relief of the irritation is to be obtained by the application of carbolic acid. An excellent method is the use of the official lime liniment to which from one to five per cent. of carbolic acid has been added. To any small areas which exhibit a specially irritable condition, a solution containing ten per cent. of the acid may be applied. Great care should be taken, however, that no large area, and especially that no extremity, be covered up by even the weaker solution. A saturated solution of oxalic acid is highly recommended by some practitioners. As the eczema dries away, zinc ointment may profitably be applied to take the place of the other applications. The Cheyenne Indians are said to employ with great success an infusion or decoction made from the herbage of *Astragalus nitidus* Pursh., a near relative of the famous loco weed (*A. mollissimus* Presl.). This infusion is applied just when the eruption takes on its "watery" character. Since the constituents of this plant are entirely unknown, the principle involved in its employment cannot be stated. The fresh juice of the wild or great celandine, or jewel weed (*Impatiens fulva*) is said to have been used with excellent results.

Almost precisely similar in action to poison ivy is the Poison dogwood or elder or Swamp or Poison sumac (*R. vernix* L.; *R. venenata* D.C.) (see Fig. 3840). This species is an erect-branching shrub or small tree with a smooth ashy-gray bark, of swamp lands, throughout Eastern and Central North America. The habit of the leaves and inflorescence is indicated in the accompanying cut. The leaves are very characteristic, on account of their deep red petioles. The leaves sometimes reach a length of one and a half to two feet, are nearly smooth, and green on both surfaces. Flowers and fruit are very similar to those of the poison ivy.

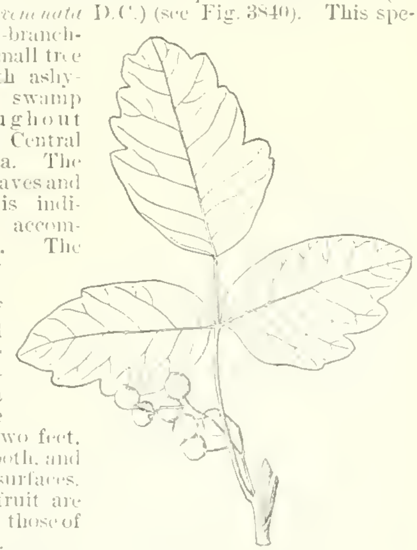

FIG. 3841.—Rhus diversiloba. (One-half natural size.)

The two species of Rhus above described pertain to the section *Venenatæ*, characterized by smooth fruits, and most, if not all, of the species of which are poisonous. The Japanese lacquer tree (*R. vernicifera* DC. or *R. vernix* Thunb.) has been already referred to. The lacquer is prepared from its milk juice, which frequently pro-

Digitized by Microsoft®

duces severe poisoning, as does the herbage. The tree closely resembles our *R. vernix* L. Species which quite closely resemble *R. radicans* are *R. microcarpa* (Mx.)

www.libtool.com.cn

FIG. 3842.—Metopium. (One-half natural size.)

Steud. (*R. Toxicodendron microcarpa* Mx.) of our North Central States, *R. Michauxii* Sargent (*R. pumila* Mx.) of the Eastern United States, and, in the West, *R. Rydbergii* Small and *R. diversiloba* T. et G. (*R. lobata* Hook.), the

FIG. 3843. Comocladia. (Reduced one-half.) *A*, Leaflet of *C. glabra*; *B*, base of leaf and fruit cluster of *C. dentata*; *C*, upper portion of leaf of *C. ilicifolia*; *D*, leaf of *C. platyphylla*.

Californian or *Pacific Poison Oak* (see Fig. 3841). The celebrated *Coral Sumac, Mountain Manchineel* or *Bumwood* of Florida and tropical America, has been referred to this genus as *R. metopium* L. or *R. oxymetopium* (Griseb., but is now called *Metopium Linnæi* Engl. (see Fig. 3842). Its close relative in Cuba, *M. venosum* (Griseb.) Engl. has similar poisonous properties. These are small trees or large shrubs, and their fruits are reddish instead of greenish-white like the others named.

FIG. 3844.—Lithræa caustica. (Two-thirds natural size.)

The genus *Comocladia* P. Browne (*Dodonæa* Plum.) represents shrubs and trees of the central portion of tropical America, including the West Indies, which are violently poisonous. Several species are known as *Guao*, and a number are here illustrated (see Fig. 3843). Poisoning by these species has been successfully treated with an application of collodion. The following possess, in their respective localities, histories of poisoning similar to those of the *Venenata* and *Comocladia* described above: in Chili the *Llithi* (*Lithræa caustica* Miers (*Rhus c.* Hook.) (see Fig. 3844); in Mexico, the *Copaljiote, Cuajiote* or *C. Blanco, Guajilote* or *Stinking Wood* (*Pseudosmodingium perniciosum* (H. B. K.) Engl. (*Rhus p.* H. B. K.); in Eastern Asia, *Melanorrhœa laccifera* Pierre; in the East Indies, *Holigarna ferruginea* March.; in Southeastern Asia, *Gluta Renghas* L.

The fixed oil of the cashew or caju nut, the ripened ovary of *Anacardium occidentale* L., a small tree, native of tropical America and largely cultivated and naturalized in other tropical countries, yields the vesicating principle *cardol*, evidently very similar to the poisonous element of Rhus. This substance exists in specially large amount in the middle layer of the pericarp, and the fatty substance thence exuding frequently causes poisoning. Cardol ($C_{21}H_{30}O_2$) is soluble in alcohol and ether. In the crude condition it varies from yellow to reddish or brownish, but can be decolorized. Poisoning

Digitized by Microsoft ®

Poisonous Plants.

by it, and its treatment, are practically identical with those pertaining to Rhus.

The only other cutaneous poisons important enough to require consideration here are certain acrid juices of the Euphorbiaceæ. Types of this class are *Aleurites* and *Euphorbium* (which see). Others are referred to in our article on *Euphorbiaceæ*. In most of these cases the poisoning agent appears to be resinous. In croton oil and some others they are apparently fat acids. In the former class the saponification treatment offers little promise. In both cases protective and soothing applications are equally efficacious as in Rhus poisoning. Manchineel is the large tropical American (chiefly West Indian) tree *Hippomane Mancinella* L. It bears large, thick, ovate, acute, finely serrate leaves and an apple-like fruit containing several silvery seeds. Its milky juice is abundant and is the poisoning agent, its active constituent being apparently volatile. Treatment is much like that applicable to Rhus poisoning.

www.libtool.com.cn

Internal Poisons.

In considering the poisonous plants which act through the entrance of their constituents into the circulation or into the alimentary canal, the primary requirement appears to be their identification. This, in a majority of cases, is most readily effected by reference to the objects themselves, rather than to the symptoms as in cases of poisoning by chemical substances. This fact has determined the following classification of these objects as plant parts.

To discuss all poisonous plants would require a large volume, and it has been deemed wise to treat the subject from the standpoint of a North American work, considering all plants of importance, or likely to become so, as poisoning agents in our own region, and including, from outside of this region, only such as are of primary importance. Moreover, no attempt is made to enumerate all those known to possess poisonous properties, since it is clear that many of them are not at all likely to be eaten. A still further restriction of the subject is made by omitting, except by mere mention, those poisonous plants or plant parts which become effective only through their medicinal employment, these having been sufficiently treated in the materia medica portion of our work.

Fruits and Seeds.

These products are placed first because of their greater liability to being eaten. Contrary to popular ideas, the

Fig. 3845.—Belladonna. Branch reduced one-half; fruit natural size.

number of poisonous fruits and seeds in North America is small. Even in country districts, where correct knowledge of this subject should be found, many perfectly innocent substances are commonly regarded as poisons.

Belladonna (fam. *Solanaceæ*).—Undoubtedly this is our most important poisonous fruit, its seeds containing the active constituents pertaining to the roots and leaves. The plant is rare in a wild state in this country, though very common in Southern and Central Europe. Its scarcity, however, renders it on some accounts the more dangerous, since it is thus not well known. It is a highly attractive, purple-black, shining, juicy berry, as indicated by one of its common names, "black cherry," and has been often eaten by children in the regions where it abounds. The accompanying illustration (see Fig. 3845) is ample for identification. The plant is a tall, widely spreading, smooth perennial herb, somewhat resembling the pokeberry plant, though not so large and wanting the strong purple stem coloration of the latter. All matters pertaining to the symptoms and treatment of poisoning by it will be found under *Belladonna*.

Bittersweet, True and False.—Rather closely related to belladonna is the true Bittersweet (*Solanum Dulcamara* L., fam. *Solanaceæ*). Leaf, flower, and fruit forms are shown on page 763, Vol. I., and the plant is there described. It is found both in Europe and in America, and grows commonly in the edges of swamps and along streams, especially where the water is stagnant, or where the ground is subject to overflow. Occasionally also it grows in other localities, as about shaded stone walls and fence rows. The branches are long, slender, sprawling, and widely spreading over bushes, and the fruits are pendulous. Nothing more attractive than these fruits can be imagined. They are of a ruby-red color, smooth, shining, and somewhat translucent, and children are very apt indeed to eat them. Their poisonous properties are rather mild unless large numbers are eaten. The seeds appear to be the poisonous portion. The properties are partly those of the drug Dulcamara, but more intense, and the poisonous constituent appears to be solanine.

False Bittersweet (*Celastrus scandens* L., fam. *Celastraceæ*) has been considered in the same connection. Its fruits are also attractive, but possess an acrid taste; hence they are not likely to be eaten in quantity. Their poisonous properties, due probably to a small amount of saponin, are comparatively slight.

Potato Fruits.—The small berries which develop upon potato plants are mildly poisonous, especially when unripe, in the same way as are the berries of true bittersweet. They have a nauseous, acrid, and disagreeable taste, and are not at all likely to be consumed.

Black Nightshade.—The fruits of black nightshade (*Solanum nigrum* L., fam. *Solanaceæ*) may be dismissed with the same remarks which have been applied to potato fruits. This plant grows like a tall, slender, and erect potato plant, in similar situations to those of bittersweet, though usually in dryer ground and more in the vicinity of barns and waste places. It is not very abundant, though somewhat common in the United States, as indeed in almost all other parts of the world. Its fruits are a little larger than large peas, and are of a greenish-black color. The fruits of many tropical species of Solanum are similarly, some violently, poisonous.

Other North American berry-like or fleshy fruits requiring consideration in this connection are the baneberries, or cohoshes, red and white, pertaining to the genus *Actæa* and the fruit of the yew.

Actæa (fam. *Ranunculaceæ*) is a genus of several species, probably more numerous than generally admitted by systematic botanists, distributed from Japan across Asia and the most of Europe, and in North America from ocean to ocean. According to ancient, and to one very recent authority, the half-score species of Cimicifuga are also included; but to most botanists familiar with the plants in a state of nature, an absurdity is involved in this association. The red and white berries have been recorded as poisonous, the medical botanist Lindley saying of them that they produce death with violent delirium, emesis, and catharsis (see Fig. 3846). The active constituents of the baneberries have not been investi-

Digitized by Microsoft®

gated, but are in all probability similar to those of larkspur seeds and stavesacre. Not enough is known of their action to suggest anything more than rational treatment, consisting of prompt evacuation, followed by alleviation

www.libtool.com.cn

FIG. 3846.—Actaea. A, A. rubra; B, A. alba. (Two-thirds natural size.)

of the painful symptoms, and support to the circulation, which is depressed as in poisoning by hellebore.

Yew Berries (fam. *Taxaceæ*).—It was for a long time supposed that the American creeping yew was a mere variety of the European, which latter is recorded as having produced various poisoning accidents. Now, however, it is recognized that they represent distinct species. The foliage and fruits are here illustrated. The plant is an evergreen and the fruit is of a beautiful bright scarlet, frequently with a somewhat glaucous surface (see Fig. 3847). The poisonous constituent, present in the seed and foliage, is the alkaloid *taxine* (C[illegible]H[illegible]NO[illegible]), which is bitter, readily soluble, in its free state, in alcohol and ether, but not in water and is precipitated by silver nitrate. Its action is very imperfectly understood though it is compared in a general way with that of digitalis. The following symptoms have been recorded: nausea and retching without much vomiting, dilated pupil, convulsions interrupting a semi-comatose condition, a cold and clammy skin, and difficult respiration. No cases of poisoning by the American plant have been recorded, though it doubtless acts similarly.

Phytolacca or *pokeberry* has already been considered as a drug. The so-called berries are in reality stone-fruits. They are of a beautiful and tempting appearance, being of a dark purple-black, shining and juicy, and are not rarely eaten by children (see Fig. 3848). After a little time the taste becomes acrid, so that large quantities are not usually consumed. The seed, which is the poisonous portion, is enclosed in a crustaceous endocarp, which is usually not crushed in eating, so that the seed is protected for some time against the digestive juices. Meantime the pulp itself is somewhat laxative, so that the dejection of the pyrenes in an entire condition is to be anticipated. Treatment should consist in prompt emesis and catharsis, followed, if irritant symptoms should appear, by that applicable to poisoning by pokeroot.

Other fleshy fruits.—In this connection brief reference may be made to the fact that although the common May apple or mandrake berry is commonly and freely eaten, yet two cases are recorded of poisoning by it, one resulting fatally. The symptoms were those of poisoning by podophyllin, although narcosis came on very early.

Such seeds as those of the cherry, plum, and peach are in all respects similar to bitter almond, and are capable, when eaten in excess, of causing prussic-acid poisoning. Two cases are reported in which intestinal impaction of wild cherry stones, followed by the freeing of the seeds by maceration, resulted in poisoning, one of the cases proving fatal. Excessive indulgence in eating the sweetish fruits of any species of juniper may result in poisoning similar to that by the ordinary medicinal juniper.

The fruit of *Tamus communis* L., the Black bryony (fam. *Dioscoreaceæ*) grows upon a tendril-bearing vine of Northern Africa, Southern Asia, and Southern and Central Europe. It (see Fig. 3849) is an active emetico-cathartic poison, producing powerful diuresis, and apparently acting much after the manner of squill.

In Southern and Central Europe, as well as in cultivation for lawn ornament, occur the peculiar fruits of *Daphne mezereum* L., which are quite actively emetico-cathartic and diuretic; they are used for fish poisoning, and sometimes poison children. They contain the glucoside *daphnin* ($C_{15}H_{16}O_9.2H_2O$) which is neutral, soluble in hot

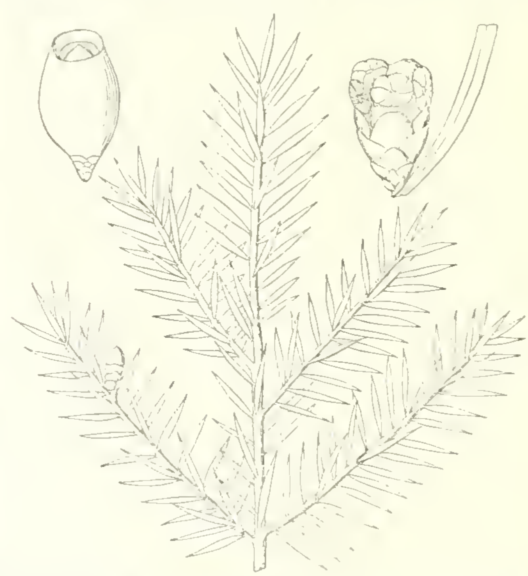

FIG. 3847.—Taxus. Branch slightly reduced; ament and fruit × 2. (After Britton and Brown.)

water and not alcohol; also the amaroid daphnetin, which is a feebly acid and astringent principle, similarly soluble. We here figure also the fruits of *Hedera helix*, the common ivy, which are discussed under the title *Ivy*, and those of *Ligustrum vulgare*, or privet, considered under the title *Privet*.

Digitized by Microsoft®

Poisonous Plants.

Finally, reference may be made to the fact that mild narcotic properties pertain to the common elderberry, notwithstanding the freedom with which this fruit is eaten. Small animals, like barnyard fowls, have been

www.libtool.com.cn

Fig. 3848.—Phytolacca. (One-half natural size.)

recorded as suffering from intoxication from eating them. Cooking or fermentation appears to destroy these properties.

Stramonium.—Among the non-fleshy fruits and seeds, probably the most important poisoning agent is Datura or stramonium, the common thorn apple. An examination of our illustration (see *Stramonium*) will show that the fruit is large and conspicuous, and very likely to attract the attention of the curious or hungry. Growing as it does in waste places in cities, whose inhabitants are not accustomed to observing vegetation, it not infrequently happens that its seeds, which are contained in abundance, are eaten, especially by young people. It is also stated that in India and other Oriental countries where this plant abounds its seeds are often eaten by starving people in times of famine, with widespread fatal effects. The Thugs were said to use them freely for the purpose of stupefying their intended victims. Such assassins were called *Dhaturias.* The symptoms are identical with those described under *Stramonium*, as is the treatment.

Henbane.—Closely related in every way to stramonium is henbane. The plant is similarly a large, coarse, widely spreading herb, with clammy foliage and heavy narcotic disagreeable odor. Its capsules are not more than half so large as those of stramonium, and they discharge by the separation of a terminal lid. Poisoning by these seeds is not common.

Cicuta.—Small fruits, usually spoken of as seeds, are those of conium and cicuta. The former has been sufficiently considered under that title. Poisoning by the latter, except as part of the plant itself, which subject will be considered under roots, is not at all likely to occur. The same may be said of the seed-like fruits of our wild parsnip, which are said to be somewhat poisonous, the action being partly acrid-irritant and partly narcotic. No authenticated cases of poisoning are recorded. The fresh juice is said to blister and the root is regarded with suspicion.

To be classed with ergot, as poisonous constituents of grain, are the darnel, the cockle, and perhaps the seeds of other species of plants in the pink family.

Lolium, Darnel, Bearded Darnel, Ivraie (Fr.), *Lolch, Taumelkorn* (Ger.), is the fruit (grain or *caryopsis*, commonly miscalled seed) of *L. temulentum* L. (fam. *Gramineæ*), an Asiatic grass, growing commonly in grain fields there and in Europe, and so introduced in this country. The general structure of this seed is that of a grain of wheat or rye. It is about a fourth of an inch long, and comes away with the palets attached and enclosing it, is convex on one side, grooved on the other, of a light brown color, smooth, starchy in structure, and gradually develops a bitter taste after chewing. Its presence in flour, if in large quantity, can be detected by the appearance of the starch grains, which are much smaller than those of wheat starch, nearly circular, white-margined, the rest of the body without markings, and having a peculiar brightly shining surface. The poisonous constituent is the alkaloid *temuline* ($C_7H_{12}N_2O$), existing with *temulentic acid.* There is a good deal of obscurity regarding the mode of action of this poison, but the substance is in general classed as a narcotic of the delirifacient type, producing much nausea, dizziness, and headache, with drowsiness. There is also at first considerable irritation of the stomach and intestines. Darnel-contaminated flour is not dangerous unless the substance is present in very large amount, from which condition a number of fatal cases have resulted.

Cockle or *corn cockle*, the seed of *Agrostemma Githago* L. (*Lychnis G.* Scop., fam. *Caryophyllaceæ*), is very common in grain fields, more so in Europe, where it is native, than in this country. The plant is a slender herb, two or three feet high, the branches terminating in handsome purplish flowers about an inch broad, and having the general appearance of a common single-flowered pink. The seeds are produced in a one-celled capsule and are numerous, black, and about as large as morning-glory seeds. Their active constituent appears to be a kind of saponin which is exceedingly common and abundant in this, the pink family. The properties of the poison are those of saponin, and a percentage of the seeds in the flour sufficiently large to produce fatal results is scarcely to be expected.

The closely related plant *Vaccaria Vaccaria* L. Britton (*Saponaria V.* L.; *V. vulgaris* Host.), the cow cockle, cow herb, or field soapwort, produces seeds which are apparently identical in action with the corn cockle. This plant is at present spreading widely through the grain fields of the Western United States, and the seeds are becoming increasingly abundant as a constituent of grain. Although they are rather easily screened out, yet their possible presence in flour is to be recognized as a distinct source of danger.

Ricinus or *castor oil* seeds have been rather fully considered under *Castor Oil*, so far as constituents and activity are concerned. These shining, reddish, and purple-spotted, bean-like seeds are very pretty and attractive to children. Their tendency to be eaten to excess is the greater because they have a bland and nutty flavor, quite free from the nauseous odor and taste of castor oil, unless they have become old and rancid. The common cultivation of the plant for lawn decoration conduces to accidents. In one case, a city resident, moving to the suburbs where a quantity of these seeds were strewn upon the lawn, fed them to his horses with the remark that it was a pity to see all those beans going to waste. The effect upon the horses was fatal.

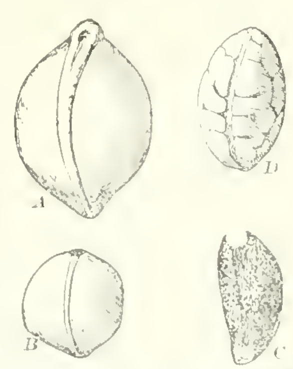

Fig. 3849. *A*, Daphne Mezereum; *B*, Tamus communis; *C*, Ligustrum vulgare; *D*, Hedera helix. (After Holmes.)

Several other Euphorbiaceous seeds were formerly much

Digitized by Microsoft®

cultivated in gardens for use as cathartics, under the name of spurge or spurge seeds, and this habit has not entirely died out. They produce, in overdoses, poisonous results similar to those of ricinus.

Coral Bean.—Acting by a toxalbumin similar to ricin, or even more like www.libtool.com.cn seeds of several species of *Sophora*, especially *S. coralloides* Benth. (fam. *Leguminosæ*), have produced fatal poisoning in Texas and the regions to the southwest. These coral beans resemble a common bean in form, some being larger, some smaller, and are of a bright scarlet color. They grow in a brown or brownish cylindraceous pod, which is constricted between the seeds, so as to resemble beads upon a stick, and separating readily into its one-seeded joints. Treatment of this poisoning has proved difficult and uncertain.

Lupines (fam. *Leguminosæ*).—Many species of the genus *Lupinus* (wild bean or blue bean) are employed, in both Europe and America, either as fresh fodder or for the production of a hay very similar to clover hay. Although these fodders are used upon a great scale, with only the best results in most cases, yet wholesale and fatal poisoning has at times resulted. Many observations, together with some careful experimentation, have apparently determined the fact that the poisoning is due to the seeds, which resemble small beans and are produced in bean-like or pea-like pods. When the herbage is eaten previous to the formation of these seeds, or after they have been discharged from the pods, no bad results follow; but if the seeds are eaten, especially when ripe, either acute or chronic poisoning may follow. The symptoms indicate a poison similar in its general nature to digitalis or, still more so, to sparteine or ononis. There is cerebral congestion, with frenzied and very active delirium. The heart is slow and strong, the blood pressure high. Convulsions, with extreme alternations of strength and weakness, and finally prostration occur. There is powerful diuresis, the urine being often bloody, as in digitalis poisoning. Death usually occurs in acute cases within two hours of the appearance of the first symptoms.

Æsculus.—The common horse chestnut (seed of *Æ. Hippocastanum* L., fam. *Hippocastanaceæ*) is regarded as slightly poisonous, and certainly contains acrid saponin-like principles (*argyræscin* and *aphrodæscin*) which, consumed in large amount, would prove disastrous. Deprived of this principle by powdering and maceration in alcohol, the residue of the kernel is highly nutritious (protein eight per cent., fat seven per cent., non-nitrogenous extract containing among other constituents fourteen per cent. of sugar), and it is now being so manufactured in Germany. It is readily conceivable that, as this industry extends, insufficient purification may lead to the distribution of a poisonous product. A western and southwestern species (*Æ. Pavia* L.), the buckeye, is apparently much more active, various fatal cases of poisoning by it being on record. Its poisonous constituent is similar to, but distinct from, argyræscin. The symptoms are violent emesis and catharsis, convulsions, and other common accompaniments of poisoning by the saponin group. It would appear from the accounts that narcosis comes on rather more quickly than in cases of poisoning by other saponin-containing drugs.

Poisonous Barks.

In the nature of the case poisoning of human beings by barks is not at all likely to occur, except in medical cases where a poisonous bark has been taken by mistake, or overdoses of the bark have otherwise been given. It is true that many barks are employed by savages as arrow poisons (see *Curare*), but this subject scarcely pertains to the present article. The poisoning of stock by the eating of nutritive barks is in general prevented through the natural instinct of the animal. In times of scarcity of food, however, grazing animals sometimes eat the bark of the common locust tree (*Robinia pseudacacia* L.) with poisonous results. This tree pertains to the family Leguminosæ, or bean family, so noted for its production of albuminoid nutrients. Its poisonous constituent has been determined by Power as a toxalbumin, very subtle and difficult of isolation. Nothing is known of the treatment, except what is derived from a knowledge that the chief symptom is extreme nausea with violent retching, persisting for days, accompanied by dizziness and great depression. In animals marked salivation has been noticed. The barks of wild cherry and of several Ericaceous plants are poisonous to stock in the same way as their foliage, and the latter will be considered under *Herbage*. The barks of various species of elder (*Sambucus*) are more or less poisonous, though it does not appear that they produce accidents. This subject will be considered under *Roots*.

Poisonous Roots.

Besides the true roots, that name is generally applied by the public to all underground parts, such as mandrake, lily of the valley, Solomon's seal and other rhizomes, the potato and the artichoke, which are tubers, and the onion and garlic which are bulbs. All these are therefore here considered together.

The two important poisonous roots of our region are pokeroot and Cicuta. Probably no year passes without some fatal cases of poisoning by these, and it occasionally happens that quite a number of them occur at about the same time.

Pokeroot has already been considered at length as a drug, under that title, and its fruits have been elsewhere discussed in this article. The root has been quite often eaten by mistake for horseradish, which it rather closely resembles, and for other edible roots. The strong acridity of horseradish tends to avert the suspicion which would otherwise be excited by that of the pokeroot. When freshly dug it is quite attractive, being large, whitish, fleshy, and succulent, and containing large amounts of starch and sugar, so that it is readily mistaken for a wholesome and nutritious article. Suspicion once aroused, pokeroot is easily recognized. The base of the stem, which is usually present in a broken condition, is seen to be divided by thin transverse partitions. The surface is finely papillose, and usually presents a spiral appearance, and the cross section exhibits a conspicuous concentric arrangement of the tissues. Since the young shoots are often cut and eaten as a substitute for asparagus, portions of the root are apt to be thus taken by too deep cutting. Thorough cooking ameliorates, but does not destroy its activity.

Cicuta (Water Hemlock, Cowbane, Brook Tongue, Children's Death, Spotted Parsley, Beaver Poison, Muskrash Poison, etc.; Ger., *Wasserchierling, Giftwütherich*; Fr., *Ciguë vireuse*) is the root of various species of the genus *Cicuta* L., fam. *Umbelliferæ*, a genus closely related and very similar to conium, some of the species even having gone by that name (see Figs. 3850 and 3851). These plants grow in swamps or other wet locations, along lakes, streams, and ditches throughout almost the entire North Temperate zone, and are particularly common and abundant in Eastern and Central North America. Our illustrations give an excellent idea of the roots, foliage, inflorescence, and fruits. The plant grows to a height of from three to five feet, and branches and spreads rather widely. The stems and leaf bases are thick, hollow, crisp, and juicy, and the former are usually more or less purplish and glaucous. The base of the petiole clasps the stem. The leaf blade as a whole, though successively much divided into small segments, is very large, often two feet or more broad and long, and is thin and quite green. The entire plant is smooth, and exhales a not unpleasant odor when bruised. The fine white flowers are in decompound umbels, terminating the branches. The base of the stem, when longitudinally cut, exhibits thin transverse partitions, though these are obscure in some species. The roots, in fascicles like dahlia roots, are usually from three to ten in number. They have about the consistency of a raw potato, are starchy, crisp, and juicy,

Digitized by Microsoft®

somewhat aromatic, and not unpleasant to the taste. They are externally of a brownish color, internally white. They are about the size of Jerusalem artichokes, which they somewhat resemble, and for which they have been mistaken. Boys visiting swamps for calamus often get hold of them. Frequently also they are turned out in

www.libtool.com.cn

FIG. 3850.—Cicuta maculata. (One-half natural size.)

ditching operations, and they have then been experimentally eaten by workmen with fatal consequences. The aromatic stem and the fruits have also been mistaken for angelica. The constituents are believed to include coniine (see *Conium*). Cicutoxin is also a very active constituent. Although the nature of the poison partakes of

FIG. 3851.—Cicuta maculata. (One-fourth natural size.)

that of conium, yet there is far more of a tendency toward irritation and convulsions. Tremors, violent contractions and relaxations of the muscles, astonishing mobility of the eyeball and eyelashes, widely dilated pupil, frothing, often bloody, of the mouth and nose, epilepsy, and after death a peculiar greenish fluid in the stomach and exuding from the mouth, cold, contracted, pale surface and some diarrhœa have been noted. Prompt emesis

FIG. 3852.—Œnanthe crocata. Reduced. (After Holmes.)

by the aid of zinc sulphate has been found effective The further treatment is indicated by the symptoms.

FIG. 3853.—Sambucus Canadensis. (One-third natural size.)

Œnanthe Crocata.—In Europe this species, closely related and rather similar to cicuta, is regarded as taking

Digitized by Microsoft®

www.libtool.com.cn

first rank among poisonous plants. Like cicuta, it grows in damp soil and produces a fascicle of fleshy roots (see Fig. 3852). Its leaves bear a strong general resemblance to those of celery, and it is free from disagreeable or warning taste. The symptoms of poisoning are only in a minor degree similar to those resulting from cicuta, and the nature of the poison is probably quite different. The symptoms develop very rapidly, death frequently occurring within an hour or two. Dryness of the mouth, with great thirst, vomiting, then dizziness, slow and weak pulse, pale and cold skin, reduced blood pressure, pupils greatly dilated and failing respiration, inducing convulsions, result. Death occurs apparently from heart failure. Judging from these symptoms, it would appear that the administration of digitalis would constitute a rational line of treatment.

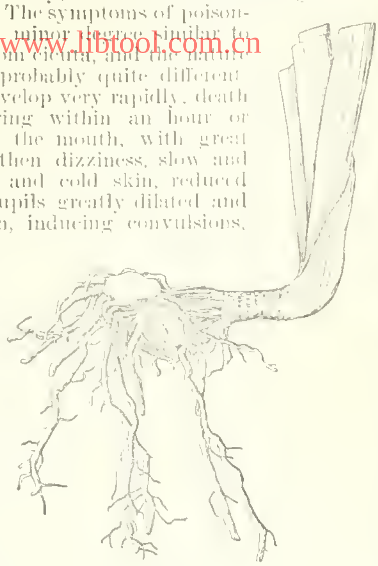

FIG. 3854.—Iris versicolor. (One-half natural size.)

Sambucus or *Elder* (fam. *Caprifoliaceæ*). (See Fig. 3853.)—Apparently closely related to cicuta as a poison, is the root of the common elder, and probably of other species of the genus. These roots (or more properly rhizomes) are elongated, cylindrical, crooked, somewhat branched, whitish, and possessed of a rather thick, juicy bark. Commonly, some small shoots can be seen upon them, and these are usually of a bluish-purple color at the place where the young leaves are forming. When bruised, these roots exhale a rather disagreeable odor, and the after-taste is acrid. Coniine is said to have been extracted from some of the elders. The symptoms of poisoning are much like those from cicuta, and promptly fatal results have been recorded.

Iris or *Blue Flag* rhizome (fam. *Iridaceæ*), growing commonly in swamps or low ground, along with calamus or sweet flag, is liable to be mistaken for the latter. The distinctions between the two, once known, are sufficiently easy for recognition. Iris grows in small or only moderately large clumps, while calamus covers large patches, almost to the exclusion of other growth, and usually in wetter situations. Its leaves are longer, narrower, less thick and fleshy, and are greener, lacking the bluish-green tinge of iris. The plant is also taller. The rhizome of calamus is long and rather uniform in thickness for a considerable distance. That of iris is much thickened at short intervals. Calamus is bitter and somewhat acrid, so that the acridity of iris, though greater, is apt to be endured by the heroic calamus chewer, thinking that he has the rhizome of the latter. The properties of iris have already been considered (see Fig. 3854). The fresh rhizome is much more irritant and violently emetic and cathartic than the dry drug.

Veratrum (fam. *Melanthaceæ*).—Growing in the same swamps with iris, though usually in more wooded or shaded situations, veratrum is often found. Although a mistake is here not easy, such a possibility should not be overlooked, as the rhizome is fleshy and succulent. Beyond referring to our illustration and to our account of the drug (see Fig. 3856) this subject requires no discussion.

Camas.—Various western species of the genus Zygadenus Mx., of the same family with Veratrum, are known by this name, and several of them are recognized poisons, especially *Z. venenosus* Watson, or Death camas, a name which has been applied to a polymorphous species, or a group of very similar species, according to the varying views of different botanists. In all probability most, if not all, of the species of this genus are poisonous, but only the death camas has produced serious results. The genus is characterized as follows: Plants smooth, perennial, from rhizomes or bulbous bases, the stem bearing linear, somewhat succulent leaves, and terminating in a raceme or panicle of yellowish-white or greenish-white marcescent flowers, the perigone six-parted, its segments gland-bearing near the base. Stamens six, borne at the base of the perigone but free from it, the anthers cordate or reniform. Ovary three-celled with three styles. Pod completely dehiscent and containing narrow, angular seeds. The genus is closely related to veratrum. *Z. venenosus* is here figured (see Fig. 3855). It is extremely common and abundant in Montana and other Northwestern grazing regions, and is very destructive to stock. All parts of the plant appear to be poisonous. The bulb, which is especially so, is recognized among the Indians as dangerous to man because of its close resemblance to several edible species. It appears to be bitter at times, quite free from bitterness at other times. It is considered fatal to about twenty per cent. of the sheep poisoned by it. The symptoms are said to be uneasiness followed by incoordination, then muscular paralysis, especially of the posterior limbs. There are dizziness, disordered vision, regurgitation of frothy matter, salivation and weak respiration, with little cerebral disorder. The nature of the poisoning may thus be regarded as paralysis of the motor centres, progressing from below upward. The nature of the poisons is unknown, though the indications are those of one or more glucosides. They are extracted both by alcohol and by water. Potassium permanganate appears to be a very efficient antidote.

Closely related to Zygadenus, and by some botanists regarded as pertaining to it, is *Chrosperma muscætoxicum* (Walt.) Kuntze (*Melanthium m.* Walt.; *Amianthium m.* Gray) the Fly poison, Crow poison, or Fall poison, a common bulbiferous perennial of sandy soil of the Eastern United States, especially near the coast, and in parts of the Southern Central States. It reaches a height of two to three feet, bears long, linear grass-like leaves, nearly an inch in breadth at the base, and large, much-branched panicles of greenish white flowers, about a half inch broad. The perigone consists of six distinct parts, without glands, and is marcescent. The stamens are six in number, and borne upon the base of the perigone segments. Ovary and pod are three-celled, the latter splitting only at its upper portion, the styles persistent upon the valves. The ovoid brown seeds are

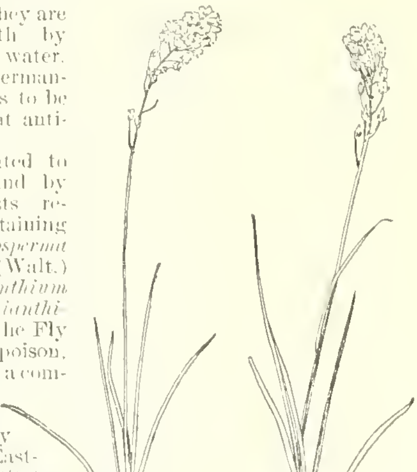

FIG. 3855. Death Camas. (One-fourth natural size.) (After United States Department of Agriculture.)

Poisonous Plants.

few and are apparently more poisonous than any other part of the plant. As its names indicate, this plant, especially the seeds, is in use as an insecticide, and it is poisonous to birds. Little is known about the nature and treatment of the poisoning, but it appears to be in a general way quite www.libtool.com.cn.

More or less closely allied to the above-named bulbs, as well as to colchicum, are those of various species of *Narcissus*, *Hippeastrum*, and *Amaryllis*, which are severely poisonous. A number of species of agave, pertaining to this family (the *Amaryllidaceæ*), as well as of Liliaceæ, yield so-called soap roots, used for their detergent properties on account of their large content of saponin, and for the same reason actively poisonous.

Other similar articles, poisonous if eaten, but not likely to be eaten except through mistake, are podophyllum, sanguinaria, leptandra, arum, and actæa, all elsewhere considered, and all so strongly acrid and disagreeable, or even painful, that no considerable amount could be consumed by a sane individual.

With convallaria, aconite, Solomon's seal, and apocynum the case is somewhat different.

Convallaria (see *Lily of the Valley*) rhizome is sweetish and not unpleasant except in the after-taste; and it is so highly poisonous that it would not be improbable for a child to eat enough to produce poisonous symptoms. So common an ornamental plant requires no description.

Aconite.—The fresh tuber of this highly ornamental garden flower is said not infrequently to have been mistaken for horseradish, incredible as this may seem. Its biting taste is even exceeded by that of the horseradish, so is not apt to excite suspicion, but it even more closely resembles other roots which might grow in the garden beside it. It is to be regarded as an exceptionally dangerous article. Its toxicology has been sufficiently described under the title of the drug.

Apocynum or *Dogbane* possesses a long cylindrical rhizome, running horizontally at a short distance below the surface, and fleshy and milky-juiced. It has an amylaceous taste, only slightly acrid, and might be eaten. Its properties have already been discussed.

Violet.—The roots of pansies and all other violets, though not likely to be eaten, should be remembered as possessing emetico-cathartic poisonous properties, almost identical with those of ipecac.

Euphorbia.—The large, fleshy, and milky-juiced roots of *E. corollata*, *E. ipecacuanha*, and other euphorbias, have been well-known and much used cathartics.

E. corollata is known as the Blooming, White, Purslane, or Large-flowered spurge, Apple root or Wild hippo, and is abundant in Eastern and Central North America. It reaches a height of about three feet, is slender, widely branched and smooth, and the flower clusters which terminate its branches are subtended by showy and petallike white involucres, each bract of which bears a green gland at its base. The root is cylindrical, an inch or more in thickness, and one and a half or two feet long, of a very dark or blackish-brown externally when dried, much lighter brown when fresh. It has a thick white bark in cross section and a radiate spongy central cylinder. Its taste is at first sweetish and pleasant, though the after taste is a little acrid. Its active constituent is a resin. Overdoses are very powerfully emetico-cathartic, the action being much like that of ipecac.

E. ipecacuanha is known as the White, Wild, North American, Milk, or Spurge ipecac or Ipecac spurge, and is very abundant in sandy soil along the Atlantic coast. Its very slender, much-branched stems are numerous and prostrate, so as to form a sort of mat-like growth. The leaves are of most diverse forms on different plants, ranging from narrowly linear to broadly oval. The herbage and inflorescence may be light green or more or less purple. The root itself is vertical, much longer and more slender than that of the last, rather lighter in color, but the woody centre more yellowish. Its properties, as well as its uses, are identical with those of the last.

Potato.—Our consideration of poisonous roots may well close with a few words concerning the poisonous properties of the tuber, and more especially of the sprouts, of the common potato. The potato at all times contains traces of the highly poisonous alkaloid solanine, and probably others, but ordinarily the percentage is too slight to produce perceptible effects. Since the greater portion of this poison exists in the external layer, the peeling of potatoes which contain it in excess, may easily prevent trouble. The substance appears to exist in greatest amount in the rhizome of the potato, upon the end of which the tuber develops. It is therefore much more likely to be present in the young ("unripe") potato than when it is fully developed. Similarly, when the sprouts (young rhizomes) develop upon potatoes in storage, the solanine becomes present in them in considerable quantity. When the sprouts are first forming and of a lurid purple color, the percentage of poison is large, gradually decreasing as they elongate, thicken, and whiten, and especially as they put forth green leaves. Wholesale poisoning has resulted when, in times of scarcity, an attempt has been made to eke out the potato supply by consuming the young sprouts. Potato tubers which form above ground or at its surface, so that they are exposed to the atmosphere and develop a purplish-green color, also contain larger amounts of solanine. Finally, it may be mentioned that very serious results have followed the eating of potatoes containing black fungus spots, the solanine percentage being greatly increased in and just about the spots themselves.

Similar to the potato, in that it is perfectly wholesome under some conditions and highly poisonous under others, is the cassava, manihot, or tapioca root (fam. *Euphorbiaceæ*), so largely used as a food in tropical America. Of this root there are two varieties—the one sweet, the other, bitter. The former is in general not poisonous, or not so much so but that thorough cooking renders it wholesome. Nevertheless, a small percentage of hydrocyanic acid is almost always contained in or to be yielded by its bark or the tissues near it. In the bitter variety an important amount of this deadly poison is always found, so that it is not safe to employ it, even for the manufacture of tapioca, without a thorough preliminary maceration and perfect cleansing. There are certain species of yams eaten in the East Indies which also have to be treated by thorough washing in order to remove a poisonous bitter constituent, although not in this case hydrocyanic acid.

The poisonous nature of the roots of belladonna, bryonia, spigelia, caulophyllum, colchicum, squill, and hellebore, will be found discussed under those respective titles, as drugs.

Poisonous Herbage.

In the nature of the case poisonous herbage is far less likely to be eaten by human beings than are fruits, seeds, or roots, and similar organs. Nevertheless, the use of leaves as salads and potherbs, especially in times of scarcity of food, as during famines or in the course of explorations, renders necessary a careful attention to some of them. Furthermore, the frequency of stock poisoning through their use is greater than that resulting from any other portion of the plant; and a reference to the more serious stock-poisoning agents is not out of place in an article of this kind.

As human poisons, tansy, aconite, chelidonium, lobelia, henbane, conium, belladonna, and viola, may be dismissed with the statement that they are scarcely likely to become effective except through accidents attending their use as drugs, which subject will be found discussed under their respective titles in that connection. Tobacco may poison, partly in this way and partly through its use as a popular narcotic, or during its application for parasites infesting plants and domestic animals, under which circumstances it has frequently caused poisoning by its entrance to the system through wounds or other openings in the skin. The symptoms and treatment of tobacco poisoning are elsewhere fully described. Absinthium is a well-known poison, either acute, through overdosage,

Digitized by Microsoft®

or chronic, through the use of beverages containing it. Both forms of poisoning are described under its title. A sufficient reference to poisoning by the foliage of the cedars, pines, hemlock, and other Coniferæ of the savin

www.libtool.com.cn

FIG. 3856. Veratrum Viride. (One-fourth natural size.)

or arbor vitæ type will be found under the poisonous family Pinaceæ. Related to these, but acting through its poisonous alkaloid, is the yew or taxus, which subject has been presented in speaking of its fruit. Poisoning by any of these is extremely unlikely to occur. The same is true of poisoning by the buttercups, clematis, etc., of the Pulsatilla type, in the poisonous family Ranunculaceæ. The foliage of the elder has already been stated as open to the same suspicions as those affecting its bark and root, and it need not be further considered. The foliage and flowers of lily of the valley, or convallaria, contain the same poisonous constituents as those of its rhizome, and there is the same slight possibility of poisoning accidents being caused by it. The occasional use of the stem and herbage of cicuta, mistaken for angelica, has already been mentioned. It contains the same constituents as the roots, and the symptoms and treatment are identical. Poisoning by the herbage of the black nightshade (see the section on Fruits and Seeds) is said to have occurred, although it is claimed that this herbage has been used as a potherb, after cooking, without injury. It is certainly open to grave suspicion. Should poisoning by it occur, it would doubtless be found identical with that of solanine from other sources. Another plant whose herbage has not been recorded as causing poisoning, but which, for obvious reasons, is to be regarded with caution, is the pokeberry, or phytolacca. Watercresses, though commonly regarded as quite innocent, are capable, when eaten in large excess, of producing dangerous and extremely painful symptoms. In one case seen by the writer, a painful, severe cystitis was established in this way. The possibility of an abortion being produced by this article, as well as by horseradish, is worthy of consideration.

Probably the two most dangerous leaf poisons in existence, all things considered, are stramonium and veratrum. The former has been fully discussed as a drug, and under poisonous seeds. It possesses the peculiarity of flourishing in periods of drought, resulting in famine conditions. The whole aspect of the plant is luxuriant and succulent, and a temptation to consume it under such circumstances may often be great. As a matter of history, numerous poisoning cases have occurred in this way, especially in India. Other cases are recorded in which travellers destitute of food have ignorantly eaten it. Veratrum (fam. *Melanthaceæ*) is a plant which grows in swamps in the vicinity of caltha, or American cowslip, the herbage of which is eagerly sought in many sections for cooking purposes, appearing as it does in early spring when fresh vegetables are scarce. Various cases are on record in which the foliage of veratrum has thus been mistaken and eaten with serious consequences. Veratrum poisoning has already been fully discussed (see Fig. 3856).

The young shoots of Tamus communis (see the section on Fruits) have been eaten like asparagus in the Old World with serious results.

Sorrel.—This name has been applied to two groups of plants, very different from a botanical standpoint, but agreeing in their sensible properties, constituents, and toxicology. The name *Wood Sorrel* has been applied to the common *Oxalis acetosella* L. (fam. *Oxalidaceæ*), which is very common in cool woodlands in both the Old and the New World, and bearing white or pinkish tinged and veined flowers. The trifoliolate leaves closely resemble a small clover leaf, but are somewhat fleshy, and the whole herbage is strongly acid. Oxalic acid, free and combined, is the poisonous constituent, and is said to have been first derived from this source. A number of very slender, branching species, with smaller and yellow flowers and smaller leaves, grow commonly as garden and roadside weeds and are known as ladies' sorrel or ladies' sour-grass. In tropical regions hundreds of species occur, some of them very large. Many species are favorites among household flowers. All have the same composition and properties.

The other group represents the sheep sorrels or field sorrels, namely, *Rumex acetosa* L. and *R. acetosella* L. (fam. *Polygonaceæ*), pernicious weeds growing in poor, gravelly, or sandy soil throughout the northern hemisphere. They are used to some extent as ingredients of salads. These also contain oxalic acid and have, like oxalis, caused fatal poisoning of both children and adults. The treatment and symptoms may be inferred from the above statement that oxalic acid is the active agent. It may be added that very large quantities of either are required to produce dangerous effects.

Ailanthus or *Tree of Heaven* (fam. *Simarubaceæ*).—These nasty smelling leaves are not at all likely to be eaten either by human beings or by domestic animals. It is said even that flies will not visit decayed meat when hung in the branches of these trees. The leaves have been utilized for the manufacture of substances both odious and toxic to flies. They have also, like the bark, been somewhat utilized in medicine; they contain a peculiar nauseous green oil, as well as an amaroid. This oil has been indefinitely stated as possessing poisonous properties. The bitter substance, though stomachic in medicinal doses, is a gastric irritant in larger doses. Chronic gastritis of a rather serious type is reported as having occurred in all members of a family, as the result of having drunk the water of a well in the vicinity of these trees. The roots extended into the water in great numbers and probably the leaves also had blown into and accumulated in the water.

Kalmia.—The members of this genus, the American laurels (fam. *Ericaceæ*), are distinctly poisonous, being frequently fatal to sheep, though not at all likely to be eaten by man, since the foliage is very bitter and disagreeable. The large species (*K. latifolia* L.) is the well

Digitized by Microsoft®

known mountain laurel or calico bush, spoon wood, or ivy bush, so common throughout Eastern North America. The smaller species of common occurrence is *K. angustifolia* L., the small, dwarf, or sheep laurel, lambkill, calfkill, or kidkill. It grows in more open situations, on dry hillsides, and rarely exceeds three feet in height. Its leaves are mostly in whorls of three, its flowers less than half as large as those of the other, and of a deep rose color. Other small species are more rare. The poisonous constituent of the laurels is the amaroid *andromedotoxin* ($C_{31}H_{51}O_{10}$), a neutral crystallizable substance, rather soluble in both alcohol and water. Mineral acids color its solution bright red. It is an extremely poisonous substance, and has been said to be, in the pure state, more emetic than either emetine or apomorphine, and more toxic than aconitine. Animals are not fond of laurel, eating it only when other food is scarce. The common symptom of poisoning by laurel is narcosis with muscular weakness. Animals become quiescent and stupid. In the early stages a staring glassy eye is notable, with great disorder of vision, objects being apparently distorted. A staggering gait progressively develops, and finally the animal lies down and goes into a condition of stupor. There is no disposition either to eat or to drink, the reappearance of such desire being a pretty sure indication of recovery. A thin liquid frequently flows from the mouth. Stomach digestion is apparently completely paralyzed. There are faint convulsive movements of the limbs, and death finally ensues from general weakness, specially of the respiration.

FIG. 3857.—Pieris Mariana. (Two-thirds natural size.)

The poisonous constituent described above occurs commonly in this family, other members of which have poisonous records by reason thereof. The most important of these is *Pieris Mariana* (L.) B. et H. (*Andromeda M.* L.), which bears the suggestive name of stagger bush (see Fig. 3857). It grows throughout the Atlantic region as far north as New England, preferring shrubbery along the salt marshes. It is a shrub, from three to five or six feet high, and its profuse flowers are whitish or purplish and of a waxy appearance. A flowering branch is here figured. The symptoms of poisoning by stagger bush are identical with those resulting from laurel. In this connection the *Rhododendrons* may be mentioned as having precisely similar poisonous properties.

Ledum or *Labrador Tea*, *Marsh*, *Swamp*, *Continental* or *James tea*, and *Marsh rosemary*, are names applied to the two species (fam. *Ericaceæ*) *Ledum Groenlandicum* Oeder (*L. latifolium* Ait.), the broad-leaved and *L. palustre* L., the narrow leaved (see Fig. 3858). They are marsh shrubs, the former ranging from Greenland through Northern North America, the latter extending also through Northern Europe and Asia. The broad-leaved species has been a much used substitute for tea among British-American voyagers, and is only moderately narcotic. The narrow-leaved species is much more active. Both are somewhat used medicinally in domestic practice. The narrow-leaved species is distinctly narcotic, the symptoms closely resembling those of laurel poisoning. If, as claimed, andromedotoxin is not a constituent, some very similar body must be present. A flowering branch of ledum is here figured. The leaves are well distinguished by their somewhat thick and leathery texture and their smooth upper and brown woolly lower surfaces. The flowers are white.

FIG. 3858.—Ledum latifolium. (Two-thirds natural size.)

The leaves of such plants as the cherry, peach, plum, etc. (fam *Drupaceæ* or *Rosaceæ*) yield appreciable amounts of hydrocyanic acid. Although the consumption of injurious quantities by human beings is not at all likely to occur, yet the leaves of the common wild cherry constitute a well-known and much-dreaded stock poison. The branches, trimmed out for fence rows or broken down by boys in search of the fruit, have very frequently been recorded as poisoning cattle, often fatally (see Fig. 3859). An unexplained but well-established fact is that cattle will eat them from the living trees without ill effects, but will be poisoned upon eating them in a wilted condition. That the effects are due to the hydrocyanic acid liberated is fully evidenced by the effects.

Delphinium or *Larkspur* (fam. *Ranunculaceæ*).—The general subject of larkspur, as to constituents and activity, has been considered under the title of Stavesacre Seed. So well known a garden flower scarcely requires description. The accompanying illustration of *D. glaucum*, the tall larkspur, often miscalled aconite, gives a sufficiently good idea of the genus in general (see Fig. 3860). Some of the species are larger, many much smaller. The flowers are usually of some shade of blue, sometimes pur-

www.libtool.com.cn

FIG. 3860.—Delphinium glaucum. (One-third natural size.) (After United States Department of Agriculture.)

plish. Many species abound in the grazing regions of Western North America, and they are much dreaded as stock poisons by herders, though the poisoning of human beings is not recorded, and is not likely to occur. These poisons are to be classed partly with aconite, to a lesser extent with stavesacre, as to the nature of their effects. The symptoms are muscular incoördination, motor paralysis, beginning at the posterior extremities, great cardiac and arterial weakness, and hypersensitive skin, with the special senses not affected. Convulsive tremors, especially of the posterior limbs, come on early and are followed by convulsions which increase in violence, and in one of which the animal usually dies. Death appears to be due chiefly to failure of the circulation. Atropine has been found a fairly good antidote, and potassium permanganate has also been found useful.

Loco Weeds (fam. *Leguminosæ*).—Although poisoning by this famous group is confined practically to stock, especially horses and sheep, yet no article on poisonous plants could be considered complete without reference to it, particularly as it represents a very large and varied class of leguminous poisons which more or less affect the human system as well. The loco weeds pertain to the two genera *Astragalus* and *Aragalus* (*Oxytropis*), and knowledge as to their specific identity is in a number of cases indefinite and uncertain. They are perennial herbs, growing mostly in tufts or hummocks, with a dense rosette of radical leaves and papilionaceous, mostly purple or purplish flowers in spikes or racemes. The leaves are elongated and pinnate, the leaflets mostly numerous and more or less oblong or varying from ovate to obovate. The fruits are constructed like small pea pods, the seeds mostly resembling small peas and often rattling loosely in the dry pod. The herbage is without disagreeable taste. Animals are not naturally disposed to eat it; but having once done so, in case of scarcity of other food, they become ravenously fond of it and forsake all else in order to eat it. The poisonous constituents are not known, though great efforts have been made to isolate them. All indications point to their being of the nature of toxalbumins. Whatever they are they are excreted in the milk of the mother, since suckling lambs are frequently fatally poisoned together with the mother. Poisoning may be either acute or chronic, the latter being much more common. The symptoms are chiefly cerebral. There are incoördination and remarkable disorders of vision, though rarely blindness, and this usually in acute poisoning. The effect upon the vision seems to be that of causing objects to appear distorted. A similar effect upon hearing is observed. There are great and progressive disorders of nutrition, and these are especially referable to the skin and its appendages, sheep frequently losing the whole or part of their fleece and the teeth becoming loosened. Death, in cases of long duration, is usually from malnutrition. Very often the animal dies as a result of accidents, incurred either through frenzy or through weakness incident to the poisoning, such as falling into the water while drinking, and being unable to rise again. There is no known treatment for this form of poisoning other than to remove the cause and apply general restorative treatment.

Henry H. Rusby.

POISONOUS REPTILES.—All poisonous reptiles, with the single exception of the lizard Heloderma, belong to the order Ophidia—snakes. It is a popular error that snakes are easily divided into harmless and poisonous ones by readily recognized characteristics. Such division, however, is by no means a simple affair. The usual classification into Colubridæ—comprising all harmless snakes,—Colubridæ venenosæ, and Viperidæ indicates the close anatomical relationship between harmless and venomous snakes, and in external appearance mimicry is so frequently displayed that no one at a hasty glance is able to distinguish a harmless snake from its venomous relation. Thus, even experts have been subject to fatal mistakes. Indeed, nothing but a close inspection of the dentition can determine the nature of a specimen in question.

Distribution of Snakes.—It is but natural that the popular mind and imagination should have been occupied since time immemorial with poisonous snakes. The frequent and almost mysterious deaths after snake-bite have surrounded the whole class with a halo of fear and reverence which has not been confined to a few localities, but, in fact, has spread throughout the whole inhabited world, for poisonous snakes are found in all countries of the temperate, and more so, of the tropical zone. Numerous genera of the Hydrophids, elegant swimmers with a laterally compressed tail, swarm throughout the whole intertropical part of the Pacific Ocean. Their bite is justly dreaded. The tropical islands, however, and the tropical countries of the old continent are haunted by the worst kind of snakes, the Elapidæ. A large number of genera and innumerable types of every genus render parts of those countries, and especially of the islands, almost uninhabitable. The chief representatives of this genus are the Cobra di capello (Naja tripudians) and the somewhat smaller, though not less dangerous Krait (Bungarus fasciatus), both living throughout the whole of East India. The most formidable is the King Cobra or Hamadryas (Ophiophagus elaps), the largest of all poisonous snakes; it attains the length of fourteen feet and it alone enjoys the reputation of attacking and even pur-

Digitized by Microsoft®

Poisonous Reptiles.

saing man. Its nearest relative, the Aspis of Cleopatra (Naja haje), the symbol of the Egyptian kings, lives throughout almost the whole of Africa. In the Western world this genus is represented by the beautiful coral snakes alone; one of them, Elaps fulvius, lives in our Southern States, where it is little feared on account of its alleged good nature, or rather its lack of irritability; its poison is, however, as active as that of its East Indian congener. Snakes are very numerous in Australia. Two-thirds of these are poisonous, and they belong exclusively to the family Elapidæ; the Tiger snake (Hoplocephalus curtus) and the black snake (Pseudechis porphyriacus) have a fearful reputation. Europe has none but various species of vipers; the well-known common viper (Pelias berus) lives in England, Germany, and chiefly in France. In the departments of Vendée and Loire Inférieure alone were reported 321 cases of bites with 62 deaths in six years, in Auvergne 14 cases with 6 deaths; in the South around the Mediterranean the more dreaded sand viper (Vipera ammodytes) is found. East India again has one of the most formidable vipers, the chain viper (Daboia Russelii), and in Africa there is the sluggish but very poisonous puff-adder (Clotho arietans). The greatest number of species of vipers are found in America, all of them belonging to the sub-family of the Crotalidæ or pit-vipers, so called from a deep pit lying between the nostril and the eye.*

The chief representatives of the pit vipers in the United States are the rattlesnakes. The banded rattlesnake (Crotalus horridus) is present throughout the whole territory from the Atlantic to the Rocky Mountains and far into Canada. Of the remaining six species of rattlesnakes we have to note the largest of all North American snakes—the diamond back (Crotalus adamanteus) of Florida and the South, and the swift prairie rattler (Crotalus confluentus) in the Mississippi Valley, and in the great Western basin; finally the smallest of all, the massasauga or ground-rattler. To the same sub-family belong the Southern water-snakes, the moccasin (Ankistrodon piscivorus)—animals so sluggish that they do not try to escape from an approaching man, and hence are not a little dreaded by the negroes working in the rice-fields, and finally, the beautiful copper head (Ankistrodon contortrix), which is not at all rare in the whole East—in fact, lives almost in the same expanse as the banded rattlesnake. In the Tropics almost all species grow to a larger size; thus the copper head is repeated in the larger *fer de lance* (Bothrops lanceolatus) of the West Indies; the rattlesnakes of Central America grow larger, as does

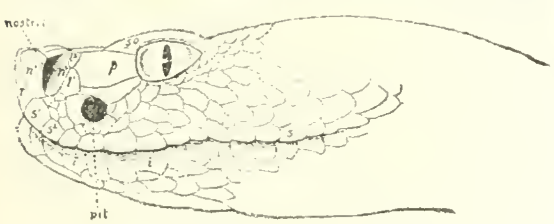

FIG. 3861.—Head of Rattlesnake.

the Crotalus durissus; and in the Orinoco Valley there lives the bushmaster of the Dutch settlers (Lachesis mutus), about as large as the Hamadryas of India.

* The object of this pit, which sinks into a cavity of the maxilla—as it were, a reversed maxillary sinus—is unknown. Leydig calls it the seat of a sixth sense, which means nothing else but that he has no explanation. At closer inspection I found the bottom of the pit not lined, but overspread by a thin membrane, the continuation of the external integument. Under this membrane, showing abundant ramifications of nerves, we find a cavity which opens by a duct at the anterior margin of the orbit. According to the careful investigations of Dr. Pollitzer, who followed it up by serial sections, the nerve connects with the auditory nerve. Pricking or any other irritation did not produce any reaction, nor did the destruction of one or both membranes have any effect upon the movements or the hearing of the snake. The hearing capacity of snakes is still a mooted subject with authorities in natural history.

Poison Apparatus.—Snakes are provided with numerous teeth—solid, pointed, recurved hooks, which serve rather to drag the prey down into the œsophagus than for purposes of attack and defence. While the teeth stand in a single row along either branch of the mandibula, they seem to be almost indiscriminately scattered all over the maxilla and palate; nevertheless, two rows of larger maxillary with two nearly parallel rows of palatine teeth are readily distinguished. These are the functionary teeth which, after being shed,—a frequent occurrence,—are replaced by the numerous succedaneous teeth scattered throughout the mucous membrane of the palate. A poisonous snake exhibits the same arrangement of palatine teeth. Almost the entire row of maxillary teeth, however, is wanting, and its strength, as it were, is concentrated into one powerful tooth, the poison fang, which projects at the anterior end of the maxilla. It is true, we often find two or three teeth at this point; these are the functional fangs with one or two succedaneous ones which replace the primary functionary whenever lost by accident or shedding. Only the Elapidæ exhibit one or two ordinary conical teeth which are situated directly behind the grooved fang. The fangs are in all cases firmly inserted in the maxilla, immovable, almost erect, in one family, the Colubridæ venenosæ (comprising the cobras and hydrophids); in the Viperidæ, however (including the true vipers and pit-vipers), the

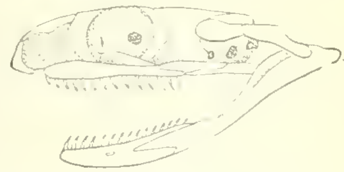

FIG. 3862.—Skull of Harmless Snake.

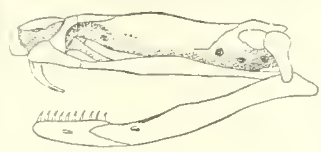

FIG. 3863.—Skull of Cobra (Elaps).

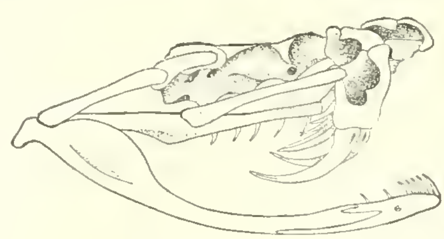

FIG. 3864.—Skull of Rattlesnake.

movable fangs are only erected for biting, and otherwise in the resting they are folded back toward the palate like the blade of a pocket-knife in a plica of mucous membrane. The maxilla of the Colubridæ venenosæ is rather elongated and horizontal like that of the harmless snakes, but it is considerably shortened and placed almost vertically in the vipers. This short jaw bone, bearing at its lower end the firmly socketed fang, articulates at its upper end with the lachrymal bone, around which it rotates by the action of the pterygoid muscle.

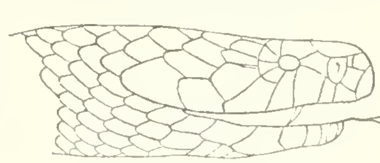

FIG. 3865.—Head of Cobra.

Some writers are of the opinion that, by looking at a wound inflicted by a snake, the species of the animal can be ascertained, and from the foregoing description it can readily be understood how from the

Digitized by Microsoft®

accompanying figures the bite of a harmless or poisonous snake could be determined. We must, however, bear in mind that a snake, while biting, very seldom implants

www.libtool.com.cn

FIG. 3866.—Impression of the Teeth of A, harmless snake; B, cobra; C, viper. f, fang; m, maxillary; p, palatine; pt, pterygoid teeth.

all its teeth, and a wound scratched sideways by a gliding fang may be more dangerous than the impression of the whole dentition.

Another classification is sometimes made by dividing the venomous snakes according to the shape of their fangs, whether they carry short, cone-shaped, furrowed fangs or long, pointed, tubular ones. This condition is brought about developmentally in the first instance by the folding of the dentine which leaves a longitudinal furrow with an indication of a perforation at the upper and lower end along the anterior surface; and in the second by a complete approximation which produces a perfect tube. The pulp cavity is entirely separated from the poison canal. To the first class, the Proteroglypha, belong the Hydrophids and Elapidæ, or cobras; the latter class, the Solenoglypha, comprises the vipers and pit-vipers. The intensity of a poisonous bite is not dependent upon the shape of the fangs, except that a longer tooth, such as that of the viperine snakes, is capable of injecting the poison to a greater depth; indeed, the viperine poison apparatus is the most perfect of any in the venomous snakes.

There is a third class of poisonous serpents, the so-called Opisthoglypha, the furrowed fangs of which, as the name indicates, are situated toward the rear of the mouth. It has long been doubted whether they should be classed among the poisoners, and for this reason they were grouped under the name of "suspecti." Recent investigations, however, have proven to a certainty that they also poison their prey, which mostly consists of small, cold blooded animals. Catching them first with the innocuous front teeth, they push them gradually backward into the reach of the poison in the back teeth, to the action of which they soon succumb.

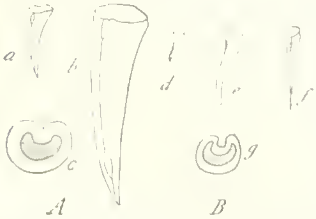

FIG. 3867.—Proteroglypha. A, Elapidæ. a, Fang of king cobra, eleven feet long (natural size, 8 mm. in length); b, the same enlarged (3 diam.); c, cross section. B, Hydrophidæ. d, Fang of pelamys (natural size, 3 mm. in length); e, the same enlarged (3 diam.); f, front view; g, cross section.

The poison gland completes the poison apparatus, the former is closely in contact with either side of the skull, directly below and behind the eye and is under the influence of the different portions of the temporal muscle. The button-, tube-, or almond-shaped glands taper to a narrow anterior duct, which carries the secretion of the gland to the base of the fang and is provided with a sphincter muscle, so that the snake is able to retain the poison at will, and, indeed, may do so for months. The extraordinary development of the glands, as in the Crotalids, gives to the head that triangular shape which was erroneously considered the characteristic of all poisonous snakes, and which gave to some species the name Trigonocephalus. The elongated glands of the Ethiopian snake Causus rhombeatus extend under the skin on both sides of the spine to the extent of one-sixth of the body's length, while in the East Indian Callophis they reach from the head into the abdominal cavity about one-third of the total length of the body. In spite of these abnormities the poison gland must be considered physiologically as the homologue of the mammalian parotid; the latter is the only one of the salivary glands which produces an albuminous secretion. It is anatomically of great interest that even in harmless snakes the beginning of a poison gland can be traced. It was long known that a part of the supralabial gland—the yellow portion (Duvernoy, Schlegel, Leydig)—is easily separable from the rest; it has not only a duct of its own which in the "suspecti" leads to the posterior grooved tooth, but it also possesses a histological structure differing from that of the supralabial gland. Undoubtedly, this yellow portion of the innocuous snakes is the analogue of the poison gland; even its aqueous extract has been shown to be poisonous to small animals (Blanchard). The structure of the poison gland is that of a compound racemose gland with elongated acini; the glandular substance has columnar, the duct pavement epithelium.

Description of Venom.—The secretion of the other salivary glands and of the mouth is alkaline, while the

FIG. 3868.—Solenoglypha; Viperidæ. a, Fang of banded rattlesnake, three feet long (natural size); b, fang of diamond-back rattlesnake, six feet long (natural size); c, the same enlarged (2 diam.); d, front view of the latter; e, cross section.

poison is always acid. The color of the latter varies from a light straw or greenish-yellow to a deep orange. The viscous fluid, either clear or turbid (bitter in Naja) is not odorless as often asserted; it has a specific smell for every species, which is not easy to describe, but easy to recognize. Thus the odor of crotalus poison may be called "mousy"; that of the *fer de lance* is said to resemble the odor of fresh salt water. Its specific gravity varies from 1.030 to 1.077; the solids are variously stated as from twelve to sixty-seven per cent.; my own samples are mostly dried down to twenty-five or twenty per cent. of the original weight. The dry poison cracks on scaly translucent chips of a light yellow or deep brown color and also has a characteristic odor. Fresh poison under the microscope shows nothing but a few scaly epithelia and a number of finely granulated, amorphous, albuminoid masses, which undergo no change in a hanging drop, even after a long while. It was often, and even is to day, asserted that bacteria or cocci exist in the poison. After thoroughly sterilizing the collecting apparatus I was not able to see the least sign of bacterial life in broth or gelatin cultures of the fresh poison; also in acid media in which the experiments were repeated no trace of life was to be found. In order to determine whether the poison, which itself destroys life, might for that reason be free from microbes, I mixed fresh poison with B. subtilis and B. coli for one half hour and then inoculated it on gelatin. The growth was lively, even more so than in the control plates, probably because the gelatin was lique-

Digitized by Microsoft®

fied at the points of contact with the poison.* A bacterial action, therefore, cannot be assumed; the rapidity alone with which the poison acts in the system would exclude bacterial influence.

Chemistry of the Venom.—The first chemical analysis was made in 1843 by Prince Lucien Bonaparte, who established the proteid nature of viper poison, and called the poison "viperin." Almost twenty years later (1861) Weir Mitchell found a similar proteid in crotalus poison, which he named "crotalin." Other investigators claimed to have found alkaloids or ptomaïns, when Weir Mitchell, associated with Reichert, published in 1883 the results of their studies, that the active principle of snake poison was of an albuminoid nature; but instead of one ingredient they had discovered two. One of them, easily dialyzable and not coagulable by heat, was called venom peptone; the other, not dialyzable but coagulable by heat, venom globulin. The proportions of both were not alike in cobra and crotalus poison; even among the Crotalidæ they found wide differences. Thus cobra poison had 98 per cent. of peptone and 2 per cent. of globulin; but moccasin venom had 92 per cent. of peptone and 8 per cent. of globulin, diamond-back only 75 per cent. of peptone and 25 per cent. of globulin. Besides the proteid there are a coloring substance, several salts, and some fat. Mitchell's report was mainly corroborated in 1886 by Wolfenden, who discovered globulin and several albumins in variable proportion in the poison of cobra and daboia; one of the latter he designated serum albumin; the other, corresponding to Mitchell's peptone, syntonin, or albumose. Kanthack's analyses likewise demonstrated the presence of a proto- and heteroalbumose in cobra poison. Martin and McGarvey Smith found a harmless albumin and two very toxic albumoses in the poison of the Australian snakes. It may be asserted that in no instance, up to the present time, has a definitive analysis of any poison been worked out; but all investigations centre in this one fact, that the active principle in all snake poisons is some form of albumose.†

Although probably both of Weir Mitchell's bodies are albumoses, we may still, in default of accurate analyses, use the convenient terms venom peptone and venom globulin in our further discussion. Not only do the various poisons differ in the percentage of peptone and globulin, but also in the toxicity of the constituents themselves. The venoms retain their efficacy for long periods of time under suitable conditions. Poison, when dried or mixed with glycerin, has proved itself as active as fresh poison, even after a lapse of twenty-two and twenty years respectively. Putrefaction destroys it after a long time; freezing, continued through weeks, does not alter it, but it is soon changed by heating when the temperature is raised to different heights, according to the different chemical composition. The globulins are rendered innocuous at 80° C. after fifteen minutes, while the peptones are destroyed only by applying higher temperatures for hours. The coagulated proteids are inert in this state, but they regain their

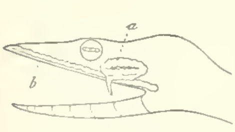

FIG. 3869. Location of the Poison Gland in Tragops belonging to the Opisthoglypha. *a*, Poison gland; *b*, supralabial gland.

toxicity when redissolved.* It is the more or less evident capability of chemicals to coagulate proteids which determines their relative power of destroying the efficacy of venoms, when they are mixed with the poison

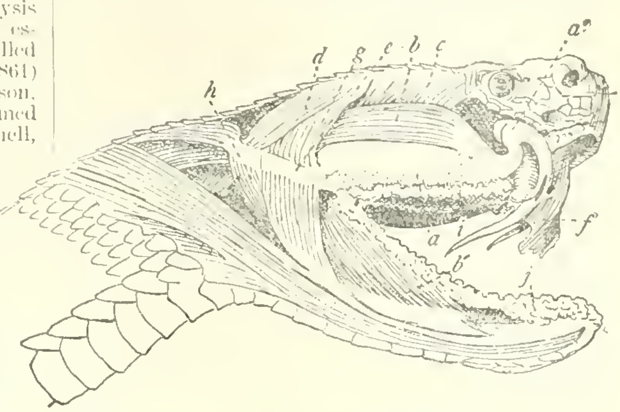

FIG. 3870.—Head of Crotalus. *a*, Poison gland; *a'*, poison duct with sphincter muscle; *b*, *d*, portions of temporal muscle; *f*, plica of mucous membrane.

in a test tube for experimental purposes. Alcohol renders it inert for a time only. Absolute alcohol seems to coagulate all poisonous ingredients, but the presence of an infinitesimal part of water is sufficient to retain the toxicity of the supernatant fluid. Poisonous serpents, when preserved in alcohol, have to be handled, even after years, with the greatest care, as has been demonstrated by a fatal accident to an assistant in the St. Petersburg Museum.

Physiological Effects.—Absorption of venom from connective tissue, whether introduced by hypodermic injection or by the bite of a snake, takes place through the blood-vessels, more rapidly when the blood-vessel is wounded directly. Serous membranes absorb it very readily. Its resorption through mucous membranes varies; rattlesnake venom seems not to be absorbed in this way; cobra venom, however, passes through the ileum and conjunctiva, but not through the stomach and rectum. Gastric juice and bile do not affect it, but the pancreatic secretion destroys it. The resulting complex of symptoms varies partly on account of the varying rapidity of absorption, but more so because of the difference in the nature of the several venoms.

The physiological effects of both ingredients named, whenever they are tested separately in animals, are widely different. The peptone, though causing some local œdema, is more productive of general nervous symptoms, which, commencing as irritation, twitching, and convulsions, finally end in paralysis; paralysis of the respiratory centre is especially characteristic. The globulin, on the contrary, incites a violent local reaction with hemorrhages around the point of injection, hemorrhages of the mucous membranes, and destruction of the coagulability of the blood. The latter phenomenon recalls to us the results of experiments performed on animals with pure peptones and albumoses of digestion; these excite not only characteristic hemorrhages and necroses, but also paralyses, the intensity of which is in correspondence with the higher hydrolysis of the albumoses. And thus, to go one step further: all the symptoms produced by snake venoms classify them distinctly among the toxins, especially those of bacterial origin.

SYMPTOMATOLOGY.—From the foregoing remarks it will be perceived that different cases of snake poisoning cannot have an identical course, and that the numerous contradictions of the mostly incomplete records of snake-bites are to be explained only when we consider each

* Experiments with sterile snake poison have demonstrated that it liquefies gelatin like some digestive ferments, *e.g.*, trypsin. Wehrmann finds that it peptonizes fibrin weakly and does not clarify amylum. Flexner states that in agar culture of B. anthracis, B. coli, and B. typhi the bacteria underwent rapid involution. My own numerous observations, recorded above, do not confirm this view.

† It is well known that albumoses, the products of the hydration of albumin, formerly called propeptones and accurately defined by Kühne and Chittenden in 1884, differ widely as to their toxicity. While our modern means do not allow yet a chemical differentiation of those albumoses which are generated by superheated steam, by gastric digestion, by bacilli, or—as in our case—by the parenchyma cell of a gland, the varying reaction of the more sensitive living organism toward them demonstrates decisively their different nature.

* Recent advices of researches going on in Germany assure me that the toxic principle does not belong to the albumoses, in fact, that it is not at all of a proteïd nature.

Digitized by Microsoft®
www.libtool.com.cn

type of poisoning separately. Leaving aside the cases of almost instantaneous death which are due to general thrombosis, especially when the venom has been accidentally injected into a large blood vessel, we have first to make a distinction between the two great classes of snakes, the colubrines and the vipers.

www.libtool.com.cn

To illustrate the first class, let us briefly describe the effects of a cobra bite: two small, scarcely visible punctures in the skin are found, whence radiates a burning and stinging pain with gradually extending moderate œdema. Within an hour, on an average, the first constitutional symptoms appear—a pronounced vertigo, like that of drunkenness, quickly followed by weakness of the legs, which is increased to paraplegia, ptosis, falling of the lower jaw with paralysis of the tongue and epiglottis, inability to speak and swallow, with fully preserved sensorium. A mass of viscous, frothy saliva is constantly dribbling from the open mouth; nausea and vomiting set in; the paralysis becomes general, the patient lies motionless. The pulse, a little accelerated, is somewhat weaker in the beginning, but keeps a moderate strength until even a few minutes after the cessation of respiration. The latter, also accelerated in the beginning, soon becomes slower, labored, and more and more superficial, until it dies out almost imperceptibly. The pupils, somewhat contracted, react up to the last moment. Slight convulsions, which we are accustomed to see in asphyxia, sometimes occur shortly before death. Absorption is exceedingly rapid; already after thirty seconds a distinct areola is visible around the bite. Death occurs at the latest within fifteen hours, in thirty-two per cent. in the first three hours. When the patients do not die of paralysis, they recover remarkably quickly and without later consequences. The autopsy reveals no changes in the skin at the point of injection; the subcutaneous tissue, however, is thickly infiltrated with reddish serum; the surrounding blood-vessels are congested. All the internal organs are congested, and the bronchi are filled with frothy mucus and perhaps with fluids which have been forced into the patient's throat. The blood is mostly liquid and dark.

Viper.—After the bite of a viper, *e.g.*, a rattlesnake, the local disturbance is most pronounced; violent pains at the bleeding wound, hemorrhagic discoloration of its surroundings, and later also of more distant parts; bloody exudations on all the mucous membranes (nose, mouth, conjunctiva), and hæmaturia or rather hæmoglobinuria. Usually, somewhat later than after cobra poisoning, but possibly within fifteen minutes, constitutional symptoms develop, viz., great prostration with nausea and vomiting. A continuous fall of blood pressure is noticed. Respiration, in the beginning accelerated, grows slow and stertorous. After a temporary increase of reflexes, which in susceptible animals and after large doses may rise to convulsions, opisthotonos, and tetanus, paresis supervenes, with paraplegia of the lower extremities, which progresses in an upward direction, ending in complete paralysis. Albuminuria appears after about six hours. In such a condition death may result inside of twelve hours. If the patient recovers from the paralysis, a septic fever may develop in consequence of the enormous and multiple hemorrhages, to which he may succumb after a lapse of time. Eventual recovery sets in very suddenly, even in the most desperate cases. Not rarely, however, there remain suppurating gangrenous wounds which granulate poorly, break open repeatedly, and may lead later on to a deep necrosis, even of the bones.

The effect of the bite of the tropical vipers, especially the East Indian Daboia Russelii, is undoubtedly more pronounced and violent. Sanious discharges from all mucous membranes are prominent features, such hemorrhagic extravasations from lungs and bowels may persist even during recovery. Albuminuria is never missed; even hæmaturia is observed as a rule. The autopsy shows a deep bloody infiltration at the bite down into the necrotic muscles, hemorrhages of distant muscles, particularly of the intercostals; all serous membranes, chiefly the endocardium and the peritoneum, are completely covered by countless ecchymoses of all sizes; the lungs show subpleural ecchymoses and infarctions; the kidneys are hemorrhagic in the glomeruli and pelvis, and there is cloudy swelling of the epithelium of the canaliculi. Hemorrhages have been observed also in the serosa and in the substance of the central nervous system. The blood is fluid and does not clot, even after a long time.

A disproportionate swelling is to be noted in poisoning by the European viper; it sometimes extends over the whole body. The poison of the African viper, the puff adder, acts in a stupefying manner from the very beginning; the animal stricken stands without motion or reaction as if the whole cerebral cortex were eliminated; complete sensory and motor paraplegia ascends gradually with sharply defined limits.

The Australian snakes occupy an intermediate position between the two types just described, for, besides a prominent cobra effect, they produce moderate hemorrhage and always hæmoglobinuria.

Wall relates a peculiar variation after the bite of the East Indian Bungarus fasciatus. Some cases cannot be distinguished from the acute cobra poisoning, yet in others a certain chronicity of symptoms is seen which can be compared only to the incubation period of infectious diseases. From two to six days may have elapsed after the bite without any symptoms, when unexpectedly a general debility sets in with albuminuria and a sanious discharge from the eyes, nose, and rectum. The patient invariably succumbs within a short time.

An interesting incident is the periodical relapse of inflammation and suppuration which is said to occur mostly annually, almost to the day of the first injury. The cases reported are too numerous, and have been observed by too good authorities, to admit of a doubt. While in some instances there appeared only a scaly or vesicular eruption of the skin, in others a suppurating inflammation set in, *e.g.*, with regular loss of a nail. All the cases on record are from the United States and include all species of snakes—copperhead, rattlesnakes, and Elaps. They have been watched for six, ten, twelve, and even eighteen successive years. Perhaps the best authenticated case is that of a draughtsman of the Smithsonian Institution, who, according to Yarrow and Stejneger, for ten years had the same inflammation of the finger, bitten by an Elaps, almost to the date of the accident. A cure was finally effected by the use of the South American herb, Micania guacho.

To use for comparison a well known and familiar complex of symptoms, we might call the sequelæ of a cobra bite an *acute bulbar paralysis* of the most furious and vehement type. Likewise, for the second type, that of viper poisoning, an analogy is found in *acute ascending spinal paralysis*, the last stage of which exhibits alike bulbar symptoms and inhibition of respiration. It should be remembered that the common ascending spinal paralysis is also ascribed to an infection. Yet, whereas in the two diseases named, the development of the nervous symptoms is very slow and gradual, and they may take years or at least weeks to advance to a fatal exitus, in snake poisoning the effect is almost instantaneous. It may, therefore, be considered firmly established that snake venoms affect the motor ganglia of the anterior horns and chiefly the medulla oblongata, exercising a selective influence upon the adjacent centres of respiration and deglutition. There exist records of a few accurate microscopic examinations of all organs after snake poisoning (Nowak). In general they resemble the changes which we are wont to find in all kinds of poisoning of whatever origin, especially by the toxins of zymotic diseases—*e.g.*, fatty degeneration of the liver with inflammation of the bile ducts, beginning as early as thirty-five minutes after poisoning; in chronic cases focal necrotic destruction of liver cells, acute parenchymatous nephritis, disseminated pneumonic patches, slight beginning of fatty degeneration of the heart muscle, etc. Of the pathological changes in the central nervous organs, we

Digitized by Microsoft®

also have some accurate records (Ewing, Bailey). As we may expect, they demonstrate a pronounced acute degeneration of the ganglion cells throughout the central nervous system. The chromatic bodies generally disintegrate with some loss of the chromatic substance, the outlines of the Nissl bodies being completely obscured; the nucleus and nucleolus may be normal or swollen and opaque; the dendrites irregular, shrunken, or detached. These changes are to be found in the cells of the cortex, the cerebellum, olfactory lobe, basal ganglia, medullary nuclei, anterior horns, and spinal ganglia, most marked, however, in the anterior horn and in the Purkinje cells and the mitral cells of the olfactory lobe. These changes were exhibited only in their beginning in those animals which had been killed in a short time by a large dose of venom, but were more advanced and involved a much greater number of cells in the cases of more chronic poisoning. Alt, after poisoning with puff-adder venom, finds the changes in the posterior columns so marked that they are perceivable to the naked eye.

www.libtool.com.cn

The old question whether snake venom is a nerve or a blood poison, therefore, must receive the answer that it is both a neurotoxic and a hæmolytic substance. Nay, recent investigations have shown that both principles are physiologically distinct, for Flexner has demonstrated *in vitro* that in a mixture of venom with an emulsion of brain substance, the chief (neuro) toxic constituent unites with nerve cells while the agglutinating and hæmolytic element combines with blood corpuscles. It is of considerable interest to analyze more accurately its influence upon the circulatory system, which is such a prominent feature in viperine poisoning, but is nevertheless of paramount influence in cobra poisoning as well. The assumption that the action on nervous tissue is but a secondary sequela of its primary action upon the circulation must be positively denied, inasmuch as extremities whose circulation is entirely obstructed by constriction respond readily to the action of the venom upon the nervous centres; neither do we miss any of the characteristic nervous symptoms in frogs, in which the blood has been entirely replaced by decinormal saline solution.

Notwithstanding the facts just related, some of the phenomena might be referred to a disturbance of the vaso-motor centres. Some investigators ascribe them to an enormously increased diapedesis, as is seen after the local application of poison to a capillary area; while others consider it to be a rupture of the capillary walls. The blood cells escape after a hypodermic injection of venom, and are destroyed to such an extent that a few hours later but one-half of the normal blood corpuscles may be counted.

The point which has been creating the greatest diversity of opinions is the poison's influence upon the coagulability of the blood. Formerly it was an accepted dogma that cobra venom increased and viper venom inhibited clotting, until recent investigations of Heidenschild and the more accurate experiments of Martin, of Sydney, have cleared up the matter. The doses as well as the mode and rapidity of introduction are matters of the greatest importance. As a rule coagulation is inhibited for a long period. A small dose injected intravenously causes a positive phase of coagulability of two or three minutes, which is followed by a negative phase of longer duration. A second larger injection brings on the same positive and a much longer negative phase. A third still larger injection, which is borne remarkably well, destroys coagulability for a long period and, as it were, immunizes the blood against further coagulative influence of the poison. At the same time the leucocytes disappear almost entirely from the circulating blood; they are massed in the liver, lungs, and bone marrow, and reappear only when the blood regains its coagulability (or perhaps inversely). Auché found the bone marrow much congested soon after poisoning, and regards it as evidence of a reaction of the blood-forming organs,—a reaction which, within a few hours, floods the circulation with an abundance of leucocytes. A hypodermic injection, and therefore the majority of all snake bites, acts in the same way as a small intravenous injection. Immediate introduction of a larger quantity of poison into a blood vessel may cause a sudden complete clotting of the whole mass of blood, with the exception of that in the pulmonary veins and the left heart. Many contradictory reports of the blood pressure, sudden stoppage of respiration, etc., are explained by the sudden massive thrombosis. The immediate cause of coagulation is probably a nucleo-albumin, analogous to the fibrinogenic substance of Wooldridge, also a nucleo-albumin. It is not preformed in the venom, but, as Martin has it, is liberated instantaneously by the action of the poison, from the stroma of the destroyed erythrocytes and from the endothelium of the blood-vessels; it brings on extensive thrombosis at one stroke. Or, according to the theory of Delezenne, which would explain the different phases of coagulability and fluidity, nucleo-histon is formed which splits into leuconuclein and histon; the former, which is retained by the liver, accelerates coagulation; the latter, which remains, retards it.

Many of the symptoms noted in former experiments are now explained by the recent interesting methods of study in hæmolysis. The first effect of snake venom upon blood *in vitro* is agglutination, speedily followed by hæmolysis; the escaping hæmoglobin is not changed, the spectrum remaining normal. A great variation in susceptibility to this latter reaction is distinguished in the different animals, but most noticeable is the difference of hæmolytic power in the several varieties of venom. Contrary to what we should expect from the prominent symptoms, cobra venom is most actively hæmolytic; those of moccasin, copperhead, and rattlesnake are hæmolytic in less degree, in the order named. The action upon leucocytes is similar to that upon erythrocytes, although the several varieties of white cells show different susceptibility.

Another important effect of snake venom is the loss of the germicidal property of the blood plasma. It is well known that normal blood serum destroys micro-organisms, or at least retards their growth. Ewing, of Washington, was the first to show, in 1894, that this faculty was annihilated in the blood of animals killed by crotalus poison, and Martin has confirmed it for the venom of the Australian black snake. This explains both the well-known rapid putrefaction of the poisoned organs and the danger of subsequent decomposition of the extravasated blood, and the resulting sepsis during convalescence. The recent hæmolytic studies mentioned above have shown that the germicidal power of serum is rendered inactive through the fixation of the serum complements by the venom.

A closer similarity in the two types of poison can be created in an artificial way by heating. The agglutinating power is destroyed by a temperature of from 75° to 80° C., a temperature which leaves the hæmolytic power undisturbed. The latter is somewhat reduced in crotalus poison by 90° to 96° C., while it requires 100° C. for at least fifteen minutes to make an impression on cobra, copperhead, and moccasin venom. A prolonged heating, however, of viperine poison destroys the intense influence upon the circulation to be ascribed to the globulin; after such heating it approaches cobra venom in character.

In briefly summarizing the mode of dying from snake poison, we might say that death occurring within a few minutes is due to general thrombosis; a patient who dies within twenty-four hours may succumb in the first hours to paralysis of the respiratory centre, later to general paralysis; lethal exitus, after such a period, days or even weeks after the bite, may be the result of sepsis or of general prostration following prolonged suppuration.

From what has been said, it will be seen that the danger of a snake-bite must vary considerably. Statistics cannot give us an adequate idea as regards this point. Not all cases are reported, and not all bites reported are those of venomous snakes. Moreover, chance is an important factor as regards the sequelæ: *e.g.*, in what condition was the snake when biting? Were one or both

Digitized by Microsoft®

fangs deeply implanted, or was the skin merely scratched? How old and in what condition of health was the bitten individual? India, as is generally known, has the largest mortality from snake bites—a fact easily explained by the enormous number of snakes, and these the most deadly of all, the cobras. Nevertheless, indolence and superstition of the population may increase the number of fatal accidents considerably. Those may be right who consider the smaller number of deaths in America and Australia as due to the greater intelligence of the people, because a rational treatment, especially the early application of a ligature, is instituted in time.* In default of reliable analyses, the only way to decide this point has been shown by Calmette to be that of comparative experiments. After carefully graded hypodermic injections, to determine how much poison may kill a kilogram of animals (mostly rabbits), the following table has been worked out:

1 gm. of cobra and aspis kills	4,000 kgm. of rabbit.
1 gm. of hoplocephalus kills......	3,450 kgm. of rabbit.
1 gm. of fer de lance and pseudechis kills.	800 kgm. of rabbit.
1 gm. of Crotalus horridus kills...	600 kgm. of rabbit.
1 gm. of Pelias berus kills	250 kgm. of rabbit.

But even this method has not yet yielded undisputed results, for Martin claims for hoplocephalus 4,000 and for pseudechis 2,000 kgm. At any rate the toxicity of snake venom is exceedingly high. A comparison with the toxins of infectious diseases shows that only that of diphtheria comes up to 4,000 kgm., toxopeptone to 3 kgm., and the albumose of anthrax to not more than 80 gm. Besides the high toxicity it is also the extremely rapid absorption and consequent early appearance of grave symptoms which distinguish snake venom from other toxins.

If the most serious cases (*e.g.*, when both fangs, and especially those of a large tropical snake, have thrown their full dose of poison into the tissues) are left out of consideration the prognosis is not so bad as is generally believed. Weir Mitchell gives the mortality of crotalus bites in one place as 25 per cent., in another as not more than 12 per cent.; that of the Australian snakes is said to be only 7 per cent.; but for India Fayrer states it at from 25 to 35 per cent. It has been mentioned how quickly an amelioration may set in, even after the most serious nervous symptoms have preceded. This is undoubtedly a reason why so many remedies have gained the undeserved reputation of being a sure cure. Most of the patients would have recovered without them. Comparing these conditions with the results obtained in experimental bacteriology, we should say that in most cases of snake-bite the minimum lethal dose of toxin is seldom injected, so that the body cells are still able to combine with and fix the toxin, in consequence of which they not only speedily recover, but also, as we shall see later on, develop a certain immunity by casting off antitoxin.

TREATMENT.—The proof of the utter helplessness of therapeutics of past years is the long array of remedies recommended and used at all times for snake-bite. The object of treatment is threefold: first, to prevent absorption of the poison; second, to accelerate its elimination; third, to destroy or neutralize it, and to treat symptoms of imminent danger. If the wounded limb, *e.g.*, a finger, cannot be amputated quickly, at least the circulation should be checked or retarded by a ligature, as practised since time immemorial. A ligature is applied as tightly as possible, not only at one, but at two or three places—*e.g.*, when a finger has been bitten, round the finger itself, at the wrist and at the elbow. The experienced Wall is so convinced of the advantages of Esmarch's rubber band that he not only recommends every physician in India to have one in readiness, but wants to see it in every well-regulated household. The ligature is relaxed at intervals of some hours to prevent gangrene, but is applied again as soon as practicable.

It has been an often recommended custom to suck the wound with the lips or to apply cups. The result of such a measure is at least doubtful, because of the finely punctured bites; the sucking ought to be preceded by a long scarification into the deeper tissues. It is still safer to excise a large area of these tissues or to destroy them with the actual cautery. Wall, taught by long experience, recommends proceeding in the most ruthless manner. By these means the absorption of poison can be limited to a possible minimum, so that the system shall gain time to overcome the whole quantity at intervals.

How can we hasten the elimination of the injurious substance? The kidneys are attacked to a greater or lesser degree by the poison, especially that of vipers; hence it is doubtful whether we should be permitted to increase their activity. The vicarious excretion by perspiration, stimulated by diaphoretics (*e.g.*, jaborandi) has had dubious results. It has been demonstrated, however, that part of the poison is excreted by the stomach. Alt found that alkaloids, chiefly morphine, after hypodermic use were excreted by the stomach almost to one-half of their amount. When he tried the same method for snake venom, it was discovered that the animals whose stomachs were washed out were saved, whereas the controls died; at the same time, the washed-out fluid was again poisonous to other animals. Hence it is probable that the use of the stomach pump may be of good service. Those who have read a minute description of, or have personally witnessed, the snake dance of the Moki and Zuñi Indians of Arizona will remember that after the performance the dancers, who are sometimes bitten by the snakes, receive a potion prepared by the priests which contains an emetic. The whole crowd stand around a certain part of the parapet to empty their stomachs freely. This custom has undoubtedly been justified by long experience.

The question then remains, Are we able to render innocuous the poison in the tissues surrounding the bite? This efficacy has been claimed for a whole series of specifics, which owe their reputation partly to old traditions, partly to experiments in the test tube. The majority of these specifics, which it is true neutralize the poison *in vitro* after a shorter or longer period (carbolic acid, *e.g.*, only after twenty-four hours), destroy all tissues to such an extent that it seems preferable to apply the cautery. Even the much-praised permanganate of potassium, recommended especially by Lacerda, of Rio, Brazil, has not fulfilled the high expectations, for neither locally applied in a one-per-cent. solution nor injected intravenously has it the elective faculty to single out snake venom for oxidation in presence of other proteids. One per cent. of chromic acid has gained somewhat of a reputation; it does not destroy the tissues simultaneously with the poison, but it merely makes them shrink. Calmette has frequently tested hypochlorite of lime in a solution of 1 to 60.* He found both its local and repeated hypodermic application near the bite as well as its internal administration of good effect; not less so a one-per-cent. solution of chloride of gold as a local remedy.

Ammonia, extensively used internally and externally, is nothing but a stimulant. Feoktistow actually advises against it, because he thinks he has seen after its use increasing hemorrhages, caused by higher blood pressure. Wall also cautions against exciting the circulation by stimulants; he advises to keep the victim as quiet as possible and to husband his strength. Neither has alcohol any local effect as a coagulating medium; it is to be rated also as a mere stimulant. It has always met with appreciation on the part of the real or, more so, of the alleged victim. Indeed, the use of this infallible specific has often been carried to such an extent that it was impossible to decide whether the patient succumbed to snake venom or to an acute alcoholism. In one case,

* The statistics of the Indian Government have given for years an average annual mortality of 20,000 persons. Recent advices, however, have called this number again into doubt, as has been done before. It seems to be the practice of officials in remote, isolated districts to ascribe in their reports any case of death to snake-bite, whenever it is thought desirable to cover a crime or even a neglect of duty on the part of the official.

* He advises against the employment of more concentrated solutions which are less active and produce eschars.

e.g., the use of five quarts of whiskey is recorded. It is, moreover, a fact that intoxicated persons, when bitten in this state, have not proved to be better protected against snake bites than sober people; and the enormous doses which we often hear of as having been administered deserve nothing but condemnation.

www.libtool.com.cn

As to a rational treatment, it is necessary to inquire first as to the prominent morbid changes which threaten life. Are they irremediable or are they transient? That they are transient is proved by the many individuals who survive a snake-bite in spite of the gravest symptoms. We have seen that the poison exerts, first, a hæmolytic action; second, a destructive influence upon the cells of the medulla. We know at present of no pharmaceutical remedy which will arrest either the escape of the hæmoglobin into the plasma or the rupture of the capillaries, nor is any drug known that will check the influence of toxin upon the nerve cells. The changes in the ganglion cells, the dissemination and disappearance of the Nissl granules, whatever this may mean, must be fully reparable, since, as we have seen, rehabilitation takes place rather suddenly without leaving any sequelæ. If we are not able, *e.g.*, to re-establish the function of the respiratory centre immediately, could we not at least tide over the dangerous period of deep depression? One method suggests itself to a medical mind, *i.e.*, artificial respiration. The heart beat ceases several minutes later than respiration, and in one experiment Fayrer succeeded in keeping up the circulation for eight hours longer by artificial respiration. Fayrer and Lauder Brunton strenuously recommend that it be continued not only for hours but for days, with or without a tracheal cannula. This advice seems to have fallen somewhat into disuse, especially since Martin claims that in poisoning by Australian snakes he saw no good results from artificial respiration, death occurring in spite of it in fifteen minutes after the heart stopped. Notwithstanding some failures, we are justified in trying it for an extended time, always keeping in mind that an abrupt change may set in in the most desperate cases.

In this connection we have to consider a remedy which even recently has been praised with a certain persistency as a specific, *i.e.*, strychnine. First used by Pringle in Australia, it was tested in India, and in spite of the little encouraging reports was enthusiastically championed by Dr. Muller, of Sydney. He declared that the failures were due to insufficient doses, and he began with a dose of at least 0.01 gm., repeated several times until slight tetanic symptoms appeared.*

Many cases in Australia have been treated with strychnine, and upon the advice of the Government Indian surgeons have also used it quite extensively. Nevertheless, the results are not so convincing that we could rely upon this drug as a specific. The experiments of Kanthack and Feoktistow were negative. Interesting, however, is the latter's positive experiment that artificial tetanus, brought on by strychnine, was arrested by snake venom. Roux states that tetanus antitoxin has a certain influence upon snake poison, but not inversely. Atropine has been recommended as a stimulant for the respiratory centre. Not many instances of its use are recorded, but there is no reason why it should not be resorted to as well as strychnine.

It may be appropriate to relate the few instances in which snake poison has been used therapeutically. Dr. Amaden, of Glens Falls, near Lake George, a country abounding in rattlers, cured a man, aged twenty-five years, with unmistakable tetanus by two injections of one drop of fresh rattlesnake poison. It should be mentioned that snake venom has been used in an unsystematic way for several other diseases (*e.g.*, yellow fever), of course without success. Recently it has been asserted that during the plague in India some successful inoculations of cobra poison (gtt. $\frac{1}{50}$ and $\frac{1}{40}$) were made, and that some similar experiments in monkeys gave equally good results. Later correspondence, however, is silent regarding these experiments. The treatment of lepra with snake venom has been without any result.

Antivenomous Serum.—The therapeutics of snake bite were in this state of hopelessness when in 1895 Calmette, and almost simultaneously Fraser, surprised both the scientific and the lay world with an antivenomous serum. It is to serum therapy and immunization, as we shall presently see, that we have to look for the successful treatment of snake-bites.

Regarding this topic the question first arises: Are there animals, as often asserted, which are immune to snake poison? In East India the mongoose, a kind of weasel, the deadly enemy of the cobra, has the reputation of immunity; and in Europe the droll, bristled hedgehog (Erinaceus europæus) is considered as the natural destroyer of vipers because of its reputed invulnerability. More accurate observers have shown that the mongoose owes its apparent safety to a low susceptibility (from ten to twenty-five times less than rabbits, Elliot) against both cobra and viper venom, but more to its agility, and that the hedgehog is partly protected by its spinous coat. It possesses, however, a higher resistance to snake poison than other animals, and from my own investigations I might figure a resistance of about four times that of a rabbit of equal weight. A relative immunity toward various toxins is well known to exist in different animals. The poisonous snakes themselves possess a perfect immunity against their own poison, the species with weaker poison a relative immunity toward those with stronger venom, and even the non-poisonous snakes enjoy a certain security against the bites of the poisonous ones. The king-snakes of our Southern States, which are the enemies and destroyers of our poisonous serpents, seem to enjoy a perfect immunity.* Although Weir Mitchell finds that, at least in some cases, crotalus is not immune against its own poison, it is a common occurrence among venomous snakes in captivity that they bite each other furiously without any evil effect. One of Cunningham's cobras resisted inoculation with an amount of cobra venom sufficient to kill one thousand fowls. This faculty is ascribed to inner secretion, to the incessant influx of toxin into the circulation. The discovery of Blanchard, that the extract of the yellow part of the supralabial gland of Tropidonotus natrix, and even its blood serum, kills small animals with distinct symptoms of poisoning, seems to corroborate this theory. Cunningham, however, finding after many experiments with cobras that their serum has no antitoxic action, comes to the conclusion "that the natural immunity of cobras is perfectly distinct in its nature from the artificial immunity, which is established in other animals as the result of continued treatment with cobra venom, and that it is unconnected with any material of the nature of an antitoxin in the blood."

The idea of immunization is by no means a modern one. Even in antiquity we hear of it, and among savage tribes of ancient and modern times, wherever poisonous snakes abound, attempts at protection against snake venom are made under various forms, sometimes associated with mystic ceremonies. The poison is rubbed into the skin, as is done in Bengal, or it is taken internally in the fresh state, or parts of the dried poison glands are eaten (as practised by the savages of South Africa). A shepherd, immunized in this way, admitted that the dried gland of the cobra had an intoxicating effect, which he compared to that of Indian hemp, except that, whereas the latter lost its effect gradually, the action of the first was not impaired by habit. Or it is used as an inocula-

* The tolerance toward strychnine seems to be quite extraordinary in these cases: thus 0.035 gm. was used in the case of a boy thirteen years of age within three and three-quarter hours, 0.05 gm. in five and one-half hours, 0.05 gm. in four and one-half hours, 0.066 gm. in seven hours, 0.25 gm. in six days.

* I have injected a king-snake (*Ophibolus getulus*) of Florida, of 700 gm. weight, with 1 gm. of fresh moccasin poison, a quantity which can never be injected by a single bite of the largest venomous snake. With the exception of a pronounced local swelling and some apparent sick feeling for a few days, the snake survived this experiment well. A crotalus of three feet in length and about 500 gm. weight received four drops of cobra venom: it sickened within half an hour and was found dead the next morning.

tion in the interior of Africa (Serpa Pinto). Sometimes one of the reputed antidotes is employed for an extended time, as, *e.g.*, the *curados de culebras* of Mexico use a composite plant, Micania guacho.*

Sewall, of Ann Arbor, Mich., was the first to introduce methodical inoculation of snake venom with the idea of immunization. His experiments, in which, by gradually increased doses, he made his pigeons secure against seven times the lethal dose of massasauga poison, were published in 1887. Calmette, director of the Pasteur Institute of Lille, France, after a number of failures succeeded in securing immunity, and at the same time in elaborating a protective antivenomous serum which, in spite of some weighty opposition, must be considered today the only reliable antidote to the deadly action of snake poison. Fraser, who worked independently of Calmette for six years on the same subject, has produced a similar serum, called by him antivenene. It is dried, in which state it is said to keep indefinitely. Calmette manufactures his serum by inoculating with cobra venom or with a mixture of cobra, crotalus, viper, and hoplocephalus venoms, in both of which the hæmolytic agent has first been eliminated by heating to 80° C. The inoculation of horses has been carried on in some instances for three successive years, so that these animals, which succumb to a dose of 15 mgm. of cobra poison, finally tolerate a dose of 2 gm. A prolonged feeding also imparts immunity, but requires larger doses and induces less protective power. Antivenomous serum is put up and sold in vials of 10 c.c. each. Its protective value is calculated by Calmette in the following way: If 1 c.c., injected into the ear vein, is found to protect a rabbit of 2,000 gm. (2 kgm.) against a dose of venom, fatal within fifteen to twenty minutes, it is said to contain 2,000 antivenomous units, and a vial of 10 c.c. consequently 20,000 units. No serum is sent out without possessing a strength of at least 10,000 units; and for the tropical countries serum of as high as 40,000 units is manufactured.

It has been shown by experiment (Myers, Martin, Semple, Flexner) that 0.1 cgm. of Calmette's serum neutralizes 0.1 mgm. of dried cobra poison, both *in vitro* and *in corpore*. This proportion holds good for the hæmolytic and antibacteriolytic and the inhibitory action of venom upon clotting of the blood. Of rattlesnake venom even 3 mgm. are neutralized by 1 c.c. of the serum. For the counteraction of the neurotoxic principle of the venom, somewhat larger doses of antivenomous serum are required. For practical purposes it may be stated that it acts as a full protective in a dose of from 5 to 20 c.c.; and the 10 c.c. contained in Calmette's vial are therefore amply sufficient for the average case of snake-bite when injected even one and a half hours after the introduction of venom. If more time has elapsed, or graver symptoms have set in—as may occur after the bite of a large tropical snake—it is advisable to inject 20 or even 30 c.c. simultaneously. Fraser recommends injections into the injured limb rather than into distant parts, and the administration of repeated smaller doses instead of one large dose; but Calmette thinks they are best made into the lax skin of the hypochondrium. Although antivenomous serum is absorbed rapidly from the subcutaneous tissue, it may not be quick enough in severe and belated cases; then it is advisable to resort to direct intravenous injection. Immunity thus conferred by antivenomous serum acts very rapidly and energetically, but disappears very soon again, inside of from two to four days, while immunity, created by gradually increased inoculations of venom, lasts for months (five to eight), the longer the larger doses were finally employed (active immunity). Even the young guinea pigs of a mother thus immunized acquire immunity for several months.

Calmette's statements have not been accepted without contradiction. Fraser does not agree with him on all points, nor did the experiments and practical experience of the Indian surgeons and of Martin thoroughly confirm his premises and predictions. Not only has controversy arisen as to the curative value of antivenomous serum, but also other questions have been stirred up in relation to the chemical and physiological action of toxin and antitoxin, questions which promise to be of the greatest importance in settling this vital problem of therapeutics. The interest of the subject warrants us going into some details as regards the controversy.

First, it was objected that Calmette asserted his antivenomous serum to be equally effective against all kinds of venom, in direct opposition to Behring's law that every toxin requires a specific antitoxin. It should be borne in mind that Calmette's horses are immunized with a venom in which the hæmolytic element has been destroyed. Hence while he may work out an antitoxin to the more important constituent, the nerve poison, he neglects the other agent entirely. And indeed Cunningham declares an antivenomous serum which is efficient against cobra venom entirely valueless against Daboia venom and inversely, while Martin claims that Calmette's serum has a slight but distinct protective effect against one of the constituents of Australian snake venom; but, on account of its present slight antitoxic strength, it is practically valueless in Australia. Calmette, after having elucidated experimentally all these points of objection, comes to the conclusion "that his antivenomous serum acts as a perfect preventive against the venom of any species of snake." He admits that in a case of viper poisoning some local disturbances may persist, even with consequent suppuration, but that fatal exitus is at all events prevented. Other experiments seem to prove that also the hæmolytic agent in venom as well is decidedly influenced by antivenomous serum (Stephen and Myers). Furthermore, we must consider that a dose of venom may not be sufficient to kill, even though only one of its constituents has been neutralized. And as a most decisive proof, a number of reports from different parts of the globe leave no doubt of the curative value of Calmette's serum. It has been used with beneficial effect in East India, in Egypt, Africa, and the West Indies, against the different serpents of those countries. Some of the failures reported by the Indian surgeons may be accounted for by the deterioration and consequent diminution of power, to which antivenomous serum is subject in a hot climate. Notwithstanding this impairment, however, there are even reports of the effective application of such weakened samples of antivenene.

Another objection was made that the curative power was entirely overrated, since Calmette used as a test for estimating its value only one minimum lethal dose of poison. Fraser thus calculates that for a man weighing 60 kgm. a dose of 330 c.c. of antivenene would be required,* an amount which because of its bulk and price would preclude its practical employment. Statistics and calculations do not, however, bear out this objection, for, with rare exceptions, not much more than the lethal dose is injected by the snake in the average instance.

More theoretical, but not less interesting, is the question of action of the antivenene, whether it is chemical or physiological. Whereas Calmette with Roux and Buchner insists that antitoxin elicits or stimulates the resistance of tissues, Fraser and Martin assert with Behring that the action can be only chemical. The experiments with snake poison and its antidote conducted by Martin and others point positively to a chemical action.

Observations of great interest were reported by Phisa-

* From facts to be reported later on, it seems not at all improbable that certain herbs may contain substances which are capable of reducing the toxicity of venom.

* The logic of this argumentation is not quite obvious. Assuming that more or less power of natural immunity is dormant in every animal which enables it to overcome a subminimal lethal dose of poison, we ought to expect that this power increases in the same ratio as the size of the animal, no matter whether the power is ascribed to the whole system or to one or several separate organs. The average dose of poison in a snake-bite will remain the same in the large as in the small victim; part of it is immunized by the injured organism itself, and only the surplus remains for the action of the antivenene. Consequently, the larger animal stands a better chance and requires comparatively less antivenene. Calmette and others have already expressed this opinion by formulating a law that the quantity of antivenomous serum required is not only in inverse ratio to the susceptibility of an animal, but also to its weight. Man shows more power of resistance than the animals experimented upon.

lix. While experimenting with viper venom exclusively he found many substances which exhibited apparently a decided antitoxic effect—*e.g.*, cholesterin, separated from biliary calculi and from carrots, or tyrosin, obtained from the bulbs of the well-known flower Dahlia, and from mushrooms.* All these bodies, some of vegetable origin and the highest final products of proteid metabolism, had a decided immunizing effect against viper venom, as had also the serum of the animals treated with these substances. They were capable, however, of raising the resisting power of the organism but little above the minimum lethal dose of venom; and, moreover, to be at all efficacious, they had to be injected at least twenty-four hours previous to the administration of the venom.† A similar antitoxic influence is exerted by the cortical substance of the suprarenal glands.

Calmette, after repeating the above experiments, has extended them by using bouillon, bile, normal and antitetanic serum, etc., with the same apparent antitoxic effect, which is little pronounced and transient. He claims that all these substances act only as cell stimulants, to counteract the deleterious influence of the venom. Advocates of Ehrlich's theory would as well say that they stimulate the cell to the overproduction of a toxophil side chain, which as antitoxin is received and kept ready for use by the blood plasma. It is immaterial which theory we may apply. The observations of Phisalix are still in an experimental stage, and, though they may result in very practical conclusions, they may in the mean time serve to unravel the mysteries of the relation between toxins and antitoxins. And to investigations of this nature snake poisons, as Martin has pointed out, are particularly well adapted. They have the advantage of being less sensitive than other toxins to light and heat, and of being comparatively easy to obtain in a form which preserves a remarkably constant composition.

To sum up, the most commendable treatment would be:

One or several tight ligatures should be made above the wound, followed perhaps by deep scarifications; then injection of antivenomous serum, if at hand. If the latter cannot be had, injections should be made of 20 to 50 c.c. of a solution of hypochlorite of lime, 1 to 60, at several points near the bite and elsewhere. Stimulation, if necessary, by either strychnine or atropine (or alcohol?); lavage of the stomach; artificial respiration for hours; and, not least of all, continuous encouragement of the victim, for a deep mental prostration goes together with the physical depression of the nervous centres.

HELODERMA.—It remains now to consider the only poisonous reptile not belonging to the snake group, the lizard heloderma, which is represented by two species.

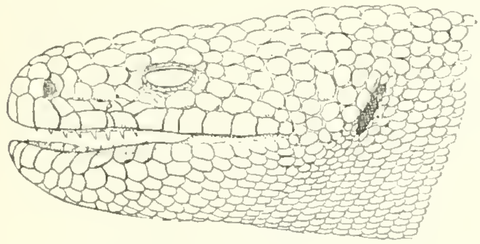

FIG. 3871.—Head of Heloderma. Side view.

The habitat of one of them, Heloderma suspectum Cope, is in the southwest of the United States, in New Mexico and Arizona, around the Gila River, while its somewhat larger congener, Heloderma horridum, lives in Central America. Its popular name, "Gila monster," denotes the awe and fear with which the animal is regarded by the native population, but the same is hardly justified by its exterior nor by its habits. The length attained by the adult animal varies from eighteen to twenty-two inches. Its skin, which is studded with innumerable horny elevations, like small, round nail-heads, exhibits a salmon or orange color, interrupted by black rings and irregular figures; the slow and sluggish, dragging gait does not enable it to make an attack or onslaught. The breath is said to be offensive and to issue from the mouth in puffs of black vapor; but only the black tongue is sometimes thrust out, and the exhalations and saliva have the pleasant odor of fresh calamus or sweetflag. Its reputation as a monster seems to be founded upon the fact that the natives have occasionally observed grave consequences following its bite. It undoubtedly bites very rarely, and then only when it is teased or cornered. When pursued it throws itself upon its back and bites in this position, holding on as tightly as a bulldog.

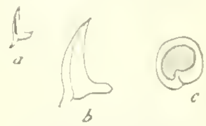

FIG. 3872.—Teeth of Heloderma. *a*, Natural size (3 mm. in length); *b*, enlarged 3 diam.; *c*, cross section.

The fact that but occasionally grave sequelæ follow the bite of a Gila monster accounts for the many discrepancies that have prevailed as to its toxicity until very recently, not only among the natives, but also among the best scientific observers. The first confirmation of its poisonous nature seemed to be established by the discovery of grooved teeth, about 3–4 mm. long, four on either branch of both maxilla and mandibula, in shape similar to those in the snakes Opisthoglypha or "suspecti."* The mandibula appears somewhat swollen, owing to the projection of its disproportionately large, elongated submaxillary glands, whose four separate ducts lead to the base of the above-described grooved teeth. The buccal secretion is whitish, transparent, slightly turbid, somewhat viscid, alkaline, mostly contaminated with traces of blood; it has the fragrant odor of calamus and shows some scaly epithelia, salivary corpuscles, and some amorphous granules. A hanging drop soon swarms with bacteria. Gelatin is liquefied with lemon-colored colonies. When biting on a rubber cord an animal yields on the average five to six drops; a large animal once gave twenty-two drops. The saliva dries in grayish-white scales to one-eighth or one-tenth of its original weight.

The arrangement of the teeth and of the glands makes us understand why opinions as to the poisonous nature of heloderma have differed so widely. When an animal seizes its victim only with the front teeth, or does not lie on its back while biting, none or very little of the buccal secretion may enter the wound. When, however, a vigorous bite has been inflicted, the consequent phenomena have proven the venomous character beyond any doubt, and the hypodermic application of the pure saliva in sufficient doses has invariably proved fatal to the animals experimented upon—rabbits, mice, and frogs.

The first effect of the injection—an inability to sit or stand—is manifested after a short time, about ten to fifteen minutes in frogs, thirty minutes in rabbits. A certain drowsiness, similar to a narcosis, overpowers the animal; paralysis and insensibility seem to proceed from behind forward. The respiration is not labored, but becomes gradually slower and superficial until the animal expires after a few hours with some hardly noticeable twitchings. The heart has first a period of increased activity, which is followed by gradual paralysis and a great fall of arterial pressure, due to vascular dilatation. While these symptoms prevail after a small dose of ven-

* There are, no doubt, many other substances of similar action, and it is not improbable that some of the popular antidotes to snake venom, like the plant mentioned before, Micania, owe their partly deserved reputation to an influence similar to that stated above as exerted by cholesterin, etc.

† Possibly in these cases the presence of a large amount of cholesterin in the blood serum acts in the same way as it does with other protoplasmic poisons, *e.g.*, saponin; it combines directly with the toxic substance, thus preventing the cholesterin of the blood cells themselves from doing so, and from being destroyed. (Ransom.)

* There is possibly another poisonous lizard in East India, Lanthanotus Borneensis, which differs considerably from Heloderma, but which is provided with shallow grooved teeth. As to its toxicity nothing is known (Steindachner).

Digitized by Microsoft®

om, large doses seem to act directly upon the heart muscle, the animals dying within ten to twenty minutes with dyspnœa and convulsions. Some investigators explain these symptoms as the consequence of general muscular paralysis (Santesson); others, as a paralysis of the central nervous organs (Van Denburgh). A faint hæmolysis is noticed *in vitro*, but in the body no effect upon the blood is visible, no exudation or hemorrhage appears. The local symptoms, with rare exceptions, are entirely wanting; it is even difficult to find the spot where the venom has been injected. Yet it ought not to be forgotten that a few cases of persons bitten by a heloderma are on record in which extensive and painful local swelling is noted.

The autopsy shows nothing but a very much dilated heart and an enormous venous congestion of all internal organs. The microscopical examination of the spinal cord, however, reveals extensive changes in the ganglion cells of the anterior horns; in fact, Bailey found the changes almost identical with those described as due to the action of snake venom. It is not hard to believe, therefore, that snake venom and the saliva of heloderma are almost identical in chemical composition. Santesson has demonstrated that this saliva contains albumoses as well as some nuclein bodies, the latter perhaps responsible for the slight action upon the blood.

Treatment.—It is to be expected that the persons bitten by a heloderma will seldom exhibit grave symptoms, except when accidentally a blood-vessel has been struck directly. A treatment after general surgical principles will suffice to subdue the local phenomena, while the organism has time to overcome the effects of the injected toxin. Yet a ligature ought not to be omitted, and otherwise the use of antivenomous serum should be resorted to as well. The similarity of the toxins of snake venom and the saliva of heloderma justifies the administration of the same antidote. Calmette even claims for his antivenomous serum the same success in stings of scorpions as for snake-bite. *Gustav Langmann.*

POISONS.—A concise definition of the term poison, which will satisfy the medical, the legal, and the popular acceptations, is a practical impossibility. To the layman a poison is any substance which, when administered in small doses, causes disturbance to health or destruction of life; in a legal sense it is any substance of a destructive or noxious character, whatsoever its nature or mode of operation, which, taken into the system, produces injurious or fatal effects. The popular definition excludes many well-recognized poisons which act injuriously only in large doses; the legal includes, or may be made to include, many substances not strictly poisonous, such as powdered glass, iron filings, and other things of a similar character, which are merely mechanical irritants. To the physician and toxicologist the term means any substance of inherent deleterious character, either organic or inorganic, and incapable of self-reproduction, which, acting chemically upon the tissues or fluids of the body, may, by causing alteration or destruction of the same, or disturbance of function, seriously affect the health or destroy life. This definition excludes mechanical agencies, direct thermal changes, electricity, bacteria, and the low forms of animal life.

The published statistics of poisoning are very meagre, but the few tables which we have are interesting in several ways, indicating the classes of substances and special substances most frequently selected or accidentally administered, at different times and in different countries, and showing the proportion of accidental, suicidal, and criminal deaths due to poisoning.

The returns made by the English coroners of the inquests held during 1837 and 1838 showed the whole number of deaths by poisoning to be 541. Of this number opium was the cause in 196 cases, the majority of which were accidental or suicidal. Arsenic stood next in order, with 185 cases, the majority of which were criminal. Thirty-two cases were due to sulphuric acid, 27 to prussic acid, 19 to oxalic acid, and 15 to corrosive sublimate and other preparations of mercury.

During the years 1863 to 1867 there occurred in England and Wales 2,097 deaths from poison. Of this number no less than 628 were due to opium and its preparations, 151 to prussic acid and potassic cyanide, 83 to arsenic, 77 to mineral acids, 66 to oxalic acid, 61 to strychnine, 58 to compounds of mercury, 15 to phosphorus, and 11 to ammonia.

In France, during the years 1851 to 1871, out of 873 cases, 287 were due to arsenic, 267 to phosphorus, 159 to copper, 36 to sulphuric acid, 35 to cantharides, while opium and its preparations were responsible for but 6.

In Finland, of 30 fatal cases occurring between 1860 and 1866, arsenic caused 7, phosphorus 5, and strychnine 4.

Out of 45 cases reported in Massachusetts during the period 1878 to 1881, opium was responsible for 18, arsenic for 13, and all others for 14.

Although poisoning is a frequent means of suicide, the percentage of these cases is not nearly so high as is generally supposed; but yet, judging from what figures we have been able to obtain, this method of terminating an unsatisfactory existence is gradually becoming more popular. In Prussia, for instance, while there was a great increase in the number of suicides from all causes during the period 1871 to 1876, the relative frequency of self-poisoning was very much greater. The increase from all causes over preceding years was 43.60 per cent., but suicide from poisoning alone had more than doubled in frequency, the increase being 126.10 per cent.; but, even then, poisoning was the means employed by but a fraction over three per cent. of the whole number of suicides. During the eight years ending with 1876, the whole number of these cases was 24,918, and of this number 786 were by poisoning (3.15 per cent.). Solid or liquid poisons were elected by 707 persons, and gaseous by 79. It is interesting to note further that, while by far the greater number of suicides were men, the proportion being 80.50 against 19.50, or more than 4 to 1, the 786 suicides by poisons were nearly evenly divided between the two sexes, the proportion being 52.9 men to 47.1 women.

Of the whole number of suicides reported in Bavaria

Digitized by Microsoft ®

www.libtool.com.cn

during the fourteen years ending with 1870, 2 per cent. were due to poisoning. In 1871 the percentage increased to 3.2; during 1872 it was 3.00; in 1873 it fell to 2.20, increased again in 1874 to 2.70, and fell off again slightly in 1875 to 2.50. The popularity of poisoning as a means of suicide varies greatly in different countries. In Sweden, from 1843 to 1855, nearly a fourth of the suicides chose this means (21.7 per cent.); in England, in 1858 and 1859, 9.10 per cent.; and in other countries as follows: France, 1835–44, 2.48 per cent.; 1848–57, 1.80 per cent.; Belgium, 1840–49, 1.80 per cent.; Denmark, 1840–56, 1.50 per cent.; Würtemberg, 1857–70, 1.20 per cent.; Geneva, 1838–55, 4.90 per cent.

Of the accidental deaths occurring in Prussia during the years 1869–76, 54,363 in number, 2,448, or 4.50 per cent., were due to poison. This number includes 1,873 men and 575 women; 348 of the victims were under and 2,100 over fifteen years of age. During the fifteen years ending with 1877 there were 77 cases of criminal poisoning in Prussia, or 0.056 per cent. of all crimes. In France, during 1826–29, out of 2,663 capital offences, 150, or 5.63 per cent., were for poisoning. In England and Wales, during 1840, there occurred 349 deaths from poisoning (181 men, 168 women); 161 cases were suicidal (74 men, 87 women); and 188 were accidental and homicidal (107 men, 81 women). Among the latter, opium caused the death in 42 children under five years of age.

Classification.—Various methods of classification of poisons have from time to time been recommended; but no system has as yet proved wholly satisfactory. The old classifications, according to source or chemical properties, such as: (1) animal; (2) mineral; (3) vegetable; or, (1) organic; (2) inorganic; or (1) acids; (2) alkalies; (3) salts, are of no value, since they convey no idea regarding the properties of a poison or its mode of action. Orfila's division into (1) irritants; (2) narcotics, and (3) narcotico-irritants; Tardieu's into (1) irritants and corrosives; (2) hyposthenisants; (3) stupefacients; (4) narcotics, and (5) tetanics; and Taylor's into (1) irritants, and (2) neurotics, are all good; but each has its defective points. Taylor's is, perhaps, the best. The irritants are derived from the animal, vegetable, and mineral kingdoms; those from the latter source may be further subdivided into acid, alkaline, non-metallic, and metallic. The neurotics are subdivided into (1) cerebral; (2) spinal; (3) cerebro-spinal, and (4) cerebro-cardiac.

The irritant poisons include many which are also corrosive in their action, causing disintegration of the parts with which they come in contact. The pure irritants exert no such chemical action, and are much slower in the development of symptoms. They cause irritation and inflammation of the parts to which they are applied, with violent vomiting and purging, intense pain, and well-marked effects on the nervous system. These symptoms occur after a greater or lesser interval, according to the nature of the particular poison. The pain, which is usually of an intense burning character, is, unlike that due to colic, much increased by pressure. Septic irritants produce additional symptoms of a character formerly known as typhoidal.

The neurotic poisons act chiefly on the brain, cord, and nerves; occasionally, the symptoms manifested partake more or less of the character of irritant poisoning. Those acting chiefly on the brain, producing stupor and insensibility, preceded by fulness in the head, vertigo, impaired vision, delirium, etc., belong to the cerebral; those affecting chiefly the cord, producing tetanic or clonic convulsions, to the spinal; those producing symptoms referable to the brain and cord, to the cerebro-spinal; and those affecting the brain and heart, to the cerebro-cardiac class.

Action.—The action of poisons may be local, remote, or both. Local action is physical and chemical, and is manifested by inflammation, corrosion, and direct effect upon the nerves, whereby the functions of organs are impaired or destroyed. If the chemical affinity of the poison for the tissues at the point of application be not great, the result is irritation and inflammation; if, however, the affinity be great, the action is most intense and we have actual corrosion. Remote action depends upon absorption into, and transportation by, the blood to the various organs which may be affected. Thus, for instance, digitalis affects the heart, strychnine the cord, and opium the brain. In any case of acute fatal poisoning, death is the result of the remote action of the poison, which may or may not have a local action.

The ordinary action of poisons may be modified by the size of the dose, by the chemical combination of the substance, by the state of aggregation or admixture, by the condition or absorptive power of the part or membrane to which it is applied, by the condition of the patient, by habit, and by idiosyncrasy. The young and old are more susceptible, as a rule, than the middle aged; women more than men; and fasting more than well-fed persons. Disease also may render the subject less susceptible, or, on the other hand, may facilitate the action of the poison. Habit diminishes the effect of many poisons, so that a much larger dose is required for the manifestation of symptoms than would be for persons not so habituated. Idiosyncrasy is a peculiar condition of the system which enables harmless substances to produce violent symptoms similar to those of irritant poisons. Thus many persons are unable to eat certain articles of food, even unknowingly—such as shell-fish, fish, strawberries, some kinds of meat, butter, honey, and other things. In the same way, many persons are seriously affected by small medicinal doses of opium, strychnine, arsenic, and other pharmaceutical preparations. A second form of idiosyncrasy is a tolerance for exceptionally large doses of poison by persons in no way protected by the influence of habit.

Absorption.—In order to produce poisonous symptoms, the presence of a certain amount of poison in the blood is usually necessary, and the amount required depends upon rapidity of absorption and of elimination. A certain amount of any poison in the blood is incapable of producing any symptoms. Beyond this is that amount which is capable of producing characteristic symptoms—the poisonous dose; then that amount capable of destroying life—the minimum fatal dose; and beyond this up to a certain point, the action is increased in violence and rapidity. The poisonous and minimum fatal doses are relatively large if absorption is slow and elimination rapid, and small if the latter conditions are reversed. The rapidity of absorption depends greatly upon the physical properties of the poison; liquids are more rapidly absorbable than solids, soluble solids more than insoluble, and gases more than liquids or solids. Some insoluble solids may be rendered soluble, and hence more absorbable, by the action of the juices of the stomach and intestines.

Poisons may be taken into the system directly through the blood, as in absorption from wounds or injection into blood-vessels; they may be absorbed through the skin or from the cellular membrane, from inflamed serous surfaces, and from all mucous membranes. Absorption directly into the blood from wounds occurs with great rapidity. Through healthy skin covered with cuticle, absorption is very slow and in small amount. It is increased by rubbing and by the addition of fatty substances or solvents of the poisons. Gaseous substances are more absorbable than watery solutions, particularly if the latter are warm or hot. On the other hand, absorption from a diseased skin is very rapid, and many fatal cases have been noted from the application of washes, ointments, and dressings to diseased surfaces.

Mucous surfaces absorb poisons in the following order of rapidity: (1) lungs; (2) stomach; (3) intestines; (4) mouth; (5) nose; (6) eyes; (7) tear passages; (8) rectum; (9) vagina; (10) uterus; (11) bladder; (12) prepuce. The mucous surfaces of the lungs and the air passages absorb poisons with great rapidity, and particularly those in the form of gas or dust. The lining membrane of the stomach and intestines is usually the absorbent surface in ordinary cases of poisoning. Fulness of these organs retards, and emptiness favors, absorption. Certain poi-

Digitized by Microsoft®

www.tiptool.com.cn

sons which are rapidly fatal when introduced into the circulation (snake poisons, curare, etc.) are harmless in a full stomach, and, indeed, are absorbed only in small amount when that organ is empty.

Concerning the absorbent power of other mucous membranes, it is necessary only to remark that all are efficient, though in a somewhat varying degree. On account of the absorption of poisons by the mucous membranes of the intestines and bladder, it is sometimes necessary in treatment to administer cathartics, or to catheterize, in order to prevent the reabsorption of substances which are undergoing elimination from the system by the saliva, the juices of the stomach, pancreas, and intestines, the bile, or the urine.

Elimination.—As soon as absorption begins, the substance is diffused through the whole body by the circulation, and at the same time the process of elimination is begun. Coincident with this is still a third process, that of deposition in the various tissues of the body, from which, however, the poison is eventually eliminated, unless death intervenes. Deposition goes on chiefly in the liver, kidneys, spleen, brain, and heart. The effect of a poison depends upon the relative rapidity of absorption and elimination, and these processes go on with greater or lesser rapidity according to the nature of the substance. If elimination proceeds as rapidly as absorption, fatal results do not occur; but with a slower elimination the poison accumulates in the system, and, provided a sufficiently large amount has been administered, destroys life. Elimination is influenced by the chemical affinity of the poison for the constituents of the blood or of the tissues of the affected organs. If this affinity is great, the process is slow; if weak, the process is very rapid.

Gaseous and volatile poisons are excreted chiefly by the lungs; others chiefly by the kidneys, though all secretions of the body play a more or less important part in the process. Certain poisons appear to elect particular secretions, though the kidneys act in most cases as the most important organ of elimination. Thus mercury elects the salivary glands, arsenic and antimony the mucous and serous membranes, and many metallic poisons the liver.

Diagnosis of Poisoning.—The diagnosis of the administration of a poison is based on the symptoms and their course, the detection of poison in articles of food and drink or in the ejecta and excreta, on the post mortem appearances, and on the detection of the suspected substance in the organs of the deceased. The symptoms are usually of sudden onset, in a person previously in good health, soon after eating or drinking. If several persons are affected at the same time there is commonly a marked similarity in the symptoms. Where the poison is administered to a sick person, the diagnosis is rendered more difficult on account of symptoms already present, which may appear to be modified or exaggerated, and the phenomena of poisoning may seem to be only the natural course of the disease. Too much importance should not be attached to the fact of recent eating or drinking, since a poison may be inhaled, injected, or applied externally. The diagnosis of the particular kind of poison involved is of great importance for the determination of the treatment to be pursued, and it is therefore essential that the medical attendant should know, if possible, the exact course of the symptoms from their first appearance, the previous history of the patient, and the exact nature of any medicines which may have been administered. Owing to the similarity of symptoms of particular diseases to those produced by certain poisons, one must often exercise great care in making a differential diagnosis. The physician is often aided in forming an opinion by the moral aspect of the case.

Acute irritant poisoning may be suspected when violent purging and vomiting, accompanied by pain in the region of the stomach or complete prostration, occur in a person without some assignable natural cause. Acute neurotic poisoning manifests itself by more or less sudden symptoms referable to the nervous system, such as stupor, insensibility, delirium, or convulsions. Chronic poisoning is more difficult of diagnosis than acute or subacute, on account of the less marked character of the symptoms, which are often, or indeed usually, ascribable to natural causes.

In making a diagnosis in a case of suspected poisoning, it is to be borne in mind that symptoms may be delayed by fulness of the stomach, sleep, or intoxication, or may be modified or intensified by disease or debility. Among the diseases which may be confounded with irritant poisoning may be mentioned cholera asiatica, cholera morbus, gastritis, enteritis, gastro-enteritis, colic, peritonitis, intussusception, and dysentery; among those which may simulate neurotic poisoning are apoplexy, sunstroke, uræmia, septicæmia, epilepsy, tetanus, diseases of the brain and of the heart, pulmonary embolism, cerebro-spinal meningitis, rupture of the stomach or gall-bladder, typhoid fever, and coma of various origin.

Of very great importance in the diagnosis and subsequent treatment of poisoning is the detection of the substance in the remains of food or drink, or in the vomitus; but as it is possible, in any case of criminal poisoning, that these substances may have been removed and others substituted, or in cases of feigned poisoning that a poison may be introduced into the food remains or vomited matters, reliance cannot always be placed upon this evidence. But the detection of the poison in the urine of the patient establishes the diagnosis beyond any doubt. Yet, at the same time, it should be remembered that the non-detection in that fluid does not by any means prove its non-existence in the body.

The Treatment in cases of poisoning depends altogether upon the nature of the particular substance involved. The first indication, except when corrosives or poisons administered otherwise than by the mouth are involved, is evacuation of the stomach and administration of antidotes, stimulants, etc. (See special poisons under their appropriate heads. See also article on *Antidotes*.)

Post-mortem Indications.—It frequently happens, in cases of suspected poisoning, that an autopsy is all that is necessary clearly to establish the cause of death, particularly in cases of sudden death, which to the uneducated mind are associated usually with suspicious circumstances. The popular belief in poison as an agent of sudden death is doubtless, in great part, due to works of fiction and the stage, where the interval occurring between the swallowing of the poison and the termination of life is so short that the two events are almost simultaneous. As a matter of fact, sudden death is much more likely to be due to disease than to poison, and, indeed, the only poison which approaches heart disease and apoplexy in rapidity of fatal effect is anhydrous prussic acid, a poison not easily obtainable. But, in consequence of the popular tendency to associate the two ideas, innocent persons frequently are suspected or accused of a heinous crime, which may be easily disproved by the appearances on section. On the other hand, with perhaps equal or greater frequency, the autopsy serves to direct suspicion or to strengthen it in cases of poisoning which have resembled disease. But it not seldom fails to throw any light whatever upon the question of the cause of death, and then a chemical examination may be required.

The external appearances indicative of poison are very few, and of no great value. Evidence of corrosive action is sometimes furnished by the skin and clothing. The presence of certain poisons may be betrayed by their odors, and of others by stains. There is nothing characteristic to be observed from the attitude of the body, rate of cooling or of decomposition, or expression of the countenance. Rigidity is usually more marked and longer continued in death from strychnine, and is often diagnostic of this poison; in other cases, no great difference is to be observed. Internal appearances vary according to the poison; they may be absent, or so slight as not to attract attention in cases of death by neurotics, or they may be very marked and characteristic where irritants, and particularly corrosives, have been employed. The chemical and physical properties of the blood

Digitized by Microsoft®

sometimes undergo marked changes; it is darkened by chloroform, ether, carbonic acid, sulphuretted hydrogen, and other gases, and by prussic acid and cyanides, oxalic acid, etc.; by morphine, strychnine, and some others, it is both darkened and rendered more fluid. The greater number of mineral poisons have no effect on the blood. The blood-vessels of the brain are sometimes observed to be engorged in narcotic poisoning, but this appearance may be very slight or entirely wanting. The principal post-mortem appearances due to poison are to be found in the alimentary canal and abdominal viscera. Corrosion of any part of the alimentary canal, softening of the mucous membrane, which is changed in color and easily detached, and evidence of intense inflammation or perforation, are diagnostic of corrosive acids or alkalies, etc. In irritant poisoning, the stomach and intestines show signs of inflammation of a more or less intense character, and sometimes ulceration and perforation, thickening of the walls, or even thickening and softening. The changes produced in other organs are chiefly engorgement and fatty degeneration; the latter occurs sometimes with surprising rapidity in the liver in poisoning by arsenic and phosphorus.

The post-mortem appearances in any case of suspected poisoning will be but imperfect evidence of the presence or results of poison, unless it is possible to distinguish them without doubt from analogous appearances which may be the result of disease. Otherwise the proof of poisoning must rest on the detection of the poison in the body, or on outside evidence. The changes which may be referable to disease or to the action of irritant poisons as well, are softening, thickening, reddening, ulceration, and perforation. Softening of the walls of the stomach may be due to poison, to disease, or to post-mortem change. If it is due to poison, similar changes are usually to be found in the mouth and œsophagus; if to disease or post-mortem digestion, these additional changes are wanting. Reddening may be due to poisoning or to gastritis, gastro-enteritis, gravitation, or to contact with the liver or spleen. But these appearances are not likely to be mistaken by one accustomed to post-mortem examinations; the redness of poisoning is usually accompanied by some peculiarity of appearance which renders it readily distinguishable. Ulceration is more commonly referable to disease than to poison. When it is due to the former, the accompanying redness is confined to the immediate locality, whereas in poisoning it is more or less widely diffused. There is also a considerable difference in the symptoms. Care should be taken not to confound ulceration, which is a vital process, with corrosion, which is chemical. Perforation of any part of the alimentary canal is, like ulceration, of more common occurrence in disease than in poisoning. When due to disease perforation of the stomach is accompanied by little if any vomiting and no purging, and death is due to peritonitis. The aperture, if due to ulceration and not to corrosion, is usually small in size, and with smooth, regular edges, instead of large, rough, and irregular. Perforation from post-mortem digestion is very rare; it may be suspected from the fact that there has been no peritonitis, nor any symptom before death, to indicate such a severe process. Perforations of the œsophagus and intestines are commonly due to ulceration from the presence of a foreign body, and in such cases the latter is usually discoverable. The intestinal wall is perforated frequently in disease, as, for instance, in typhoid fever.

Chemical Examination.—When a chemical analysis of the body is deemed necessary, the greatest precautions should be observed in performing the autopsy, and in the preservation of organs and fluids. The stomach should be ligatured at both ends before removal. On its being opened the contents should be received in a clean glass or porcelain vessel, and their quantity, color, odor, reaction, and consistency, and the presence of any unusual substances should be noted; the intestines should be treated in like manner. Each organ, on removal, should be placed in a clean vessel by itself, sealed with a private seal, and labelled. Any suspicious vials or powders, and all remnants of food, vomitus, urine, or other substances connected with the case should be sealed at the same time and delivered to the chemist. In case of exhumed bodies, where decomposition has proceeded so far that the coffin is no longer entire, it is often advisable to take, in addition, a sample of earth from above and below the receptacle. On the delivery of the organs, *et cetera*, to the chemist, it is well to give also a more or less complete history of the case, in order that he may have an idea as to the nature of the poison for which he has to search. From the symptoms and post-mortem appearances, it is frequently possible to cut the work of chemical analysis down to a minimum. Failure to detect a poison in the body is by no means conclusive that death has been caused naturally, for there are many poisons which cannot be isolated. The fatal dose of many is so very small that, even if not eliminated in great part before death, its distribution over the system renders it impossible, with our as yet imperfect means, to be isolated. In such cases the proof depends on symptoms and other attendant circumstances. Nor is the presence of poison in the dead body proof that it has caused death, for it is conceivable that poisonous substances may be introduced into the body after death has already occurred, or may have been used in the process of embalming. But the discovery of the poison in the liver and other viscera, and particularly in the urine, usually indicates ante-mortem administration. In many cases in which death is the result of chronic poisoning, it may be impossible to detect any of the substance, which, having performed its work, has been eliminated from the system. Volatile poisons also may be lost within a very short interval after death, and others may be decomposed or oxidized in the living body. In most cases, the ability to detect the poison depends upon the length of time which has elapsed after death, upon the interval between the first manifestation of symptoms and dissolution, upon the amount taken, and upon the amount remaining in the stomach and other organs when death occurs, for reasons which have been given.

Before proceeding to a chemical analysis, a careful examination of the stomach with the aid of a magnifying glass should be made. Such inspection may reveal crystals or powders admitting of ready examination, or particles of vegetable matter may be detected which may be identified from their botanical characteristics with the aid of the microscope. The organs subjected to analysis should be accurately weighed, and any peculiarities observed should be noted. It is best to divide the organs into several portions: one for preservation; one for volatile substances; one for alkaloids, etc.; one for metallic substances; and one for special poisons. The reagents and chemical apparatus used in an investigation must be free from any impurities. The work should be carried on with great precautions, and without assistance except such as is absolutely necessary; for the chemist must be prepared to swear to the identity of the organs, and to the impossibility of any tampering with his work on the part of others.

The methods of analysis to be pursued vary with the nature of the poison. Many substances require special processes for themselves alone, while others may be grouped together under a single process. It is best to look first for volatile substances which are easily lost with keeping, such as chloroform, ammonia, volatile acids, alcohol, ethereal oils, etc. The substance suspected of containing a volatile poison is rubbed up with sufficient distilled water, made acid or alkaline according to the substance sought for, and distilled; the distillate is then further examined by special tests.

The analysis for metallic compounds requires that the organic matter of the examined substances shall be destroyed, since otherwise it interferes with the characteristic reactions. For this purpose the substance is heated in an open dish, or glass flask, with chemically pure hydrochloric acid and potassic chlorate, the latter being added a little at a time until the color of the resulting liquid remains straw-yellow for half an hour after the last

www.libtool.com.cn

Digitized by Microsoft®

addition. The excess of chlorine is then driven off by prolonged heating over the water bath, or by the passage of a stream of carbonic acid through the liquid, which is then filtered and subjected to the regular process of qualitative analysis.

www.libtool.com.cn

The analysis for alkaloids, glucosides, etc., is one which requires great care and delicacy of manipulation. The amount present in any one case is usually very small and widely distributed, and it is, therefore, not at all surprising that an analysis for this class of poisons often yields negative results even in the best of hands, when the administration of the poison may be proved absolutely. The method of Dragendorff for this class is the one most favorably regarded. This process is briefly as follows: The tissues are cut up small and extracted with acidulated water for several hours at 40° to 50° C., strained through cloth, and filtered. The filtrate is evaporated to beginning syrupy consistence, mixed with three or four volumes of alcohol, and allowed to stand twenty-four hours. It is then filtered, the alcohol is driven off by evaporation, and the residue is transferred to a stoppered flask after being cooled and filtered. The fluid is next shaken in the flask with freshly rectified naphtha, and then allowed to stand until the two fluids separate into two layers. The naphtha is then decanted, and the process is repeated as long as a portion of the naphtha decanted each time leaves any residue on evaporation. The naphtha removes piperine, picric acid, camphor, and similar substances, a constituent of the black hellebore, ethereal oils, capsicin, carbolic acid, and decomposition products of aconite. The fluid is next shaken with benzol, which removes caffeine, cantharidin, santonin, caryophyllin, cubebine, absetin, digitaline, colchicine, chrysammic acid, picric acid, and colocynthin. It is next shaken with chloroform, which removes cinchonine, theobromine, papaverine, narceine, picrotoxin, helleborein, digitalein, saponin, and jervine. It is then shaken with naphtha, which removes the excess of chloroform, and next is made alkaline with ammonia, and shaken again with naphtha, which removes strychnine, quinine, sabadilline, conhydrine, brucine, veratrine, emetine, coniine, lobeline, nicotine, aniline, and trimethylamine. From the alkaline fluid benzol removes atropine, hyoscyamine, strychnine, brucine, physostigmine, quinine, cinchonine, narcotine, codeine, thebaine, veratrine, sabadilline, delphinine, nepaline, aconitine, napelline, and emetine. Chloroform is then used to remove morphine, papaverine, and narceine, and amyl alcohol for morphine and solanine. The fluid is then evaporated with glass powder and extracted with chloroform, which removes curarine. These separate extracts are evaporated each in several watch-glasses, and the residues subjected to chemical and physiological tests.

Charles Harrington.

POISONS, ABSORPTION AND DISTRIBUTION OF, IN BOTH ACUTE AND CHRONIC CASES.—All poisons are absorbed. They may enter the body by various channels, but sooner or later they find their way into the circulating blood and lymph, and are then distributed in greater or less quantity throughout the body. Toxic action is directly dependent on the absorption of the poison, and the extent of action is in direct proportion to the rate of absorption. A substance in itself insoluble and indiffusible, or incapable of being rendered soluble and diffusible by the juices of the body, is incapable of being absorbed, and hence cannot be a poison.

The fact of absorption cannot now be questioned. All poisons capable of detection by chemical or other methods are found after death in the blood itself, and in parts of the body remote from the point of introduction, and this is true whether the poison has been introduced into the body through the mouth or rectum, through the lungs by inhalation in the form of vapor, by hypodermic injection, by contact with an abraded surface, or even through the sound skin.

CIRCUMSTANCES WHICH MODIFY THE ABSORPTION OF POISONS.—Obviously, one of the most important circumstances modifying the absorption of a poison is its solubility and diffusibility. Everything else being equal, the greater the solubility and diffusibility of a poison, the more rapid its absorption, and hence the more rapid its manifestation of toxic action. As a rule, the salts of the alkaloids are more soluble than the alkaloids themselves, and hence the toxic action of the former is more rapid than that of the latter. Arsenite of potash is more rapid in its action than arsenious acid; and this is due in great measure to the rapid absorption of the more soluble compound. The action of many chemical antidotes is confined wholly to the conversion of the rapidly soluble form of the poison into a compound either wholly insoluble, or insoluble to such an extent as to delay its absorption, and thus admit of its removal from the body before it has been absorbed in sufficient amount to lead to a fatal result. Thus, in poisoning with oxalic acid the exhibition of lime water in large quantities leads to the formation of calcium oxalate, a compound comparatively insoluble and hence limited in its toxic action.

Again, the absorption of a poison naturally soluble is increased by introducing it in the form of a solution. Thus arsenious oxide introduced into the stomach dissolved in water, is more rapidly absorbed than when introduced in the form of powder. Further, when dissolved in dilute alkalies, thereby being converted into a new body, it is still more rapidly absorbed, thus introducing another feature into the problem, viz., that of diffusibility. It is here much the same as it is with certain foods: in order to have absorption we must have not only solubility, but also diffusibility. Thus raw egg albumen, while readily soluble, is of little use as food until by the action of the digestive juices it is converted into *diffusible* products. Arsenious oxide, then, when dissolved in a given volume of water, is rapidly absorbed; but the same equivalent of arsenic introduced in a similar manner, in the form of an alkali arsenite, is still more rapidly absorbed by virtue of its greater diffusibility. Hence, everything else being equal, the more soluble and diffusible the form of the poison, the more rapid is its absorption, and consequently the more vigorous its toxic action.

Again, the nature of the surface to which the poison is applied modifies materially the rate of absorption. This depends mainly on vascularity; the greater the supply of blood, the more rapidly does absorption go on. Hence the introduction of a poison in the form of vapor into the lungs leads to more rapid absorption than does injection into the intestine; and similarly, the injection of a soluble poison into the intestines or vagina is ordinarily followed by more rapid absorption than when it is introduced into the stomach. While, then, the natural vascularity of an organ or tissue has some modifying influence on the absorption of a poison, the condition of the blood-vessels also exerts some influence. Fulness of the blood-vessels opposes a mechanical obstacle to absorption and this no doubt explains, in part, why it is that poisons taken on retiring at night are sometimes delayed in their action until the morning, since during sleep the withdrawal of blood from the brain leads to an accumulation in the abdominal organs, and hence retards absorption from the alimentary canal. For a similar reason, poisons taken on a full stomach are much less rapidly absorbed than when the stomach is in a comparatively empty condition. The delayed absorption incident to the former state is, of course, due in part also to the mechanical obstacle afforded by the food itself, the latter keeping the poison for a time away from the stomach walls. Hence absorption, and consequently toxic action, is most rapid when the poison is taken into an empty stomach, less rapid when taken with food, and still less rapid when taken after a hearty meal.

In considering absorption from the alimentary canal, we have to notice, further, the modifying action of the digestive juices. Insoluble substances are not directly absorbed, but many compounds, by the action of the digestive juices, are so altered that their solubility is either increased or diminished, thus modifying their ab-

Digitized by Microsoft®

sorption, and hence their toxic action. As examples of the former there are many metallic carbonates, as lead, copper, zinc, and manganese which, when taken into the stomach, may be changed by the acid of the gastric juice into soluble chlorides, so that what was in itself an insoluble and non-poisonous substance may be converted into a vigorous poison.

www.libtool.com.cn

Disposition of the Poison after Absorption.—Once entered into the circulation, there is a twofold disposition of the poison possible. Either it is deposited for a time in the various tissues and organs of the body, or else it is at once eliminated through some one or more of the various emunctories. Ordinarily, if sufficient time intervenes between the taking of the poison and death, there is a temporary deposition of the poison throughout the body—after which, however, the deposited poison is gradually redissolved and eliminated. Careful study of collected facts further shows that, as a rule, the poison is deposited in the largest amounts in the liver, kidneys, spleen, heart, lungs, muscles, brain, and bones. In other words, these organs and tissues have the power of absorbing and retaining poisons, and furthermore, this absorbing power is not the same for the different organs. Chemical analysis in poison cases, and in experiments on animals where the conditions are known with much more definiteness, clearly testifies to the accuracy of this statement. Further, variation in the conditions under which the poison is taken modifies not only absorption as a whole, as already indicated, but also the absorption by individual organs and tissues. The form of the poison; the character of the dosage, whether small and oft-repeated, or a single large one; the mode of administration, etc., all are liable to exert their own modifying influence on the absorption of the poison by the different organs. A knowledge of such modifying influence must then necessarily be of great value, especially in medico-legal cases; for in time the accumulated facts will serve as data on which to found definite conclusions concerning the form of the poison, the mode of administration, the length of time intervening before death, and many other points of a similar nature, so important in criminal cases.

In this connection, therefore, the results of the quantitative analysis of the various organs and tissues of the body in poison cases are of great importance, for, as they show the distribution of the poison under known conditions, the time may come when it will be possible to draw deductions in unknown cases from the analytical results.

During the past few years many data have been collected in this direction, a few of which may be advantageously mentioned.

Carbolic Acid.—A man swallowed 15 c.c. of an officinal preparation of carbolic acid (100 parts phenol + 10 parts of water), and died in fifteen minutes. With the internal organs Dr. Bischoff [1] obtained the following results:

112	gm. of blood........	contained	0.0259	gm.	phenol	= 0.0231	per cent.
1,480	" liver	"	.6370	"	"	= .0430	"
322	" kidney	"	.2010	"	"	= .0620	"
508	" heart muscle	"	.1866	"	"	= .0367	"
1,445	" brain........	"	.3140	"	"	= .0217	"
12.5	" urine........	"	.0014	"	"	= .0112	"

This case is particularly interesting as showing how rapidly a readily soluble and diffusible substance may be absorbed, and how quickly it may be distributed throughout the body. Further, it is to be seen that the poison was, at the time of death, in position to be eliminated, having entered into the urine.

Oxalic Acid.—An unknown dose of oxalic acid, followed by death in fifteen minutes. The amounts of oxalic acid found by Dr. Bischoff were as follows:

In 2,240	gm. stomach, intestines, etc............	2.280	gm.	oxalic acid.
" 770	" liver....................................	.285	"	"
" 180	" heart blood	.043	"	"
" 350	" heart	.020	"	"
" 290	" kidney	.014	"	"
" 40	" urine	.007	"	"
" 730	" brain	....		

Potassium Cyanide.—An unknown case of potassium cyanide. The analysis made three days after death.[2]

223	gm. stomach and contents	contained	0.0632	gm. HCN.
595	" intestines..........................	"	.0186	"
122	" intestines..........................	"	.0031	"
505	" liver	"	.0170	"
[illegible]	" heart................................	"	.0025	"
352	" brain................................	"	.0144	"

Arsenic.—The case of an adult female who lived two days after taking a fatal dose, furnishes the following results reported by Dr. E. S. Wood.[3]

179	gm. stomach........................	contained	0.0442	gm. arsenic.
6	" stomach contents...............	"	.0097	"
490	" intestines	"	.0638	"
62	" intestines contents	"	.0205	"
1,227	" liver................................	"	.0497	"
149	" left kidney	"	.0043	"
125	" right kidney.......................	"	.0026	"
318	" uterus..............................	"	[illegible]	"
521	" brain................................	"	.0088	"

In all these cases of poisoning the order of distribution of the poison is much the same as that previously stated, the liver standing first, then the kidneys, heart, lungs, etc. In experimenting on animals, however, where the poison can be variously introduced, it has been noticed that the distribution of the absorbed poison is not always the same. It is easy to see how there might be a decided difference in an acute and chronic case of poisoning, for if elimination of the poison commences at once, it follows that the relative amount of poison contained in the liver and kidneys must necessarily be different in a chronic case than where a single large dose of the poison is taken. Again, it is not difficult to see how the *form* of the poison might modify the rate of absorption and the order of distribution. This latter fact has been clearly indicated by results obtained with arsenic, both in experiments on animals and in poison cases. Thus Scolossuboff,[4] under the impression that the muscular paralysis noticed in the extremities of animals poisoned with arsenic was accompanied by a localization of the poison in the muscles, subjected his hypothesis to the test of experiment, feeding the animals experimented on with a solution of sodium arsenite. The results obtained in this manner were all of a like nature, and in several respects different from all preconceived ideas. Thus, in one experiment with a bulldog, which had been fed for thirty-four days with the arsenite, the following amounts of absorbed arsenic were found:

100	gm. of muscle	contained	0.25 mgm.	of arsenic (As).
100	" liver.....................	"	2.71	" "
100	" brain.....................	"	8.85	" "
100	" spinal cord	"	9.33	" "

It is to be noticed in this experiment that the amount of arsenic in the brain is three times as great as in the liver. In another experiment, with a griffin dog, the brain contained, per 100 gm. of tissue, double the amount of arsenic contained in the muscles. In every experiment, comparatively large amounts of arsenic were found in the brain, thus giving evidence of a special localization of arsenic in nerve tissue; but this result was contrary to the experience of all toxicologists in arsenic cases. Scolossuboff gave his results to the world as characteristic of arsenic poisoning in general, without apparently considering that he was experimenting with a *form* of arsenic seldom used as a poison, and with which toxicologists had had little practical experience.

In the white oxide of arsenic (As_2O_3), the arsenic of commerce, and the form most commonly used as a poison, we have to deal with a substance but slowly soluble, while in sodium arsenite we have one of the most readily soluble and one of the most easily diffusible of the solid compounds of arsenic. If the amount of arsenic in the brain could be taken as an index of the *form* in which the poison was taken, whether as a soluble or as a comparatively insoluble compound, it would in many cases of poisoning be a point of great importance. But in order to have the point in question of any practical value, we must be certain, on the one hand, that

Digitized by Microsoft®

under no circumstances can the taking of the white oxide of arsenic, either in the form of powder or dissolved in water or other neutral fluids, be attended with accumulation of arsenic in the brain other than in the merest trace; while, on the other hand, the taking of a soluble arsenite should be attended with a proportionally large amount in the brain. It might be argued that in chronic cases of poisoning with arsenious oxide, where the person has for weeks or months been taking small or gradually increasing doses of the oxide, the poison might then accumulate in the brain. Such arguments have been made, but the facts at our disposal tend to show the incorrectness of such a theory. On the other hand, the use of the more soluble arsenite (and doubtless all of the other soluble salts of arsenious and arsenic acids) should be attended with a noticeable deposition of arsenic in the brain. The literature of the subject contains but little definite, the amount of arsenic in the brain being generally expressed as a mere trace or in other equally ambiguous terms; implying, however, in the generality of cases, that when present it was only in very small quantity. But recent data on this point are quite decided. E. Ludwig,[5] of Vienna, writing from a large experience on the distribution of arsenic in the organs and tissues of suicides poisoned with arsenious oxide, and likewise in the organs of dogs poisoned with the same form of arsenic, both in acute and in chronic cases, says: "In all experiments it was invariably found that most arsenic was collected in the liver, that in acute cases the kidneys also contained considerable arsenic, while the bones and brain showed but very small quantities of the poison." Ludwig, moreover, states that "in chronic poisoning with arsenic, where death does not result, the poison remains longest in the liver, while from the other organs it is excreted much earlier." Quoting one of his cases, that of a suicide, an acute case of poisoning with arsenious oxide, the following results are worthy of notice:

1,480	gm. of	liver	contained	51.90	mgm.	of arsenic (As.)
144	"	kidney	"	7.09	"	"
600	"	muscle	"	.78	"	"
1,461	"	brain	"	.59	"	"
		bones	"	only a trace.		

In 1880, the writer,[6] in conjunction with Professor Johnson, reported on two cases of poisoning with arsenious oxide, in which the poison was detected and determined in all parts of the body. In one case there was no question whatever as to the form in which the poison was taken, for a mass of the white oxide was found undissolved in the stomach itself. Here there was present in the stomach, liver, and other internal organs, 83.9 grains of the poison, while the brain contained a hardly perceptible trace of arsenic. It would thus appear that the *amount* of the poison taken has little influence on the amount absorbed by the brain. In this particular instance there was as large an amount to draw upon as is often found in cases of poisoning, yet the quantity contained in the brain could not have been much smaller and been recognizable. The length of time, however, intervening between the taking of the poison and death was probably not long, although there had been time for decided absorption by the liver and other organs. In the second case referred to, where there was decided evidence of chronic poisoning, a somewhat similar result was obtained. In this case there was present in the entire body 5.22 grains of arsenious oxide, most thoroughly and evenly distributed, even to the bones, and yet the brain contained only an unweighable trace of the poison. Again, experiments carried on in the writer's laboratory, on animals have led to the same result; whenever the animals have been fed with arsenious oxide, the amount of arsenic found in the brain has been extremely minute, while in poisoning with a soluble arsenite a much larger amount has been found in the brain. At one time it was considered that the presence of arsenic in the brain was proof positive of the ante-mortem character of the poison; that in no case would the poison, introduced into the stomach or rectum after death, find its way by osmosis to so remote a part as the brain. Sutton,[7] however, by experiments conducted on dead animals, finds that arsenic may pass by diffusion quite rapidly even to the brain. Such being the case, the only way to distinguish between ante- and post-mortem introduction of arsenic would be to determine the amount of poison contained, for example, in the outer portions of the liver, as compared with the percentage amount in the centre of the organ. Guareschi[8] has also reported on the distribution of arsenic in a case of poisoning with arsenious oxide, and he likewise found only traces of the poison in the brain. Many other cases of poisoning with the more insoluble forms of arsenic, in which the distribution of the poison has been studied, lend favor to this view, that arsenic is to be found in the brain in any quantity only when the poison has been taken in a readily soluble form. One case which came under the writer's observation is particularly important in this connection. A laboring man ate for his dinner a quantity of bean soup; almost immediately after he was seized with the ordinary symptoms of acute arsenic poisoning, and died in nine hours. The autopsy showed a marked condition of inflammation of the alimentary tract, and a chemical analysis showed 76.0 mgm. of arsenic in the liver, 0.6 mgm. in the kidney, while one-half of the entire brain contained only a recognizable trace of the poison. A portion of the soup (125 c.c.) yielded 314.6 mgm. of arsenious sulphide, while the fact that the arsenic was introduced in the form of arsenious oxide was proved by finding in the sediment from the soup an abundance of the octahedral crystals of the oxide. Such a case as this must necessarily carry considerable weight with it. Everything favored the absorption of the arsenic, yet the brain contained only the merest trace. Again, the writer has obtained like results in an acute case of poisoning with Paris green, or aceto-arsenite of copper, in which the liver (2,984 gm.) was found to contain 12.7 mgm. of arsenic; the kidneys (515 gm.), 3.4 mgm.; 735 gm. of muscle, 0.9 mgm., and the brain (1,179 gm.) only a slight trace. These results certainly indicate that the relative distribution of the poison may offer some suggestion as to the form in which the poison was administered, and that, with arsenic at least, a comparatively large amount in the brain may be indicative of a readily soluble form of the poison. In this connection, however, there are always other facts to be learned in the distribution of the poison, which may substantiate the indications obtained by analysis of the brain, and at the same time, perhaps, enable us to distinguish between an acute and a chronic case of poisoning.

It is a favorite defence in poison cases, particularly with arsenic, morphine, and some other poisons, to claim that the poison found in the body of the deceased came from some hypothetical medicine containing the poison, and which the deceased had long taken, or that the person was habituated to the daily use of the toxic agent. A study of the distribution of arsenic in acute and chronic cases of poisoning shows plainly that many times, with this poison at least, it is quite possible to decide definitely whether the poison has been for a long time in the body, taken in oft-repeated doses, or whether it has been introduced in one or two large doses.

As preliminary to a discussion of this point I will quote two results of my own experience.

(*a*) In this case there was every reason to suppose a case of chronic poisoning with arsenious oxide. The following results were obtained by analysis of the parts a year and a half after burial:

	Weight of organs. Grams.	Weight of arsenic. Grams.	Per cent.
Stomach and spleen	514	0.05359	0.01040
Kidneys	80	.00660	.00825
Liver	590	.01788	.00811
One lung and heart	441	.01451	.00329
Intestines and uterus	978	.02582	.00260
One lung and liquid from thorax	402	.00583	.00140
Bladder	73	Trace.	....
Brain	477	Trace.	....

Digitized by Microsoft®

	Weight of organs. Grams.	Weight of arsenic. Grams.	Per cent.
Upper arm (left)	665	.00542	.00081
Forearm "	[illegible]	.00158	.00055
Hand "	150	.00019	.00012
Lower leg (right)	1,323	.00864	.00065
Thigh "	3,160	.01635	.00051
Foot "	468	.00105	.00022
Thigh bone "	615	.00040	.00006
Transverse section of body above pelvis	1,920	.03011	.00156
Muscle and ribs from left breast	406	.00371	.00091
Abdominal muscle, right side	615	.00358	.00058

(*b*) In this case the evidence pointed to acute poisoning with some readily soluble form of arsenic. Following are the results obtained by analysis:

	Arsenic as As_2O_3. Grain.
Stomach and œsophagus *	0.158
Large and small intestines	.314
Liver (one-half)	.109
Kidneys	.029
Heart (one-fourth)	.028
Lungs and spleen (two-thirds)	.114
Brain (one-third)	.025
Diaphragm	.010
Trachea, larynx, and tongue	.081

* The internal organs were preserved separately in alcohol, hence the weights of tissue analyzed are not given.

	Weight of tissue. Grams.	Weight of arsenic. Grams.	Per cent.
Left arm	1,230	0.00609	0.000495
Right leg	4,650	.00764	.000164
Thigh bone	216	....	....
Transverse section of body at pelvis	4,060	.01205	.000296
Muscle from breast (right)	510	.00635	.00124
Muscle from back (left)	620	.02306	.00371

In (*a*) the total amount of arsenic was 5.26 grains, in (*b*) 3.119 grains; yet it is to be noticed in (*b*) that the brain contained a comparatively large amount of arsenic, while in (*a*) there was found only a trace. This fact, if our theories concerning absorption by the brain are correct, would imply the administration of a soluble form of the poison. Further comparison of the two series of analyses shows other noticeable points of difference which point to the same conclusion, and also throw some light on the character (acute or chronic) of the poisoning.

When there has been time for even distribution of the poison, as in chronic cases, there would seem to be no reason why one set of muscles should contain more arsenic than another, aside from such differences as might arise from differences in vascularity, etc. On the other hand, there is every reason for supposing that when death ensues only a few hours or less after the poison has been taken, the distribution might be quite irregular.

The following table shows the distribution of the arsenic through the muscle tissue in the two cases, calculated to *grains of* As_2O_3 *per pound* of tissue:

	(*a*)	(*b*)
Thigh bone	0.004	....
Leg	.033	.011
Transverse section	.109	.021
Arm	.046	.034
Muscle from breast	.063	.087
Muscle from back	....	.260
Muscle from abdomen	.040	....

In (*a*) the results, with the exception of the transverse section, show a fairly close agreement. There is not that gradual increase from nothing in the bone up to a fourth of a grain per pound as seen in (*b*). The irregular distribution of the poison in tissue of the same kind, noticed in (*b*), is certainly indicative of the arsenic having been taken but a short time before death, particularly as there was none whatever found in the bones, which fact would certainly exclude the possibility of chronic poisoning.

Again, in (*b*) the two kidneys yielded only 1.5 mgm. of metallic arsenic, while the tongue and adjacent parts (175 gm.) gave 4 mgm., and a portion of the muscles (200 gm.) gave 5.65 mgm. of metallic arsenic.

Assuming the usual order of distribution, the amount of arsenic in the kidneys in (*b*) would suggest only a proportionally smaller amount in the muscles; and yet in this particular instance the amount of arsenic contained in 620 gm. of muscle tissue is greater than the amount contained in the entire liver and kidneys together. The kidneys, however, are the organs above all others concerned in the elimination of arsenic. Elimination usually commences almost immediately, and yet in this particular case there is but 0.029 of a grain of arsenic in the kidneys, while in less than three pounds of muscle tissue there is contained half a grain of the poison. This fact would necessarily imply that elimination had but just commenced, and that consequently the poison had not been long taken. It might, perhaps, be argued that the proportionally large amount of poison contained in the muscles, as compared with the liver and kidneys, might imply chronic poisoning, but coupled with the peculiar distribution is the entire absence of arsenic from the bones. Ludwig, moreover, states that in "both acute and chronic poisoning with arsenious oxide, most arsenic is invariably found collected in the liver," and that "in chronic poisoning with arsenic, where death does not result, the poison remains longest in the liver, while from the other organs it is excreted much earlier." It is impossible, therefore, to make the results obtained in (*b*) accord with a case of chronic poisoning with arsenious oxide; and further, the amount of poison found in the brain, and the proportionally large amount in certain muscles, would apparently indicate an extremely soluble and diffusible form of arsenic as the toxic agent.

Such results as these certainly favor the belief that it is quite possible to draw definite conclusions as to whether we are dealing with an acute or a chronic case of poisoning. Further than that, it is possible, in some cases, to decide even more definitely regarding the time at which the poison was taken prior to death. In this connection, the fact to be considered most closely is the amount of poison contained in the liver, as compared with the amount present in the alimentary canal and in the different organs of the body. When arsenic, for example, is taken into the stomach, absorption by the liver through the portal circulation commences almost immediately; and, as Dr. Geoghegan[9] has plainly demonstrated, deposition of arsenic in the liver continues to increase up to about fifteen hours after the poison has been taken, after which it commences to diminish. Dogiel,[10] who has confirmed Geoghegan's results as to the time required for maximum saturation of the liver, says, "a maximum of arsenic in the liver kills the animal." The absolute amount of arsenic involved in maximum saturation of the liver must necessarily vary somewhat in different cases. Barker,[11] from his analysis of portions of the liver of Horatio Sherman, concluded that the entire liver contained nearly five grains of arsenic. In the case of Dennis Hulburt, also analyzed by Professor Barker, the liver contained over seven grains of arsenic, and it would seem as if these amounts must approach near to the maximum. When such large amounts of the poison are found in the liver, it is safe to assume that the poison must have been taken at least fifteen hours before death.

In recent cases of administration of arsenic, it has been claimed by Taylor[12] that the poison may be found in the stomach and intestines, and not in the liver or other organs. This can hardly be correct under ordinary circumstances, since death seldom results so quickly from arsenical poisoning as to prevent the absorption of at least a small trace of the poison by the liver. Dogiel,[10] who has experimented somewhat on the rapidity of absorption by the liver, found that on forcing 500 mgm. of arsenious oxide dissolved in water, into the stomach of a dog, death resulted in one hour and five minutes. In a second experiment, conducted in the same manner, death

Digitized by Microsoft®

resulted in one hour and thirty-eight minutes. In the first case the liver was found to contain 94.5 mgm. of arsenious oxide; in the second case, 137.8 mgm. Thus, judging from the amount in the liver at the end of an hour, certainly but a few minutes would have been required for the absorption of a detectable quantity of arsenic.

Arsenic having been deposited in the liver or elsewhere, gradually diminishes, and if the person should survive, entirely disappears in from two to three weeks. A case bearing directly on this point came under the writer's notice some time ago. An entire family were taken sick, directly after eating, with all the symptoms of arsenic poisoning; all of them recovered except one, a middle-aged man, who died just two weeks after partaking of the poisoned food. An autopsy was made, the internal organs were delivered to the writer for analysis, together with the various articles of food partaken of by the family at the time of their sickness. A portion of the bread (786 gm.) contained 32.7 grains of arsenious oxide, while a piece of cake (166 gm.) was found to contain 55.5 grains of arsenious oxide, thus proving the character of the poison.

Analysis of the internal organs gave the following results, showing that at the time of death elimination was nearly, but not quite, complete:

Stomach (365 gm.)	contained	0.10 mgm.	arsenic	(As).
One-third liver (428 gm.)	"	.20	"	"
One kidney (283 gm.)	"	.15	"	"
One-half intestine (487 gm.)	"	.20	"	"
Thigh muscle (389 gm.)	"	.25	"	"
One-half brain (390 gm.)	"	trace	"	"

Concise experiments on animals, carried out quantitatively, are capable of yielding many instructive results in reference to the relative distribution of a poison under different conditions. The writer has recently conducted a series of experiments with antimony,[13] a few of the results of which may be advantageously given, as confirmatory of some of the preceding statements.

(*a*) *Hypodermic Injection of a Solution of Tartar Emetic.* —0.120 gm. of tartar emetic was introduced under the skin (right thigh) of a cat weighing 1,262 gm. The animal died in two hours. Following is the distribution of the poison:

	Total weight. Grams.	Weight of Sb. Milligrams.	Sb. per 100 gm. of tissue. Milligrams.
Liver	52.0	6.35	12.21
Brain	27.5	.60	2.18
Heart and lungs	32	.70	2.18
Kidney	12	.15	1.25
Stomach and intestines	74	.80	1.08
Muscle from back	138	1.25	.90
	335.5	9.85	....

In a second experiment a smaller amount of tartar emetic (0.082 gm.) was injected hypodermatically, and instead of being introduced in a single dose, it was divided into three, and injected separately, several hours apart. As a result, the animal lived twenty-two hours after the first dose. The following results show the distribution of the poison:

	Total weight. Grams.	Weight of Sb. Milligrams.	Sb. per 100 gm. of tissue. Milligrams.
Kidneys	11.5	0.60	5.21
Liver	63	1.50	2.38
Brain	9	.20	2.22
Stomach and intestines	98	2.00	2.04
Heart and lungs	17	.25	1.47
Muscle from back	106	.70	.66
	304.5	5.25	....

The only difference of importance between these two cases is the element of time. As might naturally be expected, therefore, there is a more even distribution of the poison in the second case than in the first. Further, in the second case the kidneys stand first in their content of antimony, the liver contains a proportionally smaller amount—much smaller proportionally than was found in the first case. This is, of course, due to the fact that in the second case the animal had lived long enough to admit of extensive elimination, and, consequently, those parts which had originally contained the most, particularly the liver, had been drawn on to the greatest extent; so that at the time of death the excretory organs, notably the kidneys, were the richest in poison. Quite noticeable in both of these cases is the comparatively large amount of antimony in the brain—which fact would agree with the previous statements regarding absorption by the brain when a readily soluble and diffusible form of poison is used.

(*b*) *Injection of a Solution of Tartar Emetic per Rectum.* —0.24 gm. of tartar emetic, dissolved in a little water, was injected into the rectum of a rabbit, in two doses. Death resulted in about twelve hours. Following was the distribution of the poison:

	Total weight. Grams.	Weight of Sb. Milligrams.	Sb. per 100 gm. of tissue. Milligrams.
Stomach and small intestines	172	8.89	15.30
Brain	9	.40	4.40
Rectum and adjoining intestines	18	.55	3.05
Liver	54	1.60	2.96
Kidneys	13	.25	1.92
Muscle	100	1.10	1.11
Urine	20	.20	1.10
Heart and lungs	17	Trace.	....
	403	12.99	....

Perhaps the most noticeable feature of these results is the comparatively large amount of antimony contained in the stomach and small intestines; a result which, taken in conjunction with other similar ones, would appear to indicate special absorptive action on the part of the epithelial cells of these parts. The amount of antimony in the kidneys, and particularly the amount in the urine, indicates plainly that at the time of death elimination was going on rapidly; but the fact that the percentage content of antimony in the liver was greater than in the kidneys, might perhaps be taken as an indication that absorption was not completed.

(*c*) *Experiment on a Dog with Antimonious Oxide.*—A dog weighing 14.2 kgm. received, with his food, 2.073 gm. of antimonious oxide, during a period of seventeen days, in doses of from 0.032 to 0.125 gm. per day. The dog was then killed by chloroform eighteen hours after the last dose of antimony had been given. The following results show the distribution of the poison:

	Total weight. Grams.	Weight of Sb. Milligrams.	Sb. per 100 gm. of tissue. Milligrams.
Liver	452	23.7	5.24
Lungs	140	1.8	1.28
Muscle from [illegible]	157	1.2	.76
Brain	79	.4	.50
Muscle [illegible]	200	.9	.45
Kidneys	82	.1	.12
Heart	117	Trace.	....
Blood	440	Trace.	....
	1,667	28.10	....

In this experiment, which may be termed a chronic case of poisoning with an insoluble form of antimony, the relative distribution of the poison is seen to be somewhat different from what it was in the preceding cases. First, the brain contains relatively less antimony than in

Digitized by Microsoft®

the preceding; secondly, the liver contains a noticeably large amount of the poison, while the kidneys contain only a trace. This latter result would seem to indicate that elimination was going on quite slowly; but analysis of the twenty-four hours' urine showed that the amount eliminated by the kidneys in one day was considerable. Thus on one day, the entire twenty-four hours' urine contained 13.5 mgm. of metallic antimony; on another day, 22.5 mgm.

www.libtool.com.cn

With copper, Ellenburger and Hofmeister have found, by experiments on sheep,[14] that the liver contains the most copper when small doses have been regularly administered, and, further, that this organ retains the metal with the greatest tenacity, they having found it there forty-one days after the last dose. The pancreas was also found to retain the copper with nearly equal tenacity; the kidneys do not contain so much of the poison. Elimination is mainly by the bile or through the intestine. Deposition of copper in the nerve tissue is quite small, but still smaller in the muscles, though copper is to be found in the muscles after administration of copper salts. Ellenburger and Hofmeister also state that the deposition of copper is proportionally much greater if it is administered in numerous small doses, the cells then having time to absorb it.

With lead, Victor Lehmann[15] has obtained some interesting results. In his experiments the lead was introduced by hypodermic injection in the form of nitrate, the animals used being rabbits. Two of his series of results are given in full.

(*a*) 0.5 gm. of lead nitrate introduced at one dose.

(*b*) 0.01 gm. of lead nitrate introduced daily, until finally a total of 0.21 gm. of the lead salt had been injected.

Distribution of Lead in (*a*)

	Weight of the organ. Grams.	Content of lead. Milligram.	Lead per 100 gm. of tissue. Milligrams.
Liver	40	0.250	0.625
Kidneys	13	.625	4.807
Heart	3	.125	4.166
Lungs	6	.125	2.083
Intestine	16	.312	1.953
Muscle	30	.187	.625
Bones	7	.187	2.678
Brain	8	.062	.781
Bile	3	.125	4.166

Distribution of Lead in (*b*).

	Weight of the organ. Grams.	Content of lead. Milligram.	Lead per 100 gm. of tissue. Milligrams.
Liver	25	0.062	0.250
Kidneys	4	.125	3.120
Heart	5	.187	3.750
Lungs	2	.062	3.125
Intestine	7	.125	1.785
Muscle	10	.031	.312
Bones	3	.125	4.166
Brain	3	.125	4.166
Bile	2	.125	6.250

Very noticeable in both series is the small content of lead in the liver, an organ which, as a rule, contains the largest amount of absorbed poison. The relatively large amount of lead in the bile naturally suggests that the elimination of the metal takes place mainly through this channel, which would account for the small content of metal in the liver. Further, experiments conducted on rabbits show plainly that more lead is excreted in the fæces than in the urine, the lead in the former doubtless coming from the bile poured into the intestines. Quite noticeable also is the large amount of lead in the bones, which amount probably grows larger the longer the lead has time to act.

Naturally, such systematic work as has been done in studying the relative distribution of poisons has been confined mainly to mineral substances, but it is to be hoped that the time will come when there will be a collection of data embracing all poisons capable of detection by chemical means. When such a time does come, it will doubtless be found that we cannot establish any general laws regarding the relative absorption and distribution of poisons as a class, but rather that each individual poison or group of poisons will show some peculiarity characteristic of itself—which possibility, or rather probability, makes it all the more needful for us to acquire, as speedily as possible, accurate knowledge of the relative absorption and distribution of the individual poisons.

Post-mortem Imbibition of Poisons.—Ante-mortem distribution of poisons is, as we have seen, due to the carrying power of the blood and lymph. Poisons are absorbed, distributed, and temporarily deposited. Poisons may, however, travel through the *dead* body, after circulation has ceased, by a process of imbibition or diffusion, by the same method as that by which salt works its way gradually through a barrel of fresh pork when placed on the upper layers. The rate of imbition of poisons depends in large measure upon the interval elapsing between the death of the body and the introduction of the poison. Arsenic, for example, introduced into the rectum shortly after death, before the tissues have become rigid, travels with a fair degree of rapidity and in time may be found in distinct traces even in the brain and spinal cord, while in the abdominal organs the amount present may be quite large. Where a long interval elapses after death, the poison introduced post mortem travels more slowly, but even in this case it gradually penetrates to remote parts. In view of these facts, it is obvious that in cases of poisoning where a surplus of the poison remains in the gastro-intestinal tract after death, and the body is buried for some time prior to the autopsy, the apparent ante-mortem distribution of the poison is liable to modification by post-mortem imbibition. This is an important fact to be kept in mind in drawing conclusions from the analytical data, especially in cases in which a large surplus of the poison is unabsorbed. With metallic poisons, however, putrefaction may quickly put a stop to post-mortem distribution, since the formation of hydrogen sulphide from the decomposing proteid material is very liable to transform the metallic salts into insoluble sulphides, thereby preventing further migration. *R. H. Chittenden.*

POKE ROOT AND BERRY.—*Phytolaccæ radix*, and *Phytolaccæ fructus* (U. S. P.), Scoke, Garget. These two drugs are defined respectively as "the dried root" and "the fruit" of *Phytolacca decandra* L. (fam. *Phytolaccaceæ*).

This plant is a very large perennial herb with a thick, fleshy root and bearing cylindrical racemes of dark purple juicy berries. The root, at the crown, attains a diameter of several inches and divides into two or three large branches. It is brownish-white externally and faintly yellowish-white internally. It bears quite a close general resemblance to horseradish, a fact which has led to numerous fatal poisoning accidents. The stems, when young, are bland and juicy and are used by country people in some localities as a pot-herb. They at length attain a height of 1 to 2, in the Southern States 3 or 4 metres, are at first green, afterward red or purple,

Digitized by Microsoft®

branched widely, are smooth and cylindrical and hollow when old, though with thin transverse partitions. The leaves are large, alternate, petioled, ovate or oblong, entire and smooth. The flowers are in terminal racemes, becoming lateral and extra-axillary by the growth of the stem. They are regular and perfect, having five sepals, ten stamens, and a ten-celled ovary. The fruit contains ten thin putamina, enveloped in a purple flesh, and each containing a single seed. The fruit, when fresh, is about 1 cm. ($\frac{3}{8}$ in.) broad.

www.libtool.com.cn

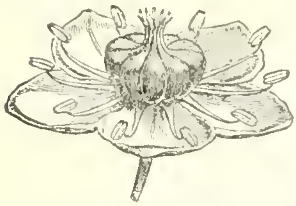

FIG. 3873.—Poke Weed Flower.

For medicinal purposes the root is gathered in the autumn, sliced lengthwise or crosswise, and dried. The berries are gathered when ripe and dried in the sun, in masses.

Description of the Root.—Consisting mostly of transverse or longitudinal slices of sparingly branched, cylindrical, somewhat tapering, usually twisted roots, rarely exceeding 7 cm. (3 in.) in diameter, externally of a rich or yellowish-brown, finely wrinkled (longitudinally or spirally) and thickly annulate with lighter-colored, low ridges; transverse slices exhibiting several concentric rings of interrupted wood wedges, the intervening zones much retracted; longitudinal slices exhibiting the wood bundles as bands, with the intervening medullary tissue greatly retracted; fracture fibrous; internally yellowish-gray; inodorous, the powder highly sternutatory; taste sweetish, afterward highly acrid.

The Fruit.—The dried fruit forms a close and heavy, agglutinated, purple black mass, the stones conspicuous as brightly shining particles, the odor slight, the taste fruity, but peculiar, acidulous and sweetish, somewhat acrid. The structure of an individual fruit is given above.

Poke root contains an actively poisonous, bitter and acrid, amorphous glucoside, which is believed to be saponin, a small amount of the white crystalline alkaloid *phytolaccine*, large amounts of sugar and starch, gum, a little fat, resin, etc. The tannin has been called *phytolaccin*. *Phytolaccic acid* occurs in the root and is, next to the coloring matter, the most important constituent of the fruit.

ACTION AND USE.—All parts of the adult plant are active, and cause in sufficient doses vomiting and purging. It has also some narcotic or stupefying power, and in poisonous doses causes, in addition to the intestinal symptoms, convulsions and coma. Death frequently follows. Its action is slow and protracted. Poke root has been administered as an emetic, but the practice is exceedingly bad. It is also recommended in rheumatism, scrofula, inflamed breasts and testicles, and as a dressing for cancers and indolent ulcers, but is in very little favor in regular practice, probably not nearly so much as its properties warrant. Enough may be absorbed from washes and ointments to produce its constitutional effects. It is said to be useful as a parasiticide in sycosis, tinea capitis, the itch, etc., but there are doubtless many better drugs for this purpose.

The Pharmacopœia, with very poor reason, provides a fluid extract of the fruit but no preparation of the root, of which latter the best form of administration is the fluid extract. The root has been given in 1 gm. (gr. xv.) doses as an emetic, as an alterative in doses of 0.06 to 0.3 gm. (gr. i. to v.), and the dose of the fluid extract should correspond. The fruit and its fluid extract are given in doses five or six times as large. The juice of the fresh fruit is often administered in country practice in doses of 2 to 4 c.c. (fl ʒ ss.–i.), but its action is very weak indeed.

Henry H. Rusby.

POLAND SPRINGS.—Androscoggin County, Maine. —POST-OFFICE.—South Poland. Springs Hotel.

This resort is located in the town of Poland, twenty-five miles north of Portland and ten miles west of Lewiston, at an elevation of about 800 feet above the sea-level. Poland is reached from Boston by the Boston and Maine Railroad. The spring boils up from a fissure near the crest of a magnificent mound of the oldest rocks at the rate of about eight gallons of water per minute. The bed of the spring is composed of gneiss, scarcely distinguishable from the original granite, this gneiss being, as the geologists inform us, the oldest of the sedimentary rocks. The unvarying temperature of the water throughout the year, as well as its freedom from organic matter, would indicate a very deep origin. The surroundings of the spring have been extensively improved since 1859, in which year, it is said, the water was first described by a physician. The Poland Spring House was erected in 1876, and after various alterations and additions reached its present proportions in 1889. It is situated upon an elevated plateau, and commands a beautiful and diversified view of the surrounding landscape. The analysis of the water made in 1879 by Prof. F. L. Bartlett, State Assayer and Chemist, resulted as follows: One United States gallon contains: Silica, gr. 1.07; calcium carbonate, gr. 1.36; calcium fluoride, a trace; lithia, a trace; organic matter, gr. 0.28; potassium sulphate, gr. 0.18; sodium chloride, gr. 0.17; alumina, a trace; magnesium carbonate, gr. 0.31; iron carbonate, a trace; sodium carbonate, gr. 0.09. Total, 3.76 grains.

This may be classed as a mild alkaline-calcic water, with very slight ferruginous properties. It has long had an extensive reputation in the treatment of rheumatism, gout, and dyspepsia, and in renal and hepatic disorders. It is best known, however, as a table water, for which purpose it has an extensive sale throughout the United States.

James K. Crook.

POLARIMETRY.—Polarimetry is the measurement of the angle of rotation of a ray of polarized light, and instruments adapted to the purpose are termed polarimeters. Polarized light is light which (as explained by the accepted theory) has been changed so that vibrations transverse to the path of propagation have been reduced to a single plane. By this change the rays become much more susceptible to interference and may be used for detecting difference of structure not appreciable to ordinary light. Polarization may be brought about by reflexion or refraction of ordinary light, and also by direct transmission through some substances, such as tourmaline, Iceland spar, and quinine iodosulphate. Of these, Iceland spar is the only practicable material, and all laboratory instruments employ it. The crystal in its natural state, composed of pure calcium carbonate, is rhombohedral and double-refracting, that is, a ray passing into the crystal is split into two rays, both of which are polarized. For the best results in polarimeters the crystal is cut in an oblique direction and the pieces are re-cemented in their original position with Canada balsam. By this means one of the polarized rays is prevented from passing through, while the other is transmitted. A crystal so prepared is called a Nicol's prism. When a ray of light, white or of any color, passes through this prism, it will not be completely transmitted through a second similar prism unless the latter is placed in the same relative position, or 180° of arc from it. At any intermediate position, more or less of the polarized ray will be intercepted, and at a 90° position—technically termed "crossed nicols"—only traces of the light pass. Many substances possess power to affect the ray in such a way that when they are placed between the nicols, these must be turned slightly from the above angles to get the maximum effect of transmission or obstruction, and such an effect is believed to be due to the fact that the intervening body twists the plane of vibration of the polarized ray, and the second nicol has to be twisted to compensate for this. Any substance which possesses this twisting (rotating) power is termed "optically active." The degree of rotation is fairly constant for any given substance under definite conditions, and hence the amount of an optically active substance may be meas-

Digitized by Microsoft®

ured by measuring the extent to which the nicols have to be adjusted in order to correct the rotation produced.

In the actual construction of polarimeters many details have to be regarded in order to secure delicacy and accuracy. Many forms have been devised, but only a few are now employed. In all these a beam of light passes through a Nicol's prism, called the "polarizer," then through the substance to be tested, then through another Nicol's prism, called the "analyzer," and then to the eye. As the mind cannot carry a recollection of the exact brightness of a field of light, some comparison is provided as a zero point, and the degree of alteration of the analyzer required to bring the whole field to uniformity is the measure of rotation. Substances differ as to the direction in which the light is rotated. When this rotation is such that the analyzer has to be moved to the right in order to compensate, the substance is termed dextrorotatory and designated +; when the opposite effect is produced the substance is termed lævorotatory and designated —.

The adjustment of the analyzer to restore the zero may be made by the direct rotation of it, and the extent measured in degrees of arc; but in the instruments now usually employed the compensation is made by means of superposed wedges of quartz, which are shifted horizontally to the right or left as required and the amount of shifting indicated on an arbitrary scale termed the "sugar scale." This is graduated and adjusted so that if a solution containing 26 gm. of pure cane sugar dissolved in sufficient water to make a volume of 100 c.c. at 20° C., is examined in the instrument, the rotation will correspond to 100. This scale has been introduced because the principal use of the polarimeter is the determination of the amount of cane sugar in raw sugar and syrups. It enables the analyst to read directly the percentage, but this applies to cane sugar only. For some purposes, monochromatic light must be used, for which a non-luminous gas flame charged with some sodium salt is the best. This gives a pure strong yellow light. The common polarimeters are now constructed to use white light from any ordinary source.

Fig. 3874 shows a form that is now extensively used, the Landolt-Lippich polarimeter, as made by Schmidt & Haensch, of Berlin. *K* is a lens and mirror for illumination and reading the scale. *J H* is the analyzer with the compensating quartz wedges. The details of the optical train are also shown in outline. At the polarizing end, also shown in detail, a large Nicol's prism, which receives and polarizes the light from the lamp, bears in front two small similar prisms, so arranged that the central rays are unaffected by them. By this means is obtained a field uniformly illuminated when the adjustment is at zero; but when any rotating body is introduced, the central segment becomes darker or lighter than the side segments. In a cheaper form of the instrument only one accessory prism is used, and a "double field" instead of "triple field" is obtained. The material to be examined is dissolved in a suitable solvent, clarified if necessary, and a portion placed in a tube of known length closed by glass caps. On now viewing the field, any rotation of the ray will be marked by a contrast in illumination, and to restore the uniformity the quartz wedges must be shifted more or less. A given substance has usually constant rotating power under given conditions, but temperature, density of solution, nature of solvent, and many other factors produce variations. Some bodies have a high rotation when freshly dissolved, but fall off much when allowed to stand or when heated to boiling. This abnormal effect is termed "birotation." Milk sugar shows it to a high degree. In order to make comparisons between different bodies, a factor termed

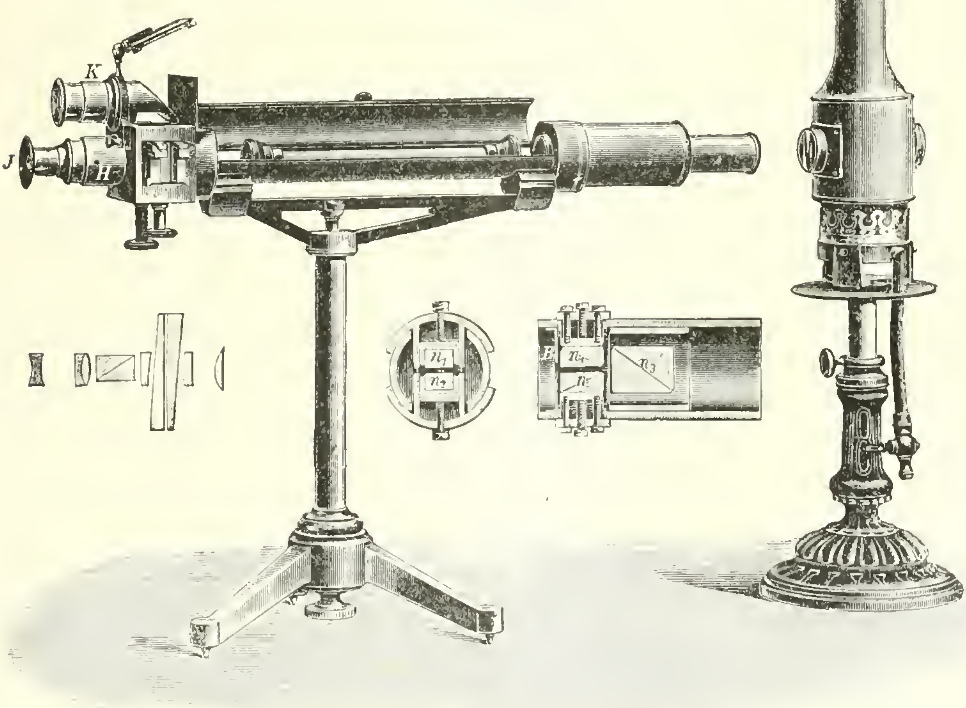

FIG. 3874.—Triple Field Polarimeter with Details of Polarizing and Analyzing Apparatus. (With permission of Eimer & Amend, New York.)

Digitized by Microsoft®

specific rotatory power, indicated by $[a]$, is calculated by the formula $\frac{100a}{cl}$, in which a is the angular deviation observed; c the number of grams of the substance in 100 c.c. of solution; and l the length, in decimetres, of column of liquid examined. As the rotation differs somewhat with light of different colors, the specific rotatory power is now usually given for yellow light corresponding to the D line of the solar spectrum (see *Spectroscope*), and the symbol is written $[a]^D$. In practice certain weights, termed "normal weights," of material are employed. At the International Commission for Uniform Methods of Sugar Analysis held at Paris, 1900, it was agreed that the normal weight "shall be 26 gm. of pure sugar weighed in air with brass weights," and dissolved in 100 true cubic centimetres. Though the principle of the operation of these instruments is simple, yet accurate results are obtained only by much care and experience.

The expense of the standard form of polarimeter has led to efforts to construct cheaper forms for clinical use. The instrument of von Fleischl has met with most favor. It employs white light and is so constructed that two spectra are shown at once with a dark band in each, the two being coincident when there is no rotating body; but one of the bands is displaced when a rotating body is introduced, and the analyzer can be revolved until the coincidence is restored. The instrument is graduated so that the percentage of rotating body can be read off directly. It is constructed for estimation of sugar.

Clinical Applications.—Polarimeters are of but limited application in clinical diagnosis. Apart from the expense, the conditions interfering with accuracy are numerous. Practically, the estimation of sugar in diabetic urine is the only medical use made of them. Albuminous substances rotate polarized light, but the fact has no diagnostic value. Diabetic urine is apt to contain several optically active bodies, not all of which are dextrorotatory; hence the observed reading will be a resultant of all the actions. The polarimeter may be of use in making routine tests in a given case to determine the effects of treatment; but even then it will be necessary to check occasionally by the chemical tests which can now be performed with ease and celerity, and with sufficient accuracy for clinical purposes.

Urine, as a rule, will require clarification and decolorization for examination in the polarimeter. A solution of lead subacetate is commonly employed; 50 c.c. of the sample are added to 5 c.c. of the official solution, the liquids well mixed and filtered through a dry filter. The first 10 c.c. are rejected and the examination is made on the next portions. The dilution must of course be allowed for by increasing the reading ten per cent.

Henry Leffmann.

POLYCHROMATOPHILIA.—(*Polychromasia.*) The term applied by Ehrlich to that condition of the red cells in which they take, not only the diffuse stain, but also the nuclear, so that they exhibit a bluish red or violet tinge, or may even take a deep blue stain when stained with hæmatoxylin and eosin, or methylene blue and eosin. By Ehrlich and others this phenomenon is regarded as essentially degenerative, a progressive "coagulation necrosis," whereby the cell loses its affinity for acid stains. They are supported in this view by the presence of such cells shortly after hemorrhage and in starving animals, and by the polychromatophilic character of megaloblasts. Further, cells showing this characteristic are usually ragged in contour or show vacuoles. On the other hand, Askanazy and others hold that the polychromatophilic cells are the *youngest* cells of the blood, and are not degenerating forms. This view is based chiefly upon the fact that a large portion of the red cells of the fœtus are polychromatophilic. According to Sherrington, the brownish color frequently seen in red cells is to be regarded as due to an incomplete oxidation of hæmoglobin. Ewing would regard this as a form of polychromatophilia and would limit the term polychromasia to this diffuse brownish color of the cell, which occurs in anæmias and is also seen in the normal marrow. On the other hand, he would class the bluish-staining granules and areas in red cells, originally designated as polychromatophilia, with Grawitz's *granular degeneration* of red cells. Even though the phenomenon be proved to be identical in significance with the last-named, it would appear best to use the term polychromatophilia in its original application by Ehrlich, and not to transfer it, according to Ewing's suggestion, to an entirely different process.

Aldred Scott Warthin.

POLYCYTHÆMIA.—The increase in number of the red blood cells, due either to an absolute increase in the number of the red cells or to a decrease in the volume of the plasma. An absolute increase in the number of red cells above the normal has not yet been demonstrated to occur. Theoretically, such an increase could be brought about by an increased formation of red cells, or through a longer life of the individual cells. A relative polycythæmia is of frequent occurrence. It occurs in the new-born, and is usually highest before nursing begins, and gradually disappears during the first few weeks. Its cause is doubtless to be found in the temporary concentration of the blood due to various factors. Ewing finds that the polycythæmia bears a rather close relation to the degree of cyanosis exhibited by the expressed drop, and believes that the concentration of blood is principally referable to a state of relative stasis which is established in the peripheral capillaries in the first hours after birth. The average count of red cells in the new-born ranges from 5,368,000 to 6,500,000. Too early ligation of the cord may cause a reduction of 500,000 to 1,000,000 (Hayem and Helot). After nursing begins, the red cells fall about 250,000 a week, until the usual average is reached.

According to many observers there occurs a polycythæmia in individuals residing at high altitudes. The change may take place within twenty-four hours, the increase amounting to a million or more, reaching the limit in two weeks and then remaining permanently high. On return to low altitudes the polycythæmia disappears very rapidly. The percentage of hæmoglobin is less affected, and the volume of the red cells not at all. The phenomenon has been variously explained: by some writers as a compensatory increased production of red cells, by others as due to concentration of the blood, by still others as an error in estimation, due to the fact that the results obtained by the blood-counter are dependent upon temperature and barometric pressure.

Polycythæmia occurs also in the diarrhœal diseases, particularly in cholera, as a result of the concentration of the blood. In chronic dysentery it may be offset by the anæmia produced. Similarly, in typhoid fever the progress of the anæmia may be obscured by the concentration of the blood. A relative polycythæmia occurs also in chronic valvular disease of the heart with passive congestion, in endocarditis, in excessive sweating, in phosphorus poisoning, after cold baths or the application of drugs causing contraction of the vessels (alcohol, etc.), and in cases of poisoning with illuminating gas. In phosphorus poisoning an increase to over 8,000,000 has been observed; it is probably due to the depletion of the blood from vomiting. An increase of 2,000,000 to 3,000,000 may be observed after large doses of salts.

Aldred Scott Warthin.

POLYDACTYLISM.—See *Hands and Fingers, etc.*

POLYFORMIN, INSOLUBLE, is prepared by dissolving resorcin in an aqueous solution of formaldehyde, and adding an excess of ammonia. It is an odorless, tasteless, yellowish brown, amorphous powder, insoluble in all ordinary solvents and rich in formaldehyde. It is used as an antiseptic.

W. A. Bastedo.

POLYFORMIN, SOLUBLE—di-resorcin hexa-methylene-tetramine—occurs in white crystals which are very soluble in water or alcohol, but insoluble in ether or oils.

www.libtool.com.cn
Digitized by Microsoft®

It is decomposed by heating in solution, setting free formaldehyde. Externally, it is employed in parasitic skin diseases, and internally has been used as an antiseptic in the alimentary and urinary tracts and as a diuretic. It is said to appear as formaldehyde in the urine.

W. A. Bastedo.

www.libtool.com.cn

POLYSOLVOL.—Solvin, sodium sulphoricinate—is prepared by acting on castor oil with strong sulphuric acid, adding a solution of sodium chloride, then neutralizing the free acid with soda. It is a thick, clear, light-yellowish oily liquid, insoluble in water, but forming with it a good emulsion. Polysolvol possesses the property of dissolving thirty per cent. of phenol, twenty-five per cent. of menthol, ten per cent. of salicylic acid, and other substances in like proportion.

W. A. Bastedo.

POLYURIA.—(Synonyms: Hyperuresis, Diabetes Insipidus, Diuresis, Essential Polyuria.)

Polyuria means an excessive flow of urine. There are numerous cases in which this occurs temporarily, and is due to dietetic or nervous changes, and a few in which it occurs persistently. The latter are best named *essential polyuria* or *diabetes insipidus*. I shall at the present time describe the latter cases. Instances of persistent or chronic hyperuresis were recognized and described at an early period of medical history, but no attempt was made to classify them. In 1670, however, Thomas Willis discovered the existence of sugar in the urine of some of them, and nearly a century later Sauvages described anew the excretion of sweet urine, as a distinct form of disease, under the name of diabetes anglicus. But it was not until near the end of the eighteenth century that Cullen and P. Frank placed all cases of persistent polyuria in two classes, the one having sugar in the urine and the other none, the first being called diabetes mellitus and the second diabetes insipidus. This distinction has been maintained by all subsequent observers. Diabetes mellitus is now classed with the morbid conditions of assimilation and nutrition. Therefore only the non-saccharine cases, or those of diabetes insipidus, are still thought of as essentially polyurias.

Etiology.—Cases of temporary polyuria are due to a variety of conditions such as the drinking of large quantities of fluid or the eating of excessively large amounts of sugar. It is also caused by such nervous diseases as hysteria and epilepsy. Chronic polyuria has been ascribed to exposure to cold, and to a residence constantly in damp and dark rooms. However, the causative influence of these conditions has not been proved. Injuries affecting the brain and spinal cord, more especially penetrating wounds in the region of the fourth ventricle and medulla oblongata; violent mental emotions and persistent functional diseases of the nervous system are known causes in certain instances. But many cases are on record which can be traced to no special cause. Age evidently exerts a predisposing influence, as shown by the following statistics: Of 242 recorded cases 18 were under five years, 32 between five and ten years, 50 between ten and twenty years, 59 between twenty and thirty years, 42 between thirty and forty years, 20 between forty and fifty years, 13 between fifty and sixty years, and 8 between sixty and seventy years, which is equivalent to 75 per cent. between the ages of five and forty years. Observations in regard to sex show more than twice as many cases in the male as in the female.

There are not a sufficient number of reliable observations on record to justify the conclusion that the disease is hereditary. It seems probable that either a functional or structural disease of the centre in the medulla which controls the blood supply to the kidneys and excretion by them exists in all cases of diabetes insipidus.

Symptoms and Clinical History.—When not the result of direct injuries to the central portions of the nervous system, or of sudden mental emotions, the symptoms of polyuria generally develop slowly and without marked changes, except the gradually increasing quantity of urine which is voided and the correspondingly increased thirst.

When the urine is greatly in excess, the skin appears dry and somewhat shrunken, but much less than in diabetes mellitus. There are some paleness of the features, mental despondency, disturbed sleep, unusual weariness from moderate exercise, excessive appetite for food as well as constant thirst, and frequent eructations and flatulence, with constipation of the bowels. As much as twenty-five to fifty pints of urine may be voided daily. In most cases the specific gravity of the urine is diminished in proportion to the increase of its quantity, varying from 1.001 to 1.008. The fluid is nearly colorless. Its reaction is often neutral or feebly alkaline. Therefore it readily undergoes decomposition. Although the amount of solids in the urine is small, the proportion of urea is often great. A considerable thirst is felt and the mouth and lips rapidly become parched. Appetite is variable. A moderate loss of flesh is the rule, but such patients do not become emaciated. In spite of an appearance of average plumpness these patients lack endurance and ambition. When the disease is not caused by, or associated with, injuries or structural diseases of the brain or spinal cord, it may continue many years, and rarely proves fatal unless from the nature and extent of complications. Some cases have been observed to present great variations in their progress, the quantity of urine sometimes diminishing to the normal, with corresponding improvement in other symptoms, and then increasing again. In some cases exacerbations are traceable to unusual mental or nervous excitement, in others to exposure to cold and damp air, and in still others to excesses in eating and drinking.

During the active progress of essential polyuria the increased quantity of urine consists entirely of water, while the quantity of the other natural constituents voided in the twenty-four hours remains nearly the same as in health.

This explains why the waste of tissues and impairment of health is so much less in this form of disease than in diabetes mellitus, even when the actual quantity of urine discharged in the twenty-four hours is greater in the former than in the latter. The condition of the digestive organs varies much; sometimes food is imperfectly digested, causing acid and gaseous eructations, flatulency, and constipation, alternating with diarrhœa. These symptoms, however, appear to depend more directly on the morbid conditions that have caused the polyuria or have existed as complications, than upon the excessive flow of urine.

Prognosis.—The duration of the disease depends almost entirely upon the nature of the causes and complications. Those cases which are associated with diseases or injuries of the cerebral and spinal centres usually either recover or prove fatal at an early period, while those which are dependent upon chronic functional disorders may continue for many years. R. Willis has left on record a case that continued for fifty years, and Neuffer one that ended fatally in four months. It is generally conceded that permanent recovery from this disease is rare, but it does occur sometimes spontaneously. Complications or intercurrent diseases cause death in much the larger number of instances.

Diagnosis.—The most reliable and characteristic symptoms of diabetes insipidus, or essential polyuria, are persistent daily excretion of quantities of urine above the ordinary maximum of health, or of low specific gravity (between 1.001 and 1.008), and destitute of sugar and albumin; unnatural thirst, increased in direct ratio to the increase in the quantity of urine voided; and a loss of endurance. At first, cases in which polyuria is caused by habitually drinking very large quantities of fluids, may be mistaken, for example, for cases of diabetes insipidus. In the early stage chronic interstitial nephritis may be mistaken for it. This can happen only when albumin does not occur in the urine or occurs only occasionally. In this stage of interstitial nephritis the in-

Digitized by Microsoft®

creased flow of urine is moderate rather than excessive, and the specific gravity is almost uniformly above 1.008. A careful study of the circulatory disturbances, which are a part of interstitial nephritis and do not exist in essential polyuria, makes a diagnosis easy.

www.libtool.com.cn

PATHOLOGICAL ANATOMY.—Essential polyuria generally continues for many years, and rarely terminates fatally except through the intervention of other diseases; few opportunities, therefore, are afforded for careful post-mortem examination. However, in some cases the kidneys have been found slightly enlarged and more vascular than natural, but often they appeared unaltered.

Much the most numerous and important changes have been found in the brain and cord. These consist of inflammatory and degenerative changes in the region of the fourth ventricle, and less frequently in the meninges; of gummata and exostoses; and of tumors. Such changes within the cranium are evidently the results of prior constitutional disorders, and are in no sense dependent on the polyuria. Chemical analyses of the blood have shown a moderate increase of the solid constituents in proportion to the water. It may be safely assumed that uncomplicated polyuria does not involve uniform structural changes either in the kidneys or in other parts of the body, but rather such a modification of the renal vaso-motor nervous mechanism as to induce and maintain an increased blood pressure, and consequent increased elimination of urine.

TREATMENT.—In the treatment of this affection, it is of the highest importance to ascertain from the history of the patient what accidents, injuries, coincident diseases, or constitutional morbid conditions, hereditary or acquired, may have been influential in developing or perpetuating the disease. In all cases in which such causative conditions can be found, the removal when possible, or alleviation when removal cannot be accomplished, should demand careful and persistent attention.

For permanently controlling the diuresis no remedies have been found to be reliable or uniformly successful. Those who suffer from this disease should live in well-ventilated, well-lighted, warm and dry rooms; should wear warm flannel underclothes, take a warm water bath, followed by rapid light friction with dry flannel, daily or at least two or three times a week; and take as much exercise in the open air daily as is possible without fatigue. Such quantity and quality of food may be eaten as the digestive organs of the patient will tolerate without developing gastric distress or much flatulency; but sugar should be eaten sparingly, for an excess of the latter in the blood will aggravate the polyuria. Very cold beverages should be avoided, and especially such as are diuretic, like beer, cider, and milk. Melons and grapes among fruit increase diuresis and must be eschewed.

Rest and sleep should be had at regular intervals and in sufficient amounts. Emotional excitement and fatigue must be avoided. To promote vicarious elimination by skin and lungs, the hot baths and friction of the skin, already advised, are important. Breathing exercise, slow climbing of hills, and a residence in a high altitude and dry climates are useful.

Among the numerous drugs which have been employed are pilocarpine and cathartics as means of provoking elimination by other channels than the kidneys. Their utility is transitory and slight.

For their effect upon the tone of the renal blood vessels such drugs as strychnine, ergot, and astringents have been tried. They all tend to increase blood pressure, which we would expect to aggravate, not to relieve, the important symptoms of the disease. Although in individual cases they have seemed useful, they cannot be said to have a specific action.

Valerian, castor, musk, asafetida, camphor, belladonna, opium, and potassium bromide are other drugs which have occasionally seemed beneficial.

Drugs, however, are not to be relied upon. They may be used to meet indications in individual patients, and hygienic and dietetic treatment is important.

N. S. Davis, Jr.

POMEGRANATE.—*Granatum. Granati Cortex*, or *Cortex Granati. Grenadier.* "The dried bark of the stem and root of *Punica Granatum* L. (fam. *Punicaceæ*)." U. S. P.

This is a very beautiful shrub or small tree, producing a dense crown of glossy dark-green foliage, handsome deep-scarlet or crimson (in one form white) flowers, and the delicious fruit well known under this name. It is a native of Southwestern Asia and is now everywhere cultivated in tropical and subtropical countries. Some pharmacopœias require the root bark only, a judicious restriction (see *Constituents*). The French Codex recognizes also the flowers and fruit, and the rind of the latter, but all these are very inferior.

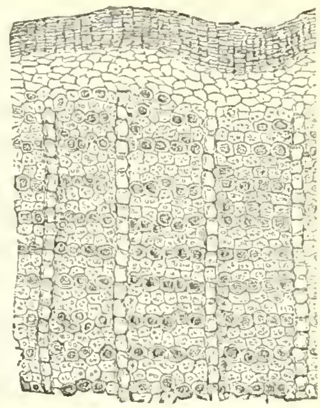

FIG. 3875.—Pomegranate Bark.

The bark occurs in quills several inches in length, and 0.5 to 2 cm. ($\frac{1}{5}$ to $\frac{4}{5}$ in.) in diameter, or in broken pieces of the same, the bark 1 to 3 mm. ($\frac{1}{25}$ to $\frac{1}{8}$ in.) thick; outer surface consisting of broad, shallow, rough, commonly short and reticulated, yellow fissures, alternating with less roughened, gray or slightly purplish-gray bands having sharp, lightly elevated margins, and usually more or less marked with small blackish spots of lichen; root bark, especially the thicker pieces, browner, less fissured, and more or less scaly and roughened; inner surface finely striate, with some longitudinally elongated, blister-like elevations, and varying in color from pale greenish-yellow to cinnamon-brown; fracture short, granular, greenish-yellow, and showing a somewhat laminated structure; taste astringent, very slightly bitter.

Constituents.—The important constituents of pomegranate bark are four alkaloids, together aggregating from one per cent. to three per cent. of the weight of the drug. Although evidence on this point is contradictory, it appears pretty well established that the root bark contains about a half more alkaloid than the stem bark and that the barks of the white-flowered variety are richer than those of the red-flowered. There is a large amount of tannin (twenty per cent. or more), some mannit ("punicin" or "granatin"), much yellow coloring matter, and a very large amount (ten to fifteen per cent. or more) of ash. The tannic acid is interesting, being partly gallotannic and partly a form peculiar to this drug. The alkaloids exist for the most part as tannates. The most important is *pelletierine* or "punicine" ($C_8H_{15}NO$), which is a volatile liquid, soluble in water, alcohol, ether, and chloroform, and rapidly oxidizing, upon exposure, into a resin-like body. Its salts are crystalline. *Methyl-pelletierine* ($C_9H_{17}NO$) is similar, but somewhat less soluble in water. This alkaloid is more abundant in the root bark, the former more in the stem bark. The other alkaloids are *iso-pelletierine* and *pseudo-pelletierine* or "granatonine" ($C_9H_{15}NO \cdot 2H_2O$), the latter occurring in prismatic crystals, soluble in water, alcohol, and chloroform, and in nine parts of ether.

Pomegranate bark deteriorates rapidly on keeping. The alkaloids undergo a change, rendering them less soluble, soon after which they become decomposed. It is to be particularly noted that the commercial substances passing as pelletierine and its salts are in reality mixtures of all the alkaloids named above.

ACTION AND USES.—The important use of pomegranate bark is as a tænicide, its alkaloids being active. Opinions differ as to whether the parasite is killed or merely paralyzed by the drug. In any case, a brisk

Digitized by Microsoft®

cathartic is required after its administration, owing to the strongly astringent effect of its tannin. Its astringent properties are often utilized for gargling and similar purposes and have been used internally, though the large doses thus used have frequently been followed by unpleasant emetic, and to some extent narcotic, effects. There is no official preparation, though an unofficial fluid extract is often employed, in doses of 2 to 6 c.c. (fl ʒ ss.-iss.), and the powdered bark is given in corresponding doses. A very good method is to suspend the latter in mucilage. The ten-per-cent. decoction is the form probably most used, in wineglass doses. The tannate of the alkaloids (so-called "pelletierine-tannate") is now very largely employed in doses of 0.2 to 0.4 gm. (gr. iij. to vi.). This is after all the best form of administration, since the inhibiting action of the free tannin of the bark is thus avoided.

The rind of the fruit (*Granati Fructus Cortex; Cortex Malicorii*) is largely utilized for its astringent properties. It contains rather more tannin than the bark, together with a still larger amount of gum, and is free from the alkaloids which, as stated above, often render the use of the bark as an astringent undesirable. This rind occurs in irregular, curved, chip-like fragments, about 2 mm. ($\frac{1}{12}$ in.) thick, externally brown, with a yellowish or sometimes reddish tint, finely tuberculate roughened, internally of a lighter or whitish color, marked with conchoidal depression indicating the position of the masses of seeds. The terminal pieces bear the thick, tubular, cup-shaped remains of the calyx tube. The fracture is short, sharp, and granular. The drug is nearly odorless and strongly astringent. *Henry H. Rusby.*

POMPHOLYX.—(Synonyms: Cheiro-Pompholyx; Fr., *Dysidrosis*; *Dysidrose*.)

DEFINITION.—An acute exudative eruption characterized by the formation of vesicles and blebs, usually of moderate size, and occurring for the most part on the hands and feet; in some instances it may be limited to the palms and soles. It is a disease seldom encountered, and is liable to be confounded with other eruptions of the bullous type.

SYMPTOMS.—The clinical features of pompholyx are well-defined and distinctive, and in most works on dermatology the disease is recognized as a distinct affection. It was first described by Jonathan Hutchinson and Tilberry Fox, of London. The former gave it the name of cheiro-pompholyx, while the latter in reporting the same case gave it the name of dysidrosis. During a period of twenty years the present writer, in encountering many thousand cases of skin diseases, has seen but one or two instances of this affection; nor could these be regarded as typical examples of the disease, for the eruption during its whole course was not confined to the regions most frequently involved—namely, the hands and feet—but extended to the forearms as well. While a student in the Black Friars Skin Hospital in London I had the opportunity of studying several cases that were regarded by Mr. Hutchinson as typical examples of the affection. In some of these, if I remember correctly, the disease likewise extended to the forearms, and frequently the feet were exempted. The disease usually begins in the summer, especially during excessively hot weather. The first symptoms complained of are burning and tingling, with the development of deeply seated vesicles which are single and later become grouped by the development of new lesions; the most characteristic position at first being the sides of the fingers, and the eruption gradually extending to the palms. When the lesions are confined to the thick skin of the palms of the hands and the soles of the feet they have been very aptly compared to boiled sago grains embedded in the skin. This appearance is due to the thickened epidermis, as pointed out by Crocker, rather than to any special variation in the lesions themselves. The eruption is usually symmetrically distributed. As the lesions develop the groups of vesicles not infrequently coalesce, forming large, irregularly outlined bullæ filled with a serous fluid, and projecting above the level of the skin. At first the contents are translucent, but later they become opaque. In reaction the fluid is neutral or slightly alkaline. At no time is there much inflammation in the surrounding skin, in which respect the disease differs from certain affections with which it may be confounded. In the course of two or three weeks the lesions begin to subside, although new ones appear from time to time. The contents become absorbed and finally the outer epidermic wall exfoliates, exposing a reddish area of delicate new skin, which marks the site of the former lesion. The disease often runs its course in a few weeks, or at most in one or two months, although it is liable to recur the following year. At times, in debilitated subjects, the lesions may assume a red color and the surrounding derma become slightly œdematous. The epidermis not infrequently becomes undermined and then soon ruptures, exposing to view a red, exudative surface. Gradually, however, this process subsides, and recovery may take place as before stated. The subjective symptoms are usually slight. Aside from the burning and tingling previously mentioned, there may be marked impairment of the general health, in which case excessive sweating is sometimes complained of. Itching is never a prominent symptom.

PATHOLOGY.—As the name given to the disease by Tilberry Fox[1] indicates, this writer regarded the affection as in some way associated with the sudoriparous glands. Later investigators, and especially Robinson,[2] have demonstrated that the lesions show no especial connection with these structures. On the other hand, it has been shown that the pathological condition is one of inflammation which takes its origin in the rete, gives rise to a serous exudate from the capillary blood-vessels, and then, collecting between the rete cells, forms variously sized vesicles or bullæ. As this effusion takes place there follows a gradual degeneration of the cells of the rete mucosum. While some of the vesicles, especially those situated on the outer surface, may rupture when the inflammatory process is more extensive, there may be a general extension of the fluid at the periphery, thus causing the undermining previously mentioned. Later, the entrance of pus corpuscles changes the translucent fluid to one of an opaque or even yellow color.

ETIOLOGY.—The disease is nearly always associated with general debility, or it occurs in those whose nerve tone is below par. It is especially liable to occur in women who have been subjected to excessive mental strain or worry; and yet, while it is more frequently met with in women, men are by no means exempted. Middle age seems to be the period of life in which the disease is most frequently encountered; only a few cases have been reported in children and the disease is extremely rare in old age. Crocker has not seen it under twelve years, and the oldest patient was thirty-eight, while Hyde[3] records a case at sixty. The disease is supposed to be due to some abnormity in the innervation of the skin, although its exact nature has not been determined. On the other hand, Unna has found a bacillus resembling the tubercle bacillus, although slightly thicker, and he is disposed to regard it as an essential pathological factor in the disease.

DIAGNOSIS.—The limitation of the disease to the palms of the hands and the soles of the feet—a characteristic which is considered by some authorities to be essential—renders the affection less liable to be confounded with other affections to which it bears some similarity; namely, with eczema, pemphigus, and dermatitis herpetiformis. In my own experience the line of demarcation is not so sharply drawn, and the affection gradually merges in type with other well-recognized diseases. When limited to the palms and plantar surfaces the only condition to which it bears a close resemblance would be blisters from slight traumatism, eczema, and an accumulation of sweat under the thickened epidermis. Eczema is seldom limited to these surfaces, and is always accompanied by inflammation and marked itching; while inflammation and itching are usually insignificant features in pompholyx. The persistence of the eruption, together with the formation of new lesions extending over a period of a week or more,

Digitized by Microsoft®

would enable one to exclude blisters arising from slight injuries. More difficulty, however, would be encountered in differentiating the affection when seen on the lateral surfaces of the fingers and on the backs of the hands. Here the affection bears a close resemblance to eczema; but in eczema there are more extensive inflammation and less tendency to the formation of bullæ, and in eczema the outer wall of the lesions easily ruptures, giving rise to excoriated itching surfaces of irregular outline. In pompholyx, on the other hand, the epidermic wall seldom ruptures and the lesions remain circumscribed, or coalesce in such a manner as to form bullæ. Furthermore, it should be borne in mind that pompholyx is most liable to occur in adults, and especially in women who are debilitated or who have been overwrought, and that the disease tends to a spontaneous recovery, and at the same time is likely to recur upon the recurrence of conditions favorable to its development. Ivy poisoning must likewise be excluded in making a diagnosis, but the acute inflammatory character of this disease and the tendency of the eruption to appear on other parts, render it, as a rule, easy to distinguish it from pompholyx. The last doubts, however, would be removed if the history of an exposure to the poisonous plant could be obtained in addition.

www.libtool.com.cn

Prognosis.—The prognosis in pompholyx is good so far as the individual attack is concerned, although there is a tendency for the disease to return with successive years. In some instances the irritation to which pompholyx gives rise has engendered an eczema which may persist indefinitely. On the other hand, the disease may not return for several years, although, upon the return of ill health, it will be very likely to appear again.

Treatment.—The treatment should be partly constitutional or general and partly local. The former seems to be of the more importance, as the individual attack is self-limited. First, all debilitating influences should be removed, and as far as possible the patient should be urged to avoid worry, over-excitement, or intense mental labor. General hygienic measures should be advocated, namely, exercise in the open air, cold bathing with vigorous friction immediately thereafter, and diversions of a relaxing nature. Change of location from inland to the seashore, or from the seashore to the mountains, is in some cases highly beneficial. In addition to this the patient should be given a generous diet and in some instances tonics, and the room which he occupies should have a sunny exposure and should be well ventilated. Aside from these general measures individual cases should be treated according to the indications present. Strychnine is a drug which must frequently be called into requisition. Iron, especially in its more assimilable forms, quinine, cod-liver oil, and in some instances arsenic, are valuable drugs.

The local treatment consists partly in soothing applications and partly in such as protect the surface from the air and from the irritation of clothing and other extraneous substances. It is best forcibly to rupture the lesions, especially when large, and flush out the cavity with a saturated solution of boric acid and water. In some cases, when the lesions rupture, black wash may be used. I can also recommend the following application: Salicylic acid 2 per cent., and diachylon ointment q. s. 100 per cent. This should be spread on some firm white cloth and kept constantly applied to the diseased area. Every twenty-four hours the surface of the skin should be cleansed with a saturated solution of boric acid, or with water to which a small quantity of carbolic acid has been added, and a fresh application of the ointment should be made. This ointment is especially valuable when the soles of the feet are involved. Stelwagon [4] recommends the following: Menthol, gr. ij.; acidi salicylici, gr. x.; emplastri plumbi, emplastri saponis, āā ℥ iss.; petrolati, ℥ v. M. The prevention of local infection is one of the main objects in treatment, and, to accomplish this, we may with benefit apply a solution of corrosive sublimate (1 to 2,000) or white precipitate ointment (five per cent.), the latter serving as a parasiticide as well as a protective agent.

William Thomas Corlett.

PONCE DE LEON SPRINGS.—Crawford County, Pennsylvania. Post-Office—Meadville.

Access.—Viâ Erie Railroad or by Pittsburg, Shenango and Lake Erie Railroad to Meadville (separate depots), thence about two miles to springs.

The Ponce de Leon Springs may be said to be in a process of development. An electric line of railway from Meadville is now being constructed, and a modern first-class hotel will soon be built. The location is very favorable for a pleasant summer resort, being twelve hundred feet above the sea-level and surrounded by picturesque hills. There are six mineral springs, only one of which has been submitted to a qualitative examination. An analysis by Prof. Henry Leffmann, of Philadelphia, resulted as follows: One United States gallon contains:* Sodium sulphate, gr. 0.17; sodium chloride, gr. 0.90; calcium bicarbonate, gr. 1.89; magnesium bicarbonate, gr. 0.47; sodium bicarbonate, gr. 16.73; silica, gr. 0.70. Total, 20.86 grains.

A second analysis by J. Singley, Ph.D., professor of chemistry in the Western Pennsylvania Medical College of Pittsburg, resulted substantially as above. The following gases were also found: Carbonic acid, 1.33 cubic inches per gallon; oxygen and nitrogen, 7.23 cubic inches per gallon; hydrogen sulphide, abundant traces.

The water is a bland antacid and diuretic. It will be found of value in certain stages of Bright's disease, especially when the urine is scanty, high-colored, and irritating. It is also useful in assisting the diminution of calcareous deposits and of uric acid in gout and gravel. The water will speedily relieve acidity of the stomach and heartburn. It is used commercially, and also for the manufacture of a number of temperance beverages.

James K. Crook.

PONS AND MEDULLA. See various articles under *Brain*.

PONTRESINA. See *Engadine*.

POPLAR. See *Willow*.

POPPY.—The principal products of the poppy plant will be found described under the titles of opium and its more important alkaloids. Some minor products are here considered.

Poppy Capsules (*Papaveris capsulæ*; *Fructus* or *Capita Papaveris immatura*) are more or less employed in medicine for the opium which they contain. Their botanical origin has been fully stated under *Opium*. For the purposes here considered, they are gathered when nearly ripe and are dried in the sun. They are more or less spheroidal, but vary in the different varieties, from strongly oblate to strongly prolate, and they range from one and one-half to three inches in diameter. The larger ones, and those of prolate form, known as the "black" variety, are generally regarded as superior. The color is pale brown, and the surface nearly smooth. At the summit there are from eight to sixteen, or occasionally twenty short, nearly sessile, recurved stigmas, indicating an equal number of placentæ, the latter projecting as sharp ridges upon the inside of the capsule. Partly concealed under the stigmas are a circle of small pores through which the mature seeds escape. The seeds are not a part of the capsule considered as a drug. Numerous constituents have been reported as occurring in these capsules, but from a medicinal point of view they may be regarded as identical with those of opium. The morphine content

* Reduced from grains per imperial gallon.

Digitized by Microsoft®

rarely exceeds a fourth of one per cent., notwithstanding that claims for a much larger yield have been made. The younger the pods the less morphine do they contain.

Poppy capsules were official in the United States Pharmacopœia of 1870, and are still so in the British Pharmacopœia, but their use in the United States has almost entirely given place to that of other and more definite forms and preparations of opium. In Great Britain the syrup is probably the most largely used preparation, and is mostly administered to children, though the extract is also considerably employed. The dose of any preparation should represent from one to two drachms of the capsule.

www.libtool.com.cn

Poppy seeds possess no narcotic properties whatever, though it is said that traces of morphine can be found in them. They are used purely for their fixed oil, which is an important article of commerce. The oil is quite bland and possesses only the nutritive and demulcent properties of vegetable fixed oils in general.

Poppy Petals, or *Red Poppy Petals* (*Rhœados Petala*) are the petals of *Papaver Rhœas* L., the common red or field poppy of Europe. They resemble rose petals, but are larger. The color of the fresh petals is a brilliant scarlet red, with a large black spot at the base, but the color becomes pale and dull in drying. They are used entirely for their coloring matter, for the tinting of pharmaceutical preparations, and hence are greatly preferred in the fresh condition. The coloring matter is divisible into two portions: *rhœadic acid*, which is dark red, soluble in both water and alcohol; and *papaveric acid*, which is of a brilliant red, soluble in water but not in alcohol. An alkaloid (*rhœadine*) exists in very small amount, but is unimportant. It is said that a trace of morphine has been extracted, but the article can scarcely be regarded as medicinal. *Henry H. Rusby.*

POROKERATOSIS.—(Synonyms: Hyperkeratosis eccentrica, Keratodermia eccentrica, Hyperkeratosis figurata centrifuga atrophicans, Porokeratose.)

Definition.—A unique form of hyperkeratosis, beginning as a small papule. This papule having slowly enlarged becomes depressed at the centre, and its margin usually develops into a ridge involving a rift and defining an area of varying extent.

In 1887 Maiocchi reported a case, marked by a singular appearance of the skin, which he diagnosed as a form of ichthyosis hystrix. After a lapse of six years the same case was brought to the notice of Mibelli, who pronounced the lesion exceptional and peculiar, claimed that the pathological process was distinctive, and finally characterized the affection by the name of porokeratosis. Simultaneously with the observation by Mibelli, an article was published by Respighi describing a number of similar cases under the name of hyperkeratosis eccentrica. The disease has been especially observed in Italy, particularly in the district of Parma. Cases occurring in the United States have been reported by Hutchins, Gilchrist, and Wende. A few cases have been noted in Germany, France and, very recently, in England.

Symptoms.—The disease is of slow development, first appearing as a papule of varying size, dirty brown, dry, and invariably surrounded at the base by a collarette of scales. As the papule increases it takes on a decided change. The lesion, the periphery of which is subject to a gradual development, extends centrifugally; the central portion becomes slightly depressed, and the margin resolves itself into a unique border which represents a non-inflammatory hypertrophy, sharply defined against the outlying sound skin, and forming a continuous or broken ridge. In the middle of this ridge is found a rift somewhat irregularly dividing the same into two lateral halves, all of which constitutes a lesion unlike any other known, and which has been characterized as a "seam," "dike," or "wall." It is dirty gray or blackish in color and usually quite pronounced, though in ill-defined cases it may appear simply as a loose rim of epidermis. The

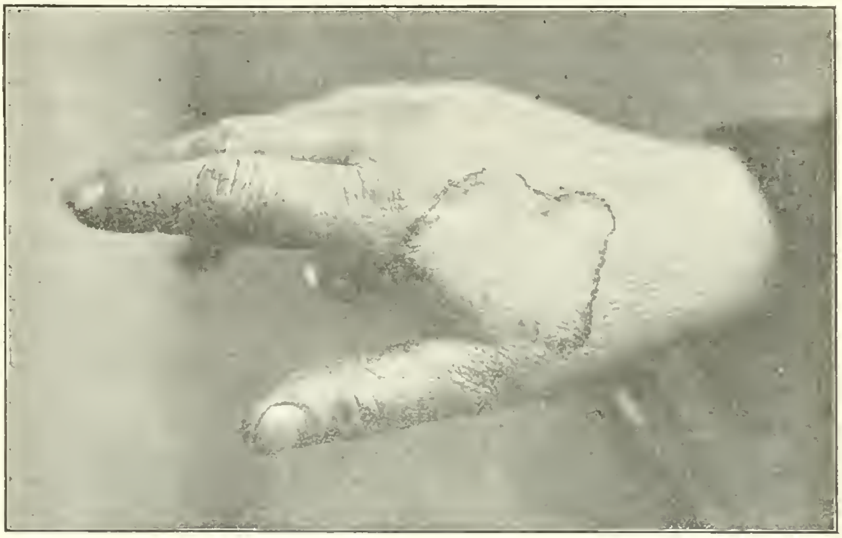

Fig. 3876.—Case of Porokeratosis of Five Years' Standing. The affected area is bounded by the characteristic rifted ridge. The lesion shown here was the only one present in this case. (From Grover W. Wende's collection of photographs of skin diseases.)

centre, so long as the lesion is small, consists of a horny, thickened, epidermic patch. After the lesion has attained a certain size the centre may become normal in appearance. Sometimes the natural furrows of the skin are erased; again, there is clear evidence of atrophy. The functions of the sweat and sebaceous glands are interrupted. In some areas absence of hair is observed. Epidermic concretions, the size of a millet-seed, are sometimes present, now divided by the furrow, again attached to the inner side of the seam; or they may appear at any point within the affected area.

The areas affected by hyperkeratosis vary in size—many do not measure over one-eighth of an inch in diameter, while some become much larger and may even cover the greater portion of an extremity. As a rule, they do not exceed an inch in diameter, and in the majority of cases they are much smaller.

The lesion is always slow in development; at times the condition remains stationary. The shapes assumed are round, oval, or elliptic; they may become polycyclic by confluence or may all run together, especially when their dimensions are greatly increased.

The lesions often affect the mucous membranes lining the mouth. All or any part of the skin may be attacked. The favorite regions, however, are the face—especially the nose, forehead, and cheeks—the ears and neck, the dorsal surfaces of the hands and feet, and the extensor surface of the forearms.

The lesions of the mouth are generally not very numerous, although present in a large number of cases. They consist of small asymmetrical spots varying from

Digitized by Microsoft®

the size of a pin to that of a lentil. Like the lesions of the skin, they may be oval, polycyclic, or irregular.

The subjective symptoms are without special importance; only occasionally does the patient complain of pruritus, either slight or intense. When the feet are affected the shoes sometimes cause pain by pressure.

The evolution of www.libtool.com.cn slow; sometimes a single focus continues during many years. Subsequently the disease extends by the development of new lesions, and, in the end, the lesions are distributed bilaterally.

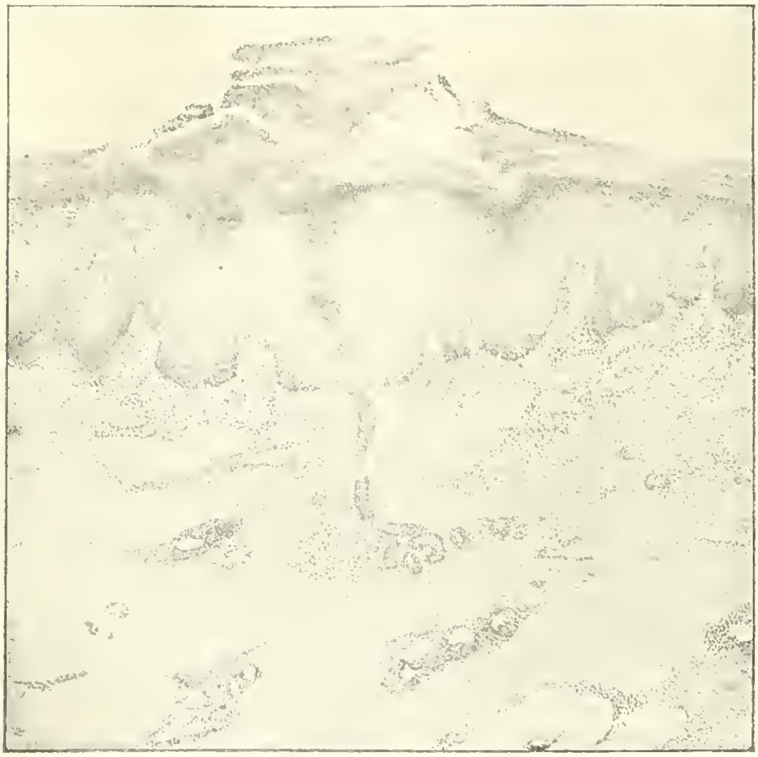

FIG. 3877.—Cross Section of the Characteristic Ridge in a Case of Porokeratosis. In addition to the condition of marked hyperkeratosis, which is revealed in the picture, there may be seen a sweat pore which is obstructed by the presence of a black horny plug that extends down to the level of the acini. (Grover W. Wende.)

ETIOLOGY.—The cause of the disease is largely a matter of conjecture. It may show hereditary tendencies, though often it does not. The possibility of hereditary transmission is shown in the cases published by Gilchrist, in which eleven members of one family were discovered to be affected in the course of four generations. Respighi also reports an instance of the malady which recurred in several generations. Most of the cases occur in laborers. Males suffer more often than females; sometimes the affection is developed in children between the ages of two and eight; generally, however, it appears in adolescents or adults.

The proof that the affection is parasitic in its nature is wanting, although in a series of four inoculations made upon as many different individuals by Wende, one was successful, undoubtedly owing to local irritation upon a susceptible skin. Respighi made experiments in transplantation, but they proved to be negative. All examinations for micro organisms have been without result.

PATHOLOGY.—The main feature of this disorder is a special form of hyperkeratosis. The elevated and circinate margin is composed of a mass of cornified cells, which however, still retain their nuclei. The lesion forms a conical plug corresponding to the interpapillary depression into which the enlarged glandular orifices combine, but are obliterated by horny masses—a condition which strongly resembles lichen spinulosus. All parts of the epidermis are involved, especially the lower horny and upper rete layers. A small amount of cellular infiltration with œdema is seen in the papillary layer of the cutis immediately underlying the affected epithelium. The derma undergoes a sclerotic degeneration in the upper layers. At first it is hypertrophied, but in the advanced stage atrophied. The sweat glands are dilated and reveal epithelial proliferation and hyperkeratinization. Epithelial accumulations in the sweat ducts and sebaceous glands, as well as in the hair follicles, have been observed by Mibelli, Respighi, and Gilchrist.

DIAGNOSIS.—The clinical characteristics of porokeratosis are so unique that a mistake in diagnosis is not likely to occur. In the early stage the lesions may be mistaken for lichen planus, but this is generally accompanied by itching, is not continuous, and does not attack several members of the same family. The essential lesions are the characteristic papules, striated on the surface, and of a dark red color. There are instances of lichen planus essentially annular, but in that case the rings are limited by a red prominence, and one does not see either the furrow or the edge of the porokeratosic circles so characteristic of the disease.

PROGNOSIS.—The disease does not affect the general health, and, beyond the possible disfigurement, need not create any anxiety. Sometimes the lesions disappear spontaneously. When located about the joints, especially of the fingers or feet, the affection may cause some pain from pressure and the interruption of functional operations.

TREATMENT.—The same treatment is required as that given to some forms of ichthyosis. The lesions, in the early stages of the disease, are to be removed by salicylic acid plasters or the use of the curette. Joseph has obtained good results by excision. Gilchrist recommends electrolysis. Both of these modes of treatment were employed in the case illustrating this article, but without favorable results. Undoubtedly this peculiar treatment is applicable, only to small lesions.

Grover W. Wende.

the springs being twenty-eight miles north of that city, and ten miles north of Dahlonega. They were discovered only a few years ago in a beautiful cove on the southern slope of the Blue Ridge Mountains. The waters have acquired an extensive reputation on account of their valuable chalybeate properties. The hotel has a capacity for about one hundred and fifty guests, and is kept open from June 15th to October 15th.

The situation is very high for this region, being more than three thousand feet above the sea-level, an elevation greater than the top of Lookout Mountain. Some of the peaks in the vicinity reach an altitude of almost five thousand feet. Although located in a semi-tropical latitude, the high elevation of Porter Springs gives the climate an invigorating, bracing character not subject to exhausting heated spells. The waters are said to contain, besides iron, hydrogen sulphide gas with sulphates of magnesia, potassa, and soda. Some of the springs contain also small quantities of iodine, lithia, and manganese. It is unknown by whom these determinations were made. A proper quantitative analysis is needed.

James K. Crook.

PORTLAND, MAINE.—The largest city and commercial metropolis of Maine, with a population of about fifty thousand, one hundred and fifteen miles northeast of Boston, is beautifully situated at the head of Casco Bay. Portland is the centre of a number of attractive seaside resorts which are easily reached from this city by sea or land. Such are Old Orchard Beach, Scarborough Beach, Prout's Neck, Kennebunkport, Pine Point, Saco Pool, and Wells Beach to the south; and Boothbay, Harpswell, Islesboro, Isle Au Haut, Vinal Haven, Deer Isle, Camden, and Castine to the northeast. Indeed, the whole coast of Maine with its innumerable indentations and many islands affords a great variety of attractive summer resorts with a cool, delightful climate. It is visited at this season by thousands of people from the inland cities of the North, South, and West. Portland itself and its picturesque surroundings offer very many attractions, and possess a cool summer climate and a steady sea breeze.

There are many fine buildings and churches in the city, a number of parks, notably the Eastern Promenade with a fine view of the city and harbor, and many points of historical interest. The drives are delightful, and excursions by water through the harbor and Casco Bay with its many islands, are numerous and pleasing. Diamond, Peak's, and Cushing Islands are favorite resorts near the city, easily and quickly reached by water. The accommodations, both in Portland and the various other resorts mentioned above, are abundant, good, and of varying prices. The following table represents the climate of Portland and will also convey an idea of the climate of the resorts lying to the north and south. In general, the summer climate is seen to be a cool marine one, with frequent sea breezes, a majority of pleasant days, and a humidity of about seventy per cent. There are often quite sudden and marked changes in temperature, and fogs are not infrequent. Such a climate is a stimulating one and well suited for the overworked, for neurasthenics, and for those suffering from anæmia, scrofula, and bone and joint tuberculosis. Convalescents from chronic diseases also do well in this climate. It is too damp and variable for laryngeal and pulmonary cases and those subject to neuralgic affections. Especial mention should be made of the exceptionally fine beach at Old Orchard, the finest in New England, extending for a distance of ten miles and affording most excellent surf bathing. This is a very much frequented resort, and offers accommodations of every kind and description. Hinsdale (vol. iv., Book II., "Health Resorts," "Physiological Therapeutics") says that the climate of Kennebunkport is not excelled on the New England coast. "The south and southwest breezes," he says, "are from the water; a hot land breeze is a rarity, and fogs are not of frequent occurrence." He recommends the climate for neurasthenics and those suffering from insomnia and melancholia.

Portland, as well as the various resorts about it, can be easily reached from Boston either by rail or by water.

Edward O. Otis.

PORTLAND, OREGON.—This is the largest city in the State of Oregon, with a population of 90,428, and is situated at the head of ship navigation on the Willamette River which flows into the Columbia. It is in no sense a health resort, but it is mentioned here, and a climatic chart is given, for the sake of contrasting the climate of the eastern and western sides of the North American continent. By comparing the charts of Portland, Me., and Portland, Ore., the contrast will be seen. "Portland, Ore., lies nearly two degrees farther north than Portland, Me., yet its mean winter temperature is no less than fifteen and one-half degrees warmer than that of its namesake on the Atlantic coast. It is within one degree of being as warm as that of Norfolk, Va., and is about ten degrees warmer than that of New York City. On the other hand, the summer at Portland, Ore., is slightly cooler than at Portland, Me., and is about seven degrees cooler than that of New York City and almost exactly the same as that of Montreal." "The range of temperature is decidedly less at Portland, Ore., than it is at Portland, Me. The rainfall is much greater, and the relative humidity is higher (especially in winter), and the number of cloudy days is much greater. The great cloudiness of the Oregon winter weather is a feature of the climate not characteristic of any other part of the United States except the Lake region and St. Lawrence Valley district" (Richards). Richards (previous edition of the HANDBOOK) calls attention to the close resemblance between

the climatic conditions characteristic of Portland, Ore., and those prevailing along the western coast of the European continent. The temperatures of the Oregon coast, he says, are strongly suggestive of those found throughout northwestern Europe; further, the almost rainless summer with heavy winter rainfall is a feature of climate in which the Oregon coast resembles the Mediterranean basin rather than the more northerly parts of Europe.

Edward O. Otis.

PORTSMOUTH, N. H., AND ADJACENT RESORTS.—This "old town by the sea" is noticed here not only on account of its own attractions, but because in its vicinity are a number of well-known summer marine health resorts: the Isles of Shoals; Rye and Hampton Beaches and Little Boar's Head; York Harbor and Beach; Ogunquit, Passaconaway, Kittery, and Newcastle.

Portsmouth, fifty-seven miles from Boston, is situated a few miles above the mouth of the Piscataqua River, and possesses an excellent harbor. It is the only seaport of New Hampshire, and in the days of wooden shipbuilding was a very prosperous town, as is evident from the stately mansions still remaining there.

The present population is about ten thousand, and the town presents a quiet, tranquil aspect quite in contrast to its by-gone activity when ships were launched from its yards and were entering and departing from its spacious harbor. The streets are beautifully shaded, and the old residences of the architecture of seventy five or a hundred years ago, with their attractive gardens, together with the water views from the decaying wharves, all combine to give this old city a most picturesque appearance. There are also many points of historic interest in and about the city, for it was first settled in 1623. On an island opposite, in the town of Kittery, is the United States navy yard. There are no meteorological observations to be had in regard to Portsmouth, but a fairly accurate idea of the climate may be obtained by striking an average of the climatic data of Boston and Portland, which are on the coast fifty miles east and west of Portsmouth, and which differ but little from each other. Estimating in this manner we have the following figures: Mean average yearly temperature, 47.3° F. Mean average temperature for the four seasons: spring 44.1°, summer 68.1°, autumn 50.3°, winter 26.8°.

The annual mean relative humidity of Portland and that of Boston are almost identical, and that at Portsmouth is, therefore, probably the same, which is 69.6 per cent., varying but little during the year. The average number of clear and fair days is: spring 58.3, summer 65.6, autumn 61, winter 59.6; year, 244.7. The yearly rainfall is 43.6 inches. The prevailing wind is from the southwest and west. All along this coast there may be a few very hot days during the summer, but generally the air is cool and delightful, and the sea breeze is almost a daily occurrence. The accommodations are good, among them one very excellent first-class hotel. Although Portsmouth is a city, yet it is such a mild and quiet one that it offers many advantages for even a whole summer's sojourn. The society is exceptionally good, to which the adjacent navy yard makes valuable contributions; the air pure and cool; the scenery in the vicinity very attractive, and there are many excursions both by land and water. There are various churches, one the historic old St. John's, a good library, a well-equipped hospital, and excellent physicians. Frequently some of the vessels of the North Atlantic Squadron visit Portsmouth during the summer, and there are always one or more warships at the navy yard.

The water supply of Portsmouth is from springs and driven wells a few miles from the city, and is regarded as of excellent quality. Sewers emptying into tide water are being slowly introduced, although many of the old-time vaults still remain.

The average yearly mortality for the last eight years (1894–1901) is 19.25 per thousand.

An old resident and practitioner of Portsmouth assures the writer that the sanitary condition is good, and that there are very few cases of sickness which can be attributed to unsanitary conditions.

One is referred to the writings of T. B. Aldrich, Lowell, and Mrs. Celia Thaxter for charming accounts of Portsmouth and the Isles of Shoals.

Newcastle.—This small island at the mouth of the Piscataqua River, about two miles from Portsmouth, is a popular summer resort, with a large hotel, boarding-houses, and cottages. The situation of Newcastle is very picturesque, and it has a beautiful and extensive ocean exposure. It is connected with the mainland by bridges, and has frequent communication with Portsmouth by land and water. There are opportunities for golf, tennis, boating, and bathing. There is a military garrison at Fort Constitution. The climate is the same as at Portsmouth, with the exception that being directly on the ocean, it is more peculiarly marine.

Kittery Point, at the mouth of the Piscataqua River, opposite Newcastle, is very attractively situated and is a popular summer resort, affording good accommodations, both in hotels and cottages. It has frequent communication with Portsmouth both by trolley and by boat.

Isles of Shoals.—This group of small, rocky islands lies about nine miles off the coast, and has communication in the summer with Portsmouth several times a day by a comfortable steamer, the voyage occupying about an hour. Appledore is the largest of the group, which consists of eight islands, and contains two hundred and fifty acres. The formation of these islands is granitic, and they present a rugged picturesque appearance, barren and with very sparse vegetation. Huge, irregular reefs jut out into the ocean, and after a storm the play of the

Digitized by Microsoft®

surf is very imposing. Only two of the islands provide accommodations for summer residents, Appledore and Star Island, there being extensive hotels on both islands. The accommodations are rather more elaborate and expensive on the former (Appledore), and there are several cottage annexes. These islands have been a popular summer resort for many years, owing to the cool, equable marine climate found there, with an absence of dust and flies. Here one can experience all the climatic influences of a sea voyage without the discomforts incident to ship life. They are far enough removed from the mainland to be free from all contaminating influences, and from whatever quarter the wind blows it brings pure air. From a "weather record" for the summers of 1897–98 (June 25th to September 15th) kindly furnished the writer by Dr. J. W. Warren, who has been a summer resident of Appledore for over twenty years, the following data are condensed:

Mean temperature (Fahrenheit scale) from two daily observations at nine and four o'clock. June (25th to 30th) 63.2°, July 65.7°, August 67°, September (1st to 15th) 64.8°. The maximum temperature for this period was: June (25th to 30th) 70°, July 81°, August 78°, September (1st to 15th) 80°. Minimum, June (25th to 30th) 56°, July 56°, August 53°, September (1st to 15th) 56°. The summer temperature is said to be several degrees cooler than it is on the coast. Cold, raw days are infrequent, and the difference in temperature between day and night is slight, so that one can generally sit out in the evening. In general, the variations in the temperature are never as pronounced as on the mainland.

The average number of fair days for the two years was: June (25th to 30th) 4, July 15, August 17, September (1st to 15th) 9. Number of partly cloudy, misty, or foggy days: June (25th to 30th) 2, July 13, August 10, September (1st to 15th) 2. Partly rainy or rainy days: June (25th to 30th) 1, July 1.5, August 1.5, September (1st to 15th) 1.5.

The prevailing summer winds are southwest and south-southwest, and are not generally high. Fogs are not so prevalent as farther east, although they occasionally occur. The average number of rainy days is said to be much less than at Portland or Boston.

Therapeutically this climate has been found to be of great benefit to convalescents and to certain cases of neurasthenia. It is peculiarly valuable for those who, for one reason or another, wish to be much in the open air and at rest, for there are few inducements or opportunities to take exercise. Many years ago the late Dr. H. I. Bowditch considered the summer climate of these islands favorable for early cases of pulmonary tuberculosis, and they surely possess the requisite of pure air. Many cases of hay fever find immunity here. On White Island is a lighthouse, a prominent object from the mainland. There is good sea fishing and sailing about the islands. A steam launch affords frequent communication between Appledore and Star Island.

For much of the above information the writer is indebted to Dr. J. W. Warren.

York Harbor and Beach.—These resorts, on the Maine coast, are about nine miles distant from Portsmouth, and can be reached from the latter place by steam railroad, or by ferry, and a most attractive trolley ride. York Harbor is the principal resort, and enjoys a wide popularity. Cottage life predominates, although there are several good hotels. The coast is bold and rocky, and the York River winds inland for some nine miles, and has a large flow of tide water. The residential portion of the town is built upon ledges with little or no subsoil, so that there is good surface drainage, aided by the natural declivity of the land toward the sea. Further inland are wooded districts and tillage lands. The climate is a particularly stimulating one, favorable for convalescents, for whom a marine climate of this nature, combined with sea bathing, is desired. The air is generally cool and the temperature equable, an extremely hot or cold day in the summer being rare. Fogs are unusual. The following climatic chart was obtained through the kindness of Dr. Seabury W. Allen, a summer resident of York Harbor, as also much of the information contained in this account. The prevailing wind is southwest to southeast during the summer months, and is only exceptionally of sufficient velocity to interfere with canoeing or sailing.

CLIMATE OF YORK HARBOR—PREPARED BY DR. SEABURY W. ALLEN.

	June.	July.	August.	September.	October.
Temperature, Degrees Fahr.—					
Average or normal	62.3°	69.9°	65.8°	58.4° } For three years, 1892–1894	
Highest or maximum	92.3	95.5	87.3	79.3	
Lowest or minimum	45.0	51.6	48.3	39.6	
Precipitation—					
Mean annual precipitation for twenty-five years, 40 to 50 in.					
Mean monthly average rainfall (April to September) twenty-five years, 3.4 in.					
Average number of days in which rain fell (for three years).	11	9	7	9	
Average daily temperature (for nine years)	8 A.M.—67 8 P.M.—68	8 A.M.—67 8 P.M.—67	8 A.M.—65 8 P.M.—70	8 A.M.—56 8 P.M.—57	8 A.M.—45 8 P.M.—46

Thunder storms are frequent in summer, but a continuously rainy day is the exception. The water supply is excellent; it is obtained from an inland lake some five miles distant. The ice, milk, and farm produce are also of good quality. The larger houses and hotels have sewers running into the sea, the smaller ones either connect with one of these sewers or have cesspools of their own.

So far as known there have been no cases of illness attributable to imperfect drainage. Indeed, this resort enjoys almost complete immunity from zymotic and infectious diseases. Gastro-intestinal disorders, especially in children, are rare. Such a climate, or indeed any cool marine one, is obviously not suitable for patients suffering from rheumatism, bronchial and pulmonary affections.

York Beach, situated a few miles to the eastward of York Harbor, possesses essentially the same characteristics as the latter, with the exception of the drainage. Here, on account of an extended swamp, lying behind the beach shingle, and which is imperfectly drained, there is always more or less stagnant surface water, and for this reason this locality is not so desirable as a place of summer residence.

Several miles beyond York Beach and to the northward is the Passaconoway Inn, on a rocky promontory, affording good accommodations, and still farther along the coast is the extensive Ogunquit Beach, reaching toward Wells.

Rye Beach.—This well-known and favorite summer resort is eight miles distant from Portsmouth by electric road, and is also easily reached from Boston by rail to North Hampton and thence by trolley. The air is warmer than on the Maine coast, but is fresh and cool, with an almost daily sea breeze. Moreover, the humidity (about seventy per cent.) is considerably less than at many other marine resorts. The majority of summer days are clear or fair, and the rainfall at that season is moderate. The general healthfulness of this resort is noteworthy, and children especially thrive here. The rapidity with which delicate and sickly children improve in this climate is often quite remarkable. It is also fa-

Digitized by Microsoft®

vorable for the aged and delicate persons and convalescents from various diseases. The surf bathing is good, although the water is cold, averaging about 60° to 65° F. during July and August.

The drives are very delightful, over good country roads, and through pleasant pastoral scenery. An ocean boulevard extending along the whole coast of New Hampshire is in process of construction at Rye Beach, and when completed will afford an exceedingly attractive drive of about eighteen miles from the Piscataqua River, on the north, to Hampton River on the south.

www.libtool.com.cn

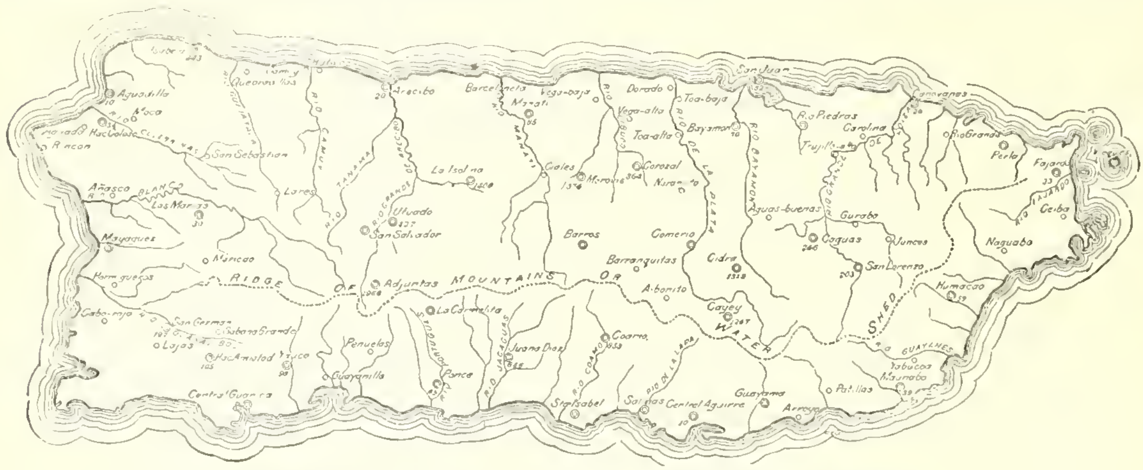

FIG. 3878. Island of Porto Rico. (Figures near names of places indicate altitude in feet.)

There are well-kept golf grounds with an attractive club-house, and a picturesque stone Episcopal church near the water, "St. Andrew's by the Sea." The sanitary conditions are generally good, and all the hotels and large boarding-houses have sewers running to the sea. The water supply is from springs, artesian and surface wells. The accommodations are excellent, though rather expensive, and there are many social attractions. Cottage life here as well as at the neighboring Little Boar's Head has become quite an important feature.

Little Boar's Head, situated about a mile south of Rye Beach, possesses the same characteristics as the latter. The name is derived from the bluff upon which it is situated. The views over the marshes and toward the sea are particularly charming. The accommodations and class of visitors are quite like those at Rye Beach. Indeed, both from its contiguity and identity of interests, Little Boar's Head can be regarded as a portion of Rye Beach. It is reached by trolley from Portsmouth or from Boston by railroad and trolley.

Hampton Beach.—Although not so fashionable as Rye Beach, this is a much-frequented resort, with several hotels of moderate price and fair accommodations, and many small cottages stretching along the beach. There is a long, hard, sandy beach extending for some miles, and affording excellent surf bathing. In the rear of the beach are extensive marshes. There are many attractive drives in the vicinity, although the wooded and cultivated land does not approach the water so closely as at Rye Beach.

This is a favorite resort for excursions, and consequently might not be so attractive to the permanent guest. It is reached by electric road from Portsmouth and Exeter, and is within three miles of the steam railway. *Edward O. Otis.*

PORTO RICO.—Porto Rico (*Spanish*, Puerto Rico), aboriginal name Borinquen, in size the fourth island of the West Indies, is situated between latitudes 17° 50′ and 18° 30′ north, and longitudes 65° 30′ and 67° 15′ west, Greenwich. On the north is the Atlantic Ocean, on the south the Caribbean Sea, on the west Mona passage separates the island from Hayti, and on the east lie the Virgin Islands and Saint Thomas. Porto Rico is about 1,000 miles southeast of Florida, and about 1,500 miles from New York City. The shape of the island is that of an elongated quadrangle, its long axis running east and west. The greatest length of the island is 108 miles and its average breadth is 37 miles. The estimated area is 3,600 square miles, or about 1,000 square miles greater than that of the State of Delaware and 1,300 square miles less than that of Connecticut. In appearance Porto Rico is an agglomeration of hills and mountains channelled with innumerable steep and narrow valleys. The hills and mountains abut more or less abruptly on the ocean, with but here and there an intervening strip of flat or gently sloping shore. Notwithstanding the striking unevenness of the island, there is a definite orographic system traced as a sinuous crest from near the southwestern corner eastwardly, and about one-third nearer the southern coast than the northern. In the eastern part of the island this crest bends sharply and terminates near the northeast extremity of the island in the peak, El Yunque, 3,609 feet above sea-level, the highest point in Porto Rico. The general elevation of this crest ranges from 2,000 to 3,000 feet above sea-level, with here and there a pass somewhat lower or a peak somewhat higher. From this general crest the mountains and hills decline coastward. The coastward fall is much greater toward the south as a consequence of the proximity of the mountain crest to the southern coast. This crest divides the island into practically two watersheds, the larger one draining north and west, the smaller draining south and east. Flowing down these two sheds, rapidly and often precipitously, are more than thirteen hundred named streams. But few are navigable, and then only for a few miles. The coast, unlike that of Cuba, has but few fringing reefs to interfere with the close approach of vessels to the shore. There are a number of good natural harbors. San Juan, on the north, is the most important commercially. It now has a depth of twenty-nine feet in the roadstead and twenty-two feet at the wharves. Other ports that may be entered by the average ocean-going vessels are Arecibo, Aguadilla, Mayaguez, Guanica, Arrayo, and Fajardo. When it is considered that the total coast line is not much more than three hundred miles, Porto Rico appears well provided with harbors. Viquez, a small inlet off the east coast, has two excellent harbors.

Geology.—Though one of the earliest colonized islands of the New World, practically nothing is known of the geology and mineral resources of Porto Rico. The early Spanish settlers worked some placer gold, and some is still to be found in the rivers of the northeast part of the

Digitized by Microsoft®

island. Mercury, magnetic iron ore, copper, coal, salt, and several other minerals are found, but till a systematic survey is made no estimate of the actual importance of these minerals and of others not mentioned can be given. Several thermal and mineral springs, and one or two caves of interesting formation and beauty are known.

www.lbtool.com.cn

Fauna.—The indigenous mammalian fauna have practically disappeared with the exception of a few species of rodents, of which the only peculiar one is the somewhat squirrel-like agouti (common also to all the other West Indies). A number of bats are found. The curious marine mammal, the manatee, frequents the shoal waters of the coast. Fish, both fresh- and salt-water varieties, are plentiful. Noxious reptiles are said not to exist, and insect pests are not over-plentiful. The usual domestic animals thrive well, and good beef is to be had throughout the island.

Flora.—Vegetable life flourishes even to the tops of the highest peaks. However, it is now only on the more inaccessible mountain slopes and tops that considerable remnants of the once large indigenous forests are found. Some of the native woods possess properties that are peculiarly suitable for certain purposes, but their scarcity precludes their general use. Intelligent reforestation would seem to offer returns of commercial value. Among the many native trees, Baron Eggers describes a beautiful talauma with immense white odorous flowers and silvery leaves, a hertella with crimson flowers, an unknown tree with orange-like foliage and large purple flowers, and most conspicuous of all, the Cocoloba macrophylla, with its great purple spikes of more than a yard long. Of woods common to other of the West Indies, there are found hard and soft Spanish cedar, sandalwood, and ebony. Tree ferns are numerous and of large size. The absence of epiphytes is in striking contrast to their abundance in the forests of the neighboring islands. Coffee, of excellent quality, sugar cane, yams, oranges, cocoanuts, and many of the other tropical fruits are cultivated and yield well. A species of rice, requiring no irrigation, is found growing upon the highlands, and forms one of the staple foods of the laboring class. An excellent grass, Hymenachne striatum, covers the lowland pastures, and on it is fattened the beef for which Porto Rico is esteemed by its neighboring islands.

Climate.—Though somewhat nearer the equator than Cuba, Porto Rico is not correspondingly warmer. On the contrary its temperature, taken as a whole, is slightly more comfortable. This is due to the situation of the island farther out in the ocean, and at the windward angle of the Antillean system. This position, combined with its slightly more southern latitude, gives it the unobstructed flow of the northeast trades at all seasons of the year. Porto Rico, again compared with Cuba, owes somewhat of its more agreeable temperature to its smaller size, giving it a nearer approximation to the true marine air temperature of its latitude. The only statistical data of value in determining the climate of Porto Rico are the observations made by the United States Weather Bureau station at San Juan. This station was established late in 1898. At the same time a number of what are now known as voluntary stations were established, but the data furnished by them are not yet accurate enough to be of much use, climatologically. The table given below shows the principal climatic values for San Juan, as determined from four years' observations.

Temperature.—A record of temperature was kept by the Jefutura de Obras Publicas, prior to American occupation of the island, but it does not present on its face that evidence of accuracy that well-kept meteorological records exhibit. However, the results are given that they may be compared with those of the annexed table. The average annual temperature for twelve years was 78.9°; the highest recorded temperature 100.8° and the lowest 56.1° F.

The hottest season of the year is from July to October, inclusive, with an average temperature of 80° to 81°. The coolest season is from December to March, inclusive, with an average temperature of 75° to 77°. It appears probable that this regimen holds for the island generally. Local differences in altitude and exposure should be taken into consideration as affecting the numerical size of the values given. If we take two interior stations, Cayey, 1,205 feet elevation, and Adjuntas, 1,970 feet elevation, the records of which, though broken, may still give an approximation of the inland temperature, we shall find that the average seasonal temperatures are from two to six degrees lower than those of San Juan. The highest temperature in three years at Cayey was 97°, and at Adjuntas in the same years 92°. The lowest recorded was 52° at both places. At San Juan the average diurnal range of temperature is about 10° to 11°, and at the two other stations it appears to be about 20°. Cayey is in the east central part and Adjuntas in the west central part of the island.

Rainfall.—The average yearly rainfall at San Juan for four years was 75.52 inches. From the records of the Spanish authorities before referred to it appears to have been 61.2 inches. Fair records of the rainfall in other parts of the island are not yet to be had. However, there is no doubt that the rainfall varies greatly, even in localities but few miles apart. The rainfall is much greater on the northern watershed than on the southern, and much greater on the northeastern part of the first-named shed. Generally speaking, the rainfall is everywhere greater on northeast exposures. On the southern watershed there are many localities where the rainfall is insufficient for the tropical vegetation and barren tracts are not uncommon. Irrigation is necessary in many localities on this shed.

The greatest amount of rain falls from May to October. The months of February and March are comparatively dry, February noticeably so at San Juan. In Porto Rico, as in other tropical regions, the greater part of the rain falls as an accompaniment of the almost daily thunder storm. The usual cloud regimen is clear skies in the

morning, cloudy in the afternoon, and clearing and clear at night.

Wind.—The prevailing winds are remarkably constant from the east or between northeast and southeast. The velocity is steady and averages ten miles an hour. It is subject to a regular diurnal range, rising gradually to a maximum at the hottest part of the day and subsiding from that time to a minimum at the coolest part of the day, just about sunrise. This regularity and steadiness of the wind cannot be over-estimated in its relation to the comfortable habitability of Porto Rico.

Storms.—Though visited August 8th, 1899, by one of the most destructive storms of recent years, the island is well to the east of the usual tracks of West Indian hurricanes. Thunder storms, though of almost daily occurrence and accompanied by great electrical display, are not destructive, and one soon becomes used to their apparent violence.

History.—Porto Rico was discovered by Columbus in 1493. The first settlement was made by a party of Spaniards under the leadership of Ponce de Leon, at Caparra, A.D. 1510, but it was shortly afterward abandoned. San Juan was founded by the same leader in 1511. The town was sacked by the English under Drake in 1595, and again under the Earl of Cumberland in 1598. Since then it has successfully withstood the assaults of the Dutch in 1615, the English in 1678 and in 1797, and the United States in 1898. On July 25th, 1898, the island was invaded by the United States forces, who landed without opposition at Guanica on the southern coast. Only a feeble resistance was subsequently encountered. The Spanish formally evacuated the island October 18th, 1898. By the treaty of Paris, December 11th, 1898, Porto Rico was ceded to the United States. A census taken by direction of the War Department, 1899, gave a total population of 953,243 inhabitants. Unlike most, if not all, the other West Indian islands, Porto Rico has a larger white than black population. In 1899 there were 589,426 whites and 363,817 blacks. The density of population is also great, averaging 264 persons to the square mile, a density equal to that of New Jersey and twice that of Pennsylvania. The greater part of the population is rural. The population of the largest cities in 1899 was: San Juan 32,048, Ponce and its port 27,952, Mayaguez 15,187, and Arecibo 8,008. The ratio of illiteracy is high, but twenty-three per cent. of the population over ten years of age being able to read. Agriculture, such as it is, is the chief occupation, employing about sixty-three per cent. of the working population. The most important products are coffee, sugar, and tobacco. The total value of exports from July, 1898, to December, 1899, was $11,621,049. The imports during the same period amounted to $12,654,542. Transportation facilities before American occupation were poor. There existed but one hundred and thirty-seven miles of railroad, and with the exception of the excellent military road from San Juan to Ponce, and a few connecting branches, there were no common roads at all. Much has been done since to improve matters in this respect. The sanitary conditions were equally in keeping with the general indifference shown in other improvements. Few, very few, houses had any efficient sewage disposal systems. In many the systems were even worse than none, being in their ultimate workings actually pernicious. The average death rate, calculated from reported deaths for eleven years, is 30 per thousand. There is reason to think that this is considerably less than the actual. The chief causes appear to be: Anaemia, 22.50 per cent.; tuberculosis, 6.78; diarrhoeal diseases, 3.83; cerebrospinal meningitis, 1.12; typhoid fever, 1.43; tetanus, 3.57. Smallpox was, prior to 1899, one of the chief causes of mortality, averaging annually 623 deaths. It is now, happily, no longer a factor of importance, owing to the thorough vaccination of the entire population carried out by the United States military authorities. Yellow-fever epidemics have occurred occasionally. The large mortality from anaemia appears to be due to the general infection of the drinking-water by the intestinal parasite, ankylostomum duodenale. Ordinary care exercised in filtering or otherwise purifying the water used for culinary and drinking purposes should be followed by a great reduction in this disease.

W. F. R. Phillips.

POST-MORTEM EXAMINATIONS. See *Autopsies*, and *New-Born, Pathology of*.

POTASSIUM.—I. General Medicinal Properties of Compounds of Potassium.—In its physiological relations potassium is the most individual of the alkali metals, producing effects sufficiently pronounced to be seen characteristically in the case of all its compounds that are capable of absorption. Such effects are as follows: Locally, potassic compounds are irritant—less so than the average of soluble compounds of the heavy metals, but yet sufficiently so to make a large portion of a strong solution of a potassic salt dangerous on the score of irritation alone. In the intestines, potassic salts tend to increase the secretion of fluid, so that salts of this base that are of low diffusion power prove watery purges. Constitutionally, the prominent effects are certain derangements of function and certain effects that find their simplest explanation in the assumption that potassium quickens the rate of oxidation within the organism as it does in laboratory experiments. The derangements of function are, first, an enfeeblement of the heart's action, passing, in poisonous dosage, to permanent arrest in diastole. The effect seems to be due, as results of all experimentation agree, to a directly paralyzing influence upon the musculature of the organ itself. Secondly, but requiring relatively larger dosage, there follows general motor paralysis, voluntary and reflex. This effect is proportionately much more strongly marked in cold-blooded than in warm-blooded animals, and, in therapeutic dosage in man, is practically not seen at all. It is probably accomplished by an action on nerve centres, nerve trunks, and muscles conjointly, but an action which is most intense upon the nerve centres and least so upon the muscles.[1] The effects commonly assigned to a quickening of oxidation are, in the healthy, an increase in the solid excreta of the kidneys, with a proportionate increase in the volume of the urine, and, in the lithæmic individual, a diminution in the amount of uric acid excreted, with a simultaneous increase of urea and appearance of calcium oxalate. These effects in lithæmia are translated to mean an oxidation of much of the uric acid into oxaluric acid, which product then splits into urea and oxalic acid.[2] In large doses, long continued, potassic compounds prove noxious to nutrition, the blood becoming thin and unduly fluid, newly formed and lowly vitalized tissues, such as cheesy deposits, tending to liquefy, and health and strength generally to suffer. Therapeutically, the effects of applications of potassic compounds, determined by the potassium element of their composition, are to depress the heart in sthenic fever, to oppose the lithic diathesis, and to provoke catharsis or diuresis. Other uses are derived from individual peculiarities of the different compounds.

II. The Compounds of Potassium Used in Medicine.—The compounds of potassium official in the United States Pharmacopœia divide, for purposes of study, into two groups—the one embracing compounds whose effects are either derived from the potassium or are *sui generis* to the salt, and the other such as owe their effects mainly to the acid radical of their composition. The members of the former group, which alone will be discussed in this place, are the *hydroxide*, *carbonates* (normal and acid), *citrate*, *acetate*, *tartrates* (acid and potassio-sodic), *sulphate*, *nitrate*, and *chlorate*. The second category comprises the *hypophosphite*, *bromide*, *iodide*, *sulphide* (in the preparation, *potassa sulphurata*), acid *chromate*, *cyanide*, *ferrocyanide*, *permanganate*, *arsenite*, (in the preparation, *liquor potassii arsenitis*), *potassio-aluminum sulphate* (alum), and *potassio-ferric tartrate*. For discussion of these compounds see, severally, *Hypophosphites*, *Bromides*, *Iodides*, *Sulphides*, *Chromium*, *Cya-*

nides, Ferrocyanides, Manganese, Arsenic, Aluminum, and *Iron.*

Potassium Hydroxide (Potassium Hydrate): KOH. This is the compound which is both commonly and officially known as *Potassa*, Potassa, called also *caustic potash*. It is obtained first in aqueous solution by precipitating with lime a solution of acid potassium carbonate. Such aqueous solution, when rapidly boiled down, yields a fluid of oily consistence—simply the hydroxide melted by the heat—which, poured into cylindrical paper moulds, hardens on cooling into the cylindrical sticks in which form potassa is commonly met with. Potassa thus obtained is a white, hard substance, having a faint alkaline odor, and a very harsh, caustic taste. It is exceedingly deliquescent, and readily soluble in water and alcohol.

Beside the stick form, potassa is official in five per cent. aqueous solution under the title *Liquor Potassæ*, Solution of Potassa. This solution is made as just described, and is a clear, colorless liquid, odorless, but with the acrid, caustic taste of potassa. It should be kept in green glass bottles, glass stoppered, and the stoppers should be coated with vaseline or a thin layer of melted paraffin. Specific gravity about 1.036.

Potassa produces physiological effects which spring in part from an intense affinity for water, in part from its powerful alkalinity, and in part from its operation as a compound of potassium. Locally, in concentrated application, potassa is intensely caustic. A moistened stick swept even lightly over a tender surface produces speedy corrosion, which extends finally beyond the area of original application, the tissues breaking down widely into a brownish, slimy, pultaceous material. Taken internally, therefore, in strong solution, potassa is a corrosive poison. In such poisoning, the acrid, alkaline taste of the potion is followed immediately by severe pain in the pharynx, œsophagus, and epigastric region. These symptoms are in turn speedily succeeded by violent vomiting, where the ejecta have the greasy aspect and pultaceous consistency of tissues corroded by potassa, and prove strongly alkaline to test paper. The mucous membrane of the lips, mouth, and throat may be bright red from irritation, if the solution swallowed were not overstrong, or may, in the case of strong potions, show direct corrosion, being covered by a brownish film having a greasy or soapy feel. Loss of voice and extreme difficulty of swallowing are exceedingly common, but intestinal symptoms are generally wanting. Constitutionally, the symptoms are those of shock, from the suddenness and severity of the corrosion. In survival from serious grades of the poisoning, stricture of the œsophagus is a very common sequel. In the treatment, the only peculiar feature is to give harmless acids to neutralize the alkali, but since the damage is generally already fully done before the physician arrives, this chemical neutralization rarely avails for much. Vinegar or lemon juice are the acids most available, from their being strong but non-corrosive themselves, and at the same time readily procurable. Locally applied, in non-corrosive strength, potassa operates as a powerful and harsh alkali. Acids are neutralized, grease becomes saponified, epithelial tissues swell and soften, and acid secretions, such as the gastric juice and the sweat, tend to be called forth. Upon the skin, potassa lotions cleanse from dirt or the crusts of dried secretion and epithelium resulting from skin disease. Taken internally, the remedy excites appetite and increases the flow of the gastric digestive fluid, or in cases of fermentation of the food neutralizes acidity and so relieves the heartburn and nausea which such acidity excites. Constitutionally, medicinal doses of potassa produce, of course, the effects of all potassium compounds as already set forth, and also, because of free alkalinity, tend to neutralize morbidly developed acid in the blood or tissues, to diminish the acidity of the urine, or even to reverse the reaction of that secretion to the alkaline. Probably in part because of the peculiar action of potassium as such, and partly because of the alkalinity of potassa, this compound is of special efficacy in the diatheses leading, severally, to rheumatism, gout, and lithæmia, and in the skin diseases urticaria, psoriasis, eczema, lepra, acne, and recurring boils.

The medical uses of potassa are for the purposes above detailed, yet, except as a caustic, it is not so much used as its acknowledged potency would seem to suggest, simply because it is rough and harsh, while at the same time other and milder potassic compounds are equally efficient. Thus for direct local alkaline action the carbonates, and for constitutional alkalizing, the citrates and tartrates, are respectively preferable.

To *cauterize* with potassa, the adjacent parts should be protected by adhesive plaster, and the doomed area, if covered by skin, should then be rubbed with a moistened stick of the caustic until discoloration appears. If the part be a mucous membrane or raw tissue, a single light sweep of the caustic is sufficient for even a profound cauterization. In no case should the agent be used where an exact limitation of the caustic effect is essential, as where the part to be destroyed is in close contiguity to important, or large, blood-vessels or organs. To render the corrosion of potassa less spreading, a mixture of equal parts of potassa and quicklime has been devised, and is official in the United States Pharmacopœia, under the title *Potassa cum Calce*, Potassa with Lime. This mixture, commonly known as *Vienna caustic*, is a grayish-white, deliquescent powder, soluble in hydrochloric acid. It is less diffusive in its action than potassa, by reason of the peculiar action of the lime of its constitution. For use the powder is made into a paste with a little alcohol.

For a potassa lotion, the solution of the Pharmacopœia is to be prescribed, diluted with several volumes of water. For internal giving, the same solution is employable, in doses ranging from 0.65 to 4 gm. (♏ x. to fl. ʒ i.) greatly diluted with some syrupy or mucilaginous fluid. But potassa, as an internal remedy, is very objectionable for any but a very temporary medication.

Normal Potassium Carbonate: $(K_2CO_3)_2.3H_2O$. The salt is official in the United States Pharmacopœia under the title *Potassii Carbonas*, Potassium Carbonate. It is a white, granular powder, very deliquescent, odorless, having a strongly alkaline taste, and an alkaline reaction. It is readily soluble in water, but is insoluble in alcohol. Potassium carbonate is so deliquescent that unless carefully put up in well-stoppered bottles it will eventually transform itself into an oily fluid, by dissolving in moisture attracted from the atmosphere.

Physiologically, potassium carbonate is simply a weakened potassa, yet not so weak but that, in strong solution, it may prove a corrosive poison. Its use is mainly in ointment or in aqueous solution as a strong alkaline potassic application in skin diseases. Ointments of the carbonate are made with lard, the strength ranging from two to ten per cent. Solutions of the salt for service as lotions range in strength from one-half to one per cent.

Acid Potassium Carbonate: $KHCO_3$. The salt is official in the United States Pharmacopœia under the title, *Potassii Bicarbonas*, Potassium Bicarbonate. It occurs in colorless, transparent, prismatic crystals, and differs from the normal carbonate in being permanent in the air. It is odorless, and of a slightly alkaline taste and reaction. It is soluble in 3.2 parts of cold water and is decomposed by boiling water. It is practically insoluble in alcohol. It should be kept in well-stoppered bottles.

Physiologically, this carbonate is similar to the normal salt, but weaker. The taste is mild, though mawkish; the alkalinity feeble, and the salt is hardly capable of being corrosive. The uses are, locally, as an alkaline application in skin disease, in preparations such as are described above in speaking of the normal carbonate, and, internally, as a stomachic or constitutional alkali. But for stomachic purposes sodic salts are more agreeable, and for constitutional alkalies the potassic citrates and tartrates. If given internally, the dose ranges from 1 to 4 gm. (from gr. xv. to ʒ i.).

Normal Potassium Citrate: $K_3C_6H_5O_7.H_2O$. This salt, formerly known as *Salt of Riverius*, is official in the

Digitized by Microsoft®

United States Pharmacopœia under the title *Potassii Citras*, Potassium Citrate. It is a deliquescent salt occurring in transparent prismatic crystals or as a granular powder. It is odorless with a slightly alkaline and cooling taste. It dissolves readily in water, but slightly only in alcohol. Potassium citrate is a not disagreeable tasting, cooling salt, which is devoid of all local harsh effect, and yet after absorption seems to undergo decomposition as regards its acid radical, becoming converted into a carbonate. Such secondarily formed carbonate thereupon exerts the usual action of an alkaline potassic compound, as detailed under Potassa above. Potassium citrate is thus available as a gentle diuretic, diaphoretic, and cardiac sedative in fevers, and also as an agreeable and yet efficient agent for constitutional alkalizing. It may be given freely in doses of from 1 to 2 gm. (gr. xv. to xxx.) in water or in effervescing water, sweetened or aromatized to taste. In order to obtain the salt in effervescing solution, in which condition it is more grateful to a fevered stomach, the following preparations are official in the United States Pharmacopœia: *Potassii Citras Effervescens*, Effervescent Potassium Citrate. This preparation is a powder consisting of a dry mixture of citric acid, potassium bicarbonate, and sugar. When added to water, reaction instantly takes place between the citric acid and the potassium bicarbonate, with the formation of potassium citrate and carbon dioxide. One or two teaspoonfuls make a dose, to be taken in water and drunk during effervescence. Such effervescent solution takes the place of the old, so-called "neutral mixture," or "mixture of citrate of potassium," formerly but now no longer official. Such mixture was simply fresh lemon juice, strained, and neutralized with potassium bicarbonate. *Liquor Potassii Citratis*, Solution of Potassium Citrate: This is a simple aqueous solution of the salt effected by bringing together in water six per cent. of citric acid and eight per cent. of acid potassium carbonate. It contains nine per cent. of potassium citrate, and should be made fresh when wanted. But the effervescing draught made from the "effervescent citrate" is a better way of getting the same solution.

Potassium Acetate: $KC_2H_3O_2$. The salt is official as *Potassii Acetas*, Potassium Acetate. This is an exceedingly deliquescent salt, having a warming, mildly pungent, salty taste. Very soluble in water and in alcohol. It must be kept in well stoppered bottles. Potassium acetate is generally similar in properties to the citrate, undergoing, like that salt, conversion into a carbonate after absorption, and so operating constitutionally as a potassic alkali. It is not so agreeable to the taste nor so grateful to the stomach as the citrate, but has a considerable reputation as a diuretic, as evidenced by its old cant name of *Sal diureticum*. As a matter of fact, however, it—often, at least—does not prove more diuretic than the citrate or other potassic salts. Potassium acetate may be used for the same purpose and in the same doses as the citrate.

Potassio-sodium Tartrate: $KNaC_4H_4O_6.4H_2O$. This well-known salt, commonly called Rochelle or Seignette's Salt, is official in the United States Pharmacopœia under the title *Potassii et Sodii Tartras*, Potassium and Sodium Tartrate. This salt occurs in colorless, rhombic crystals, or as a white powder. It is odorless, with a cooling, saline taste, and effloresces slightly in dry air. It dissolves readily in water, but is almost insoluble in alcohol. This salt is decomposed by acids, with the production of a crystalline precipitate of acid potassium tartrate ("bitartrate"), and also by soluble plumbic, calcic, and basic salts.

Rochelle salt is mild in flavor and local action, agrees well with even a sensitive stomach, and differs from the citrate and acetate in being of low, rather than high diffusion power. Hence in full dose it is purgative, but as compared with the average of saline purges ranks among the milder. In non-purgative dose, especially if given well diluted, it is absorbed, changes to carbonate after the manner of the citrate and acetate, and then exerts, as efficiently as other salts, the specific action of alkaline potassic compounds. From its mildness it is preferred by many to other potassium preparations as a constitutional alkali in rheumatism, lithæmia, etc. For constitutional action as an alkali or as a diuretic the salt is to be given in comparatively small but frequently repeated doses, not to exceed, as a rule, 4 gm. (ʒ i) at a time. As a purge, the dose will range, according to the intensity of the effect desired, from 8 gm. to 30 gm. (ʒ ij. to ℥ i.) in water, plain or aromatized. A favorite mode of administration is in effervescent solution, as obtained by use of the official *Pulvis Effervescens Compositus*, Compound Effervescing Powder. This is the well known *Seidlitz powder*, and consists of two parts, one a powder in blue paper, made up of about 2.60 gm. (gr. xl.) of acid sodium carbonate ("bicarbonate") and about 8 gm. (ʒ ij.) of Rochelle salt, and the other a smaller powder in white paper, consisting of about 2.25 gm. (gr. xxxv.) of tartaric acid. Each portion is to be dissolved separately in about 60 gm. (fl. ℥ ij.) of iced water, sweetened and aromatized if so desired, and the solution of the acid then to be added, half at a time, to that of the salts, and the potion drunk during the effervescence which immediately occurs. The reaction upon mixing the solutions is, of course, the decomposition of the sodium carbonate by the tartaric acid, with the formation of a sodium tartrate and the evolution of carbon-dioxide gas. A single "powder" is a medium purgative dose.

Acid Potassium Tartrate: $KHC_4H_4O_6$.—This well-known salt, the *cremor tartari* or *cream of tartar* of common parlance, is official in the United States Pharmacopœia under the title *Potassii Bitartras*, Potassium Bitartrate. It is prepared by a process of purification from the impure salt occurring as an incrustation developing in casks of wine, especially of acid wines. Such incrustation is called *argol*, or *crude tartar*, the latter name being derived from the *tart* quality of the wines that furnish the greatest yield of the substance. The purified salt may be in crystals, but as furnished to pharmacists it is in fine powder, to which condition especially the cant name of "cream of tartar" applies. The salt is permanent in the air, and has an agreeable, subacid taste. It is peculiar in being comparatively insoluble in cold water (201 parts), although much more soluble in boiling water (16.7 parts). It dissolves sparingly only in alcohol. The solubility in water can be increased till the salt dissolves in one part, by the addition of borax, two parts to five of the tartrate. Commercial cream of tartar always contains more or less calcium tartrate, which salt is a normal constituent of crude tartar, but, according to the pharmacopœial standard, the proportion should not rise above six per cent. Besides this natural impurity adulterations are often found, such as chalk, gypsum, clay, sand, or flour. Purchase of the article in crystals affords the surest way to avoid these sophistications.

Cream of tartar is a cooling, acidulous salt, agreeing well with delicate stomachs. Like Rochelle salt, it is of low diffusion power and is therefore cathartic, and in its purgative action is characterized by the copiousness of the watery dejections it determines. For this reason it is a favorite ingredient of cathartic mixtures intended for carrying off a dropsical effusion, such as the compound powder of jalap of the United States Pharmacopœia. In non purgative dosage the salt is refrigerant and diuretic —perhaps more generally diuretic than any other potassic compound, but, unlike the other potassic salts of organic acids, it does *not* appear to suffer the usual conversion in the blood into a carbonate. Such, at least, is the inference from the clinical observation that cream of tartar is not of the same value for constitutional alkalizing as are, respectively, the other tartrates, the citrate, and the acetate. The uses of the present salt are therefore restricted to its application as a purge, a diuretic, or a grateful, cooling saline in feverishness. The doses are substantially the same as those of Rochelle salt for the same several purposes. The powdered cream of tartar may be suspended in water or mixed with molasses for giving as a purgative, or, for use as a fever draught,

www.libtool.com.cn
Digitized by Microsoft®

may be dissolved in boiling water, and the solution, when cold, given sweetened with sugar. The old-fashioned, so-called *imperial* draught is made by dissolving one per cent. of cream of tartar in boiling water, adding one per cent. of sliced lemon and eight of white sugar. *Cream of tartar whey*, so called, consists of one and a half per cent. of the salt in milk.

www.libtool.com.cn

Normal Potassium Sulphate: K_2SO_4. The salt is official in the United States Pharmacopœia under the title *Potassii Sulphas*, Potassium Sulphate. It is a permanent salt, occurring either in transparent, colorless rhombic crystals, or as a white powder. It dissolves in about 9.5 parts of cold water, and in 4 parts of boiling water. It is insoluble in alcohol. Potassium sulphate is, like all sulphates, comparatively harsh, and in large concentrated dose has caused fatal irritant poisoning. It is of low diffusion power, therefore purgative, and its medical use has been as a saline cathartic. It is, however, little used, because of its occasional harshness. The dose will range from 8 to 16 gm. (ʒ ij. to iv.), to be given in solution, well diluted. This is the salt formerly called *vitriolated tartar* and *sal de duobus*.

Potassium Nitrate: KNO_3. This salt, the well-known substance *nitre*, or *saltpetre*, is official in the United States Pharmacopœia under the title *Potassii Nitras*, Potassium Nitrate. This is a permanent salt, occurring in colorless, transparent, six-sided rhombic crystals, or in a crystalline powder. It is odorless, with a cooling, pungent taste. It dissolves in about four parts of cold water and in less than one part of boiling water. It is almost insoluble in alcohol. It deflagrates when thrown upon red hot coals. Under the name of *sal prunelle* or *crystal mineral*, nitre is also to be found in the shops in small circular cakes, moulded from the salt, fused. Commercial refined saltpetre is the quality of the salt to be employed in medicine, and an article in small crystals is preferable to one in large, since large crystals are apt to contain some water, mechanically entangled in the process of crystallization.

Potassium nitrate, like the sulphate, is a powerful salt in local operation, but, unlike the sulphate, is of high diffusion power, so that even a large dose will be comparatively quickly absorbed. Taken internally it is therefore doubly potent, and even poisonous, a large dose exciting severe irritant poisoning, and consecutively producing in the highest degree the dangerous constitutional effects of the potassic compounds generally. The salt undergoes no decomposition in the system, and is therefore incapable of exerting any *alkaline* effects, either local or constitutional. In medicinal doses nitre produces the antifebrile effects of the potassium salts generally, being cooling and grateful to the stomach, and tending, after absorption, to quiet a bounding heart and at the same time to prove gently diuretic and diaphoretic. Being of high diffusion power, it does not purge except in considerable dose. A peculiar property of nitre is that, mixed with fresh venous blood, it turns the blood bright red and impairs its coagulability; but in spite of much theorizing, the fact does not lead to any special therapeusis. Medicinally nitre is nowadays rarely used internally, except as an ingredient of fever draughts or of diuretic mixtures. Formerly it had considerable reputation in the treatment of acute rheumatism, being pushed in full doses, but alkalies and salicylates have now supplanted the salt for this application. The single dose of nitre should not exceed 2 gm. (gr. xxx.), and the salt is best given in dilute solution. Considerable single amounts, especially if in concentrated condition, are dangerous, but so rapid are the absorption and elimination of the nitrate that, by means of small and frequent doses, properly diluted for the taking, a very large quantity—from 30 to 62 gm. (℥ i. or ij.)—can be passed through the system in the course of a single day without injury. A special therapeutic application of saltpetre is the inhalation, for the relief of spasmodic asthma, of the fumes arising from its combustion. As usual in antispasmodic medication, some cases find relief from the agent and others do not, or even suffer aggravation thereby. For the application, white unsized paper, free from wood, is steeped in a twenty-five-per cent. aqueous solution of nitre and allowed to dry. A piece is then burned, and the patient, with the face as near as can be borne without undue irritation, inhales the white fumes that are given off. Such prepared paper is official in the United States Pharmacopœia under the title *Charta Potassii Nitratis*, Nitrate of Potassium Paper. It is sometimes called *asthma paper*. Toxicologically nitre is of some importance, cases of poisoning by the salt not infrequently occurring. An ounce, swallowed at a draught, has proved fatal in a number of instances. Taken, as it commonly is in such cases, in pretty strong solution in mistake for purgative salts, it produces symptoms of severe gastro-intestinal irritation—burning pain in the stomach, violent vomiting and purging, the dejecta being sometimes bloody, and general collapse. Whether the constitutional symptoms are merely symptomatic of shock from the irritation, as occurs so commonly with powerful irritant poisons like the mineral acids, or whether they are in part the expression of the specific potassium poisoning of nerve and muscle, is not always easy to determine, and is of no practical bearing on the treatment of the poisoning. Special symptoms are urinary suppression, with strangury, tenesmus, and bloody urine, and aphonia. These may or may not occur. Death may take place in two hours after the swallowing of the poison. There is no chemical antidote to nitre, so that the treatment of a case of poisoning must be conducted simply on general medical principles.

Potassium Chlorate: $KClO_3$. The salt is official in the United States Pharmacopœia under the title *Potassii Chloras*, Potassium Chlorate. This is a permanent salt, occurring in colorless, shining, prismatic crystals or plates, odorless, and having a cooling, saline taste. It dissolves in 16.7 parts of cold water, but in 1.7 parts of boiling water. It is slightly soluble only in alcohol. If heated or triturated with organic substances, such as sugar, tannic acid, or cork, or with easily oxidizable chemicals, such as sulphur or phosphorus, a dangerous explosion is likely to occur. The salt should, therefore, be kept in glass-stoppered bottles and handled with care.

The chemical relationship between chlorates and nitrates is paralleled, as usual in such cases, by resemblance in physiological action. The present salt thus closely resembles nitre in its effects, the principal difference being in intensity of power, the chlorate being the weaker—a fact probably in part due to the less ready solubility of the salt. Yet the chlorate is strong enough, in full concentrated dose, to be fatally poisonous, with symptoms of intense gastro-intestinal irritation, and, in too lavish medicinal use, as has been the fashion in diphtheria, to be the likely cause of much of the nephritic disorder thoughtlessly assigned, in etiology, to the disease instead of to the medicine.[3] For, like the nitrate, the chlorate of potassium has a distinct tendency to irritate the kidneys, which, in the choked condition of the organs common in diphtheria, may easily lead to dangerous congestion. Potassium chlorate was forced into medicinal notoriety largely by the theoretical consideration that, since chlorates readily part with some of their oxygen, thus proving active oxidizing agents, the salt ought to serve as a constitutional source of oxygen within the animal system, and so prove of benefit in diseases that tax the nutritive powers of the organism. Clinical experience, however, does not bear out the prognostications of theory, and physiological chemistry accounts for the failure by finding that, under the conditions of the animal circulation, potassium chlorate suffers no decomposition, but is eliminated by the kidneys and other organs unchanged. The only rational place of this salt in medicine hinges on the following fact: The chlorate is largely eliminated by the salivary glands, and probably also by the mucous follicles of the mouth and pharynx, and in inflammatory conditions of the surface textures of these parts distinctly tends to healing. Sore mouth or sore throat, catarrhal or ulcerative, is therefore treated with advantage with potassic chlorate in the form of

Digitized by Microsoft®

wash or gargle, or, better still, for the sake of continuous application to the parts through the avenue of the saliva and buccal mucus, given internally. A convenient practice is to prescribe a five-per-cent. aqueous solution of the salt, which is upon the verge of a saturated solution, and direct this to be used as a mouth wash or gargle every two hours, and at the same time a couple of teaspoonfuls to be taken internally. Such quantity will represent about 0.50 gm. (gr. viij.) of the salt—a moderate single internal dose. Among the varieties of buccal disorders amenable to potassium chlorate may be mentioned mercurial stomatitis; and some practitioners even combine the potassium salt with their mercurials in constitutional mercurialization, with the view of lessening the risk of salivation. In diphtheria, also, the chlorate is a good deal used, the good effects being probably the local ones only, and the risk to kidneys or heart from too free dosage being genuine and considerable. Of preparations, the United States Pharmacopœia makes official *Trochisci Potassii Chloratis*, Troches of Potassium Chlorate, the ingredients being the salt, sugar, and tragacanth, and a little of spirit of lemon for flavoring. Each troche contains 0.30 gm. (about gr. v.) of chlorate. In ordinary sore throats or sore mouths, for the treatment of which affections the preparation is especially intended, these lozenges, if allowed to dissolve naturally without chewing, may be taken continuously through the day.

Edward Curtis.

POTASSIUM, TOXICOLOGY OF.—Independently of the corrosive action which characterizes the oxid, hydroxid, and carbonates of potassium, those compounds of potassium with acids, which have little or no toxic qualities, such as the chlorid, sulfate, or tartrate, exert a distinctly poisonous action. In this respect the potassium compounds differ notably from those of sodium.

Experiments on dogs demonstrate that the injection of from 1 to 2 gm. of potassium chlorid, nitrate, sulfate, etc., directly into the circulation, produces death very quickly from cessation of the heart's action. Smaller quantities produce a slowing of the pulse, more or less gastritis, dyspnœa, convulsions, and sometimes death.

Diluted doses seem to have a less serious effect than the same weight of the salt in a concentrated form.

All fatal cases of poisoning in the human subject by the potassium salts of non-toxic acids have been due to ignorance or accident.

Potassium Bromid—KBr.—Two cases have been reported in which death followed the administration of very large quantities of potassium bromid. Duncan (*British Med. Journal*, 1882, Part I., p. 616) relates a case of a child three years old, who died in less than half an hour after taking between 5 and 6 gm. of the drug. The other case was that of an adult female, to whom was administered by her physician 4.2 gm. every four hours for four days. The patient died five days after taking the last dose (Hamer, *Columbus Med. Journal*, vol. iii., p. 259).

Aside from bromism several non-fatal cases are on record, in some of which the patient exhibited a peculiar idiosyncrasy as regards the tolerance of this substance.

Potassium Chlorid—KCl.—The poisonous action of this compound upon animals has been to some extent investigated. When injected into the blood supply of a nerve, the latter loses its excitability. The salt is eliminated with the urine, but much more slowly than sodium chlorid. I find no fatal cases reported as a result of the poisonous action of this salt upon human beings.

Potassium Nitrate—KNO_3.—This substance is commonly known by the name of nitre or saltpetre. Its use as a preservative of meat and other articles, and among agriculturists in the treatment of diseases of domestic animals, makes it one of the common household drugs.

In poisoning by potassium nitrate it is quite certain that the acidulous constituent plays no small part in the toxic action. This conclusion follows from observations upon man and lower animals, when subjected to the action of sodium nitrate (see two cases of poisoning by sodium nitrate, Collischorm, *Deutsche med. Wochenschrift*, vol. xv., p. 844). Large doses (3–5 gm.) cause uneasiness in the stomach and intestines, followed by vomiting, diarrhœa, and generally a frequent desire to urinate. Fifteen to twenty grams produce an acute gastro-enteritis, the vomit tinged with blood, pronounced weakness, cold sweats, and cramps, especially in the calves of the legs.

Woodman and Tidy ("Forensic Medicine and Toxicology") report six fatal cases in which the dose varied from 15 to 45 gm., and the duration from two to sixty hours. Wormley ("Micro-Chemistry of Poisons," p. 69) mentions an instance of an aged man who died in half an hour after taking a quantity of potassium nitrate in mistake for sodium sulfate. Size of dose not given. Bailey (*Phila. Med. and Surg. Reporter*, June, 1872, p. 75) records a recovery after taking 125 gm.

Lesser (*Vierteljahr. f. ger. Med.*, 1898, 3. F., xvi., 93) reports the case of a woman aged forty-six, who died twelve hours after taking about 70 gm.

Most of the cases of poisoning by potassium nitrate have been due to mistaking the substance for magnesium or sodium sulfate or sodium chlorid. In several instances overdoses produced serious results.

The symptoms consist of a severe burning pain in the abdominal region, nausea, vomiting, purging, vomit and stools containing blood, coldness of the extremities, facial tremors, weak and irregular pulse, and collapse. Difficult respiration was observed in some cases.

No chemical antidote is known. The treatment should be to remove the poison from the stomach, give mucilaginous drinks, and treat the symptoms.

Post-mortem Appearances.—The stomach is usually highly inflamed, with dark-colored patches, and the mucous membrane partially detached. Similar appearances have been observed in the duodenum and intestines. Sometimes the indications of asphyxia are present; the lungs are congested, and the right heart is filled with thick, very dark blood.

Potassium Sulfate—K_2SO_4.—This substance was formerly employed to produce abortion, several fatal results having occurred from such use. Bayard reports a case (*Ann. d'Hygiène*, April, 1842) in which 33 gm. of potassium sulfate were administered as a laxative after delivery. Death followed in two hours. A case is recorded in the *Medical Times and Gazette*, 1856, p. 420, in which 8 gm., administered to produce abortion, caused death.

The symptoms noted were pain in the stomach, nausea, vomiting, purging, and cramps in the limbs. A post-mortem examination showed the stomach to contain a reddish liquid, and the mucous membrane to be of a purple color.

Potassium bitartrate—$KHC_4H_4O_6$.—Although this substance, commonly called cream of tartar, may be found in every household, I find recorded but two fatal cases of poisoning by its use. In Tyson's case (*Lancet*, vol. i., 1837–38, p. 162) death followed in four days the taking of 125 gm. Roger reports a case (Friedreich's *Blätter f. ger. Med.*, xxviii., 1887, p. 196) in which 200 gm. caused death in twelve hours.

The prominent symptoms were severe abdominal pain, persistent vomiting and diarrhœa, thirst, feeble pulse, and paralysis of the legs. A post-mortem examination showed the interior surface of the stomach covered with red streaks and patches, and the intestines somewhat inflamed.

ANALYSIS.—Since potassium compounds are normally present in the body fluids and tissues, the analyst cannot report them as having been introduced into the system, unless he can prove them present in abnormal quantity, or in unusual combination. Cream of tartar, on account of its sparing solubility, may be found in the stomach in the solid form.

POTT'S DISEASE. See *Spine, Diseases of.*

POWDER SPRINGS.—Cobb County, Georgia. Post-Office.—Powder Springs.

Access.—Take Western and Atlantic Railroad to Marietta, and from thence private conveyance to the springs, ten miles distant.

www.libtool.com.cn

These springs were discovered about fifty years ago, but for want of improvements their reputation has been confined to the surrounding country. There are four springs, one of which has been approximately analyzed as follows:

One United States gallon contains: Iron sulphate, gr. 2; calcium sulphate, gr. 1; iron oxide, gr. 1.50. Total solids, 4.50 grains. The contained gases are: Carbonic acid, 1 cubic inch; hydrogen sulphide, 1.5 cubic inches.

The other springs contain about the same ingredients. The flow of water is about two and a half gallons per minute. The waters are evidently chalybeate, and we are informed that they have been found highly useful in depressed and debilitated states of the system where a fairly potent ferruginous tonic is indicated.

James K. Crook.

POWHATAN LITHIA AND ALUM SPRINGS.—Powhatan County, Virginia. Post-Office.—Tobaccoville.

Access.—From Richmond viâ Farmville and Powhatan Railroad to Tobaccoville station, forty-eight miles west, thence three-quarters of a mile by private conveyance to springs.

These springs are two in number, one known as the Lithia, the other as the Alum Spring. They yield about five hundred gallons of water per day. A qualitative analysis of the lithia water by Dr. W. H. Taylor, State chemist at Richmond, showed the presence of lime, magnesia, soda, lithia, potash, iron, silica, sulphuric acid, carbonic acid, and chlorine. The alum water was analyzed at the Smithsonian Institution and found to contain about the same ingredients, except that the lithia was replaced by alum. The water is sold to some extent, but the property has never been much developed and no hotel accommodations have been provided.

James K. Crook.

POWNAL SPRING.—Cumberland County, Maine.—Post-Office.—West Pownal. Hotel.

Location.—Eighteen miles from Portland and ten miles from Poland Spring.

Access.—Viâ Grand Trunk Railroad to West Hanover Station, or Maine Central Railroad to Pownal Spring Station.

The surroundings of the spring are very pleasing to the eye. The White Mountains, in the distant northwestern horizon, form an impressive background, while to the southward a wide panorama is unfolded to the view of the beholder, even Portland harbor being easily seen by the aid of a small glass. The location of the spring is upon land higher than any other in the immediate vicinity, thus giving no opportunity for surface pollution. The water comes apparently from the solid rock, and is clear and sparkling. The average temperature of the water as it emerges is 42° F. This is subject to a variation of only one degree in either direction during the entire year. The following analysis was made by State Assayer Franklin C. Robinson, professor of chemistry at Bowdoin College in 1893:

Reaction neutral. One United States gallon contains: Silica, gr. 0.41; iron carbonate, gr. 0.04; calcium carbonate, gr. 0.33; magnesium carbonate, gr. 0.02; sodium carbonate, gr. 0.09; sodium sulphate, gr. 0.08; sodium chloride, gr. 0.16; potassium carbonate, gr. 0.02. Total solids, 1.15 grains.

Organic and volatile matter, 0.01 grain. The water is bottled and sold. It is recommended for the table, and is said to be useful in dyspeptic and urinary complaints, but the remarkable attenuation of the water would appear to require the ingestion of large quantities in order to secure appreciable therapeutic effects.

James K. Crook.

PREMATURE INFANTS.—By premature infants we mean those babies which are born before the two hundred and eighty days, considered the normal length of intra-uterine gestation, have elapsed, and after the period of viability of the child. This period, however, is only arbitrary, and varies within relatively wide limits. In this respect much depends upon the nourishment of the fœtus prior to birth, the health of the mother during pregnancy, the conditions demanding or leading up to the interruption of pregnancy, the character and duration of labor, the difficulty attending its birth, as well as the care of the infant after its advent into the world. Consequently, in a syphilitic, tuberculous, or albuminous mother, in a case of placenta prævia or of accidental hemorrhage or eclampsia, in a dry, protracted labor, after a breech, forceps, or version delivery—in all these conditions, on account of the immature development of the vital organs, the chance of survival of the baby is very much reduced.

There are cases on record in which it is claimed that the child in utero reached only the twenty-fourth week and yet lived. Perhaps, in the future, advances in our knowledge of their care will enable such infants, born before the date supposed to be compatible with life, to survive. It is more likely, however, that such cases are reported with mistaken calculations.

There are no characteristic appearances, no exact development upon which we can definitely state the age of the infant when it is born. The weight, the length, and development all vary for a given length of gestation and statistics given are only approximate, but yet of sufficient value to guide us somewhat in the management of such infants. It is therefore generally the rule that if the infant is born alive, we must endeavor, without regard to size and characteristics, by the best care and latest knowledge, to preserve its existence.

The general characteristics in the clinical picture of a premature child are as follows: The head is very large in proportion to the body, the abdomen is prominent, the movements are very weak, the body is limp, and the child has a senile, emaciated, and wizened-up appearance.

At the *twenty-fourth week* of intra-uterine life a fœtus, when born, usually breathes feebly. Some cannot cry, although others will give a faint mewl. The infant is covered by lanugo. Its eyelids have separated, though it is so feeble that it cannot often open and shut them. There is very little subcutaneous adipose tissue. It measures about 28–34 cm. (11¼–13¾ in.) in length and weighs 676 gm. (℥ xxiii.). The testicles are only at the inguinal rings. This fœtus may live from a few hours to fifteen days, but would in all probability die from insufficient assimilation after a weak digestion of food, from rapid loss of heat or from imperfect respiration. At the *twenty-eighth* week the fœtus measures in length from 35 to 38 cm. (13.75 to 15 in.) and weighs 1,170 gm. (41¼ oz.). The soles of the feet and palms of the hands are not covered by lanugo. The pupillary membrane, which had hitherto obscured the pupil, has now disappeared. The skin is still wrinkled, covered by vernix caseosa. The child still has an emaciated appearance. Such an infant with good care can live, but most of them die. There persists, however, in the minds of some of the old practitioners and among the laity, the idea that a child born at the seventh month is more apt to survive than one born at the eighth month. Of course this is nonsense, for the development and functions of the vital organs are by far less advanced at the earlier than at the later date, and it stands to reason that the elder fœtus will be stronger thereafter. Professor Parvin, in his "Science and Art of Obstetrics," tells how this superstition has descended through more than two thousand years from Hippocrates. The Greek explained it in this manner, that the fœtus is placed with its head at the fundus in the uterus until the seventh month when the increasing weight of the head causes it to descend to the lower zone. As soon as this occurs, the fœtus attempts to escape, and if it is strong it succeeds; but if the attempt fails, it tries again

Digitized by Microsoft®

at the eighth month, and if the infant now succeeds in escaping from the uterus, being exhausted by its previous effort, it is more apt to succumb.

At the *thirty-second* week the fœtus measures 39–41 cm. (15½–16 in.) in length, and weighs 1,571 gm. (3½ lbs.). The hair on the scalp is longer and more abundant; the down on the face is disappearing. One of the testicles, usually the left, has descended into the scrotum. The nails are firmer, but do not quite reach the finger tips. There is ossification beginning in the lower epiphysis of the femur. The child has lost some of its senile appearance and emaciation due to the increased deposition of subcutaneous fat. At this period, with proper care, the child ought to live. At the *thirty-sixth* week the infant measures 42–44 cm. (16½–17¼ in.) in length, and weighs 1,942 gm. (4¼ lbs.). There is a decided increase in subcutaneous fat. The nails are not yet perfectly developed. The lanugo has disappeared and the bones of the head are still soft and very compressible. The infant is much stronger, but is still in a condition to die easily unless well cared for.

A detailed description of a premature child is as follows: The *head* is excessively developed and consequently its contents (the brain) are excessively developed in comparison with the diminutive characteristics of the rest of the body. Yet the head is very soft and compressible, for the bones themselves are very poorly ossified, thin, and parchment-like, crackling under pressure, and the sutures and the fontanels are wide open. Consequently the symmetry of the head is easily destroyed, considerably so in the moulding of delivery, not only by the bony pelvis, but also even by a rigid cervix or perineum, yet more so in prolonged positions of the head after birth. The moulding is usually temporary and the bones ordinarily quickly resume their proper relations. However, if the child continuously lies on one side of its head, even though the pillow is very soft, from its mere weight a marked deformity develops. This can be avoided by letting the child lie on alternate days first on one side and then on the other.

Abdomen.—The abdomen is almost always relatively distended, due in a great measure to the large size of the liver and the accumulation of gas in the intestines whose peristaltic movements are very weak. This distention may last for many weeks, and the gradual return of the abdomen to a normal size is a good sign in the gradual development of the infant to the status of a child born at term.

Skin.—The skin is of a dull, brownish-red, more markedly so at first than at a later period; when the child cries this color changes to a brighter and healthier red. Aside from this, the color is apt to vary considerably at different times, for premature infants are prone to erythematous rashes, and are almost regularly icteric after the second or third day. If the child is doing poorly the skin is pale, transparent, dry, scaly, and waxy white, sometimes œdematous. It is soft and delicate, so thin in some spots, especially over the forehead and skull, that the superficial veins shine through. In other places it is very wrinkled, due to lack of adipose tissue; a condition which gives to the body and extremities an emaciated appearance and to the face a senile expression. There is present a varying amount of lanugo, depending on the degree of prematurity. The nails are soft and short, they do not reach the ends of the digits; this is more noticeable on the toes. The sweat glands are supposed to be undeveloped, but certainly many premature babies perspire profusely if the temperature of the incubators is too high. On the other hand, the sebaceous glands are moderately active, yet more so before birth than afterward.

The *extremities* are thin and emaciated, with apparently atrophied muscles. According to Dane the instep is as well developed as is that of an adult.

The *movements* are few and slow, but at times spasmodic.

The *respirations* are shallow, irregular, and superficial, and often suspended for a time. The little one sucks slowly and weakly, and swallows with difficulty, and the mere effort is followed by more or less exhaustion.

The *tissues* of the infant are not yet sufficiently developed to meet the demands of extra-uterine life; this is especially true of the *gastro-enteric tract*. The capacity of the stomach is small, varying with the weight and size of the child. The walls are weak and thin, and an organ holding at first two or three drachms will easily dilate until it has a capacity of an ounce or even an ounce and a half, much to the infant's loss. Even absorption is slow and inefficient, and the digestive juices are lacking in ferments. The amylolytic function is practically suspended, and should not be depended upon at all for the digestion of starches. Sugar, on the other hand, is a foodstuff most easily taken care of by simple absorption. It is needed to keep up the animal heat, which is so easily lowered in the premature child, and consequently is of great importance. At first it should be given in lower percentages till the gastro-enteric tract is accustomed to the new work which it is required to perform. The function of digesting fats and albuminoids is far inferior to that of a full-term child; and all formulæ should consequently at the beginning be very low in such ingredients; even breast milk must be well diluted in the more premature children for a number of days after birth.

The *intestines* of a premature child contain meconium, and after a few days, if the digestion is good, the fæces assume the normal golden-yellow color. These infants, however, are prone to constipation on account of weak peristalsis, and often the stools contain curds, and too easily become frequent, green, acid, and slimy.

The *heart* is relatively large, but its action is weak. The foramen ovale often remains patulous for a longer period than if the infant were born at term. Inasmuch as the air cells of the lungs are by no means all in use for oxygenation, and inasmuch as the blood soon becomes impoverished from insufficient nutrition, large demands for increased work are made upon this vital organ. Consequently the infant should be kept quiet and no useless extra work should be put on the circulation, which is in such a precarious condition, not only on account of the many changes which occur with the first respirations in different structures of the body, but also for the reasons mentioned above. The pulse is more rapid than that of a normal infant, but it is not permissible to base a prognosis upon this fact.

The *blood* at birth contains an excessive amount of hæmoglobin, but it is loosely held in the red corpuscle, and the infant readily loses it and becomes anæmic. Destruction of hæmoglobin is going on rapidly and its manufacture progresses but slowly and for many days does not make up the loss. The blood itself, especially in those cases which are doing poorly, soon becomes thin, watery, and deficient in all its solid and vital ingredients. The child consequently often becomes waxy-white and œdematous.

The *animal heat* of the infant is easily affected. Deprived of its source of combustion and insulation (the subcutaneous fat), variations occur quickly and readily. Thrust at birth suddenly into an atmosphere twenty-eight degrees lower than that to which it had been accustomed hitherto, no wonder the temperature falls simply from radiation. The metabolism is too slow to manufacture enough heat to maintain a constant temperature, and the strain upon an uneducated heat centre is not borne. Again, another reason why the temperature is subnormal is that the premature infant with all its vital organs undeveloped is called upon to furnish more heat than the child at term, for we all know that the smaller the animal the greater is the surface exposed for radiation. Consequently the temperature is lowered both by an insufficient heat production and by an excessive loss of heat, which the heat centre is powerless to control and therefore to set in equilibrium. So spasmodically does this centre act that the temperature of the child will for trivial causes run very high. This is especially the case during the first few days of life, and it is often very difficult, even in a well-regulated incubator, to keep this

Digitized by Microsoft®

temperature normal. Besides, slight gastro-intestinal troubles, as vomiting, constipation, or diarrhœa, will cause sudden rises which do not occur so readily in the full-term baby.

The *lungs* are also in a very undeveloped state, and although they are sufficiently developed to carry on their functions in extra-uterine life, the tissues of the respiratory tract are very sensitive and easily become inflamed. Especially is this true of the nose, nasopharynx, and mouth, for here infection readily occurs from inhalations of dirt and dust. Besides, even though the baby has cried very well at birth, the respiratory efforts do not at once aërate more than the anterior lobules of the lungs. Some of the children remain blue, breathing and crying weakly, and die in a few days. Others gradually make a greater use of their lungs, but from slight causes they acquire a secondary atelectasis in addition to the fœtal condition posteriorly. The irregularities of the respiration are very marked. Adriance explains this condition on the basis of his studies of the embryology and pathology of the lung. Before the fourth month of fœtal life there are no alveoli, and the bronchioles are far apart in the mesenchyma. In the development the tubes ramify rapidly. From this we see that, if a child is born prematurely, the bronchi predominate and the few alveoli are enclosed in connective tissue. The blood-vessels of the lungs are composed of a rich, unsupported capillary network, whose elastic walls are readily stretched and so encroach upon the air vesicles. The feeble respiratory movements permit of collapse of the air vesicles and engorgement of the vessels—conditions which result in hypostasis and atelectasis, posteriorly and inferiorly. Besides, the bony framework is poorly adapted for aëration. Being cartilaginous and very elastic, even with a strong muscular effort at respiration, the lower part of the chest is drawn in, especially over the sternum, and only a very little air really enters the alveoli. Cyanotic attacks consequently are very frequent and often fatal. The respiratory centre, like that of heat control, is spasmodic and weak in action. These respirations are often delayed, feeble, and even Cheyne-Stokes in character, and this undeveloped centre is often responsible for the cyanosis which ensues. Every autopsy on premature children who have died within a week or so after death shows atelectasis, and the weak pulmonary organs are responsible for most of these deaths.

The *liver* is very large and fills over one-half the space in the abdominal cavity. Bile is secreted in great quantities, and it is probably to over-production by the liver cells and to engorgements of the ducts that we must attribute the regular and early occurrence of icterus neonatorum.

The *kidneys* also perform their functions irregularly. For a day or two no urine is voided. Uric acid is secreted in abundance, for the napkins of the child are often stained with the characteristic pink color, and the pyramids almost always on autopsy are found to be plugged with uric-acid infarctions.

Prognosis.—The weight of a premature child varies, for the same duration of intra-uterine life, for many reasons; consequently we must base our prognosis less upon the weight at birth than upon the general condition of the child. Yet it goes without saying that, other things being equal, the more premature the child the less is the probability of its survival. The daily progressive gain, on the other hand, furnishes by far the best indication that matters are progressing satisfactorily; yet one has to wait a long time before this is manifest. Premature children, even though weighing less at birth, have a greater initial loss, and a loss which extends over a longer period, than the full-term child. It is not uncommon for a child weighing three and three-quarters pounds or thereabouts to lose from ten to fourteen ounces and to continue to lose for from ten to seventeen days. This is due to the immaturity of the digestive tract, and to the fact that the babies are invariably intensely jaundiced. On account of the latter condition they lie in a stupor, are with difficulty aroused, and take their nourishment very poorly; then besides, they gain more slowly. If the infant has, at the end of three or four weeks, regained the weight which it had at birth, it will have done very well. If, on the other hand, the loss is progressive, sooner or later there will be a fatal outcome. The prognosis then depends on the general condition at birth, on the degree of prematurity and most of all on the subsequent care. Extremes of temperature must be guarded against. Attacks of cyanosis are not necessarily fatal, but they render the chance of survival very doubtful. If the child lives for four or five days, and the attacks are decreasing in number, the outlook is more hopeful.

Treatment.—There are four distinct objects which must be kept in view in the care and management of premature children.

1. The maintenance of a proper temperature.
2. The prevention of exhaustion.
3. The administration of the proper amount and kind of nourishment.
4. The avoidance of infection.

Premature children can be divided into three classes: (1) Those treated as babies at term. (2) Those wrapped in cotton. (3) Those placed in the incubator.

The weight, length, appearance of the baby, and even the assumed period of gestation, calculated from the mother's last menstruation, are simply relative in estimating the exact duration of fœtal life. It is by far a better procedure to consider the general condition of the infant, together with the above, before we put it into one class or the other. The majority of the babies would do better if they were to be placed in the last class from the beginning. Without a couveuse the best plan is to put a baby in cotton and surround it by hot bottles. Some babies will thrive in this way, but most of the very premature will not.

There are many kinds of incubators in use, notably those of Denuce, of Bordeaux, who in 1857 produced the first one which gave satisfactory results. In 1880 Tarnier constructed one which was afterward improved by Auvard. Credé also invented one which was successfully used. The brooder of Dr. Rotch, of Boston, is a very intricate and elaborate affair, in which the baby can be weighed without removal. The best one is probably that of M. Lion, of Nice, first used in 1891. It is composed of a parallelopiped of metal, standing on iron supports. It can be disinfected without deterioration by means of a steam stove under pressure or by cleansing with a solution of carbolic acid or with formalin gas (Fig. 3879). Ventilation is obtained by means of a tube, of about three inches in diameter, which enters the compartment low down on the left side. The exit is through a chimney in which is a fan, indicating by its rotation the strength of the current of air. The air on entrance is filtered by a gauze and cotton diaphragm. The front is fitted with glass doors, through which the infant can be seen, while at the side is a glass window by means of which the nurse can attend to the infant's wants without removing it. The baby is placed in the middle on a soft pillow, the warm, fresh air circulating about it. The air is kept moist by a large pan of water placed in the bottom. A thermometer is hung close to the door, and a hygrometer is fastened to the posterior wall of the chamber. The heating is effected by means of a siphon through which hot water circulates, and which communicates with a reservoir at the side. The temperature is automatically regulated by a metallic thermostat, which lifts or lowers a cap over a flame. This apparatus is very expensive, and therefore adapted for use only in hospitals or in wealthy families. Besides the Lion incubator, there is available a cheap modification of the Tarnier or Auvard couveuse, which any carpenter can make at a small expense. The main point in its construction is that there should be plenty of inlets and outlets for free ventilation. The disadvantages of this apparatus are, first, the lack of filtration of the air, and, second, there is no thermostatic regulation of the temperature. To ob-

Digitized by Microsoft®

viate the latter difficulty, therefore, careful attention will be necessary. A temperature as near constant as possible is to be obtained by varying the size of the flame and its distance from the tube connecting with the main tank of water (Fig. 3879).

In order to secure the maximum amount of fresh air the incubator—whatever kind is used—should be placed in the hall or in a large cool room. The direct rays of the sun ought never to strike it, because their heat would quickly unbalance a constant temperature. Before putting a baby into the chamber the apparatus should be thoroughly disinfected, as these infants are very susceptible to infection. The baby should lie on a very soft pillow.

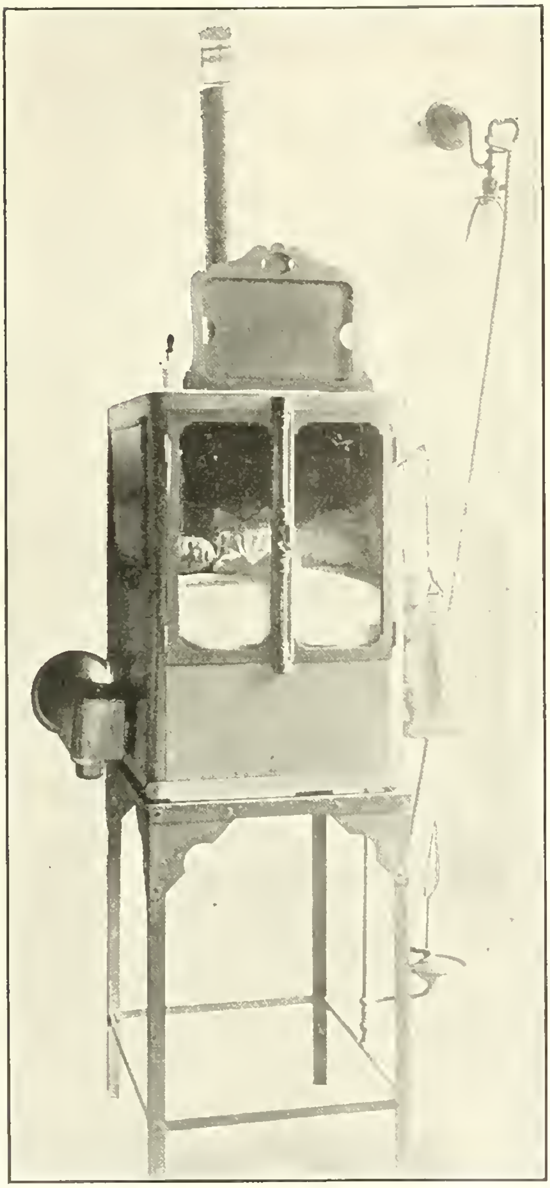

FIG. 3879.—Incubator of M. Lion, of Nice, France. (From the *Archives of Pediatrics*.)

The temperature should vary with the infant. It should be one which will keep the baby's temperature normal without exciting perspiration. I have found that a temperature of from 86° to 92° F. is about right. A variation of a degree or two makes but little difference. If a premature baby is expected, an incubator, the air of which is at a proper temperature, should be in readiness, at the time of its birth. The baby itself is first made to cry lustily (not with harsh methods of resuscitation, but mainly by the employment of hot baths and light titillation, and perhaps by easy swinging), and then the cord is quickly tied off and suitable dressings are applied. After the child has been weighed and anointed with albolene, but not bathed, it is dressed. A mistake is made in enveloping these infants in cotton. So wrapped up they will be too warm and will perspire too freely. The best clothing is a small light shirt and a napkin from the waist down, pinned over the feet and legs (Fig. 3881). When the baby is placed in the incubator it should not be removed, except to be weighed or nursed. The latter is not permitted until it is thriving. The weight is taken every five, seven, or ten days, and about once a week the infant is lightly sponged.

The napkins should be changed three or four times a day, only often enough for cleanliness, and in such a manner as to disturb the baby as little as possible. Before feeding, however, especially when the baby is stupid or sleepy, a light tap on the hand will make it take the bottle with much less coaxing and more rapidly.

The infant should be kept in the incubator until it has reached the development of full term, or longer if it is not improving. Some of the babies, nevertheless, will do well in cotton after having been given a good start in the couveuse. If possible, the temperature of the incubator should be gradually lowered almost to that of the nursery, before the baby is permanently subjected to the variation in the temperature of the air of an ordinary room.

In the administration of nourishment the amount and quality should depend on the age and digestive powers of the infant. Ordinarily, six hours after birth, the child should be given a warm sugar solution (five to six per cent. lactose in distilled water), about one-half to one drachm every hour. After from twenty-four to thirty-six hours an equal part of breast milk should be added. This is obtained by massage and expression, by the breast pump, or by spontaneous expression while a baby is nursing the other breast. If the best results are to be obtained, this milk should not be taken from the mother, but from a wet-nurse at least seven or eight days post partum—*i.e.*, at a time when the quality of her milk is about established, or at any rate when it is comparatively free from colostrum.

The amount of fluid nourishment administered is to be gradually increased, a drachm at a time, so that by the end of a week the child will be taking from six drachms to an ounce every hour. If the stools are normal, the breast milk can be gradually increased and the sugar solution gradually diminished; or, by the addition of a little lime water, the infant can often be put on pure breast milk at the end of two weeks. On this plan there should be little or no vomiting, and the stools should be normal, or nearly so, from the beginning.

The method of feeding can in almost all cases be carried on by means of sucking through a small nipple, especially if a little coaxing is resorted to. In some cases a medicine dropper or a feeder, such as is recommended by Rotch, can be tried if the baby refuses to suck. In others who are extremely weak and who will not swallow, gavage is necessary. In the experience of most men these cases do not do well; one likes, therefore, to get back to the bottle as soon as possible. The infants are apt to regurgitate, the milk fills the nares or nasopharynx, and when the baby takes its next inspiration some of the fluid is drawn into the larynx and even into the bronchi. This may cause an immediate asphyxia, an atelectatic area in the lung, a bronchitis, or a bronchopneumonia, which will soon end in death.

As soon as the baby is strong enough and is perceptibly gaining, it can be tried at the mother's breast. At first, two or three times a day is sufficient. If the child

Digitized by Microsoft®

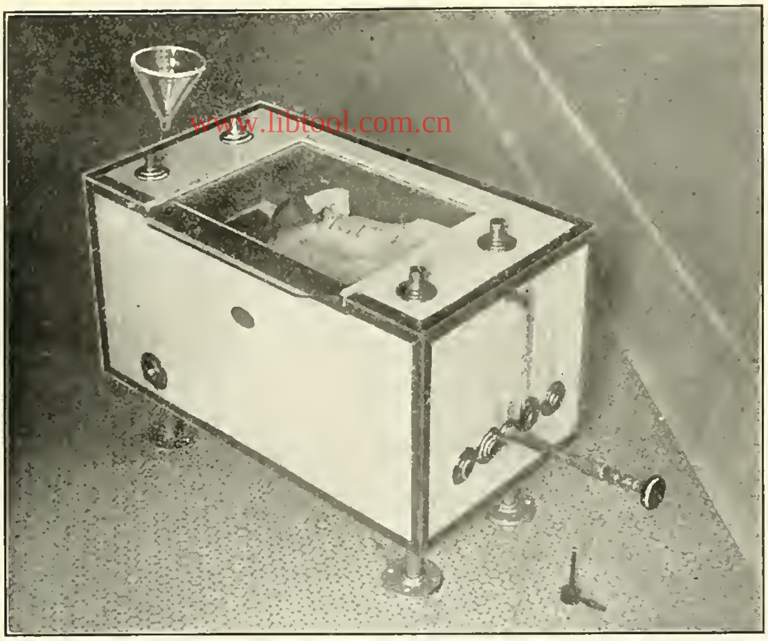

FIG. 3880.—Cheap Incubator in Use at the Sloane Maternity Hospital. (From the *Archives of Pediatrics.*)

does well, the number of nursings is gradually increased to every two hours. At the same time it is generally necessary to give the child the breast between these stated periods, and also to supplement the nursing by the bottle.

Dr. Rotch says that the best method of feeding premature infants is to give them the food which is carefully prepared at the milk laboratories; this food being, as he believes, far superior to mother's milk. In the experience of others, although weak modifications of cow's milk—as fat one per cent., sugar six per cent., and albuminoids 0.33 per cent., or even lower percentages—have been used, the results have not proved satisfactory, except in a very few cases. Mother's milk is the ideal food, and when it is possible to obtain it, every premature child should have it. Yet the variation in the composition of this breast milk in the first few days must be thoroughly understood if good results are to be obtained, for it often acts as a rank poison to the child. The colostrum is already well known as a highly albuminous laxative secretion, and in many cases it purges the new-born infant to an extreme. For a more complete and positive chemical analysis of human milk we are indebted to John S. Adriance. He has demonstrated the peculiarities in its composition during certain periods of lactation. His results are as follows: During the first few days the irregularities are most marked. The colostrum in the breast of a woman delivered at term shows a wide variation in amount of fat; the sugar is low at first, but increases rapidly, and by the end of the first two weeks makes a marked increase; the proteids, on the other hand, fail rapidly during the first few days from a maximum amount on the second day, but less rapidly thereafter. This colostrum then is rich in proteids, due to the sudden assumption of the mammary function and to the transudation of serum from blood-vessels into the breast secretion.

Even to a greater degree are these characteristics shown in the colostrum after a premature labor, and the high percentage of proteids exists for a much longer time. Consequently, the premature child should not at first nurse its mother, but a wet-nurse secured at least temporarily.

In the mean time the mother's breasts should be pumped and massaged or nursed by a baby at term, so that they will not dry up. After a time the mother's milk can be given diluted with a sugar solution, and this should be kept up until the mother's milk becomes normal, the change from wet-nurse to mother being made gradually. In this way gastro-enteric symptoms may be avoided.

In some babies the color is poor from the beginning, and at any time they are especially liable to attacks of cyanosis. For these conditions a little slapping to cause a good cry or the administration of oxygen will dissipate the blueness. Often the administration of a few drops of brandy in hot water every two or three hours will prevent further trouble. One must be very sure, however, that nothing has been aspirated into the larynx.

A great danger in the care of these babies is their susceptibility to infections. The incubator itself is a great germ carrier and should be regularly disinfected. The weakness of the lungs and gastro-enteric tract makes the infants especially vulnerable. Unless the air is filtered, dirt is carried in continuously; consequently the streptococcus, staphylococcus, and pneumococcus are always present.

Digitized by Microsoft®

seeking an avenue of entrance. Through the skin in eczematous spots or in areas of irritation, at the navel, through the eyes, nose, mouth, larynx, lungs, stomach, and rectum, the bacteria can gain admission. To prevent infection, then, the most careful cleansing is necessary, both of the incubator and of the baby itself. Undoubtedly many of the later deaths can be traced to this source.

www.libtool.com.cn

Finally, in the carrying out of the above essentials in the proper management of the premature infant, the most patient and painstaking attention on the part of the nurse is necessary, and upon her conscientiousness depends the chance of its survival.

Results.—The statistics furnished here are taken from 2,314 births which occurred at the Sloane Maternity Hospital in the two years from October 22d, 1897, to October 22d, 1899, before which time there had been no incubator in use.

Four hundred and ten of these babies were premature, but of these 74 were still-births, which included macerated fœtus and the still-born babies of cases of placenta prævia, accidental hemorrhage, eclampsia, and the like. There remained, therefore, 336 which were suitable for treatment.

Among these cases was a set of triplets and there were 18 pairs of twins; 85 were treated as infants at term, and of these 4 died—a mortality of $4\frac{7}{8}$ per cent.; 145 were put in cotton, and of these 12 died—a mortality of 8 per cent. Some of this class should have been placed in the incubator, but for lack of room it was impossible to do this; 106 were incubator babies. These are divided into two classes: I. Those that died within four days of birth; II. Those that lived longer than four days.

I. Twenty-nine of the incubator babies died within four days. All of these but 3 were more or less asphyxiated at birth; 9 were breech cases, and of these 5 were difficult extractions; 3 were delivered after an accouchement forcé in placenta prævia. The rest were vertex presentations; but, of these, 2 were forceps deliveries; 6 were under seven months of uterine gestation; 22 had reached a period of between seven and eight months, and 1 a period of eight and a quarter months.

The causes of the premature labor were as follows: an endometritis in 14, syphilis in 2, albuminuria in 1, placenta prævia in 3, accidental hemorrhage in 1, persistent vomiting in 1, twin in 1, violence in 1, and in 4 the labor was induced. The largest baby weighed $5\frac{7}{16}$ lbs.; the smallest, $2\frac{7}{16}$ lbs. Only 5 infants lived over twenty-four hours; 24 were in such poor condition at birth that they survived only a few hours. In 16 of these cases autopsies were held, and in all of these there was marked atelectasis; in 7 hemorrhages of some degree, either into the brain or into the serous membranes; in 2 the foramen ovale was still patent.

II. Seventy-seven incubator infants survived the first four days; 51 were children of primiparæ, 27 of whom were out of wedlock; 3 infants were under seven months of gestation; 8 were over eight months, and the rest between seven and eight months along; 9 were breech presentations; 1 a transverse and the rest vertices; 2 were of triplets associated with albuminuria; 18 were in twin deliveries, associated with albuminuria or hydramnios. The causes of the premature labor were: endometritis in 27; syphilis in 4; phthisis in 2; albuminuria in 7; accidental hemorrhage in 1; placenta prævia in 1; in 2 the labor was induced for albuminuria and eclampsia; 1 was a Cæsarean section; another an ectopic gestation; the cause, in the remainder, was unknown. Seven were delivered by forceps, 2 by version, 1 by accouchement forcé, 1 by Cæsarean section, and the ectopic gestation by a laparotomy; 12 were slightly asphyxiated at birth, 9 moderately so, and 5 deeply asphyxiated; 2 after one and a half hours' work of resuscitation were put in the incubator, head downward, and their condition was so poor that they were expected soon to die, but they left the hospital gaining in weight; 5 weighed less than 3 lbs., 38 between 3 and 4 lbs., 33 between 4 and 5 lbs., 1 over 5 lbs.; the average weight was $3\frac{13}{16}$ lbs. During their incubator life 28 had one or more attacks of atelectasis. All but 10 were more or less jaundiced. The initial loss of the infants was from 1 to $17\frac{1}{2}$ oz.; the average was 7 oz. These figures are not quite correct, as the babies were weighed at different intervals, some on the fifth day, some on the seventh day, and others not till the fourteenth day.

The period of loss lasted for from five to twenty-two days, the average, eleven days; 10 lost steadily till death; 1 baby was in the incubator only three days, while another lived there eighty-two days. The average time was nineteen days. Some were removed early to make room for others who needed the place more urgently.

Only 3 of the 77 cases vomited. The stools were normal in 32.

One was discharged from the hospital as early as the eleventh day, and others also too soon, at their mothers' demand. One was eighty-nine days old, the average was twenty-four days.

In 16 diluted breast milk was supplemented, at times, with a mixture of cow's milk and water with Russian gelatin and lactose. In 10 a 1% proteid, 6% sugar, and 0.33% albuminoid modification of cow's milk was used. In all the rest diluted breast milk was relied upon. Twenty-seven never nursed at the breast; of these 12 died. A few nursed as early as the third or fourth day, two or three times a day; others not for three weeks, and one not till the sixty-eighth day. Of the 77, 13 died in the hospital, a mortality of nearly 17 per cent. The cause of death was atelectasis and bronchitis in 7, acute asphyxia from a curd in the larynx in 1, syphilitic pneumonia in 1, cerebral hemorrhage in 1, gastro-enteritis in 3, and a patent foramen ovale and ductus arteriosus in 1. The condition of 3 was poor at time of discharge, fair in 24, and very good in 37; 32 were above their birth weights and 57 were gaining in weight. To letters written about January 1st, 1900, no answer was obtained from 28. Thirteen were reported as having died; 1 of these lived fourteen months, 1 nine months, 1 four and a half months, 3 lived two months, 6 lived six weeks, 1 only a month. Five of these children died at the Nursery and Child's Hospital and 2 died at Bellevue Hospital. They were bottle-fed, and the probable cause of death was gastro-enteritis. Twenty-one were found to be *alive* and doing well. Some had nursed and the others were bottle-fed. The oldest baby was twenty-two months and almost all were good specimens of healthy children. One baby at seven months weighed 16 pounds. It weighed $4\frac{1}{16}$ pounds at birth and nursed its mother after leaving the hospital. The ectopic and the Cæsarean babies were in fine condition.

STATISTICS.

Incubators.	Tarnier.	Charles.	Sloane Hospital.	At the Sloane Hospital, not counting those which died in a few hours.
Saved at 6 months.	16 per cent.	10 per cent.	....	....
" $6\frac{1}{2}$ "	36 "	20 "	22 per cent.	66 per cent.
" 7 "	49 "	40 "	41 "	71 "
" $7\frac{1}{2}$ "	77 "	75 "	75 "	89 "
" 8 "	88 "	....	70 "	91 "

From this table it appears that the statistics* at the Sloane Maternity Hospital are not so good as Tarnier's, unless those babies who were in very poor condition at birth and who died in a few hours, are omitted.

PRESBYOPIA—Pr—from πρέσβυς, old, and ὤψ, eye; Fr., *presbytie*, from πρεσβύτης, an old-sighted person—is "the condition in which, as the result of the increase of years, the range of accommodation is diminished, and the vision of near objects interfered with" (Donders[1]). The range of accommodation diminishes year by year, from about 15 dioptries, at the earliest age (ten years) at which accurate observations have been made, to about 1 dioptrie, at the age of sixty-five or seventy; at forty it amounts to something less than 5 dioptries, and at forty-five to about 3.5 dioptries.[2]

Of the 15 dioptries of accommodation which the child of ten years is able to bring into exercise, from two-thirds to three-fourths (10 to 11 dioptries) may be lost without greatly incommoding an emmetrope in ordinary near vision. In emmetropia the distance (P_2) of the binocular near-point (p_2) is the reciprocal of the number of dioptries representing the binocular range of accommodation; hence, with a binocular range of accommodation of 5 dioptries, $P_2 = \frac{1}{5}$ metre (20 cm.), at which distance the smallest print in ordinary use is easily deciphered by eyes of average visual acuteness; when the binocular range of accommodation is reduced to 4 dioptries, $P_2 = \frac{1}{4}$ metre (25 cm.), at which distance ordinary newspaper print may still be read easily; with the loss of another dioptrie of accommodation (leaving but 3 dioptries available), $P_2 = \frac{1}{3}$ metre (33.3 cm.), and the reading of fine print becomes difficult, except under the conditions of good illumination and perfect acuteness of vision. These several values of P_2 correspond, in emmetropia, to ages ranging from about thirty-eight to about forty seven years, and comparatively few emmetropes attain the latter age without seeking aid from convex glasses in reading or other fine work; the adoption of convex glasses by an emmetrope under forty is generally determined either by the exceptionally exacting nature of the work in which he habitually employs his eyes, or by the fact that his acuteness of vision is somewhat below the normal. When at the age of from fifty to fifty-five years the range of accommodation has become reduced to 2 dioptries, $P_2 = \frac{1}{2}$ metre (50 cm.), and the book must then be held at arm's length, at which distance only the larger sizes of print can be read; but, even with this range of accommodation, a public speaker may be able to read fluently from a plainly written manuscript lying before him upon a reading-desk or table.

The diminution of the range of accommodation with advancing years is a strictly physiological change, and is directly related to the progressive hardening of the crystalline lens, in consequence of which it becomes less and less capable of undergoing the change in curvature required for the adjustment of the eye for near vision. As this hardening of the crystalline occurs in all eyes alike, irrespective of their refractive condition as determined by the relation of the curvature of the refractive surfaces to the length of the axis of the eyeball, it would seem to be scientifically correct to define presbyopia as the loss of accommodative power incident to advancing years. Immemorial usage has, however, associated the name with the particular condition in which, as a result of increasing age, near vision becomes indistinct while distant vision remains either absolutely or relatively unimpaired. As thus defined, presbyopia is an incident in the life-history of all emmetropes and hypermetropes, and also of myopes whenever the myopia is of low grade—3 dioptries or less. In myopia of higher grades, 4 dioptries or more, the distance of the far-point remains within $\frac{1}{4}$ metre (25 cm.) of the eyes; so that, even with total loss of accommodation, it may still be possible to read fine print without the aid of glasses.

The striking contrast between the vision of myopes, who see only near objects distinctly, and that of presbyopes, who see distant objects clearly, while near objects appear confused, was very early recognized,[3] and, in the absence of any definite theory of accommodation, presbyopia was, for more than two thousand years, regarded as the opposite condition to myopia. Hypermetropia, the true opposite of myopia, remained confounded with presbyopia until after the middle of the nineteenth century, when the demonstration of a change in the form of the crystalline lens in accommodation by Cramer,[4] and, independently, by Helmholtz,[5] and the masterly analysis of the phenomena of accommodation in its relation to the several anomalies of refraction, by Donders,[6] dispelled the cloud of obscurity in which the whole subject had been so long enveloped, and through which only occasional glimpses of the truth had been previously enjoyed by a few exceptionally acute investigators.[7]

Premonitory signs of presbyopia may often be detected in emmetropes as early as the thirty-sixth year; exceptionally fine print, such as No. 1 of Jaeger's scale, being no longer read with the same perfect fluency as in youth, especially if the illumination is defective. Within the next five years newspaper print loses a little in sharpness of definition, and the finest needlework becomes difficult and perhaps deteriorates somewhat in quality. If the acuteness of vision (V—see *Optometry*) is normal, and the print not too fine, relief from the increasing strain in accommodation is obtained by holding the book or work a little farther from the eyes; but if vision is subnormal, or if the print is bad or very fine, a stronger illumination may be demanded, without increasing the reading distance. By the age of forty-five the disability has generally increased to the point that only fairly large print can be read with ease by ordinary artificial light, and a more powerful lamp is procured or the book is held nearer to the light; about this time the need of help from glasses commonly suggests itself.

A hypermetrope habitually wearing neutralizing (convex) glasses, or a myope wearing neutralizing (concave) glasses, experiences the disabilities of presbyopic vision at about the same age, and in about the same degree, as the emmetrope; thus, between the ages of forty and forty-five, the hypermetrope discovers that his convex glasses are no longer quite sufficient in reading, and similarly, the myope discovers that his concave glasses have become something of a hindrance in near vision, although in both cases the neutralizing (convex or concave) glasses continue to serve perfectly for distant vision. A change to stronger convex glasses by the hypermetrope, or to weaker concave glasses (or, perhaps, the temporary removal of his glasses) by the myope, is the remedy which now suggests itself, and which is, sooner or later, adopted. With a change of glasses reading again becomes easy, but with a corresponding falling off in the distinctness of distant vision. For this reason, an elderly emmetrope either removes his glasses or looks over them when not engaged in near work, and a presbyopic ametrope ordinarily requires two pairs of glasses, the one pair (neutralizing) for distance, the other pair (stronger convex or weaker concave) for reading and other near work; the inconvenience attending the use of two pairs of glasses may be obviated, in many cases, by wearing so-called bifocal glasses, in which both corrections are mounted in a single setting before each eye (see *Spectacles*).

A hypermetrope, not wearing convex glasses, experiences the disabilities of presbyopia at an earlier age than the emmetrope, after having, perhaps, passed through a more or less protracted stage of suffering from asthenopia (see *Asthenopia*). In myopia, on the other hand, if of low grade, the reading power with the unaided eyes is retained to a more advanced age than in

Digitized by Microsoft®

www.libtool.com.cn

emmetropia; in the higher grades of myopia it is retained indefinitely.

As a result of the very gradual increase in the resistance which must be overcome in order to effect such degree of accommodative adjustment as is still possible in presbyopia, the relation of the accommodation to the convergence undergoes a notable change, the binocular accommodation (A_2) associated with convergence for the habitual reading distance becoming at length nearly equal to the absolute accommodation (A). In other words, the binocular near-point (p_2) comes more and more nearly to coincide with the absolute near-point (p). Following closely upon the acceptance of convex glasses in near work, the distance (P_2) of the binocular near-point (p_2) undergoes a rapid increase, so that such reading power as may have been retained up to the time of the adoption of the glasses is speedily lost, and reading without glasses becomes impossible. Hence the common experience of presbyopes, that having once formed the habit of using convex glasses, their continued use becomes imperative; and this whether the glasses have been adopted somewhat prematurely, or only after the need of them has become urgent. The too early use of convex glasses is, therefore, to be deprecated, as entailing the disabilities of presbyopic vision several years, perhaps, before the normal age; on the other hand, as there is a positive limit to the range of accommodation at any given age, the use of convex glasses cannot, as a rule, be deferred by an emmetrope much beyond the forty-fifth year, unless he be content to forego the use of the eyes in reading ordinary print or in other fine work.

The total disuse of the accommodation for a considerable period, as in the case of protracted and exhausting illness, may lead to the premature development of presbyopic symptoms, which are apt to be interpreted as an indication for the immediate adoption of convex glasses. If glasses are used in such a case, they should be of the least power compatible with the use of the eyes under favorable conditions of illumination, and the patient should be encouraged in the hope that, as the accommodative power increases with use, the glasses may be laid aside. In cases of this kind it is often possible to bring the accommodation again into effective use by the instillation, once or twice daily for a few weeks, of a weak solution of pilocarpine, and thus to put off the use of glasses for perhaps several years.

In addition to the impairment of the accommodation, which is the essential characteristic of presbyopia, the refraction undergoes, in the course of time, a slight but positive diminution, so that ultimately an emmetrope becomes slightly hypermetropic (H *acquisita*—see *Hypermetropia*), a hypermetrope somewhat more hypermetropic, and a myope somewhat less myopic; a very low grade of myopia may thus give place to emmetropia, or may even pass through emmetropia to hypermetropia of low grade. A low grade of hypermetropia, which late in life necessarily becomes absolute (H *absoluta*), is, in fact, the ultimate normal condition of all emmetropes, so that in advanced age weak convex glasses come to be required for perfect vision at a distance; hypermetropes similarly require a moderate increase in the power of their convex glasses, and myopes require a corresponding diminution in the power of their concave glasses. This falling off in the refraction is ordinarily scarcely to be detected at the age of forty-five; at sixty it may amount to perhaps 0.5 dioptric, at seventy or seventy-five to 1 dioptric, and at eighty to 2 dioptrics or more.

The *treatment* of presbyopia consists essentially in the palliation of the disability by the use of such convex glasses as are needed to supplement the failing accommodation. A person originally emmetropic may, at the age of seventy, require convex glasses of as much as 5 dioptries, in order to read fairly good print at a distance of from 25 to 30 cm.; and if the acuteness of vision is below the normal, it may be necessary to use glasses of 6 or 7, or even 8 dioptries, in order to admit of reading at some shorter distance. In the case of a person originally hypermetropic, the measure of the required glasses will be increased by a quantity equal to the grade of the hypermetropia; in myopia the measure of the glasses will be similarly diminished.

The convex glasses first given to a presbyopic emmetrope of from forty to forty-five years of age, should ordinarily not much exceed 1 dioptric, and in some cases even weaker glasses may be more acceptable to the patient. These glasses should be used at first for only such work as is performed with difficulty without glasses, in order that the habit of using the accommodation may not be needlessly or prematurely abandoned, and they should not be exchanged for stronger glasses so long as they continue to afford the needed assistance. Subsequent changes should always be made with reference to the glasses already in use, adding perhaps 0.5 dioptric at each change, and it is often advisable to retain the old glasses for a time for reading by daylight, reserving the stronger glasses for more exacting work. It follows that a presbyope should always preserve a record of the power of the glasses which he is using, in order that, in replacing a lost pair, he may not be reduced to the necessity of selecting new glasses at random, or after hasty and generally imperfect tests made by a shopman whose knowledge, very probably, may be limited to the trick of selling his wares.

A presbyope, using glasses perfectly suited to his condition, is able to use his eyes in near work freely and without fatigue; glasses of insufficient strength fall short of affording the full measure of relief, and glasses of excessive strength compel the holding of the book at too short a distance, thus imposing needless work upon the recti interni muscles and so possibly giving rise to muscular asthenopia (see *Asthenopia*).

The clinical investigation of any case of presbyopia involves, first of all, the careful testing of the eyes in respect of the acuity of vision and for the estimation of any hypermetropia, myopia, or astigmatism that may be present (see these titles). As has been already explained, the measure of any hypermetropia that may be detected must be added to, and the measure of any myopia subtracted from, the value of the glasses ordinarily required by an emmetrope of corresponding age, in order to arrive at an approximation to the glasses to be given for reading. These tests are best conducted at a range of at least 5 metres, and only after the satisfactory determination of the refraction should a trial of reading glasses, chosen with reference to this determination, be made. The final tests are made in reading fine print. If astigmatism is present, it should, as a rule, be accurately corrected by having one surface of the glass ground to the appropriate cylindrical curvature (see *Astigmatism*).

A rapid falling off in near vision, necessitating frequent and considerable additions to the power of the reading-glasses used by a presbyope, should be regarded with especial solicitude as indicating the possible beginning of glaucoma. In view of the recognized danger of precipitating an acute glaucomatous outbreak, the routine employment of mydriatics in the investigation of the refraction of presbyopes is to be especially deprecated.

Repeated changes from weaker to stronger glasses, attended with a shortening of the reading distance after each change, point to a falling off in the acuteness of vision, oftenest from failure in the perceptive power of the retina, or of the conductivity of the optic nerve.

A marked diminution in the apparent grade of presbyopia is occasionally observed late in life as a result of the development of a myopic state of the refraction; this change, which is popularly known as "second sight," is a not infrequent symptom of incipient cataract.

PRESERVATIVES.—Food preservation has been employed from a very early period. Many methods are available: drying, salting, pickling, smoking, the use of heat and cold, and addition of sugar, saltpetre, and various aromatic and astringent substances. The exigencies of modern food supply have greatly extended both the number of preservatives and their applications. Low temperature is probably the least objectionable method of preventing decay, but its application is limited and costly. It is unsuitable for some articles. In food preservation reliance is now largely on chemical substances that have decided antiseptic or germicide effect.

All preservation, even that by cold alone, affects to some extent the digestibility and nutritive value of food, but these changes are less objectionable than those caused by decomposition. Sterilization by heat finds wide application and has the advantage of producing a condition which permits of some exposure to the air without decay occurring. The medical questions which arise in this connection are mostly those concerning the newer preservatives. These are salicylic acid, benzoic acid, sodium benzoate, boric acid, borax, formaldehyde, sulphites, fluorides, beta-naphthol, saccharin, and a few synthetic products of complex composition and limited use. Each substance is found to be adapted to special uses. Thus, boric acid and borax are used largely for meats, milk, and butter; sulphites and fluorides are used in fermented beverages; salicylic acid, saccharin, benzoic acid, and sodium benzoates are used in jams, jellies, mince-meat, and preserved fruits and fruit juices. Formaldehyde is largely used in milk, and is the most common preservative in market milk and cream in the summer season. For the preservation of many vegetable products, sterilization in hermetically sealed cans is employed and no preservative material is needed.

The physiological effects and methods of detecting the different preservatives have been subjects of extended study. The latter problem has been solved in most cases, but the former is still under active discussion. At present, the weight of information seems to be that salicylic acid, formaldehyde, the sulphites, and the fluorides are objectionable either from inherent toxic qualities or by reason of interferences with digestive functions. Numerous investigations into the effects of boric acid and borax have failed to show that in moderate amount it has any injurious action, and the tendency is to permit its use in meats and butter, in which it satisfactorily replaces common salt. Sodium benzoate seems to be safe for use in fermentable foods, such as jams and jellies. Betanaphthol is but little used, but it and saccharin are probably objectionable except in special cases and under supervision.

Most of the substances above enumerated are not actively germicidal nor capable of coagulating proteids, but are rather inhibitory of bacterial growth and enzymic action, and thus prevent decomposition.

A dangerous phase of the modern use of preservatives is that many of them are sold under misleading names and their nature and effects misrepresented by manufacturers. Formaldehyde, for example, is sold in forty-per-cent. solution as "formalin," which is not an objectionable title, but weaker solutions are sold to milk purveyors under such fanciful names as "freezene," "icene," and the sellers' agents assert that the material is harmless and permissible. It has been found that a mixture of boric acid and borax is usually more efficient than either alone. This mixture is often sold under the title "boron preservative." Another danger is that chemical substances may be used to make up for deficiency in quality or sterilization of foods.

The regulation by law of the use of preservatives has so far been unsatisfactory. Wholesale prohibition of any but the old-established forms, such as smoking or pickling or salting, has been attempted in some places, but has resulted in much litigation and quarrelling. The question must be approached in a scientific way, and the regulations must regard the exigencies of trade as well as the interest of the consumer. For a comprehensive study of the main questions the report of the British Commission (Blue-Book, Cd. 833) will be found valuable.

Henry Leffmann.

PRIMROSE, EVENING.—The leaves and tops of *Onagra biennis* (L.) Scop. (*Œnothera biennis* L.—fam. *Onagraceæ*). This plant is an exceedingly common weed in waste fields and along roadsides throughout the United States, especially in the northeastern and central parts. It is hairy, the stem stout, erect, and branching, and is readily recognized by the large yellow flowers, with four obcordate petals, eight long versatile anthers, four linear stigmas, forming a cross, and the quadrangular ovary at the base of a long filiform calyx tube. It contains much tannin, with considerable gum, thus making it astringent and at the same time emollient to the intestine. It has consequently a considerable employment in the household in the treatment of diarrhœa. The dose is 2–8 gm. (ʒ ss.–ij.), and the infusion is the best form of administration. A number of species of the related genera Œnothera, Epilobium, etc., have a similar composition and use.

Henry H. Rusby.

PROAMNION.—This convenient term was introduced by Ed. van Beneden to designate that part of the *area embryonalis* at the sides and in front of the head of the developing embryo which remains without mesoderm for a considerable period, so that the ectoderm and entoderm are brought, in the region of the proamnion, into immediate contact. As found in one stage of the rabbit, it has already been figured in this work (Fig. 267, Vol. I.). A later stage in the rabbit, as seen in longitudinal section, is figured by Kölliker in his "Grundriss d. Entwickelungsges.," 2te Aufl., p. 107. We find that it had been observed in the chick by Remak, His, and Kölliker. Strahl was the first to direct special attention to it. It has since been observed by various writers; van Beneden and Julin have described it in the rabbit, Heape in the mole, Selenka in the opossum, and recently its exact history has been admirably worked out in the chick by Ravn, and in many birds and reptiles by Schauinsland. The proamnion, then, has been observed in representatives of the classes Reptilia, Aves, and Mammalia; hence we may conclude that it is common to all Amniota. It will be remembered that the mesoderm grows out in all directions from the blastopore, or hinder end of the primitive streak. In a chick of twenty-seven hours, the front edge of the mesoderm is a somewhat irregular transverse line, which crosses the germinal area about at the front border of the head. This line is well shown in His' drawings, *loc. cit.*, Pl. xii., Fig. 14. As the mesoderm expands, it does not grow forward in the median line, but does grow forward at the sides of the *area pellucida* in front of the head of the embryo. A space is thus enclosed between the mesoderm on each side; this space later becomes the proamnion; it contains no mesoderm. Later on, the lateral portions of the mesoderm approach the median line again, some distance in front of the head, so that now the proamniotic area is completely surrounded by mesoderm. We see, as the next phase of development, the head amniotic fold arising in such a position that the proamnion is embraced between the arc of this fold and the head of the embryo; the proamnion, therefore, constitutes the floor of the pit formed by the upgrowth of the head amnion. In the chick the proamnion never acquires any considerable development, but gradually disappears by encroachments of the mesoderm upon all sides, as has been well described by Ravn, whose Fig. 3, *loc. cit.*, Pl. xxi., will serve to give a clear general notion of the relation of the proamnion to the head, and to the true amnion in the chick. The disappearance of the proamnion in the chick involves some curious appearances in sections of embryos, which Ravn has correctly and fully elucidated.

Digitized by Microsoft®

In the rabbit, according to van Beneden and Julin, whose observations have been confirmed to a certain extent by Kölliker and Heape, the rôle of the proamnion is more considerable. The history of the proamnion, as given by van Beneden, may be followed easily by the aid of the accompanying diagrams (Fig. 3882), copied from van Beneden. In A, the proamnion, *pro.A*, is very small, and the allantois, *Al*, is just growing out. In B, the embryo, which for greater clearness has been shaded with stippling, has grown very much, and the anterior half of its body is bent down at a sharp angle into the yolk sac. The embryo, however, remains separated from the cavity *Y*, of the yolk sac, by the proamnion, which forms as it were a hood, *pro.A*, over the anterior extremity of the embryo. The amnion proper is as yet developed only over the posterior end of the embryo. For the further history of the amnion see *Amnion*, Vol. I. of this HANDBOOK. The proamnion, as can be seen in C and D, retains its importance as a fœtal covering for a considerable period, during which the amnion *am*, and allantois *Al*, are rapidly pursuing their development. After the stage shown in Fig. 3882, D, by the expansion of the cavity marked *Coe*, the amnion proper, *am*, encroaches more and more upon the proamnion, *pro.A*, until at last the embryo is entirely covered by the true amnion, and the proamnion is altogether lost. It is to be noted especially that the amnion develops principally over the posterior end of the embryo, and grows forward. To this fact reference will be made again directly.

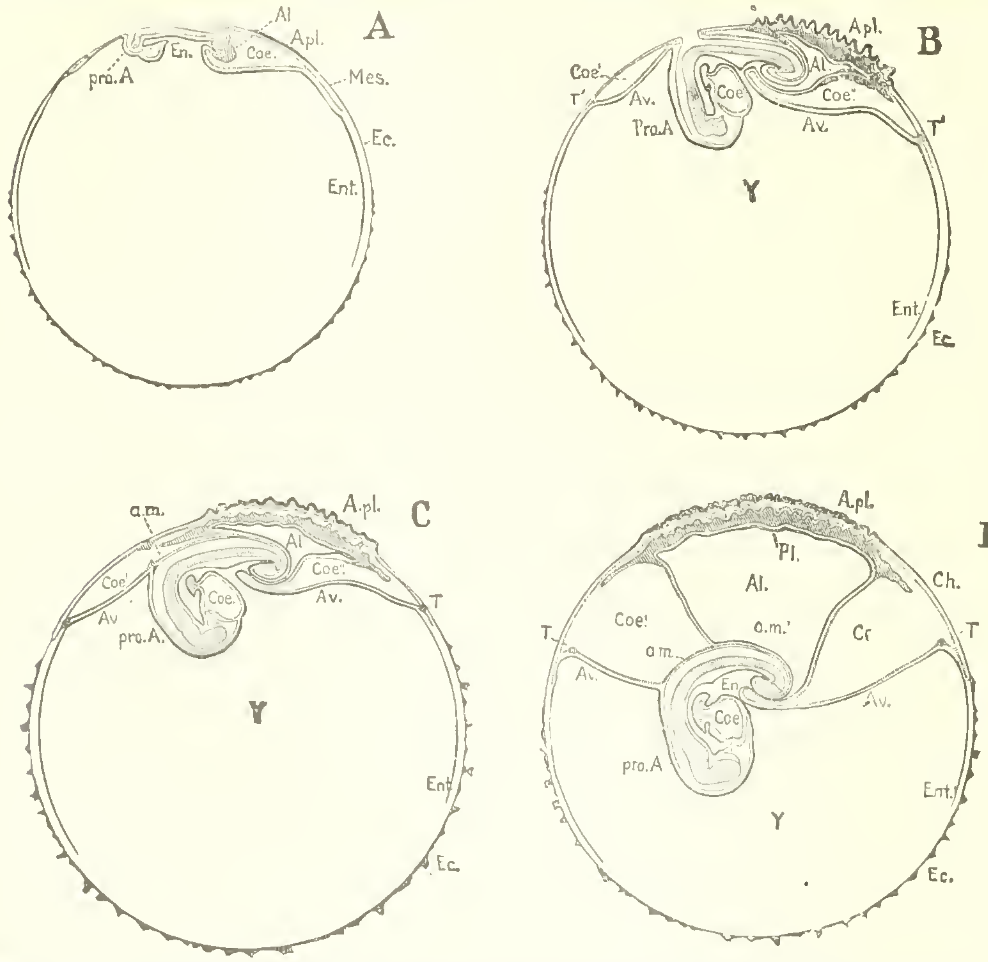

FIG. 3882.—Diagram of the Development of the Fœtal Adnexa in the Rabbit. (After van Beneden and Julin.) *A, B, C, D*, Successive stages; *pro.A*, proamnion; *Av*, area vasculosa; *Coe*, cœlom; *Coe'*, *Coe"*, extra-embryonic portion of the cœlom; *En*, entodermic cavity of the embryo; *Ent*, extra-embryonic entoderm; *Ec*, ectoderm; *Mes*, mesoderm; *Apl*, area placentalis; *Al*, allantois; *T*, terminal sinus of the area vasculosa; *Y*, yolk sac; *am*, amnion; *am'*, portion of the amnion united with the wall of the allantois; *Ch*, chorion.

We possess no observations, at present, as to the existence of a proamnion in man, and it is probable, owing to the precocious development of the human amnion and of the extra embryonic mesoderm, that no proamnion occurs in the course of human development.

PROSTATE, THE.—The prostate gland (Gr. προστάτης, from πρό and ἱστάναι, to set, or ἵστημι, I stand) derives its name from its position at the entrance to the bladder.

Anatomy.—The prostate is a body largely glandular in character, and in shape much like a Spanish chestnut. In the upright position of the body it lies just below the bladder and behind the symphysis pubis. The base of this heart-shaped gland is in contact with the bladder and vesiculæ seminales, while the apex rests upon the posterior layer of the deep perineal fascia; the anterior surface looks toward the pubis, and the posterior surface rests upon the anterior rectal wall.

The urethra, as it leaves the bladder (pars prostatica urethræ), traverses the prostate from near the middle of its base to its apex, and rather more than one-half of the gland lies behind the canal.

The prostate weighs from five to six drachms, and measures approximately one inch and a half in length, one and a half to two inches in breadth, and one inch in thickness (antero-posterior diameter). Slight longitudinal furrows along its anterior and posterior surfaces show an indistinct tendency toward a division into two lateral lobes, although the two halves are structurally continuous with each other. In this connection it is worthy of note that in some animals the prostate consists of two separate lobes.

That portion of the gland which lies between the ejaculatory ducts and the urethra (pars supramontana, Mercier) is usually known as the middle lobe (Home). Situated upon the floor of the urethra, just at the entrance to the bladder, it often forms a little prominence continuous with an elevation of the vesical floor (uvula vesicæ).

The portions of the gland behind and in front of the urethra, connecting the lateral lobes, are known as the posterior and anterior commissures.

The substance of the prostate is made up mainly of three tissues: (1) Glands; (2) unstriped muscular fibres; and (3) fibrous tissue.

The glands are of the acinous variety, and are most abundant in the lateral portions of the organ, their ducts coalescing and opening along the floor of the urethra. The muscular fibres are disposed in circular bands which are continuous at the junction of the bladder with the circular fibres of that viscus. Hyrtl also describes a system of these fibres radiating from the caput gallinaginis. The fibrous tissue forms a firm enveloping capsule which sends off-shoots through the substance of the gland.

Just below the point of entry of the urethra the two ejaculatory ducts enter the prostate, one on each side, and, running forward through its substance and converging, they enter the floor of the urethra.

The prostatic urethra (pars prostatica urethræ) is slightly narrower where it enters and leaves the gland than it is within it. The hollowed floor of this portion of the canal is called the sinus prostaticus, and is divided into two equal furrows by a longitudinal ridge (verumontanum), the end of which farthest from the bladder is composed of erectile tissue, and is capable of considerable dilatation into a little round prominence which, with the verumontanum running back from it, presents a fancied resemblance to the head of a snipe—hence its name *caput gallinaginis.*

On the top of this little eminence is the opening of a minute sac—the utricle or sinus pocularis—which is thought to be the analogue of the uterine cavity in the female. Close to the edge of this sinus, and sometimes within it, are the orifices of the ejaculatory ducts. Along the sides of the verumontanum open the prostatic glands proper, to the number of from twenty to thirty.

The prostate is enclosed in a tough fibrous capsule which is a part of the pelvic fascia. Besides its attachments to the bladder and deep perineal fascia, it is further held anteriorly by the pubo-prostatic ligaments, and posteriorly by the recto-vesical fascia. Its slight mobility is provided for by the levatores prostatæ—muscular bundles, really parts of the levator ani—which, arising from the posterior surface of the pubis, are inserted along the lateral borders of the gland.

Its blood supply is derived from the internal pudic, the vesical and hemorrhoidal arteries, and the veins which form a plexus around the gland empty through the hypogastric vein. The nerves are branches of the hypogastric plexus of the sympathetic.

Physiology.—The prostate is a sexual gland. After birth it remains in a quiescent state up to puberty, when it begins to increase in size and development. It attains its full growth at about the twenty-fifth year.

The secretion of the glands, which are especially active during sexual excitement, is a slightly turbid fluid of feebly alkaline reaction, with a specific gravity of 1.010.

It is especially rich in chloride of sodium (one per cent.), and, as solutions of this salt are known to excite the spermatozoa to movement, its presence in the prostatic fluid is thought by some to perpetuate their activity. Probably the most important function of this secretion is in producing coagulation of the secretion of the seminal vesicles.

The prostate, further, in its character as a muscular organ, acts as an involuntary sphincter of the bladder. As the urine accumulates a point is finally reached at which the tension of the detrusor urinæ muscle pulls open the rings of involuntary fibres around the neck of the bladder and allows the urine to enter the pars prostatica urethræ. Its presence there causes an urgent desire to urinate, and the escape of the water is then prevented only by the compressor urethræ muscle, which is the voluntary urinary sphincter. If this muscle does not relax and allow urination to be completed, the prostate closes down and forces the contained urine back into the bladder, where it stays until the further increased tension brings on another "besoin d'uriner."

Malformations.—The prostate may be wholly wanting, in connection with a general lack of development of the urinary organs.

In exstrophy of the bladder there is no roof to the prostatic urethra, and the gland ducts may be seen opening through the mucous membrane over the site of the organ.

Injuries and Wounds.—The deep-seated position of the prostate makes it little liable to injury from without. In severe crushes of the pelvis with fracture about the pubis, it may be wounded. In perineal lithotomy it is always incised, and often somewhat contused by the extraction of the stone. If the crushing and laceration of the parts have not been serious, healing usually takes place kindly.

Injury of the prostate occasionally results from the passage of instruments through the urethra. This occurs most commonly in cases of hypertrophy, in which the irregular enlargement of parts of the gland has made the canal tortuous.

A specimen in the museum of the Harvard Medical School shows a very much enlarged middle lobe which so obstructed the entrance of the catheter that the instrument had been forced directly through it and had entered the bladder beyond.

The knowledge that such injuries are possible should lead to their avoidance. Much force is never needed in the passage of an instrument which is properly guided, but a thorough understanding of the nature of the possible obstacles, and considerable patience and care in overcoming them, are necessary to success in these cases.

Inflammation of the Prostate—Prostatitis—may be either acute or chronic.

Acute prostatitis is commonly the result of the extension of an inflammation from adjacent parts

Digitized by Microsoft®

A gonorrhœal urethritis is by far the most usual exciting cause. In this case the inflammation runs back along the urethra to the prostate. That this is not the usual course of a gonorrhœa is due to the protection afforded by the constrictor urethræ muscle. This sphincter, surrounding the membranous urethra, prevents the discharge from penetrating to the prostate and bladder, and usually protects these deeper parts from participation in anterior inflammations. Occasionally the passage of an instrument, or the forcing of an injection through the constrictor, may convey infective discharges past this natural barrier.

www.libtool.com.cn

A non-specific urethritis or an inflammation of the bladder may, in similar manner, extend to the prostate. The passage of instruments, the application of caustics, the use of strong injections, the presence of calculi in the bladder or prostate, accidental injuries, or operations may be the exciting cause of an acute prostatitis.

Among other causes cited as occasionally giving rise to prostatitis may be mentioned sexual abuses, acrid irritating conditions of the urine, the use of stimulating diuretics such as cantharides and turpentine, the abuse of stimulants, and the presence of inflammation in the rectum. Probably these conditions are rarely, if ever, competent to excite an acute prostatitis in a healthy state of the gland, but only act to aggravate an already existing inflammation.

A stricture of the urethra greatly aggravates any deep inflammation of that canal, and makes its extension to the prostate much more liable to occur.

Pathology. In acute inflammation the prostate is much congested, with great swelling and œdema, which extend to the surrounding parts. The prostate itself may be enlarged to three or four times its natural size, and even with this degree of inflammation, resolution and a return to a comparatively normal condition are possible.

If, however, the inflammation runs a more acute course, it may lead to the formation of abscesses, which, starting as minute points of pus, may gradually enlarge and coalesce until, in an extreme case, the whole organ may be reduced to one abscess cavity.

Spontaneous opening may take place backward into the rectum, into the urethra, or into the bladder, and the pus may even occasionally find its way down through the ischiorectal fossa, or into the perineum, and point externally. Rarely, the abscess may open into the peritoneal cavity, or into an adherent coil of intestine.

Symptomatology. The prominent symptoms are pain deep in the perineum and in the rectum, with tenesmus of the bladder and the rectum. Urination is very frequent, and is accompanied by great pain, especially during the passage of the last few drops of water, which are frequently colored with blood.

Accompanying these local symptoms there is usually considerable fever, which may or may not be ushered in by a chill There is also often severe pain in the back, loins, and thighs.

As the inflammation increases the pains become even more severe, the urine in its passage scalds intensely, the pressure and throbbing pain in the rectum become very distressing, and defecation, which is constantly desired, is, when it happens, a new source of suffering.

The stream of urine becomes small and hard to start, owing both to the swelling of the prostate and to the spasmodic contraction of the constrictor urethræ muscle, and finally complete retention may result

If a gonorrhœal discharge previously existed, it may disappear at the onset of prostatic inflammation, or it may be changed into a slight mucous discharge.

There is usually a good deal of tenderness in the perineum, and sometimes also close above the symphysis pubis. A rectal examination is difficult on account of the extreme sensitiveness of the parts, accompanied by spasm of the sphincter muscle.

If the inflammation gives rise to an abscess, its formation is often heralded by rigors with high fever. If the abscess breaks into the urethra or bladder, there may be a sudden escape of pus in the urine, with an improvement of the general symptoms.

If the pus cavity attains any considerable size, its character may be made out through the rectum, where it is to be felt first as a hard, boggy swelling, which later softens and gives evidence of fluctuation.

If the abscess extends into the loose cellular tissue along the rectum pyæmic symptoms may develop, and in case of rupture into the peritoneal cavity the characteristic symptoms of peritonitis will come on abruptly, with a speedily fatal issue.

Treatment. Absolute rest is the first and most important measure when acute inflammation of the prostate makes its appearance.

The patient should keep in a horizontal position with the hips somewhat raised.

If severe pain is present—especially if frequent spasms of the bladder are aggravating the inflamed gland—opiates should be given; and it is to be borne in mind that these, by inducing rest from spasm, exert a really curative effect. Morphine and atropine subcutaneously, or opium and belladonna suppositories, may be administered under these circumstances.

All irritations from instrumentation, injections, or stimulating diuretics should be avoided.

The bowels should be kept gently open by aperients, if necessary, and this point should be carefully looked after when opiates are being used.

The urine should be rendered as unirritating as possible by the use of diluents and alkaline diuretics, and nourishment should be given in a bland, unstimulating form. Farinaceous gruels, milk, and light broths may form the bulk of the diet. Alcohol should be entirely avoided in the acute stage of the disease.

If at the outset the fever runs high, it may be somewhat mitigated by the use of quinine or some more temporary febrifuge, such as aconite or phenacetin. Late in the disease, when it has run a severe course—especially in case of exhausting suppuration—strong concentrated foods and alcoholic stimulants may be required.

Locally, all possible measures for limiting the severity of the inflammation should be employed. In an early stage of the disease, leeches applied to the perineum may be of considerable service. From six to eight should be put on along the raphe and close to the anus. The bleeding may be encouraged, especially in plethoric persons until from fourteen to sixteen ounces have been withdrawn.

Hot applications, either by fomentations or by hot-water bottles, to the perineum and over the pubes, are useful in diminishing pain and spasm, and probably assist somewhat in limiting the inflammation. Hot hip baths are recommended for this same purpose; but the exertion and the unfavorable position required for these add so much to the pelvic congestion as greatly to diminish the otherwise favorable effect of the heat. If used, they should not be prolonged for more than five or eight minutes, as the maximum effect on the surface is produced in that time.

If retention of urine occurs, it must be relieved by the careful introduction of a small, soft catheter (Nos. 12–14 French scale).

Sometimes, when there is a spasmodic stricture at the compressor urethræ, a soft catheter will not pass, and a stiff instrument must be used, requiring, of course, the greatest gentleness of manipulation.*

When the retention persists and requires repeated catheterization, an instrument tied into the bladder (*sonde à demeure*) will often cause less irritation than would its frequent introduction.

The possibility of abscess formation is always to be kept in mind, and the condition of the gland should be watched by rectal examinations. If fluctuation is made out, the abscess should be opened at once. This may usually be done through the rectal wall with a curved

* For the discussion of catheterization see under Hypertrophy of the prostate.

Digitized by Microsoft®

bistouri caché, and the opening should be rather a puncture than a long incision. This is for the purpose of avoiding hemorrhage: and it is a good plan, with this same object in view, to make a careful examination before the puncture, to see that no vessel of any size in the rectal wall stands in danger of injury by the knife. In case of bleeding, ice www.libtool.com.cn into the rectum, and if these fail, pressure should be applied by a thorough plugging of the lower part of the bowel. If the abscess is a large one a drainage tube may be introduced into it through the rectal opening.

If examination shows that the abscess is working toward the perineum, it may be opened by an incision from that direction, and thus a urethro-rectal fistula with prolonged suppuration may be avoided.

When the abscess communicates with the rectum thorough irrigation of the bowel should be carried out, and an antiseptic, free from poisonous properties, should be selected, on account of the absorptive power of the rectal mucous membrane.

If the disease ends in resolution, care should be taken that the recovery is complete, for an acute inflammation may, if neglected, leave a chronic condition which is sometimes extremely hard to relieve.

Chronic Prostatitis.—Chronic inflammation of the prostate may, as has been said, follow an acute attack. It may, however, on the other hand, originate as a chronic or subacute affection.

What has been said in regard to the etiology of acute, will for the most part apply to chronic, prostatitis; but while the former is seldom the result of sexual errors alone, these are not infrequently almost wholly responsible for a chronic inflammation of the gland; and it is to be noticed that the imperfect sexual indulgence of masturbation, or partial intercourse, is much more productive of prostatic trouble than is the normal excitement of proper coition. This is probably due to the unrelieved congestion of the gland, left after these unnatural practices.

Pathology. A chronically inflamed prostate is usually somewhat enlarged, but may be natural or diminished in size. The gland is less firm than in health, and its texture is more open and spongy. Upon section the cut surface is red or dusky in hue, and moister than normal. Little points of suppuration may exist, but are usually few and small.

The mucous membrane has an increased vascularity and may be thinned, particularly if the prostatic urethra is dilated in consequence of an anterior stricture. It may, on the other hand, be thick and spongy, denuded partly of epithelium, or much roughened with spots of ulceration; sometimes, in cases of long standing, it is pigmented. The sinus pocularis and dilated gland ducts about it may contain pus. Sometimes an abscess cavity exists in communication with the urethra.

Symptomatology. Patients with chronic prostatic inflammation are troubled with increased frequency of micturition, which in a mild case may be scarcely noticeable, but is often very troublesome—occurring sometimes with intervals of less than an hour.

There is sometimes pain of a dull, heavy character, referred to the perineum and lower rectum. There may also be considerable pain low down in the back, with twinges shooting into the thighs and testicles. A slight, persistent urethral discharge, often most marked in the morning, may be the only symptom. In some cases the symptoms may be almost entirely of a sexual character, such as are often spoken of as sexual neurasthenia.

The bladder, when full, may make its condition known by a feeling of discomfort or actual pain, with intensely urgent call to urinate.

The passage of urine may be accompanied by slight scalding sensations, and there may be a twinge at the end of micturition, when the bladder shuts down upon the sensitive prostate. Occasionally tenderness in the perineum may be felt upon deep pressure.

The urine may be cloudy and contain, more or less abundantly, clumps of muco-pus mixed with epithelial cells. These are little accumulations of secretion washed out of the dilated gland ducts, and differ from the loose threads of mucus so common in chronic urethritis in being smaller, more coherent, and rounded in form. When the urine is passed in two portions, the first part is apt to be more cloudy and to contain these clumps of mucus more abundantly than the second part. Not infrequently, however, even when the inflammation is confined to the prostate, the pus is distributed throughout the urine and both portions are cloudy. The reason for this has been very clearly stated by Ultzmann,* and is as follows. The internal sphincter of involuntary fibres surrounding the vesical orifice of the urethra is comparatively feeble, while the compressor urethræ muscle, just in front of the prostate and surrounding the membranous urethra, is strong and competent, and, being under the control of the will, it forms the voluntary sphincter of the bladder.

As discharges collect in the prostate they cannot force their way forward past the constrictor, but readily escape backward into the bladder, where they diffuse themselves through the urine. Even in these cases, however, when the urine is universally cloudy, the first portion will still be somewhat more cloudy than that which follows, and will contain many more of the mucous prostatic clumps. The urine in mild cases may be clear with a moderate number of "prostatic plugs" which settle rapidly to the bottom of the urine glass.

The urine, when examined microscopically, will often be found to contain, besides the pus, a considerable number of blood cells, and occasionally also a few spermatozoa. The blood may not infrequently be perceived to come at the end of micturition, when the bladder closes down upon and squeezes the congested prostate.

A chemical examination frequently shows the presence of a little albumin, often in larger quantity than the pus and blood would account for. In other respects the urine is usually normal.

If the character of the stream is noticed, it will often be found that its force is decidedly diminished, and that after the completion of urination a few drops dribble away. Sometimes partial or total retention may occur.

This interference with urination is to be partly accounted for by the swelling of the prostatic mucous membrane, but is often largely dependent on a spasmodic contraction of the constrictor urethræ muscle; and if under these circumstances a sound is passed, it will meet with decided resistance when it reaches the voluntary sphincter. This spasmodic stricture may be so close as greatly to aggravate the difficulty and pain of micturition, for, as the bladder forces the urine into the prostatic urethra, if its further escape is prevented, the undue pressure in this sensitive part is productive of very great suffering. Usually the spasm of the constrictor is finally overcome by the accumulating intravesical pressure, and urination, beginning first by drops, presently comes with more or less freedom.

As we have said, the constrictor muscle hinders prostatic secretions from escaping anteriorly and appearing as a urethral discharge. A very slight gleet in the morning is not infrequently observed. Sometimes also in these cases a glairy discharge of prostatic mucus is pressed out and escapes while the patient is at stool; especially is this the case when the bowels are constipated and much straining is required. This is commonly interpreted by the patient as an escape of semen, and he becomes convinced that he is a victim of spermatorrhœa.

Usually the microscope fails to find spermatozoa in this discharge, which consists mainly of mucus, with sometimes a little admixture of pus and blood.

Besides the local symptoms and manifestations that have been described, we see in these prostatic cases often marked changes in the general condition of our patients. They are nervous and hysterical, or may be depressed and despondent, with often a hypochondriacal over estimate of the gravity of their trouble. Sometimes a true neurasthenic condition may be induced in a case of long

* "Pyuria," p. 26.

Digitized by Microsoft®

standing. Digestive disturbances and palpitation of the heart may occur.

Physical Signs. An examination of the prostate through the rectum shows it sometimes slightly enlarged, but often normal or diminished in size. In consistency it is usually somewhat softer than in health.

If the urethra is explored with an instrument it is commonly very sensitive, but may be anæsthetic, the latter condition being noticed usually in old cases. The urethra should be carefully examined for a possible stricture, and it is to be remembered that the constrictor muscle will often be found to make a spasmodic contraction just behind the triangular ligament. The passage of the sound through the prostatic urethra is almost always painful, and may excite an intense desire to urinate, or an ejaculation of semen.

Diagnosis. The disease which we are considering is peculiar to young and middle-aged men, and is to be kept distinctly separate from hypertrophy of the prostate, which occurs only in the old. Inflammatory symptoms, it is true, are not uncommon in this latter affection, and will be discussed later.

Tuberculosis of the prostate offers many points of resemblance to chronic prostatitis, and a differential diagnosis is often difficult, and may be for a time impossible. The detection of small nodules in the prostate and a marked tendency of the disorder to become worse as a result of local treatment are suggestive of tuberculosis. The constitutional tendencies of the patient should be taken into consideration, and a careful search should be made for evidences of tuberculosis in other organs. An examination of the urine for tubercle bacilli may help to a solution, but a failure to find them even after careful search leaves the question where it was before, for they are often sought in vain in undoubted cases of genito-urinary tuberculosis.

The discrimination between prostatitis and deep urethritis after gonorrhœa is sometimes almost impossible.

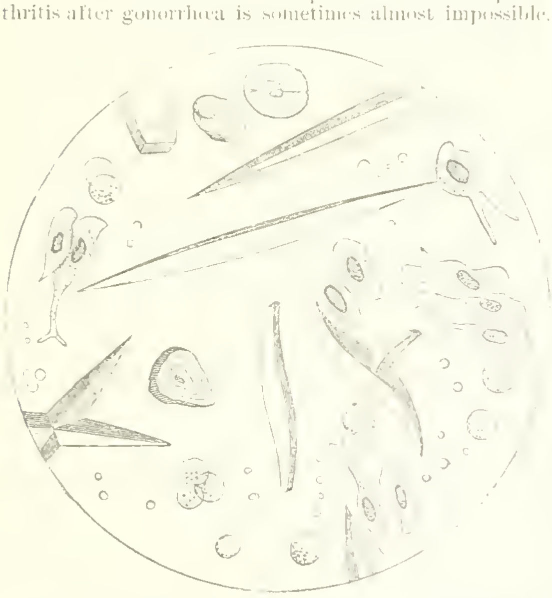

FIG. 3883.—Sediment from Prostatic Discharge, Containing Pus and Epithelial Cells, Granules, Amyloid Bodies, and Böttcher's Crystals.

The rectal examination of the prostate may help to a decision, but not infrequently it gives negative results.

A microscopical examination of the discharge obtained by pressure on the prostate through the rectum may give valuable information but this, too, is often misleading. The discharge in either case contains pus and large and small round epithelial cells. Amyloid bodies and cylinder or caudate epithelium may be found in considerable abundance when the discharge is prostatic.

The formation of Böttcher's crystals upon the addition of a drop of a one-per-cent. solution of phosphate of ammonia to a drop of the secretion shows beyond question that it contains prostatic fluid.

This reaction should be conducted on a microscope slide, under a cover-glass, and within an hour, usually, crystals such as are shown in Fig. 3883 make their appearance. They are composed of a phosphate formed from a base which exists in prostatic fluid, and which is supposed to impart to it its peculiar odor. Unfortunately, the mixture of urine with the secretion prevents the formation of these crystals, and so limits very much their diagnostic usefulness.

It is always to be borne in mind that a combination of urethritis and prostatitis is not uncommon.

Treatment should be addressed to both the general and the local condition.

The general treatment should be tonic, especially in the cases in which much nervous depression exists.

A generous, unstimulating diet, with moderate exercise in the open air, and with cold sponge baths in the morning, when the patient's strength will admit of them, are to be advised.

The laws of sexual hygiene should be carefully explained to the patient, and the importance of their observance made plain to him.

Preparations of strychnine and iron are often of benefit, and they may be advantageously combined with quinine or ergot, both of which seem to exert a soothing influence upon the prostate. Iodide of potassium may be of assistance when the inflammation affects the glandular portions of the organ, and the addition of bromide of potassium is sometimes distinctly useful in quieting sexual excitement.

If the urine is highly acid or otherwise irritating, its character should be modified by demulcent drinks and by alkaline diuretics.

For a more direct local effect, cantharides, turpentine, sandal wood oil, or copaiba may sometimes be administered with advantage, especially when the inflammation is mostly confined to the prostatic urethral mucous membrane.

Various local measures of treatment may be expected to contribute to the cure.

Counter-irritation to the perineum, either with tincture of iodine or with fly blisters, is often of great use. Cantharidal collodion is a convenient blistering medium, and should be applied to a small surface close to the raphe.

Whatever counter-irritant is used, care should be taken that it does not come in contact with the scrotum or anus. After the application is dry, it is a good plan to fix a pad of absorbent cotton in the perineum with a T-bandage. This takes up the perspiration and prevents the blister from spreading to the side opposite to that where it was applied.

When there is much pain in the prostate and rectum, hot injections into the bowel may help to palliate it, and to reduce the congestion in the same manner that hot douches act upon the female pelvic organs.

The most important local treatment, however, is that applied directly to the prostate itself, and consists in the passage of sounds, massage of the prostate through the rectum, and in applications and injections into the prostatic urethra.

The use of sounds in chronic inflammation of the prostate has long been recognized as of advantage, and the benefit from them has been variously explained.

Some surgeons think that they should be used cold, and ascribe their efficiency to the astringent action of the cold. Others consider that their pressure within the prostate exerts some beneficial influence by forcing the blood out of the gland.

While some good may perhaps be attained in either or both of these ways, it is probable that the stretching of the constrictor urethræ muscle, and the consequent relief from spasmodic contraction of the same, will account, in a large measure, for the good results that follow their use. As has been said above, this sphincter is not infre-

Digitized by Microsoft®

quently put in a spasmodic state of contraction by the proximity of the prostatic inflammation, and in this state of stricture it has a tendency to aggravate the deep inflammation, just as an organic stricture tends to increase and perpetuate a urethritis posterior to it. It can be readily understood, therefore, that the relief of this spasmodic contraction would act favorably upon the inflammation behind it.

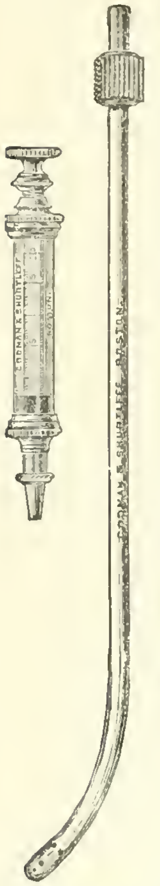

FIG. 3884.—Ultzmann's Prostatic Syringe. A capillary tube and graduated syringe for the introduction of strong solutions. The curve of this and of the irrigating catheter is modified from Ultzmann's instruments. See text.

As large a sound as will pass comfortably through the urethra should be used, and it should be introduced with the greatest gentleness. A sound passed roughly down through the anterior urethra will sometimes find the constrictor tightly closed against it, when, had more care been exercised, the urethra would not have resented its introduction, and it would have readily passed the moderately contracted sphincter.

If the spasmodic stricture is a tight one, it will sometimes be found necessary to precede the introduction of the sound by the passage of a French, olive-pointed, conical bougie; which, insinuating its point through the obstruction, readily dilates it and prepares the way for the larger instrument.

When excessive irritability or an access of inflammation make the application of cold to the prostate desirable, it may best be accomplished by the use of the cold sound. This is a hollow instrument, which after its introduction can be chilled down by passing a stream of water through it. It should usually be kept in place for about five minutes.

We now come to speak of local applications to the prostatic urethra, and in these we recognize the most efficient means at our command for subduing chronic inflammation of this part.

The cases which are particularly suited to this form of treatment are those in which prostatic clumps are present in the urine, with or without a purulent secretion; in short, in which the mucous membrane is distinctly affected. Medication may be conveyed to the pars prostatica urethræ either by the injection of a few drops of a strong solution, or by irrigation with considerable quantities of a weak solution.

The application of soluble drugs to the prostatic urethra is probably best accomplished by the injection of solutions.

The constrictor muscle, situated just in front of the prostate, prevents the penetration of an ordinary urethral injection, and special instruments are therefore needed for medication in the urethra posterior to it. Figs. 3884 and 3886 represent such catheters for prostatic medication.

The curve shown in these instruments has advantages both in the ease of introduction, and in the readiness with which the location of the point can be determined from the position of the handle.

When the instrument is vertical* the point necessarily rests just in front of the triangular ligament; now, upon bringing it down to an angle of forty-five degrees, and at the same time advancing it slightly, the point slips on through the constrictor muscle, but never passes beyond the prostate unless a special effort is made to push it on toward the bladder. Fluid injected through the catheter, when in this position, cannot pass forward through the constrictor, but washes out the prostate and escapes backward into the bladder.

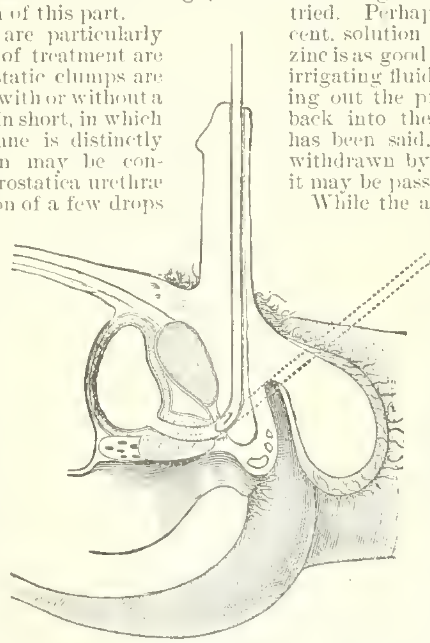

FIG. 3885.—Diagram showing that if a short-beaked instrument is held with the handle vertical, the point rests just at the triangular ligament. The dotted figure shows how the point slips through the constrictor muscle when the handle is brought to an angle of forty-five degrees with the axis of the body.

Of the various drugs used for prostatic application, nitrate of silver is perhaps the most valuable.

Two or three minims of a one- to two-per-cent. solution should be thrown into the prostatic urethra through the capillary catheter (Fig. 3884).

Some pain of a burning character, with often considerable tenesmus, follows the application; but this usually passes off in an hour or two. The injection should be repeated every four or five days, and its effect may sometimes be heightened by the previous passage of a sound. As convalescence is established, the intervals in the treatment should be gradually lengthened.

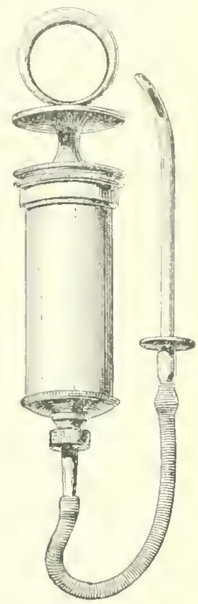

FIG. 3886.—Irrigating Catheter. (After Ultzmann.)

Irrigation of the prostatic urethra may often be practised with great benefit. In case there is much irritability of the neck of the bladder, with considerable muco-purulent secretion, a soothing antiseptic wash is of use. A two-per-cent. solution of borax or boracic acid, with the addition of a little glycerin, is a good injection for this purpose.

If the use of an astringent wash seems indicated, any of the mixtures useful in gonorrhœa may be tried. Perhaps a one-per-cent. solution of acetate of zinc is as good as any. The irrigating fluid, after washing out the prostate, flows back into the bladder, as has been said, and from there it may either be withdrawn by slightly advancing the catheter, or it may be passed by the natural efforts.

While the above-mentioned procedures are addressed to the urethral aspect of the prostate, further relief may be afforded by massage of the rectal face of the prostate. This is done by the forefinger introduced into the rectum, and should aim at expressing the contents of the prostate. The amount of pressure which may be safely used will depend on the acuteness of the inflammation, of which the tenderness will prove a safe guide. Massage should not be given at too short intervals, and is often wisely made to alternate with the other local measures above outlined.

After any manipulation or treatment of the prostate the patient should keep quiet, if possible recumbent, until all serious discomfort passes away, and should

* Throughout this article, when the manipulation of instruments is described, it is supposed that the patient is in a horizontal position.

Digitized by Microsoft®

avoid any exposure to chill or fatigue for several hours.

HYPERTROPHY OF THE PROSTATE, ENLARGED PROSTATE. — *Etiology.* — The causes of enlargement of the prostate are difficult to establish by any adequate proof.

www.libtool.com.cn

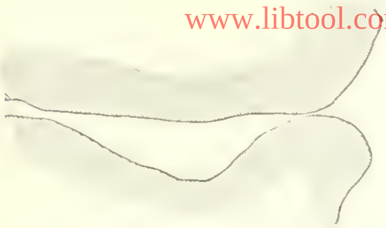

FIG. 3887. — Diagram to show the Shape of the Urethra in a Vertical Section Through a Prostate with an Enlarged Middle Lobe.

The one thing which seems to be essential to the existence of the disease is the advanced age of the patients. Hypertrophy of the prostate is practically unknown before the age of fifty, whereas after that it is extremely common.

Stone in the bladder, stricture of the urethra, irritation by the frequent use of instruments, sedentary habits, gouty or rheumatic diathesis, and exposure to cold and damp, have all been cited by surgical writers as predisposing circumstances; but none of these conditions has ever been positively shown to stand in a causative relation to the disease.

On the other hand, there is no doubt that, when prostatic hypertrophy exists, any of these conditions may greatly aggravate its symptoms; and besides those already named we may mention excesses in drink or in venery, prolonged voluntary retention, and the recumbent posture as familiar causes of increased prostatic congestion.

Pathology.—Hypertrophy of the prostate may occur through hyperplasia of the glandular portions of the organ, of the interstitial tissue, or of both.

As the normal size of a particular prostate can never be known, it may be hard to say, even on post-mortem examination, whether a given specimen is enlarged or not. For approximate determination, however, a prostate weighing six drachms may be regarded as normal in size, and anything over that is to be considered hypertrophied.

Upon section of a prostate which is hypertrophied, the cut surface bulges irregularly above the capsule. It may be grayish-yellow in color or mottled with blotches of red, yellow, and gray, with occasional dark pigmented spots.

FIG. 3888. Diagram of a Horizontal Section through the same Organ, showing how the urethra divides and goes on either side of the middle lobe.

If the glandular element predominates the surface is soft, and exudes a fluid rich in cells. In interstitial hyperplasia the surface is dryer and firmer.

Sometimes little projecting bunches announce the formation of fibrous or glandular tumors within the organ.

Usually the hypertrophy affects all parts of the gland simultaneously, but not all in the same degree.

The shape of the prostatic urethra—a matter of the first clinical and surgical importance—depends largely upon the partial or general character of the hypertrophy. If the enlargement is pretty evenly distributed throughout the organ, the urethra is in the first place considerably lengthened, sometimes measuring even 7 cm. When the hypertrophy is partial the elongation is less, though it is still marked.

Furthermore, in cases of general hypertrophy, as the lateral lobes enlarge they compress the urethra from the sides, until it becomes a slit-like canal with tolerably firm walls in close apposition. As the lateral diameter is thus diminished, the antero-posterior diameter is correspondingly increased.

It will be readily seen that, as long as the enlargement is symmetrical, the direction of the urethra is not materially altered; but, on the other hand, it is equally evident that, if the hypertrophy is partial, and not evenly distributed, the unequal pressure from one side or the other of the canal will cause lateral deviations, and that, if the middle lobe is unduly enlarged, the posterior portion of the urethral floor will be raised, causing a deviation upward or toward the pubis (see Fig. 3887).

The projection upward of this lobe may make the internal urethral opening crescentic in shape, and if the middle coalesces with either of the lateral lobes, this orifice is pushed over toward the opposite side.

Sometimes the middle lobe grows out into the bladder as a distinct tumor, which may be attached by a broad base, or may stand off in a pedunculated polypoid form.

Besides the changes in the prostate itself, there are other alterations in associated organs which we must consider in connection with this disease, as they are instrumental in producing many of the symptoms which we shall have to study.

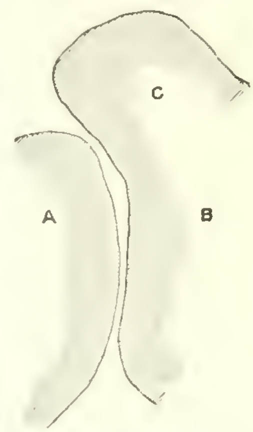

FIG. 3889.—Diagram of a Horizontal Section through a Prostate in which the right lobe, *A*, is moderately enlarged, the left lobe, *B*, somewhat less so, while the middle lobe, *C*, is much enlarged and is joined to the left lobe, causing a deviation of the vesical end of the urethra to the right.

As the prostate enlarges the internal meatus is raised and a pocket is formed in the bladder just behind the enlarged gland. The bladder wall also becomes thickened, partly in consequence of hypertrophy of the muscular coat, owing to the increased resistance against which it has to work, and partly owing to a sclerosis of the interstitial fibrous tissue, like that which has occurred in the prostate.

Interlacing muscular bands often stand out from the vesical wall under these circumstances, forming trabeculæ between which there are, not infrequently, considerable pouches of mucous membrane.

The walls of the ureters and pelves of the kidneys may also be somewhat thickened, and the interstitial renal tissue undergoes frequently a hyperplasia.

As a later result of the prostatic obstruction the bladder, ureters, and pelves of the kidneys may become greatly distended.

Guyon and Launois have laid particular stress upon the fact, already hinted at and partly understood by earlier writers, that coincident with these changes in the urinary tract a general sclerosis, affecting specially the walls of the blood vessels, is going on throughout the body.

When from any cause inflammation of the bladder, ureters, or kidneys has associated itself with hypertrophy of the prostate, we have the familiar pathological appearances of cystitis, pyelitis, and pyelo-nephritis engrafted upon the organs already seriously altered by the prostatic obstruction.

For a full consideration of these complications see the articles on *Bladder of the Male* and on *Kidneys, Diseases of.*

Natural History.—The progress of the disease is slow. The organs affected are not of vital importance, and the changes in them may reach a very advanced state before they seriously threaten life.

Guyon has divided the history of the disease into three

Digitized by Microsoft®

periods: *First*, that of congestion, affecting mainly the prostate, but also in less degree the bladder and kidneys. *Secondly*, that of partial retention of urine. And, *thirdly*, that of distention of the bladder with usually secondary changes in the kidneys.

This somewhat empirical division gives us perhaps as good a framework as any for the classification of the clinical phenomena.

www.libtool.com.cn

In the first stage, that of congestion, we have some enlargement of the prostate and functional disturbances, especially in the matter of urination. This condition may persist for a long time, and in certain cases, in which for any reason the calibre of the urethra is not greatly interfered with, it may exist almost indefinitely without showing any tendency to pass on to the second stage, that of retention.

Usually, however, sooner or later the obstruction to the passage of the urine becomes greater than the force of the bladder can overcome, and a state of habitual partial retention is the result.

When this condition comes on slowly, the accumulation of residual urine may be very insidious, and escape the observation of patient and physician alike; on the other hand, an increase in the prostatic obstruction may occur suddenly, and the unexpected complete stoppage of the urine may be the first announcement of trouble.

When the retention of the second stage of the disease develops gradually, and is not discovered and treated, the point may be finally reached where the bladder has completely lost its tone and is so distended that the urine escapes almost constantly by an overflow (retention with incontinence). This same condition of things may follow also an acute retention which has not been relieved by catheterization and in which nature has finally established a leakage.

The third stage of the disease is now entered upon, and if nothing is done for such a case the distention of the bladder becomes extreme, and a secondary dilatation of the ureter and of the pelves of the kidneys takes place. This is soon followed by atrophy of the secreting portion of the kidney, and an increase of its interstitial tissue (interstitial nephritis).

The secondary changes in the heart and blood-vessels, usually associated with chronic nephritis, are likely to make themselves noticed at this time, if they have not already done so, and the disease becomes a constant and serious menace to life.

It is in this advanced stage of the disease that inflammatory processes, starting in the bladder, rapidly extend backward to the kidneys, and uræmic symptoms presently usher in the closing scene.

Symptomatology.—From what has been said in regard to the history and progress of the disease, it will be seen that the symptoms of the first stage are mainly dependent upon the condition of congestion in the prostate, bladder, and kidneys. And as this congestion is most considerable in the prostate, the most noticeable symptoms caused by it are disturbances of micturition and of sensation, due to the irritated state of the neck of the bladder.

In the second and third stages we have, in addition, a series of symptoms due to the mechanical obstruction to micturition, and to the changes in the bladder and other organs consequent upon this obstruction.

We shall have finally to consider the symptoms arising from various morbid conditions likely to appear as complications in the course of prostatic disease.

The first appearance of symptoms usually announces a morbid condition which has already been coming on for some time. When the enlargement takes place in such direction as not to encroach seriously on the calibre of the urethra, it may reach very considerable proportions before it causes any inconvenience to the patient.

One of the first symptoms to be noticed is an increased frequency of micturition, which is specially marked at night or early in the morning. Guyon regards this as evidence of congestion, which is aggravated during recumbency and sleep. He calls attention also to the frequent existence of erections in these patients, on waking, as further evidence of an increased congestion of the prostate during sleep.

Pain is ordinarily not very noticeable in the early stages of the disease, although a dull aching or heavy dragging sensation in the perineum, rectum, and behind the pubis is not uncommon.

If attention is paid to the manner in which urination is accomplished, it will be found that early in the disease the stream is slow to start and diminished in force. This is due largely to a loss of power in the bladder, but is to be partly explained by the swelling in the prostate, and by a spasmodic contraction and stammering action of the constrictor muscle.

The diminution in the force of the stream in a prostatic patient differs from that seen in cases of stricture, in that, while a strictured patient can, by voluntary effort, increase the force of his stream, a man with enlarged prostate cannot do so.

Second Period. The symptoms which have their origin in congestion continue during this period, and are, indeed, intensified. Added to them we have other symptoms due to the retention, which is the characteristic condition of this stage of the disease.

The retention may be complete or incomplete.

Complete retention may be acute and appear suddenly, or it may be preceded by a period of partial retention which always develops slowly.

The symptoms which accompany a complete retention are easy of recognition, and a physical examination reveals the bladder distended above the pubis. Incomplete retention, on the other hand, comes on very insidiously, and is often overlooked for a long period, at just the time when recognition and treatment of the condition are of great importance.

Although, as has been said, partial retention comes on quietly, still a careful examination of the symptoms will usually elicit evidence of a changed condition of things, at or soon after the time when the bladder begins to fail of emptying itself. The feeling of weight behind the pubis is likely to be increased, and the frequency of micturition, which during the first stage was decidedly more pronounced at night, begins to be almost equally noticed in the daytime. The intervals between the acts of urination become short, and the call is imperative. In short, the bladder being always partly full, it takes but a small additional quantity to distend it to its full capacity.

The only positive means of determining the conditions of the bladder is by a physical examination, and this should be made in every doubtful case.

Sometimes the bladder shows extraordinary tolerance, and the distention becomes so extreme as to cause incontinence from overflow, before the patient feels obliged to call upon a physician; and sometimes also, unfortunately, before the medical attendant recognizes the nature of the difficulty.

This incontinence is evidence of a very great degree of distention, and shows that the disease has entered upon its third stage. Usually, before it appears, the disease has already extended backward and has begun to affect the kidneys.

There is one symptom which may appear and give evidence that the disease has reached the third stage, before incontinence begins. This is polyuria. If the quantity of urine in the twenty-four hours is measured, it will be found considerably to exceed the normal.

Pain, which was an insignificant symptom in the first stage, may assume considerable importance in the second and third stages.

Besides the discomfort in the perineum and back due to the congested and irritated prostate, there is also considerable pain before and during micturition, caused by the distention of the bladder and its unavailing or partially successful attempts to empty itself. The passage of the urine through the prostate is also sometimes painful, and this is especially the case when the occurrence of inflammation has rendered the urine pungently alkaline and has made the parts particularly sensitive.

The examination of the urine may give negative results

Digitized by Microsoft®

during the early stages of prostatic disease; but when the congestion of the kidneys is considerable there are usually albumin and a few casts. During the last stage of the disease, when polyuria has established itself, the specific gravity is low (1.003–1.006) and there is generally a small amount of albumin, although this may not be present. A few casts will usually be found at this time, too, but they may be absent even when the kidneys are extensively diseased.

www.libtool.com.cn

In the presence of inflammatory complications the character of the urine is greatly changed, as we shall see later.

In addition to the more local symptoms which we have been considering, there are also certain general disturbances which are likely to appear in advanced prostatic disease. These are of two kinds, digestive and febrile.

Obstinate indigestion in an old man, especially if accompanied by nausea, should always lead us to take the condition of the prostate into consideration. These patients are also very liable to a low feverish condition, with extremely dry mouth and tongue, and this may announce the extension of inflammation from the bladder back into the kidneys.

We now come to the consideration of the complications which are likely to arise in prostatic cases, and of the symptoms, or variation in symptoms, to which they give rise.

They are cystitis, pyelitis (pyelonephritis), hæmaturia, and stone in the bladder.

Cystitis is so common in prostatic hypertrophy that it may be looked upon almost as a necessary result. It sometimes appears without apparent cause, sometimes in consequence of excesses in drink, or from exposure to cold, and in this case the infection probably comes from the rectum or through the blood. Far more commonly, however, it follows as a consequence of the use of the catheter or other instrument, and when it is once established it is rarely got rid of—but may, as we shall see, by appropriate treatment, be kept within very reasonable bounds.

When the inflammation of the bladder is at all acute, the pain and frequency of micturition are greatly increased. If the prostate shares in the inflammation, a great weight and bearing down pain in the rectum may be felt, with a frequent urgent desire for defecation.

The urine becomes thick from the admixture of pus and mucus, which often settles at the bottom of the vessel in a thick, ropy mass. Presently, in the majority of cases, it undergoes alkaline fermentation, becomes ammoniacal, and has a strong pungent, often fetid odor. The sediment now contains, besides the pus, prostatic cells and abundant crystals of triple phosphates, often associated with finely granular amorphous phosphates.

If the inflammation extends from the bladder back through the ureters to the kidneys, the resulting pyelitis or pyelonephritis makes itself known by pain in the back, high fever, more or less diminution or even suppression of urine, and uræmic symptoms.

This course of things is especially liable to occur late in the disease, when neglect of catheterization has allowed the ureters to become greatly distended. Under these circumstances, any exposure to cold or instrumentation may be sufficient to start the fatal access of inflammation.

Occasionally, when the use of the catheter has been neglected after the time when it should have been begun, the final entrance upon the catheter life, instead of being a conservative measure, gives the final push toward a fatal issue. The existence of polyuria, with urine of a low specific gravity, should always lead us to fear this result.

Stone in the bladder not infrequently occurs in prostatic patients as a consequence of cystitis, in which case the stone is of the soft phosphatic variety; or a stone composed of uric acid, oxalate of lime, or cystin may form, and owe its origin primarily to a constitutional condition.

In either case the prostatic hypertrophy may be regarded as partly responsible for the formation of the calculus.

In the first case, that of the phosphatic stone, the obstruction, by causing the cystitis and fermentation of the urine, stands in a pretty close causative relation to the calculus. In the second case, in which the deposit of crystals from the urine is due to a constitutional tendency, the obstruction at the prostate may be the condition which decides whether a stone shall form or not. For, when the bladder is completely emptied at each urination, the crystals as they form are thrown out and do no harm, whereas when there has been formed behind the prostate a pocket in which there is always residual urine, the sand collects there and soon agglomerates itself into a concretion.

When a stone forms behind an enlarged prostate the pain is usually much increased, and is less amenable to treatment. It is referred often to the glans penis, and is greatly aggravated by motion, especially by riding in a jolting vehicle. It is commonly less marked at night or during rest.

Hæmaturia in case of stone is very likely to appear after exercise or riding, while prostatic hemorrhage from congestion seems to be independent of any jarring of the bladder—in fact, is rather more likely to come at night, when recumbency favors prostatic congestion.

The sudden stoppage of the stream in the midst of urination, by the rolling of the stone against the opening of the urethra, is less likely to occur in case of an enlarged prostate than in a healthy bladder, owing to the lodgment of the stone behind the prostate, below the urethral orifice.

If the presence of the stone affects the frequency of micturition, it tends to increase it rather in the daytime, when motion causes the stone to move about, than at night, when it is at rest.

Hæmaturia, as has been said, may result from the congestion of the prostate with or without ulceration, or from the presence of a stone. We may also have hemorrhage of considerable amount and duration, following the use of instruments; and, lastly, the too sudden emptying of an over-distended bladder may lead to an attack of hæmaturia, from the capillary oozing from the vesical wall.

Sometimes clots of large size may form in the bladder, and cause much pain and discomfort before they are broken up and expelled.

Physical Examination.—After it has been decided from the symptoms that there is a probability that prostatic hypertrophy exists, a thorough examination should be made of the prostate and bladder.

The objects of this investigation are to ascertain the stage at which the disease has arrived, to learn the amount of obstruction and the configuration of the prostatic urethra, and to discover any complicating conditions which may exist.

The patient should first empty the bladder, so far as possible by the natural efforts, and the hypogastrium should then be explored by palpation and percussion, to see whether enough distention of the bladder remains to be detected in this region. The normal variations in the position of the bladder and intestines render this examination often unsatisfactory, especially when the abdominal wall is thick or rigid.

The examiner should then explore with the forefinger the rectum. This is best done with the patient on the back.

If the prostate is enlarged it will be felt pressing down the anterior rectal wall. Its size, shape, and consistency should be noticed.

The relative enlargement of the lateral lobes can usually be well made out, and nodular projections are sometimes felt, caused by irregularities in the hypertrophy of different parts of the gland. Rectal examination, unfortunately, gives little or no information in regard to the condition of the third lobe, which is so often the cause of a serious obstruction to the flow of urine.

Incidentally, the degree of tenderness to palpation will be discovered.

The condition of the prostate itself having been deter-

Digitized by Microsoft®

mined, the examining finger should be carried up along the posterior vesical wall, if that be possible, and the condition of the bladder should be learned. In this investigation the bimanual manipulation between the finger in the rectum and the hand above the pubes, so commonly practised in examinations of the female pelvic organs, is useful, and by it the amount of distention of the bladder can often be most accurately made out.

www.fltbtoof.com.cn

Lastly, the urethra and bladder should be explored.

The existence of a stricture will probably be detected in the passage of instruments for deeper exploration. But in case of doubt the canal may be thoroughly examined with large bulbs. A short-beaked sound should be passed, and as it runs through the prostate deviations of the urethra will often be shown, by the feeling of resistance on one side or the other and by the turning of the handle.

The sound in entering the bladder may sometimes be felt to slip up over a bar, or may turn to one side around a prominent third lobe.

After a proper search has been made for a possible stone, the sound should be depressed until it lies in the axis of the body, and then withdrawn until the concave side of the beak comes against the neck of the bladder; it may then be rotated, and, as the beak sweeps the vesical face of the prostate, any irregular outgrowths or projections will be felt to arrest its movements.

If the sound has been felt to ride over an obstruction at the neck of the bladder and if, after it is in, it rotates freely, this points to a bar rather than to a globular enlargement of the third lobe, which last would arrest the beak of the sound in rotation.

As the instrument is withdrawn slowly through the prostate, the deviations due to projections into the urethra are often felt even more plainly than during introduction.

Finally, the urine may be withdrawn with a catheter and the exact amount of residuum thus discovered. This will be found to vary much at different times, and depends somewhat upon the amount of urine which the bladder contained before the last urination.

When the bladder is full and the urine consequently rushes out with some force in a considerable stream, it will often be found that there is much less water left in the bladder than is the case when urination is attempted before complete distention has been reached.

Diagnosis.—The conditions with which enlarged prostate is likely to be confounded are stricture of the urethra, stone in the bladder, atony of the bladder, cystitis, cancer or other tumor of the prostate, tuberculosis of the prostate, and tumor of the bladder.

The physical examination, if thoroughly made, usually enables us to eliminate the first two of these conditions, and if enlargement of the prostate with residual urine is found we may, in the absence of other discoverable cause, decide that an existing cystitis is dependent upon the prostatic trouble. It may, however, be impossible to demonstrate the absence of stone behind an enlarged prostate except by a thorough examination under ether with the lithotrite.

The decision between a tumor of the prostate and simple enlargement is extremely difficult, unless the tumor has assumed considerable proportions or has begun to invade surrounding parts. The physical examination by way of the rectum gives us our best help in diagnosis, but the irregular growth of a tumor may at first simulate the irregularities sometimes seen in hypertrophy.

The pain attendant upon the growth of a tumor is more severe than that appearing early in hypertrophy, though this is by no means constant.

In case of a cancer the enlargement of neighboring glands may help us to the right solution of the question, and occasionally the microscopic examination of the urinary sediment will show the presence of cells characteristic of a new growth. Not infrequently, however, it will be necessary to wait until the progressive growth of the tumor declares its character.

Tuberculosis of the prostate usually occurs earlier in life than we could look for hypertrophy. In case of doubt, tuberculous deposits must be sought for in other organs (epididymis, seminal vesicles, lungs, etc.).

A tumor of the bladder may give rise to hemorrhages and difficulties of micturition which simulate those caused by enlargement of the prostate. Also a tumor may be present in the bladder behind an enlarged prostate, and so complicate the symptoms.

The hemorrhage from a tumor is ordinarily very much greater than that from a congested prostate. But this is not always the case, and whenever there is persistent or intermittent hæmaturia, however slight, a careful search should be made for villi or other bits of the tumor which may be detached and passed in the urine, and which may be recognized under the microscope.

Examination of the bladder with the sound may, when a tumor is there, reveal a projection somewhere from its wall. But sensations of this sort are very misleading, and it is well, after a thorough sounding, to wash out the bladder with the litholapaxy evacuator, with the object of obtaining bits of the tumor, if one is there.

After definitely settling the diagnosis of prostatic hypertrophy, it is always important to go further and to decide in what stage the disease is, as we shall see that treatment should vary according to the varying conditions.

The steps to this decision have been sufficiently indicated above.

Treatment.—As has been described, the disease under consideration consists essentially in a tendency to congestion of the prostate, bladder, and kidneys, with an accompanying hypertrophy and sclerosis.

For convenience we have divided it into three stages: First, of congestion, with functional disturbances; second, of simple retention; and, third, of retention with distention, often incontinence, and perhaps involvement of the kidneys.

First we will consider those measures of treatment, hygienic and medical, which are applicable to all stages of the disease.

Anything which has a tendency to increase the congestion should be carefully avoided. A chill of the surface should be especially guarded against. The patient should wear flannels next the skin, and should carefully avoid draughts or long exposure to chilly and damp air.

The feet should be kept dry and warm, and if the patient gets up at night to pass water, use the catheter, or for other purpose, he should cover his feet and legs warmly. Neglect of these precautions may at any time bring on an attack of retention, of cystitis, or even of pyelonephritis.

Excesses in eating and drinking are to be avoided. Large quantities of rich or highly seasoned food must not be indulged in, and wine and beer are for the most part better left alone. This caution should be understood to apply only to overeating, as a sufficient quantity of nourishing food is of importance. If the patient has been in the habit of taking a stimulant, a little light claret, or some whiskey and water, may be allowed with meals.

Especial warning should be given against holding the water over the ordinary time, particularly if any call to pass it is felt. An attack of complete retention or of cystitis may result from disregard of this rule.

Venereal excesses are, of course, to be avoided.

The effect of sedentary habits and of horizontal decubitus in increasing the passive congestion must be borne in mind, and moderate gentle exercise is to be advised. The patient will do well, when engaged in any occupation that keeps him long in one position, to take an occasional turn through the room; and at night or in the morning, when he gets up for the purpose of emptying his bladder, a short walk about his chamber will often materially assist him in making his urination thorough and satisfactory.

Constipation should be carefully guarded against. In prescribing for this condition, the violently acting drugs,

Digitized by Microsoft®

which produce more or less congestion of the pelvic organs, should not be used.

The greatest assistance will often be obtained from rectal injections. These are especially useful when the mechanical obstruction of the prostate, pressing as it does upon the rectum, is largely responsible for the failure of the bowels to act.

www.libtool.com.cn

Cold injections are usually to be avoided, though they may sometimes render good service in helping to restore the functions of an atonic bladder. Hot injections (112°–115° F.) will sometimes assist in reducing congestion.

The functions of the skin should be stimulated as far as possible. Rubbing and massage are to be employed to this end, and baths also serve a useful purpose if care is taken against a subsequent chill. A hot bath ending with a sponge off in cold water, and vigorous friction with a rough towel, may be of real benefit, by bringing the blood to the skin and so relieving internal congestion.

In selecting a climate for a prostatic patient, preference should be given to dry inland localities, where sudden changes of temperature are less likely to occur than on the seacoast. Sometimes, however, when the general condition is depressed and a stimulating climate is desirable, the seaside may be tried, special precautions being taken against surface chills.

General medication directed against the disease itself has but little to offer.

The iodides may have a trial, in virtue of their reputation in the treatment of sclerotic conditions of the blood-vessels and other organs. If used they should be persisted in for a long time, with occasional intermissions. They have the disadvantage of sometimes disagreeing with the stomach, and it may be necessary to discontinue them on this account.

Of the medication required in the various morbid conditions which may from time to time need correction, we shall speak in considering the treatment of the various periods.

Local treatment may be divided into palliative and operative.

Palliative Treatment.—Treatment in the first period is almost wholly hygienic and medical.

In the absence of complications, and before there is any retention, the less instrumentation the better, as it only aggravates the congestion, and introduces the danger of infection from dirty instruments.

If the urine is irritating from too great acidity, an alkaline diuretic, such as citrate or acetate of potash, is indicated.

In case of pain, belladonna or hyoscyamus should be administered either by the mouth or by the rectum. Opiates should be avoided, if possible, as they derange the stomach and constipate the bowels. When urgently required, however, they may occasionally be resorted to.

Ergot, strychnine, or nux vomica in some form and quinine are sometimes useful, and act apparently by diminishing the congestion, and perhaps also by stimulating the contractions of the bladder. If the circulation is not good, cardiac stimulants may be of assistance.

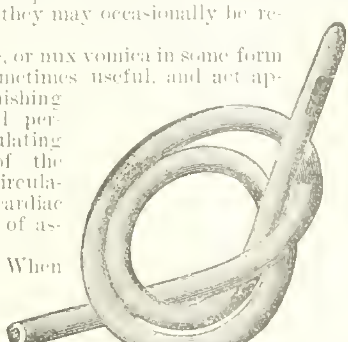

FIG. 3890.—Soft-rubber Catheter.

Second Period. When the stage of partial retention has set in and the patient passes water, but is not able completely to empty the bladder, it is necessary to resort to the use of the catheter. So important is this that every patient who is seen in the first stage and put upon general treatment, should be warned that the time will almost certainly come when catheterization will be required, and that as there is no sure means by which he can tell when he reaches this state, he should occasionally present himself for examination to decide this point.

Sometimes the partial retention is due to some accidental increase of congestion, which may disappear under the use of antiphlogistics. In such a case the patient may be put to bed with leeches to the perineum, followed by hot applications assisted by opiates, if necessary.

FIG. 3891.—Elbowed Catheter (Sonde Coudée of Mercier).

If these measures fail, it will be necessary to draw the water, and it will sometimes be found that, after a short systematic use of the catheter, the bladder will recover itself and again become able fully to expel its contents. Thus the disease may occasionally be moved back from the second period into the first.

When complete retention comes on suddenly the catheter is indispensable, but in this case again its use may perhaps later be given up.

When entering upon the use of the catheter, we may often learn whether it is really needed by noticing the effect upon the symptoms. If these are relieved or ameliorated, we are evidently on the right track.

It is to be remembered, however, that not infrequently, on commencing catheterization, a cystitis develops itself, owing either to the too sudden evacuation of a distended bladder, to the introduction of dirt upon the catheter, or simply to the irritation from the constant use of instruments. It is important that the aggravation of symptoms caused by this inflammatory onset shall not lead the patient or doctor to infer that the catheter is doing harm and should be given up, for it is by continuing its use that the attack of cystitis may be most quickly and surely relieved.

FIG. 3892.—Double-Elbowed Catheter (Sonde Bicoudée).

Let us now consider how and with what instruments the catheterization is to be carried out.

As has been described, the walls of the urethra are pressed together and may be somewhat deviated by the inequalities of the lateral lobes. The posterior part of the urethral floor is also often raised by the projection of the third lobe.

Our object is to reach the bladder through this sinuous passage with the least possible amount of irritation.

If a soft, red rubber catheter will find its way into the bladder, it is, by all odds, the best instrument to use. It requires no skill for its direction, and can do no damage to the urethral walls—a point of great importance, as it enables us to entrust its use to an unskilful patient.

When, owing to the narrowness or tortuousness of the urethra, the rubber catheter will not pass, we must resort to a stiffer instrument, and must adapt its form in reference to the difficulties which it has to overcome.

The obstructions which it will meet project from the lateral walls and floor of the canal, and our effort must be to carry the point of the instrument along the upper or anterior wall.

Mercier devised for this purpose a flexible webbing catheter with the point sharply turned up (sonde coudée), so that it might ride over the obstructions on the floor.

For those cases in which the hypertrophy of the third lobe was very pronounced, he used a catheter with a second bend, designed to lift its point still higher.

In introducing these instruments, care should be taken that the point be kept turned toward the roof of the canal, and after it has passed the triangular ligament the

Digitized by Microsoft®

penis should be depressed as much as possible between the thighs, so that the catheter may be pushed straight upward in the axis of the body.

The English gum-elastic catheter may often be used with advantage, either with or without its wire stylet. If it is introduced without a stylet it is a good plan to exaggerate the curve of the instrument, as has been suggested by Thompson. When used thus it should be introduced cold and carried as rapidly as possible through the anterior urethra, for as it warms it becomes flexible and loses its form. By passing it rapidly but carefully, its curve often carries it over the obstructing third lobe.

If it meets an obstruction and, warming in the urethra, becomes flexible, the forefinger in the rectum should be used to lift the point of the catheter into the prostate, while at the same time the handle should be brought down to the axis of the body, and the instrument, which is then practically straight, should be pushed steadily into the bladder. This should be done without the exercise of much force, as the point, when properly guided, slips along quite easily and when it catches there is danger of its making a false passage if pushed.

If the gum-elastic catheter is introduced with a stylet it should be curved into the form of a prostatic silver catheter. Sometimes, when the point catches it may be lifted over the obstruction by the simple manœuvre of slowly withdrawing the wire while slightly advancing the instrument. This curls the point upward and often enables it to ride over the obstacle

Occasionally, when other flexible instruments fail, the French conical bougie catheter will succeed in worming its way through the canal. It should be used with great caution, as its comparatively sharp point may catch in and perforate the mucous membrane.

Failing with other instruments, we may have recourse to a metallic catheter of large curve.

The beak of this instrument should be long enough to reach easily through the enlarged prostate, which may be one inch and a half longer than in the normal state. If the curve is too short the point does not reach the bladder, but being engaged in the prostate, runs considerable risk of making a false passage when the handle of the instrument is depressed.

The forefinger in the rectum may give great assistance in guiding the passage of this catheter.

In using any instrument in a urethra with false passages it is a good plan always to withdraw for a considerable distance when the point is caught, and then to try to pass the pocket by carrying the beak down first one wall and then another until the right passage is found. Ordinarily the false passages exist in the floor of the urethra; but this rule has many exceptions.

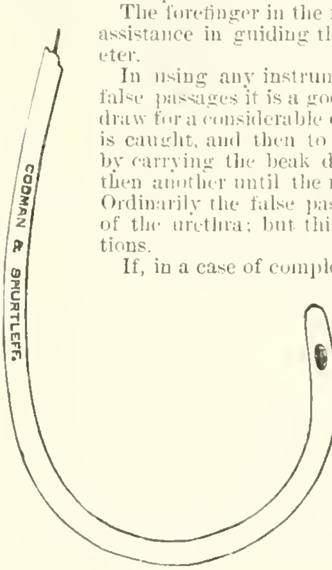

FIG. 3893.—English Gum-elastic Catheter with Exaggerated Curve on Stylet. (After Thompson.)

If, in a case of complete retention, after careful and thorough attempts we do not succeed in reaching the bladder, recourse must be had to puncture with trocar or aspirating needle.

This was formerly done through the rectum with curved trocar, but as this method cannot be used antiseptically the suprapubic puncture is to be preferred. This may be done with a fine needle introduced close above the pubis, and, if necessary, may be repeated two or three times daily for a considerable time. Usually, however, drawing off the urine in this way is followed by such a subsidence of the swelling as presently to allow the introduction of the catheter. Leeching the perineum and the administration of ergot may also be of service in reducing the congestion.

The evacuation of a distended bladder, whether by catheter or by aspiration, should be performed slowly and carefully. When the distention is extreme, the bladder should not be wholly emptied at one time, for if the internal pressure is too suddenly relieved we are likely to have a great congestion of the vesical mucous membrane, with the escape of blood into the urine, followed often by considerable inflammation.

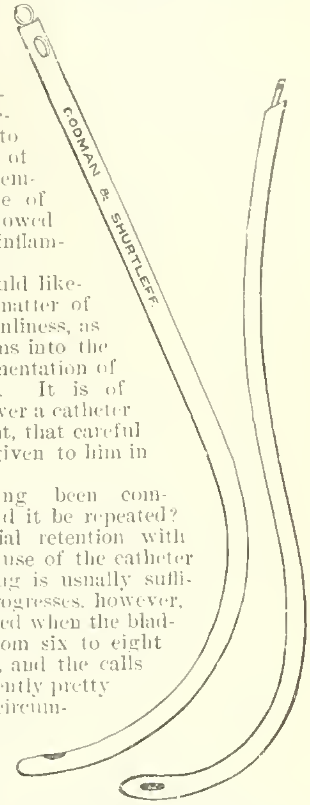

FIG. 3894.—Silver Catheters of Curve Appropriate for Use through an Enlarged Prostate.

The greatest care should likewise be taken in the matter of thorough antiseptic cleanliness, as the introduction of germs into the bladder may start a fermentation of the urine with cystitis. It is of course important, whenever a catheter is entrusted to a patient, that careful instructions should be given to him in regard to this.

Catheterization having been commenced, how often should it be repeated?

In the cases of partial retention with moderate residuum, the use of the catheter each night before retiring is usually sufficient. As the disease progresses, however, a point is presently reached when the bladder habitually holds from six to eight ounces of residual urine, and the calls to urinate are consequently pretty frequent. Under these circumstances the regular use of the catheter is required

If now the patient can get along comfortably while using the catheter four times a day, he is fortunate, and may live for twenty or more years with his artificial urination. Not infrequently catheterization will be required six, seven, or even more times in the twenty-four hours. Especially is this the case when cystitis is present. The water should always be drawn when the desire to micturate is urgent and persistent.

When catheterization is required so often as to become a decided source of irritation, and if the bladder is so irritable as to be constantly liable to painful contractions, it will be found best to tie in the catheter for a time (sonde à demeure). Usually in a few days, after the bladder has had a rest, the catheter can be again left out and the patient can resume regular catheterization.

During the time while the patient is becoming accustomed to the use of the catheter and the bladder is acquiring a tolerance of instrumentation, it is wise to give some urinary antiseptic almost as a routine measure. Of the antiseptics now at our command urotropin and sandal oil are the most useful. Urotropin may be given in doses of five to eight grains two or three times a day, and is a most useful drug, but it will occasionally act as an irritant, especially in the presence of ulceration of the prostate, and in these cases sandal oil is to be preferred. Sandal oil is a more soothing drug, and is especially useful where the tendency to irritability of the bladder exists.

Third Period. In this stage of the disease, systematic emptying of the bladder is as urgently called for as at any earlier time. The serious changes, however, which

www.libtool.com.cn
Digitized by Microsoft®

are likely to have occurred in the ureters and kidneys, with the condition of passive congestion which exists throughout the urinary tract, make the use of the catheter a matter of considerable danger, which in some cases may be so great that it will be better practice to leave the bladder undisturbed.

www.libtool.com.cn

In these cases the patient's condition of comparative health—troubled, it is true, by frequent and often partly involuntary micturition, but not debarred from ordinary occupations—makes a striking contrast with the state of things which may rapidly develop upon entering on the "catheter life." For a slight added irritation to the bladder may be suddenly followed by a pyelonephritis, or even more abruptly by renal congestion with suppression, uræmia, and death.

These dangers are alarming and imminent enough to make us hesitate, but what is to be hoped from allowing the disease to take its course? Nothing but a certainly fatal issue, which is likely to come in a few weeks or months, and which may be precipitated at any time by an exposure to cold, by fatigue, or by a slight indiscretion in diet.

On the other hand, when catheterization is successfully established, the disease may be moved back from the third to the second stage, and the patient who was in such danger may be put in a state of comparative security.

It is, then, of the first importance to distinguish the cases in which catheterization is so dangerous that the patient had better be left to follow out the natural course of the disease; and in all except these most advanced cases the catheter should be used.

Each case must be decided on its merits, and so much depends on attention to detail that we should sometimes be deterred from commencing catheterization with a careless and slovenly patient, when we should have resorted to it could we have counted on his intelligent co-operation.

Guyon has laid down, for these advanced prostatic cases, a good rule of practice. He puts the patient upon general tonic treatment, and if he finds that he is wanting in strength sufficient to benefit by it, he does not regard him as in a state likely to be helped by interference with his bladder. If, however, he improves decidedly in his general condition, then Guyon regards it as wise to resort to the catheter.

The precautions to be observed in accustoming the patient to the catheter are the same that are required in the second stage of the disease, but they are now even much more important.

Especially should the sudden emptying of a distended bladder be guarded against. It may often require two or three weeks of catheterization before the bladder acquires such tolerance that it may safely be left empty.

During the preliminary period the catheter should always be passed with the patient horizontal, to guard against the too rapid flow of water; afterward, when the complete emptying of the bladder is desired, the vertical position is the best for this operation.

Operative Treatment.—It is impossible in the space at our command here to do more than suggest the outlines of operative treatment and of the more important procedures.

Radical operations aim at a cure; that is, at the complete restoration of the function of urination. While they often fall far short of this ideal, yet many cases are practically cured. Perhaps the main reason why operative treatment has not been more generally successful is to be found in the age of the patients, for in the majority of cases we have to deal with men between fifty and eighty years of age, and it is obvious that severe operations become more dangerous with advancing years. The willingness of the surgeon to operate in any individual case will also often be influenced by the social condition of the patient, for a man of the lower classes who cannot afford the time, trouble, and careful attention to detail necessary to make catheter life tolerable, may wisely be advised to have some operation done, whereas a man in easy circumstances may be kept comfortable by less radical and safer measures.

Operation during First Stage.—As the symptoms of the first stage are largely those of engorgement and irritability, comparatively few patients will be seen at this time, and as it is obviously impossible to decide definitely how long a time may elapse before a patient reaches the second stage, or whether this stage will be reached at all, it is seldom that patients in the first stage are to be advised that an operation should be done. Of course, it must be admitted that the earlier such operations are done, the better, if they are to be done at all, but the progress of this disease is so variable that sound conservatism will rarely be found in favor of operation at this time.

Operation in the Second Stage.—The second stage of prostatic enlargement is, as will be remembered, that of beginning obstruction. At this time, the bladder will usually be in good, or, at least, fair condition, and comparatively little damage will have been done to other parts of the urinary tract. This time is, therefore, in most cases the time of election for radical operative procedures. The patient is usually not too advanced in age, his blood vessels are probably in good condition, and the bladder and kidneys have not been irreparably damaged. If, however, a patient, though in the second stage, be found to have evidences of a chronic nephritis, a damaged heart, or sclerotic arteries, the outlook will be correspondingly less favorable.

Operation during the Third Stage.—The third stage being that of complete obstruction accompanied as a rule by more or less damage to the kidney will be an unfavorable time for radical operation. The mortality at this time is almost prohibitory, and there is little hope of restoring completely, or even in great measure, the function of the bladder. These patients may sometimes, however, by careful catheterization or drainage of the bladder, be so improved that an operation can later be resorted to with reasonable hope of success. Hitherto the rule has been to resort to radical operations only in the more difficult and desperate cases. As a result of this practice the mortality of such operations has been high.

The ideal time to choose for interference is when the obstruction has become considerable, but before it has led to serious changes in the bladder, kidneys, and heart. Could most of the operations be done at this early date, the mortality would doubtless be much lower.

Unfortunately, patients at this stage of the disease are usually too comfortable to be willing to face the risks of operation.

The Various Operative Procedures.—The radical operations may be divided into two general groups: the internal ones, or those done through the urethra or through a small perineal opening, and the external, or those which involve suprapubic cystotomy or a large perineal opening.

Internal Operations.—Of these the so-called Bottini operation is the most prominent. This is done with an electro-cautery, somewhat resembling a lithotrite, though much smaller and more delicately made.

The male blade is connected with an electric battery and acts as the cautery knife. The instrument is introduced into the bladder, and the beak hooked over the prostate, the contour of which is mapped out as accurately as possible. A furrow is then cut with the cautery blade through the prostate in the middle line, the length of the furrow being regulated accurately by a scale in the handle of the instrument. Two lateral furrows are then also cut each at an angle of about forty-five degrees from the median furrow. When the sloughs caused by the cautery have come away, the urethral obstruction is often considerably lessened.

This operation is applicable to some cases which would not stand more radical procedures. The relief is often far from complete, and total failures are not uncommon. The operation may be done under local or under general anæsthesia.

Some operators prefer to introduce the instrument

Digitized by Microsoft®

through a small incision in the membranous urethra. In this way shorter instruments are required, and they are more easily guided by the hand. The operation does not, however, essentially differ in its results from the regular Bottini operation.

External Operations.—Of the external operations there are three general types, suprapubic, perineal, and combined.

www.libtool.com.cn

Suprapubic Operations.—All of the suprapubic operations begin with an ordinary suprapubic cystotomy. The bladder having been opened, two types of operation are at our command. First, the partial operation in which portions of the prostate, such as a projecting third lobe or a prominent bar, are removed, and no attempt is made to remove the bulk of the prostate. This method may be carried further and the prostate may be nibbled away with cutting forceps, until the greater part of the obstruction has been removed. Operations of this type have been practised for a considerable length of time, and while sometimes giving almost or quite perfect functional results, they very frequently fail completely to remove the obstruction. In cases in which only a polypoid third lobe, or a small projecting bar is removed, the operation is of less severity, and carries with it a correspondingly lower mortality than in the cases in which complete removal is attempted, and it may, therefore, occasionally be applicable to cases in which the patient cannot stand a more extensive operation.

Of late years complete enucleation of the prostate by the suprapubic route has been frequently practised, and in selected cases it is an operation giving brilliantly successful results. The prostate is surrounded by a very distinct capsule, formed largely from the layers of the pelvic fasciæ. It is, therefore, possible to shell the gland out from this capsule without excessive hemorrhage, and in these cases the operation can be done rapidly and bleeding readily controlled by packing the cavity with gauze. When the enlargement is very great, and especially when the glandular type of hypertrophy exists, the hemorrhage may be alarming and the raw surface left behind is a great menace on account of absorption of septic materials and extensive sloughing of torn and bruised tissues. The cases likely to prove most favorable under the employment of this method are those in which the prostatic tumor projects chiefly into the bladder, is not of excessive size, and is of the fibrous rather than the glandular type. To avoid the obvious dangers of leaving a large wound upon the floor of the bladder the *perineal operations* have been devised. The underlying principle of all perineal operations is to bring the prostate into view by a free perineal incision, which may be vertical or crescentic; then to separate the prostate from the lower segment of the rectum, and, after incising the prostatic capsule, to proceed to enucleate the gland with the finger much as in the suprapubic operation. In favorable cases this may be done without damage to the floor of the bladder, and is at times also a very successful procedure. The obvious dangers, however, are those resulting from extensive tears of the floor of the bladder and prostatic urethra, and from the not very infrequent accident of tearing the anterior rectal wall in the course of the operation. The cases most suitable for operations of this type are those in which the prostate is well within reach of the finger, and in which the outgrowth has been toward the rectal aspect of the prostate, and in which ulceration of the bladder does not exist. In order more accurately to study the requirements of each case Alexander has devised a *combined operation* in which the bladder is first opened above the pubis, and then if the case be favorable for perineal enucleation, a perineal incision is made and the fingers of one hand in the suprapubic wound push the prostate down while enucleation is done with the other hand through the perineal incision. Some operators do not open the bladder above the pubis, but carry the suprapubic incision down to the bladder wall, and then with the fingers above press down the prostate and make it accessible from the perineum.

It is important to remember that the careful selection of the operation best suited to each case is of the first importance, and it is, therefore, often wise to examine the bladder carefully with the cystoscope before deciding which operation should be undertaken, or whether any operation is likely to give permanent relief.

Orchidectomy and Vasectomy.—The subject of operative treatment of prostatic hypertrophy can hardly be dismissed without making mention of two operations which have been advocated for the relief of the condition, and which may still be done from time to time.

The operation of double orchidectomy, which was ably advocated by White, had many advocates at the time of its introduction. In some cases it appears to give very marked relief in cases of congested prostates, but this relief is likely to prove but temporary, and in the most favorable cases does not result in radical cure. It has been followed in a few instances by very marked mental symptoms, amounting in certain cases to insanity, and this, together with the frequency of total failure to relieve the symptoms, has made it an operation which is very rarely to be advised, and the interest in it at present is largely historical.

Vasectomy.—This operation, which consists of the ligation and division of both vasa efferentia in the region of the external inguinal ring, was strongly advocated by Mr. Harrison. It was hoped that it would have a result equally favorable with that of orchidectomy, but without its unfortunate results. This hope has hardly been justified, and the operation seems to be valuable largely for the relief of those cases in which recurrent attacks of acute epididymitis are a serious cause of discomfort to the patient. It can be done if desired under local anæsthesia, and its technical details present no difficulty.

Treatment of Complications.—Cystitis, which is the most common complication of prostatic hypertrophy, is to be treated according to the rules laid down under *Bladder, Diseases of The*, on pages 795 and 796, in Vol. I. of this Handbook. When it occurs in the first stage of the disease, general treatment is first to be thoroughly tried, and local treatment through a catheter is to be resorted to only when simpler measures fail. In the second and third stages, when partial retention exists, the systematic evacuation and irrigation of the bladder is the most efficient means of treatment at our command.

Nephritis, or pyelonephritis, must be treated on general principles. Mustard poultices over the lower dorsal and lumbar regions are indicated during the acute stage, with, afterward, careful rubbing and friction to keep up the action of the skin; a bland, non-stimulating, but nutritious diet in abundant quantity; and regulation of the bowels. If uræmia threatens, pilocarpine and hot-air baths may be used to promote elimination, and to relieve the congestion of the kidneys.

A stone in the bladder can usually be removed readily by litholapaxy through an enlarged prostate, unless it is of great size and hardness, or unless the careless use of instruments has produced false passages. The pocket behind the prostate often holds a small stone concealed, and makes it hard to seize, in which case the hips may be raised so that the stone rolls back toward the fundus, where it is easily found and crushed.

When micturition is very difficult, it may sometimes be thought wise to remove small stones by perineal incision, in the hope of at the same time relieving the obstruction.

When litholapaxy is impossible on account of the size and hardness of the stone, it is usually necessary to resort to the suprapubic incision. By this operation, too, a prominent middle lobe, or other cause of obstruction, may sometimes be removed.

Atrophy of the prostate may occur as the result of mechanical pressure, or of destruction of portions of the organ by inflammation. It may also appear in the course of an exhausting disease, or as a consequence of old age. It gives rise to no symptoms and calls for no treatment.

Tumors of the Prostate.—These may be classified as follows:

Digitized by Microsoft®

Cysts	Retention cysts. Hydatids.
Myoma .... Adenoma	Adeno-myoma.
Sarcoma	Round cell. Spindle cell. Lymphoma.
Carcinoma	Scirrhus. Colloid.

www.libtool.com.cn

Retention cysts formed from dilated gland acini occur in many old prostates. They are always small, and give rise to no inconvenience. Their contents are sometimes inspissated, forming little concretions.

Hydatid cysts of the prostate are so rare that Thompson could, in 1883, learn of but one; and even in that case it is doubtful whether the cyst started in the prostate or near it. When discovered they should be at once emptied.

Pure myoma is very rare; adenoma is somewhat less so, but adenomyoma is the most common of prostatic growths. Paul thinks ordinary hypertrophy should be ranked under this head.

The universal, symmetrical enlargement can hardly, as it seems, be classified as a tumor, and yet the pathological process is the same in it and in the circumscribed masses which we recognize as new growths. These may project into the urethra, the bladder, and in other directions, or they may be buried in the midst of the gland tissue, from which they can be easily shelled out.

These tumors have sometimes been removed during section of the gland in lithotomy or other operations, and the removal of projections into the urethra has been considered above.

Sarcoma is occasionally observed in the prostate, where it may start primarily, or to which it may transplant itself from the testicle or elsewhere. It usually appears early, but may develop late in life.

Carcinoma is more common than sarcoma, and appears ordinarily after middle life. It may assume a scirrhus or a colloid type.

In either of these last two malignant forms of growth there may be a good deal of pain and considerable hemorrhages, especially after instrumentation.

In carcinoma the neighboring lymphatic glands are likely to be early involved.

Any cyst or tumor of the prostate may give rise to symptoms of obstruction. The difficulty of micturition may reach a point at which some operation for its relief will be required. In opening the bladder for drainage under these circumstances, either the perineal or the suprapubic incision may be used, and the selection would depend somewhat upon the size of the tumor.

If this is large and of a malignant character, which makes its removal evidently impossible, suprapubic drainage would be preferable.

On the other hand, in the case of a smaller or non-malignant tumor the perineal incision should be used, as by it the exact condition of things can be ascertained and possibly benefited. Harrison reports a case in which he removed a cancerous growth as large as the last phalanx of the thumb from the prostatic urethra. The operation was followed by great relief from distress in micturition, and the patient lived for fourteen months.

Tuberculosis of the Prostate occurs often secondarily to tuberculous conditions in other parts of the genito-urinary tract. It probably also sometimes appears primarily in the prostate.

As patients with genito-urinary tuberculosis usually die when the disease is far advanced, it is rarely possible to decide at autopsy where the disease originated; and as the organs are many of them deep-seated and beyond the reach of physical examination, it is likewise impossible during life to be sure that the prostate was primarily affected.

On the other hand, this gland is situated at the junction of the genital and urinary passages, is as it were at the crossroads through which any tuberculous material from the kidneys or testicles must go in its passage from the body. This situation makes it peculiarly liable to secondary infection, and, as a fact, it is almost always sooner or later involved.

The tubercles may appear as little isolated gray granules, scattered throughout the tissue of the organ, or they may be agglomerated into masses which, if they reach a moderate size, ordinarily become cheesy in the centre and finally break down into abscesses.

Sometimes almost the whole prostate is thus destroyed, and its place is occupied by an abscess which usually communicates with the urethra and bladder. It may break through into the rectum, forming a recto-vesical or a urethral fistula directly through the prostate.

The *symptoms* are those of a chronic prostatitis (see above) with a special tendency to hemorrhage. They may be associated with evidences of tuberculosis elsewhere.

Physical examination by the rectum may reveal little or no alteration in the gland. Ordinarily, however, inequalities are felt which may give it a distinctly nodular character. This may be associated with enlargement, or the prostate may preserve almost its normal size.

The ejaculatory ducts and the vesiculæ seminales should be felt for, and if the disease has affected them, they may be found as thickened, resistant, cord-like bodies. This is especially to be observed when the disease started in the testicle and worked its way up to the prostate.

Not infrequently a little shot-like mass is felt between the rectum and the prostate, or it may be a little behind and to one side of the gland. It is not attached to the prostate, rectal wall, or seminal vesicles, but is loose in the tissues between them.

Dr. Bryson, of St. Louis, thought that in one case, in which he had an autopsy, he made it out to be a cheesy mass within a vein. Possibly it is sometimes an infected lymphatic gland.

The testicles, epididymides, and vasa deferentia should also be examined, and the urine should be investigated for evidences of kidney complication and for tubercle bacilli.

These last are very difficult of detection in the urine, and their apparent absence does not argue against tuberculosis. When unmistakably present they are conclusive confirmatory evidence. In all cases of doubt the urinary sediment should be inoculated into a guinea-pig.

The physical investigation should also include the examination of the lungs, which may share in the tuberculous process.

Diagnosis.—The disease may be confounded with chronic prostatitis or cystitis, with stone or tumor in the bladder, or with pyelitis when accompanied by frequent micturition.

While a careful consideration of the symptoms and inherited tendencies of the patient may enable us to form a probably correct idea of the condition, it is only by a careful physical examination that we can reach a positive diagnosis.

Besides the examination described above, an exploration of the bladder, under ether if necessary, will be needed for the detection or elimination of stone and of tumor of the bladder.

There will be a certain number of cases in which a diagnosis is at first impossible, and in which the true interpretation of the condition can be reached only when time has developed characteristic symptoms.

Treatment.—Most important is the constitutional treatment with cod-liver oil, hypophosphites, and iodides. A healthy out-of-door life, with moderate exercise and good food, is to be enjoined.

Thompson advises against local treatment, and it is certainly important to avoid rough manipulation.

In the early stages of the disease, however, gentle local measures may serve rather to allay than to excite irritation, and should be tried.

Irrigation of the prostate and bladder and the introduction of iodoform pencils may be of service. Occa-

Digitized by Microsoft®

sionally the passage of a sound is useful by removing the contraction of the constrictor muscle. The pain and frequency of micturition may sometimes be much relieved by these means.

While the prognosis is necessarily grave, and the permanence of improvement is always doubtful, still these cases are not always hopeless ones.

www.libtool.com.cn

Prostatic Calculi.—In the ducts and dilated tubules of the prostatic glands are found not infrequently little yellowish or brownish bodies, composed of an organic substance allied to protein.

These, if they increase beyond a moderate size, begin to have earthy salts deposited in and around them, and finally become prostatic calculi, which may reach the size of a walnut or even of a larger object.

These calculi are usually multiple, and are facetted from mutual attrition. They are hard, take a high polish like porcelain, and are white or light brown in color.

Chemically, they are composed almost wholly of phosphate, with a slight admixture of carbonate of lime, and are to be distinguished from urinary calculi by the fact that they do not contain any of the triple phosphate of magnesia and lime, which is so large a constituent of vesical calculi.

When prostatic calculi are made out they may be removed by a median or lateral perineal incision. The operation is usually one of no serious danger, as the bladder is not opened.

PRUNE.—*Prunum*, U. S., Br. The partially dried ripe fruit of *Prunus domestica* L., or, according to the British and some other pharmacopœias, *P. domestica Juliana* De C. (fam. *Rosaceæ*). The fresh fruit of the latter variety is oblong, that of others subspherical.

The prune, coming originally from southwestern Asia, is now everywhere cultivated in temperate regions. Probably the best prunes for medicinal uses are those grown in southern Europe, since they are more acid. The prune requires no description. It should not be overdried, should possess a very slight odor and a pleasantly sweet and acid taste. It owes its slightly laxative properties to the presence of acids, chiefly malic, free, and combined with potassium and other bases. There is present also sugar, to the extent of about one-third of the weight. The seed contains amygdalin and yields prussic acid, and should, of course, be removed.

Prunes have no other medicinal value than that of a very mild laxative, similar to many other fruits, but the concentrated juice is useful for administration to small children, because of its pleasant taste. The only official preparation is the confection of senna (see *Senna*). Prunes are very largely consumed upon the table for their laxative effects, as well as for their food properties. As served upon ocean steamers, they usually have some senna boiled with them. *Henry H. Rusby.*

PRURIGO.—Prurigo is a malady *sui generis*. The condition usually appears about the end of the first year, but may appear as late as the thirtieth year. The affection usually starts as a lichen urticatus, the characteristic lesions of prurigo appearing later. There are two forms: prurigo ferox or Hebra's prurigo, and prurigo mitis, but a distinct line cannot be drawn between the two. In prurigo ferox there are repeated eruptions of pale red or skin-colored miliary papules, which itch violently. This eruption is generalized, but it is thickest on the extensor surfaces of the lower extremities. The papules are so small and project so slightly that they often cannot be seen, although they can be felt. Scratching produces excoriated tips, and these become covered with blood crusts. Other lesions appear as the result of scratching, such as excoriations, pustules, crusts, pigmented areas, and a dry, scaly, and thickened skin

During the first few years wheals are frequently found, but they disappear as the papules increase. A secondary eczema in all forms may also be seen. In nearly all cases there is enlargement of the superficial lymphatic glands, the femoral being most marked. The flexures are usually free from eruption. As a rule, the eruption diminishes upon the advent of summer. This form is incurable, but the patient can be relieved to such an extent as to be free from the eruption at times. In prurigo mitis the papules are fewer and the itching is less; consequently the secondary lesions are much milder. Most of the cases met with in this country are of this type. In some of these cases a perfect cure may be obtained by careful and persistent treatment. When untreated, prurigo has a marked effect on the patient both mentally and physically.

Etiology.—In discussing the causation of this affection we can do no more than mention certain conditions with which it frequently occurs. It is usually found in poorly nourished and scrofulous children. Occasionally there seems to be an hereditary predisposition, several children in one family being affected. It is possible that there is some congenital anatomical malformation of the skin as is seen in ichthyosis.

Pathology.—The affection probably starts as a vasomotor neurosis. Microscopically the papules are composed of a round cell infiltration, with œdema of the papillæ. Swelling of rete cells occurs and later there is a hyperkeratosis.

Diagnosis.—The diagnosis is difficult at first, as in the beginning the eruption consists mostly of wheals. The condition is also misleading when large eczematous areas cover the lesions of prurigo. The following points are characteristic, and when they are present the disease cannot be mistaken for any other condition: A constantly recurring eruption of miliary papules, resembling in color the normal skin, appearing in early childhood, and most marked on the extensor surfaces; the enlarged glands; and secondary lesions from scratching.

Treatment.—Very little can be expected from internal medication, unless the patients are scrofulous or poorly nourished; in which case cod-liver oil and general hygienic measures will be beneficial.

Crocker speaks highly of cannabis indica as an effective remedy for controlling the itching, as in pruritus. The dose should be gradually increased to thirty minims of the tincture, well diluted, after each meal. Phenacetin and antipyrin are among the most valuable remedies for the itching. Rest, an even temperature, and alkaline or sulphur baths will make the patient more comfortable. For the local treatment, naphtol, sulphur, and tar are the remedies most likely to relieve the itching and decrease the papular eruption. The usual way of using sulphur is by the application of the official ointment or Wilkinson's ointment. Tar can be used pure or diluted with oil or lanolin. Naphtol should be used as an ointment in the strength of two to five per cent. Whatever local treatment is used, it should be vigorously continued until there are no fresh papules and the skin is smooth and flexible. Occasionally it will be found necessary to use first some bland ointment to cure the secondary eczema which so frequently accompanies this condition.

Howard Morrow.

PRURITUS.—Pruritus is an affection of the skin characterized by itching without any external cause. It is an independent disease, and must be distinguished from

Digitized by Microsoft®

the symptomatic itching common in such pruritic conditions as eczema, scabies, etc. It is a sensory neurosis due to a functional disorder of the nerves independent of any source of irritation on the skin. The symptoms may be so mild as to produce but temporary discomfort, or so severe as to cause profound misery or even such a degree of nervous depression as may result in insanity. Scratching is the patient's method of relief, and the excoriations produced are often preferable to the itching. Although scratching frequently relieves the itching in a certain place, it usually excites it in other parts. From the scratching we may get excoriations, pustules, wheals, and pigmented areas. A rare result of such chronic scratching is the condition called lichenification, in which the skin is thickened and the natural lines are deepened, leading to the formation of irregularly shiny papules. This condition is usually found in the flexures, and is often mistaken for eczema and lichen planus.

Pruritus is either general or confined to certain areas. The former is frequently spoken of as pruritus universalis, and although the itching is general, it is seldom felt all over at the same moment, and there are frequent remissions from any itching. The most frequent causes of this affection are disorders of the alimentary tract, functional derangement of the liver, cancer of the stomach or liver, uterine disorders, malaria, gout, rheumatism, and Bright's disease. Pruritus is always worse when the sufferer is in bed, and is excited by exercise, forced rest, and sudden changes of temperature.

The itching which accompanies jaundice is not a true pruritus, for it is produced by the mechanical pressure of the biliary coloring matter which is deposited in the skin. Senile pruritus is an accompaniment of senile degeneration of the skin. Although it is general, it is usually most marked on the lower extremities. It is very persistent.

Pruritus hiemalis and pruritus æstivalis are terms given to varieties of generalized pruritus which occur during the cold and hot seasons respectively. Some authors consider these forms distinct affections. Pruritus hiemalis is due to the dryness and brittleness of the epidermis which is caused by the cold of winter. Pruritus æstivalis is occasionally found during the warm weather of summer.

In the *local forms*, although we can have itching in any part of the body, the following varieties are most common: pruritus ani, pruritus vulvæ, pruritus scroti, pruritus palmæ et plantæ. Pruritus ani may be due to fissures, hemorrhoids, ascarides, or pelvic tumors producing local congestion. Pruritus of the vulva may be caused by ovarian or uterine disease, diabetes, or urethritis. Pruritus of the scrotum is usually associated with eczema. Pruritus of the hands and feet is mostly found in the gouty, and frequently is associated with hyperidrosis.

In the different forms of local pruritus it is occasionally impossible to discover the cause. The prognosis of senile pruritus is unfavorable. In the other forms the pruritus will usually cease if the cause is found and removed.

DIAGNOSIS.—All chronic diseases which are associated with itching, such as prurigo, urticaria, scabies, and the irritation from fleas, bedbugs, and lice must first be excluded. It is often impossible to differentiate chronic urticaria, as these two affections frequently occur under the same etiological conditions. Careful investigation must be made as to the presence of any renal, hepatic, or digestive disorders.

The diagnosis of senile pruritus must be made by exclusion. In cases of persistent itching around the anus and vulva, careful examination may show a definite point from which the patient says the itching starts. The skin at this point may appear to be perfectly normal, but it must be treated before the itching will cease.

TREATMENT.—A great deal depends upon the cause, and the sooner this is found out the sooner the patient may be put on appropriate treatment. The internal treatment is dietetic as well as medicinal. The food should be easily digestible and all stimulating liquids should be avoided. The bowels must be carefully regulated. Calomel followed by saline aperients is often necessary at the start. From now on, the internal treatment must be in accordance with the general principles of medicine, and the condition of each internal organ should be investigated. Of the various internal remedies which are used as nerve sedatives, cannabis indica is the best. Ten to twenty minims of the tincture should be given, well diluted, after each meal. Carbolic acid, gr. ij. in each pill, one after each meal, is recommended by Brocq. Antipyrin acts well at times.

External treatment is necessary even if it is not curative, because it enables the patient to abstain from scratching, and this temporarily relieves the irritated nerves. In the mean time other remedies can be directed to the origin of the trouble.

For general pruritus lotions are preferable to ointments. One of the best is composed of liquor carbonis detergens, ʒ iij.; liquor plumbi subacetatis, ʒ iv.; glycerin., ʒ iv.; distilled water, q.s. ad ℥ viij. Another is carbolic acid, two per cent., in camphor water. Bichloride of mercury, gr. ij. to an ounce of fifty-per-cent. alcohol, is a good odorless lotion. A mixture of aromatic spirit of ammonia and water, equal parts, is frequently used.

Five or six ounces of bicarbonate of sodium to an ordinary bathtubful of hot water may be used with advantage. Bran baths are soothing. They should be made by adding from four to six pounds of bran to a tubful of water. After a bath the surface should not be rubbed dry, but should be patted gently with a soft cloth and dusted with some soothing powder.

For pruritus hiemalis alkaline baths and emollient preparations have proved most serviceable. A two-per-cent. solution of salicylic acid in almond oil is an excellent remedy. Similar applications are indicated in senile pruritus.

For local pruritus, dozens of remedies have been recommended, but until the cause is ascertained most of them will give but temporary results. If the patient can locate a definite point from which the itching starts, the destruction of this point by the actual cautery gives immediate relief. Simpler methods, as a matter of course, should be used at first.

For pruritus ani, mercurial applications give the most satisfaction; such are: ammoniated mercury, gr. xx., in zinc ointment, ℥ i.; calomel, ʒ i., in lard, ℥ i. These two are frequently combined. Hot compresses are very agreeable. Carbolic acid in two-per-cent. solution can be used in a compress or in an ointment. A suppository of extract of belladonna, gr. ss. at bedtime, often gives relief; morphine may be added to this. Cocaine, gr. ss. in a suppository, gives temporary relief. On the surface cocaine is frequently used in a boric-acid ointment, or in combination with menthol, two per cent. of each. Camphor-chloral is commonly used. Hydrocyanic acid, naphtol, and ichthyol are useful at times.

For pruritus vulvæ, hot compresses of a saturated solution of boric acid sometimes give relief. Tincture of benzoin painted on the parts daily with a camel's hair brush is also an excellent remedy. *Howard Morrow.*

PSAMMOMA. See *Sarcoma.*

PSEUDOLEUKÆMIA. See *Hodgkin's Disease.*

PSEUDOLEUKÆMIA INFANTUM.—(Synonyms: Anæmia infantum pseudoleukæmica; Anæmia splenica infettiva dei bambini; Anæmia splenica [Splénomegalie primitive]; von Jaksch's anæmia.)

DEFINITION.—A disease occurring in infants, usually in the first two years of life, characterized by great pallor, considerable enlargement of the spleen, moderate enlargement of the liver, a low erythrocyte count, a moderate leucocytosis, consisting chiefly of an increase of the lymphocytes, numerous erythroblasts, low hæmoglobin, the absence of especial enlargement of the lymph nodes, and at times accompanied by hemorrhages (hæmateme-

Digitized by Microsoft®

sis, hæmaturia, purpura) without any known cause. The course of the disease is usually subacute or chronic.

Historical Notice.—The term "anæmia infantum pseudoleukæmica"* was originally adopted on the ground that the disease was one form of pseudoleukæmia (Hodgkin's disease). Of late years it has been so clearly shown to be different from Hodgkin's disease, in that the condition of the spleen is not the same, that the name "pseudoleukæmia" is evidently a misnomer and, strictly speaking, should not be used in connection with the class of cases under consideration. On the other hand, there are as yet so much dispute and such varying opinions among those who have carefully studied the group of symptoms which are supposed to represent the disease, that there is no other name which at present had better be applied to it, since the evidence is very strong that no such disease exists apart from severe cases of secondary anæmia with enlarged spleen. It is supposed at present to correspond to the so-called cases of splenic anæmia in adults. The same difference of opinion exists as to the recognition of a splenic anæmia in adults as separate from severe cases of secondary anæmia with enlarged spleen. It is thought better, therefore, to describe the symptoms of what has been supposed to be a separate disease by the name under which it was first spoken of, always wishing it to be fully understood that this description merely represents what is known about the subject up to the present time, and does not intend to give the impression that the author necessarily believes that it is a separate disease because he describes a set of symptoms under the term "anæmia infantum pseudoleukæmica." The subject is still *sub judice*, and much further investigation must be carried out before a final decision can be made to give up the idea that there is such a disease separate from severe cases of secondary anæmia.

We wish, however, to have it understood that it is the so-called "splenic anæmia" of adults with which the disease, if such disease exists, is associated rather than with pseudoleukæmia.

Formerly, anæmia infantum pseudoleukæmica was considered a primary disease of the blood, but it was soon differentiated from the different forms of leukæmia, and later from pseudoleukæmia (Hodgkin's disease). It is, however, still believed by some writers to be a primary disease of the spleen.

As far back as 1866 a case of a child suffering from a severe form of anæmia accompanied by an enlarged spleen was reported by Gretsel. Cases have since been described, but in a somewhat indefinite manner, and the next important work which appeared on the subject was that of Banti in 1883. Banti, however, although believing that anæmia splenica was a primary disease of the spleen, considers it also a splenic form of pseudoleukæmia, and it is from Banti's description that the characteristic symptoms of the disease are taken as well as the pathology. Following Banti a number of writers have recorded cases which they considered to represent the disease splenic anæmia; but their cases, in the light of more modern investigation, are so closely allied in their description to those of pseudoleukæmia that they would at the present time scarcely be accepted.

In 1891 Bruhl published an article on splenic anæmia, and suggested the name "splénomegalie primitive." Bruhl's work, however, was very much in the same line as Banti's, and therefore need not be further referred to. Williamson in 1893 reported a case of a boy nine years old who died, and a description of the lesions found in this case will be given under pathology. Later writers, such as Hawthorne in 1895, in the case of a child eleven years old who recovered, and Taylor in 1896, in the case of a girl thirteen years old in whom the symptoms were very similar to those of pseudoleukæmia, have added nothing new to our knowledge of the subject. In like manner Goepel reported the case of a boy eleven years old on whom splenectomy had been performed with recovery, but no histological report was made as to the condition of the spleen, and although he stated that the operation was performed for pseudoleukæmia, no enlargement of the superficial lymphatics was present at the time the operation was performed, and the blood was stated to have been normal.

In 1900 Osler reported fifteen cases which he considered to be cases of "primitive splenomegalie," but his cases occurred in adults. He also reported some additional cases of splenic anæmia at the annual meeting of the Association of American Physicians in Washington, April 29th and 30th, 1902. The opinion of those who discussed Osler's paper gives the impression that splenic anæmia as a primary disease is not universally accepted, and, in fact, most authors consider it to be a form of secondary anæmia.

In 1884 Somma, under the title of "anæmia splenica infantilis," reported thirteen cases in infants and young children. Fedde in 1889 and in 1890 spoke of this disease under the title of "anæmia splenica infettiva," believing it to be an infectious disease of infants. No details of his cases, however, were given.

In 1890 at the Pediatric Congress in Rome, Somma and Fedde presented papers on "Anæmia Splenica Infettiva dei Bambini." Somma's conclusions are that "anæmia splenica infantilis" is a disease which occurs in infancy as a rule, but that adults are not exempt.

It is significant that a number of the cases, reported by various authors, of the disease in early life show a condition of rhachitis.

Cases have also been reported by Senator, Luzet, Baginski, Alt, Weiss, Hock, Schlesinger, Koplik, Monti, Berggrun, Audioud, Glockner, and others, but in all these cases rhachitis or some other condition of malnutrition was present which could produce changes in the blood identical with those which occur in the secondary anæmias of early life.

Pathology.—The pathology of splenic anæmia has mostly rested on the findings in the autopsies described by Banti previous to 1883. The pathological lesions in these cases were not those of leukæmia or pseudoleukæmia, and on this fact Banti laid much stress in his argument that the condition is due to a primary disease of the spleen. In Williamson's case, that of a boy nine years of age, the patient was under observation for four months, and finally died. The pathological lesions as described by Banti were marked fibrous changes in the trabeculæ and the follicles of the spleen, and a great diminution of the cells. There were many large phagocytic cells containing red corpuscles, the bone marrow was red and showed a lymphoid condition, but the lymph nodes were not enlarged. The spleen weighed two pounds seven ounces, the liver weighed two pounds twelve and one-half ounces. The blood showed a diminution of leucocytes, and the red corpuscles were between 2,000,000 and 3,000,000 per cubic millimetre. The temperature varied for four months, sometimes as much as four degrees between morning and evening. There was no history of rhachitis, syphilis, or malaria.

In the reports of the autopsies of Somma's cases of anæmia splenica infettiva dei bambini nothing very definite is added to our knowledge of the disease, nor are the reports satisfactory or conclusive. The spleen is firm and large, sometimes congested, sometimes with a thickened capsule. Various conditions, such as anæmia of the organs, pulmonary congestion, serum in the ventricles of the brain, and enterocolitis, and in one case pneumonia of both lungs, are recorded. Lorenzo reports the autopsy of one case in which there was an increase of the connective tissue of the spleen and sclerosis of the follicles.

Fedde states that the only characteristic lesions are found in the spleen, liver, and blood, that the glands are normal or slightly enlarged, the liver often enlarged from congestion and from a slight increase of the connective tissue, with fatty degeneration and atrophy of the liver

* The title which is placed at the head of this paper was chosen merely for reasons of convenience, *i.e.*, simply because the time had gone by when the article might have been placed under the title which I consider to be preferable.

Digitized by Microsoft®

cells; the spleen large and firm, with hypertrophy of the connective tissue, and the pulp rich in lymph cells and with the follicles hyperplastic.

Gianturco and Pianese report the pathological findings in a case of Fedde's as a spleen showing no increase in interstitial tissue and with the follicles little developed.

www.libtool.com.cn

Mya and Trambusti reviewed the lesions found in the spleen and liver, and came to the conclusion that they were more or less diverse. In one of their cases the lesions in the spleen were similar to those found by Banti in cases of adult splenic anæmia, there being marked increase in the fibrous tissue, together with atrophied follicles and thickened trabeculæ.

Von Jaksch, in his description of anæmia infantum pseudoleukæmica, gives very few and very unsatisfactory reports as to the pathological appearances of the disease; he considers them to be a chronic hyperplasia of the spleen affecting in different degrees parts of the organ, with the liver showing slight increase in the connective tissue.

Hayem and Luzet report in their examination of the blood in anæmia infantum pseudoleukæmica large numbers of nucleated red corpuscles, in some of which there was evidence of karyokinesis of some of the nuclei, and they consider this to be of great diagnostic value. Fowler also lays great stress upon the presence of large numbers of nucleated red cells out of proportion to the diminution of the erythrocytes.

It is very evident that there does not seem to be satisfactory post-mortem evidence to warrant a definite pathological condition representing the splenic anæmia of infants. There seems to be present in most cases a chronic hyperplasia of the spleen, while in other doubtful cases the spleen is not altered.

Etiology.—In regard to the etiology of anæmia infantum pseudoleukæmica nothing definite has been proved. Although pathological micro-organisms, finding conditions favorable for their growth in the spleen, may, according to Somma, find their way into the circulation and thus produce changes which are represented by certain clinical symptoms, yet there is no doubt that the true nature of the disease, if such exists, has not yet been discovered. Nothing has ever been found bacteriologically to show a direct relation between the micro-organisms present and the production of the disease.

Symptoms.—It is difficult to describe the symptomatology of a disease which is so closely identified with cases of secondary anæmia with enlarged spleen, and in which the group of symptoms that are supposed to represent anæmia infantum pseudoleukæmica, are somewhat diverse. Both sexes are equally liable to present these symptoms, and the patients are usually between the ages of ten and eighteen months; one has been reported of seven and one-half months, and one at three and one-half years. The onset of the disease is gradual, the nutrition is poor; there are considerable emaciation, a waxy tint of the skin, at times hemorrhages from the mucous membranes and the skin, a spleen much enlarged, and the liver moderately enlarged. There is no tenderness over the bones, and there are often a venous bruit in the neck and functional cardiac murmurs. The blood shows the characteristics of a secondary anæmia of varying intensity, that is, a diminished number of erythrocytes, low hæmoglobin, variations in the size and shape of the erythrocytes and in the number of erythroblasts present. The leucocytes are not characteristic, being markedly increased in some cases and in normal proportion in others. The lymphocytosis, reported by many writers, may occur under any condition, giving rise to an increased number of white cells.

Diagnosis.—There seems to be no doubt that anæmia infantum pseudoleukæmica and anæmia splenica infettiva are the same condition, and, as there does not seem to be reason for believing that the spleen is primarily affected in either of them, they need not be differentiated one from the other. The differential diagnosis should first be made from leukæmia and pseudoleukæmia. The proportionately low leucocytosis and the absence of either a general lymphatic enlargement or an excess of myelocytes in the blood would differentiate it from the former, while the absence of enlarged lymph nodes would exclude pseudoleukæmia. As there are so few cases in which a thorough and reliable examination of the organs has been made in which rhachitis was not present, the diagnosis between rhachitis with enlarged spleen and secondary anæmia, and this supposed especial group of symptoms, would be very difficult and seemingly impossible.

We know that in infants the same blood changes which have been mentioned above often occur in connection with an enlarged spleen in the course of or following any disease of nutrition. We are therefore in the position of attempting to make a diagnosis between two conditions which may in the future be proved to be practically the same. In making a diagnosis we should limit the term anæmia infantum pseudoleukæmica to those cases in which no cause for secondary anæmia can be found, and in which the clinical symptoms and changes in the blood already described are present.

Prognosis.—The prognosis varies according to the extent and serious nature of the cause which produces the condition. The symptoms run an essentially subacute or chronic course; the large size of the spleen does not necessarily imply a fatal ending. When, however, secondary changes in the blood have occurred to such an extent as to warrant the diagnosis of a severe form of anæmia, and when a spleen of considerable size is detected in connection with these blood changes, the prognosis is very bad, as the infants usually die.

Treatment.—What has just been said of the prognosis in this class of cases may also be said of the treatment, which is, in fact, that of a case of secondary anæmia, and depends upon what is most reasonably supposed to be causing the condition that is present. This may be malaria, rhachitis, gastro-enteric disease, or some unknown cause which, simply representing the conditions of anæmia, calls for the usual treatment of arsenic, iron, proper food, and hygiene.

An extensive bibliography of the subject will be found in an article by Dr. A. H. Wentworth in the "Medical Communications of the Massachusetts Medical Society," vol. xviii., No. 3, 1901. *Thomas Morgan Rotch.*

PSEUDOMYXOMA PERITONEI.—The occurrence of free mucoid or colloid-like material within the peritoneal cavity, as the result of the rupture of an ovarian cyst or cystadenoma, or of the direct secretion of a neoplasm into the cavity, gives rise to a reactive proliferation of the peritoneal surfaces covered by such substance and the more or less complete organization of the latter. As a result of such partial organization the peritoneal surface is found to be covered with a jelly-like layer containing blood-vessels and strands of connective tissue, closely resembling myxomatous tissue. To this condition the term pseudomyxoma peritonei is applied.

The gross appearances vary with the amount of colloid or mucoid material lying on the peritoneal surfaces, and with the degree of organization. In the very early stages the surfaces of the peritoneum are covered with a jelly-like substance of varying thickness, which is easily scraped off, or may even be scooped out of the peritoneal cavity owing to the fact that it lies free therein. If organization has begun, the portion of the colloid material lying next to the peritoneum is not so easily scraped away, appears more opaque, and contains minute vessels, as shown by the fine red lines running through it. The peritoneal surface has therefore a reddish, roughened appearance, and is covered with fine whitish or reddish strands enclosing jelly-like colloid substance. As organization progresses there is developed above the peritoneal surface a zone of fibroblastic tissue which in time becomes changed into fibrous connective tissue, so that the peritoneum becomes greatly thickened, the condition resembling that of a chronic fibroid peritonitis. If the amount of colloid material scattered over the peritoneum is small, it may be completely organized and the peritoneum become more or

Digitized by Microsoft®

less thickened. On the other hand, a thick layer of colloid (several inches) is but slowly absorbed and organized, and may remain in the abdomen for a long time with but little change except where it comes into contact with the peritoneal surfaces. The reaction on the part of the peritoneum appears to vary greatly; in some cases it occurs immediately, in others it may be delayed for a long time.

www.libtool.com.cn

Microscopically, sections cut through the peritoneum and the overlying mass of colloid show a fibroblastic proliferation of the subendothelial layer of the peritoneum, a wandering of fibroblasts into the colloid, and the formation of new blood-vessels which run out into the colloid substance. As organization progresses interlacing strands of connective tissue supporting blood-vessels are formed throughout the colloid substance, enclosing between them masses of the jelly material which have not yet been absorbed. These give the tissue an appearance resembling myxomatous tissue, even under the microscope. It is easily seen, however, that the structure is not that of a true myxomatous tissue, but represents an organization of a jelly-like foreign substance. All stages of organization may sometimes be seen in the same case. The writer has seen a number of cases representing different stages; in one of two years' duration the organization of the colloid was almost complete, the peritoneum being converted into a thick hyaline layer of connective tissue, enclosing here and there bits of unabsorbed colloid. Contraction of the mesentery and matting of the intestinal coils occur in this stage, and the appearance resembles very much the condition of the peritoneum in diffuse scirrhous carcinoma. The surfaces of the liver and spleen are similarly involved, and in the late stages present a picture of marked perihepatitis and perisplenitis.

Localized pseudomyxoma occurs when, from the rupture of a small ovarian cyst or cystoma, a small mass of mucoid substance is distributed in small portions over the peritoneal surface. These show the same stages of organization, hyaline change, etc., and finally come to represent localized thickenings of the peritoneum. This condition occurs most frequently in the pelvis.

If portions of living epithelium or of papillæ are set free into the peritoneal cavity with the mucoid material, after the rupture of an ovarian cystoma, these may proliferate and set up implantation metastases. These may become malignant; if the primary tumor has already undergone carcinomatous change, these implantations are likewise carcinomatous. In the case of the ordinary cystoma the implanted epithelium forms small cysts which become stationary after a while and do not form large growths. When the primary is a papilliferous cystadenoma the implantation metastases are much more likely to develop into larger tumors. It is conceivable that the implantation metastases of epithelium arising from a benign growth may later become malignant.

Small cysts lined with hypertrophic endothelium may also be found in the pseudomyxomatous tissue of the peritoneal covering. These are probably derived from the remains of the surface endothelium. It is also within the range of possibility that these may form centres for the formation of a new growth of malignant character.

Pseudomyxoma of the peritoneum is not in all cases formed by the rupture and discharge into the peritoneal cavity of an ovarian tumor containing mucoid or colloid material. Surface papillomata of the ovary may secrete such material directly into the peritoneal cavity; further, cystic carcinomata of the stomach, intestines, or testicles may give rise to the presence of mucoid or colloid substance in the peritoneal cavity, either from rupture of the primary or from secondaries located in the peritoneum.

In the great majority of cases, however, the mucoid or colloid substance comes from the rupture of a large ovarian multilocular cystoma, in which one chamber has been developed at the expense of the others; or from a primary unilocular cystoma. If the cyst contents are of a thin serous character they may be absorbed by the peritoneum without the production of peritoneal proliferation. The more jelly-like or colloid the contents the more likely the occurrence of pseudomyxoma. In order to excite peritoneal proliferation the substance must be of a fairly firm consistency and not easily absorbed. Pseudomucin may or may not be present in the cyst contents, but in the majority of cases it is a pseudomucin cyst that ruptures. The jelly-like material of the pseudomyxomatous tissue may give both mucin and pseudomucin reactions. Pseudomucin is, however, not necessary to the production of pseudomyxoma. This term should be taken as signifying the formation of a tissue resembling myxomatous tissue. Though spoken of as colloid, the cyst contents in all cases are mucoid, but when firm and jelly-like they may be appropriately designated as colloid or colloid-like.

The cyst contents when poured over the peritoneum act as a foreign body and set up a reactive proliferation which is of the nature of an inflammatory process. The presence of fibrin throughout the pseudomyxomatous tissue may often be shown by Weigert's fibrin stain. Localized collections of leucocytes may also occur throughout the organizing zone. In case of an infected cyst, or following infection as a result of operation, the picture of pseudomyxoma and that of a fibrinous peritonitis may be combined. The writer has seen one case of pseudomyxoma in which the cyst contents were scattered over a peritoneum showing a marked subacute fibrinous peritonitis. The colloid material was deposited on top of a thick fibrinous exudate which was undergoing organization. Organization of the colloid from the new fibroblastic tissue had begun in some areas.

To recapitulate, the writer holds that pseudomyxoma peritonei is a condition of the peritoneum due to a partial organization of a mucoid or colloid material, which has been deposited over the peritoneum as the result of the rupture of an ovarian cystoma or of other cystic tumor containing such material, or from the secretion of certain tumors directly into the peritoneal cavity. This view, however, is not held by all authors. Netzel, Wendeler, and others regard the condition as due, at least in part, to a chronic productive inflammation of the peritoneum associated with myxomatous degeneration. This view may be explained by the presence of pseudomucin in the lymph spaces of the peritoneum, following an absorption from the peritoneal cavity. Westermark and Annell regard the jelly masses on the peritoneum as the product of a specific form of peritoneal disease. Alshauser, Strassmann, Pfannenstiel, and others regard the process as due essentially to an implantation metastasis of tumor cells over the peritoneum. On the other hand, Werth (to whom we owe the designation *pseudomyxoma*), Veit, Kretschmar, and others hold practically the same view as the writer, namely, that the colloid masses are not metastases but are to be explained as the non-absorbable mucoid contents of a ruptured cyst, which, scattered over the peritoneum, act upon it as a foreign body, become enclosed in inflammatory adhesions, and undergo organization after the manner of a thrombus, finally being replaced by hyaline connective tissue.

The prognosis in pseudomyxoma is not necessarily bad. Large masses of colloid material may be kept within the peritoneal cavity for a long time without especial symptoms. Small amounts may be completely absorbed and organized, and the resulting condition of the peritoneum may give rise to the same sequelæ as those which follow chronic adhesive peritonitis. In operations for the relief of pseudomyxoma after the rupture of ovarian cysts, it should be borne in mind that the peritoneum, after the removal of the overlying colloid material, represents a more or less denuded, hyperæmic surface, through which infection may easily take place, giving rise to a fibrinopurulent peritonitis. The general resistance of the peritoneum appears to be lowered as the result of the presence of the foreign substance in the cavity. The danger that a malignant growth will arise from the implantation metastases is not very great in the case of a simple multilocular cystoma, but in the case of a papilliferous cystoma the danger of such an occurrence is much greater.

Digitized by Microsoft®

Such metastases may occur in the operation wound. On the whole, the safest procedure is to operate as soon as possible after the rupture of the cyst, before organization has begun. A more or less marked ascites, which complicates the diagnosis, is often associated with pseudomyxoma; this is particularly true in the case of associated infection. It may occur, however, as the result of the irritation produced by the presence of the foreign body. Recurrence takes place when the primary tumor or the metastases which produce the mucoid or colloid are not removed; or when the implantation metastases become active, and either burst or secrete into the cavity. Recurrence is much more likely to take place in the case of papilliferous growths. *Aldred Scott Warthin.*

PSEUDOPEPSIN.—When the gastric mucosa is allowed to digest for some time in a slightly alkaline medium and in the presence of an antiseptic like toluol, some of the proteids enter into solution and the tryptophan reaction (see *Tryptophan*) can be demonstrated with the latter. According to Glaessner this self-digestion is due to a specific proteolytic enzyme, to which he has applied the name *pseudopepsin*, and which in some respects resembles the trypsin of the pancreas and the autolytic enzyme of the liver. Pseudopepsin is characterized: (1) By acting in alkaline solutions, in which pepsin is destroyed; (2) by forming tryptophan as a product of its activity; (3) by acting in the presence of free acid even to the extent of 0.3 per cent. HCl, and in the presence of pepsin which destroys some enzymes. This behavior toward acids distinguishes it from trypsin. Pseudopepsin occurs in both the fundus and the pyloric portions of the gastric membrane, and in about equally small amounts. According to Glaessner the proteolytic action of the pylorus mucosa is probably entirely due to pseudopepsin. It is also apparently the characteristic proteolytic enzyme of the glands of Brunner—an observation which is of interest in view of the assumed histological resemblance between these glands and those of the pyloric portion of the stomach. It is not unlikely that pseudopepsin, or a similar enzyme, occurs in the pyloric appendages of many fishes. Pepsin can be obtained free from pseudopepsin by appropriate chemical methods. In ordinary commercial preparations the writer has found evidences of tryptophan-forming enzymes in very few instances. The existence of pseudopepsin as a specific enzyme of the stomach has been denied by Klug. *Lafayette B. Mendel.*

PSEUDOTUBERCULOSIS.—It seems that the word pseudotuberculosis was first used by Eberth in 1885 as a name for a disease in rabbits, which, although it resembled ordinary tuberculosis of these animals somewhat, was not caused by the bacillus tuberculosis Kochii. Later, the term has been used in a broader sense for all conditions which resemble genuine tuberculosis, but which are produced by organisms other than the tubercle bacillus. Baumgarten and others have objected to the use of the term, and it certainly is not a very good one. If we use the word tuberculosis in an etiological sense, meaning a disease produced by the tubercle bacillus, pseudotuberculosis might be interpreted as meaning a disease caused by pseudotubercle bacilli, that is, by those bacilli which resemble the tubercle bacillus more or less closely; which, at least according to the common acceptation of the term, it does not, altho pseudo-tubercle bacilli sometimes may produce pseudotuberculosis. If, on the other hand, we prefer to use tuberculosis in its anatomical sense, meaning a disease in which there is a production of tubercles, that is, nodules in the tissues, even then the term "pseudotuberculosis" is not very fortunate. The nodules in this disease also are certainly present and not in any way spurious, coinciding, in some instances at least, with true tubercles in all respects, even down to the least histological detail. Nevertheless, despite all these objections, the word will have to be retained for the want of a better one until, perhaps, medical nomenclature is revised and put on a scientific basis, a revision of which it certainly is very much in need.

Taking the word in its broadest sense as meaning a disease with the production of tubercles, that is, nodules of some sort, but not caused by the tubercle bacillus, we find that such a condition may be produced by many different etiological factors.

There is first the pseudotuberculosis of the rodents (the tuberculose zoogléique of the French authors). This form of pseudotuberculosis occurs chiefly among rodents (guinea-pigs, rabbits, hares, mice), but also among birds, particularly chickens, in the form of epizootics. Occasionally it has been produced by the inoculation of the most varying materials—*e.g.*, tissue from a hypertrophied tonsil (Bettencourt), cotton through which the air of the rooms of phthisical patients had been filtered (Chantemesse), material from a case of suspected tuberculosis of the elbow, and also from a nodule from a cow with pearl disease (Courmont), material from a caseous nodule from a child (Malassez and Vignal), pus from a cow suspected of suffering from tuberculosis (Nocard and Masselin), and milk (Parietti). The disease runs a more rapid course than ordinary tuberculosis. At the post-mortem examination one finds small caseous nodules in the spleen, liver, often in the kidneys, more rarely in the lungs, heart, brain, peritoneum. Quite frequently the Peyer's patches in the intestines are diseased and the mesenteric lymph nodes show large irregular areas of caseation and suppuration. On microscopical examination the nodules show more the appearance of chronic abscesses than that of typical tubercles, but at times nodules with large giant cells and typical caseation have been found. Woronoff and Sineff report that giant cells are very numerous in the lesions in chickens, whereas in rodents they found them occasionally only. Apostopoulos found nodules with all the characteristics of genuine tubercles in the liver of rabbits which he had inoculated by way of the anterior chamber of the eye. The disease is produced by a short, rather coarse, non-motile or very slightly motile bacillus, which does not stain with Gram's method, does not form any spores, and does not liquefy the gelatin. It grows luxuriantly except on potato. It does not ferment sugar, does not coagulate milk, does not produce any indol. Some authors describe irregular polar staining. At times the bacilli are arranged in short chains. It is difficult to stain them in the tissues. Tartakowsky has announced recently that in beef tea they form growths resembling stalactites, like those of the bacillus of bubonic plague. The cultures have an unpleasant odor, which is variously described by different authors. The organism seems to belong to the group of bacteria called by Kruse in Flügge's text-book "bacteria of hemorrhagic septicæmia," although Kruse himself classifies it with the bacillus mallei, to which it certainly does not show much similarity. Lehmann and Neumann put it with the bacilli of hemorrhagic septicæmia.

There are two cases on record purporting to be cases of infection with the bacillus pseudotuberculosis rodentium in the human being. One of these was published in 1891 by Hayem and Lesage. The patient suffered from Addison's disease. At the necropsy the left adrenal was found destroyed by caseation. Tubercle bacilli could not be demonstrated, nor were there any typical tubercles or giant cells in the sections. From the blood and the caseous areas the bacillus pseudotuberculosis rodentium was obtained. The other case is that of a child suffering from bronchopneumonia and empyema. In the pus from the empyema, Massa and Mensi (1895) claim to have found the bacilli. We might also cite a case of Courmont, who inoculated a guinea-pig with material from a case of what was suspected to be tuberculosis of the elbow. The guinea-pig developed a typical pseudotuberculosis. In view of the small number of cases recorded, and the possibility of error in the bacteriological diagnosis of the organism, and also in view of the fact that the bacillus pseudotuberculosis rodentium seems to be quite common, and therefore frequently

Digitized by Microsoft®

found as a contamination in all sorts of material. I believe we are justified in being a little sceptical about the nature and importance of the bacteria found in these cases, until more abundant and absolutely conclusive evidence shall have been furnished.

Then, besides, we find reported in literature isolated cases in which a similar disease was caused by other bacteria. Some of them are more or less closely related to the bacillus pseudotuberculosis rodentium. In Du Cazal's two cases, for instance (both in man, one with caseous nodules on the surface of the peritoneum and similar nodules of the size of a nut in pancreas and liver; the other with large caseous nodules in brain, in pleura, along spinal column and in both kidneys), he found a bacterium which differed from the bacillus pseudotuberculosis rodentium largely only by the fact that it liquefied gelatin. Legrain found a similar organism in the pseudotuberculous lesions of a rabbit that had been inoculated with sputum from a case of pulmonary phthisis.*

In other cases the bacteria encountered were quite different. Preisz, for instance, and also Kutscher found organisms which resembled diphtheria bacilli. Still other and even more uncommon bacterial forms of pseudotuberculosis in animals have been reported by Cherry and Bull, Galli-Valerio, Vallée, and others but we cannot very well enter here into a fuller consideration of these forms.

Again other forms of pseudotuberculosis are caused by certain filamentous bacteria. In Eppinger's case of this kind there were a cerebral abscess, a very chronic tuberculosis with calcification of lungs and peribronchial lymph nodes, and tuberculosis of the pleura. The disease was caused by a form of cladothrix (asteroides), which when inoculated into rabbits and guinea-pigs produced pseudotuberculosis. Flexner reports a case which clinically had all the symptoms of pulmonary phthisis. At the necropsy he found pulmonary cavities and tubercle-like nodules in the lungs, omentum, peritoneum, liver, and spleen. Although histologically the nodules were identical with tubercles, no tubercle bacilli were found, but instead branching threads which stained well with Gram's method. Cultures could not be obtained. An inoculated guinea-pig died, but not of tuberculosis.

Infection with certain mould fungi is also one of the many causes of pseudotuberculosis. By intravenous injection of the spores of certain moulds in rabbits, for instance, one can produce a most beautiful disseminated pseudotuberculosis, as Grawitz has demonstrated long ago. An interesting form of pseudotuberculosis, produced by mould infection, is described by Chantemesse and others as occurring in pigeons. The disease starts with a caseous ulcer in the mouth, which is later followed by the formation of nodules in lungs, liver, more rarely œsophagus, intestines, kidneys. Histologically the lesions resemble tubercles very closely. The cause of the disease is the aspergillus fumigatus. The disease seems to be communicated at times to breeders of pigeons, who stuff young pigeons by introducing food into the mouth of the animals directly from their own mouths, in imitation of the parent birds.

Nodules which resemble tubercles very closely are produced in the skin in certain forms of blastomycetic dermatitis, and even more regularly are they found in another rarer form of fungus disease, which has been first described by Wernicke in Buenos Ayres, and has since then been observed several times in California. The disease generally begins as a chronic cutaneous trouble resembling hypertrophic lupus; later, a disseminated pseudotuberculosis of nearly all the internal organs except the heart and gastro-intestinal canal develops. I have seen cases, however, which did not show any cutaneous lesions, but in which the primary infection seems to have taken place by inspiration into the lungs. The fungus which causes the disease in the tissues multiplies by endogenous sporulation, only without formation of mycelia or budding, and was on that account first described as a protozoan by Wernicke and Rixford and Gilchrist, who studied the earliest cases in California. I succeeded, however, in cultivating the organism in artificial culture media, and in these it grows out into long spore-bearing hyphæ. The classification of the fungus is as yet doubtful, and until our knowledge of it is more complete I have proposed the name fungus coccidioides. I can only confirm the reports of earlier investigators that the similarity in the histological structure of the lesions produced by this fungus to typical tubercles at times is truly remarkable. A histological differential diagnosis between them, apart from the difference in the causative factor, is in these instances absolutely impossible. With such typical tubercles one finds simultaneously in the lesions numerous submiliary chronic abscesses, very much like those which commonly occur in glanders.

With this long list of vegetable parasites our list of producers of pseudotuberculosis is by no means exhausted. Among the animal parasites we find quite a few of the smaller parasites or their eggs, which when accidentally disseminated in the tissues can cause the formation of tubercle-like nodules around them. De Jong, for instance, describes cases of pseudotuberculosis in sheep and goats produced by intestinal worms (strongylus rufescens), and claims that to the naked eye the differential diagnosis from ordinary tuberculosis is difficult. Marsden also reports cases of large, more or less tubercle-like nodules in lungs, liver, and kidneys of sheep, hogs, and goats, due to the eggs of filaria strongylus. In 1884 Laulanié entertained the Société Biologique in Paris with the account of pseudotuberculosis of dogs produced by demodex folliculorum, and in 1899 Helbing read a paper at a meeting of the Freie Vereinigung der Chirurgen Berlins, in which he describes a case of pseudotuberculosis of the peritoneum in man caused by the dissemination of the eggs of a tapeworm. The nodules had the typical histological structure of tubercles; the eggs or fragments of them were enclosed in giant cells, but there was no caseation.

Even small dead foreign bodies, particularly when they are of a somewhat irritating nature, will cause the formation of nodules in the tissues. As early as 1869 Waldenburg proved this by experiments, which he relates in his monograph on "Tuberculosis, Pulmonary Phthisis, and Scrofulosis" (Berlin, 1869), a piece of work which is not so well known as it deserves to be; and even before him Cruveilhier ("Traité d'Anatomie pathologique générale," iv., 1862) had attempted to produce, and to his own satisfaction succeeded in producing, tubercles in the lungs by injection of small droplets of metallic mercury into the trachea of dogs. Only recently Meyer described a case, observed in Hanau's laboratory, of pseudotuberculosis produced by foreign bodies. In this instance a gastric ulcer had perforated and small particles of food had been scattered through the peritoneal cavity. Around these small particles of food a development of tubercles had taken place. A similar observation was made in another case in which an ovarian cyst had ruptured and a large number of cholesterin masses were disseminated through the peritoneum.

When we consider the great variety of causes which have just been enumerated, the question seems natural, Are we really justified in calling all these conditions, which are so manifold *ætiologically*, by the one name pseudotuberculosis? We shall be all the more inclined to ask this question when we learn that in many instances the lesions histologically do not resemble one another entirely. In the pseudotuberculosis of the rodents, for instance, the nodules on microscopical examination usually present the appearance of chronic miliary abscesses, such as they are observed, for instance, in glanders, and not that of typical tubercles. The same is true of the lesions caused by infection with certain pathogenic moulds. In these lesions giant cells and caseation which are considered to be the more important

* In the last issue of Ziegler's Beiträge (1902, xxxii., 526) Wrede reports an interesting case of pseudotuberculosis in an infant. Pharynx, œsophagus, intestines, liver, and adrenals were full of gray submiliary nodules. The condition was caused by a bacillus which closely resembled the bacillus pseudotuberculosis rodentium, but which differed from it in staining with Gram's method.

Digitized by Microsoft®

characteristics of true tubercles, are often absent. Yet under other conditions the same parasites may produce nodules which in histological structure resemble ordinary tubercles very closely. In chickens, for instance, we learn from Woronoff and Sineff that the nodules produced by the bacillus pseudotuberculosis rodentium contain many giant cells. One must also not forget that in ordinary tuberculosis the nodules show remarkable differences in histological structure according to the age of the nodule and the number and virulence of the tubercle bacilli present. Tubercle bacilli also at times may produce chronic miliary abscesses. Since my attention has been called to this occurrence by some observations made while studying the ependyma of the ventricles of the brain in tuberculous meningitis ("Ueber Ependymveränderungen bei tuberculöser Meningitis," *Virch. Arch.*, cl., 1897, 305), I have seen chronic miliary abscesses produced by tubercle bacilli—and by tubercle bacilli alone without associated infections—quite frequently in other parts of the body in man and animals. In infections with the fungus coccidioides the simultaneous occurrence of "typical" tubercles and chronic miliary abscesses in the same organ, produced by the same parasite, is very bewildering; indeed one is finally forced to recognize that the difference between these two conditions is not a fundamental one—as a matter of fact, I have seen transitional forms of otherwise typical tubercles with central abscess cavity filled with pus cells,—and that whether the tissues respond in one way or the other depends only on the amount of irritation to which they are subjected. If the irritation is less marked, a "typical" tubercle develops; if it is more intense, a chronic miliary abscess is produced. It seems, therefore, that in spite of the variety of causes, and in spite of the varying appearance of the nodules under the microscope, it is advisable to group all these conditions which are closely akin to one another under one name, "pseudotuberculosis," provided we keep in mind that in so doing we use the word "tubercle" in its broadest sense for a nodule, without assuming anything too definite about its exact histological structure.

PSEUDOTUMOR.—The term *pseudotumor* is applied to certain enlargements or swellings of non-neoplastic character which clinically present features by which they may be mistaken for true neoplasms. In the majority of cases such false tumors are found in the abdominal region. They may be produced by a great variety of causes. When the swelling cannot be constantly felt, but comes and goes, it may be designated as a *phantom tumor*. Such enlargements have no organic pathological foundation, and are dependent upon temporary conditions. On the other hand, enlargements or swellings of the abdominal organs due to organic disease may also simulate neoplasms; these conditions should be included under the designation of *pseudotumor* or *apparent tumor* proper. When caused by inflammatory masses of granulation tissue which later contract and disappear, the condition may be spoken of as *vanishing* or *disappearing* tumor.

Phantom tumors may be caused by a contraction of the abdominal muscles or by meteorism. Those caused by muscle contractions are found usually in the upper part of the abdomen. The right rectus near its costal margin is most frequently the part contracted, but the contraction may affect any segment or portion of the abdominal muscles. The contractions are often spasmodic. The entire rectus may be rigid. Usually, however, but a single segment is affected, the contraction being almost always unilateral. The patients are usually hysterical females who present marked stigmata of hysteria; there are usually coexisting constipation and enteroptosis. The contraction may sometimes be made to disappear in a hot bath; but in cases of marked hysteria anæsthesia or hypnotic suggestion may be necessary for the differential diagnosis. The superficial character of the tumor, its flat, horizontal shape, slightly rounded and indistinct edges, etc., in connection with the stigmata of hysteria, make the diagnosis easy.

Phantom tumors due to meteorism or localized distention of the intestines with gas, are of frequent occurrence in the same class of patients as described above, and are often found in connection with the muscle contraction. The character of the swelling, the percussion signs, etc., make the diagnosis easy. The swellings occur usually in the lower portion of the abdomen, particularly in the appendix region, and above the pubis. They are found frequently in women who either pretend or believe that they are pregnant (pseudocyesis). The associated stigmata of hysteria, and the characteristic physical signs render the diagnosis of slight difficulty.

www.libtool.com.cn

Apparent tumors of the epigastrium are, according to Einhorn, of infrequent occurrence. He reports forty-two cases, eight occurring in men and thirty-four in women. The tumors presented in the epigastrium or in the left or right hypochondrium, and formed in the majority of cases smooth masses of the size of a hen's egg or a man's fist. They were frequently pulsating, could not always be distinctly felt, and on light percussion yielded a dull sound. They ran a long course, and there was usually a history of a long-continued malnutrition. The tumors remained unchanged or diminished in size. They were caused by prolapse of the left lobe of the liver, exposure and thickening of the abdominal aorta, hypertrophic conditions of the muscles of the abdominal walls, and probably adhesions around the lesser curvature of the stomach. If the tumor is caused by the prolapse of the left lobe of the liver, it is found usually in the median line below the ensiform; it is of large size and gives a dull tone on percussion. Between the dulness of the tumor and the ensiform there may be an area of tympanitic tone. If the tumor is the aorta, it is deep, usually about two inches long, and one to two thumbs in breadth, and pulsates. Hypertrophic conditions of the abdominal muscles are superficial, usually horizontal, and not globular, and are located at one side of the median line.

In very thin individuals the head of the pancreas may be felt and mistaken for a tumor. Likewise floating kidney, liver or spleen, rolled-up omentum, excessively fat mesentery, fæcal impaction, distended urinary or gall bladder, tuberculous thickenings of omentum or mesentery, hydro- or pyosalpinx, cystic dilatation of the appendix, etc., may sometimes be regarded as presenting the clinical appearances of malignant tumors of these regions.

Inflammatory thickenings, tuberculous and syphilitic nodules, encapsulated hæmatomata, encysted parasites, infective granulomata of unknown origin, localized hypertrophy of muscle, local œdema, etc., are also often mistaken clinically for malignant tumors.

The term pseudotumor is also applied to the nodules of a chronic inflammatory nature caused by the experimental injection of blastomycetes and other fungi. Similar nodules may be produced by the introduction of foreign bodies or the injection of certain chemical substances into the tissues.

Disappearing tumors of the abdomen are usually the result of acute inflammatory tumors of the omentum, following appendicitis or salpingitis. The absorption of exudates and the contraction of the granulation tissue lead to the diminution in size or total disappearance of the tumor. Similar disappearing tumors occur in the skin, subcutaneous tissues, periosteum, and intermuscular connective tissue as the result of the formation of granulation tissue following trauma or hemorrhagic extravasation. These may sometimes be mistaken for sarcomata, both clinically and microscopically. The presence of numerous plasma cells, the character of the blood-vessels, and the general appearance of the granulation tissue are points upon which the differential diagnosis should be based. (See also *Omentum* and *Abdominal Tumors.*)

Aldred Scott Warthin.

PSITTACOSIS.—An infectious disease occurring in birds, particularly in parrots, and transmissible to man. The disease in parrots is of the nature of a chronic enteritis, characterized by diarrhœa, wasting, loss of appetite, and falling of feathers. In man the symptoms are those of a grave typhoid, with diarrhœa and a malignant atypical pneumonia. The disease may be transmitted directly from parrots to man or through intermediate objects, and, according to some observers, from man to man. The period of incubation is from seven to twelve days; the symptoms begin with malaise, epistaxis, and digestive disturbances, followed by bronchitis and pneumonia. The urine contains a small amount of albumin. There is high fever lasting for from three to four days, and falling by crisis. These symptoms then recur in this order several times, defervescence finally taking place by lysis. During the attack the spleen is enlarged. Sometimes there may be seen a roseolar or petechial eruption. The disease lasts about thirty days. The mortality is about thirty-seven per cent. The prognosis is good if complications do not occur. In the majority of fatal cases, death is due to pneumonia.

Eberth in 1880, and Wolff in 1883, observed the occurrence of a fatal mycosis in parrots which had been imported in great number from the west coast of Africa during 1880. Transmission to man was not observed. In 1879 Ritter saw a house epidemic of severe pneumonia which he thought was referable to a contagion from parrots, or rather from the cages in which the birds had been transported. The clinical and anatomical picture of the disease was that of an atypical pneumonia. Similar cases were observed in 1882 by Ost, and by Wagner in 1882 and 1886. The disease was introduced into Paris in 1891 by some parrots from South America. In 1892 there was an epidemic of the disease in this city, in which fifty persons were affected. Cases of the disease were also observed in Paris during the next four years, and advantage was taken of the opportunity to study the disease closely. The relation of the disease in man to the affection of the parrot was clearly proved. Cases have been observed also in Italy and Germany.

According to Nocard, the cause of the disease is a specific bacillus resembling that of typhoid fever. The organism is short, rather thick, with rounded poles, is motile, and is a facultative aërobe. It does not stain with Gram's method, does not ferment sugar, does not coagulate milk, and does not form indol. The bacillus is very virulent; subcutaneous injections in rabbits, mice, and pigeons kill within from fourteen to forty-eight hours. In the Paris epidemic this bacillus was not found in the human body; but, three years later, Gilbert and Fournier found it in one case, in the heart blood of a woman dying from the disease. Palamidessi observed an infectious disease transmitted from parrots which he regarded as resembling chicken cholera. The organism obtained by him was regarded as identical with that observed by Nocard. Other observers have failed to find the Nocard bacillus; and Leichtenstern and others believe that the disease of the parrots known as psittacosis may be caused by various bacteria (staphylococcus, streptococcus, pneumococcus, colon bacillus, and proteus), and that house epidemics of atypical pneumonia in man may occur without such diseases of the parrot playing any etiological rôle therein. These writers, however, admit the probability of such a relation in certain cases, as in the Paris epidemic of 1892.

On the other hand, Nicolle reports an epidemic attacking eight persons (four dying), in which the Nocard bacillus could not be found; but the serum from these cases produced a typical agglutination of a culture of the bacillus furnished by Nocard, in dilutions of 1 to 50 and 1 to 60. The blood of one of the cases also agglutinated typhoid bacilli, although the patient had never had the disease.

Widal and Sicard claim that typhoid and psittacosis can be differentiated by the Widal reaction. In dilutions of 1 to 10 the reaction occurs with both; but the masses of psittacosis bacilli are smaller and more crowded. In dilutions of 1 to 40 there arrives a moment when the bacilli of psittacosis no longer react.

The bacteriology of psittacosis and the true relations of the parrot disease to the atypical pneumonia in man remain yet to be determined definitely. Further, it should be observed that in the popular mind psittacosis is regarded as a form of avian tuberculosis, and that cases have been reported of a supposed transmission of tuberculosis from the parrot to man, whence the origin of the error.

Aldred Scott Warthin.

PSOAS ABSCESS is a *cold abscess* located in the psoas muscle. The purulent material gains entrance into the muscle after destroying the vitality of a portion of the sheath by pressure and infiltration.

The iliac fascia which ensheaths the whole muscle con-

Digitized by Microsoft®

fines the pus and directs its course through the substance of the muscle, the result of such burrowing being extensive destruction of tissue. The infiltration may involve the muscle on either or both sides of the body. The purulent material may accumulate until the sheath becomes a mere pus sac with the lumbar plexus of nerves crossing its cavity, the muscular tissue being destroyed.

The cavity is irregular in shape, bulging laterally, and constricted, sometimes closed at the diaphragm and beneath Poupart's ligament.

An abscess resulting from tuberculosis of the bodies of the lower dorsal or upper lumbar vertebræ will, as a rule, perforate the psoas sheath.

The pyriform pus sac so formed lies along the sides of the dorsal vertebræ, this lateral position being determined by the presence of the anterior and posterior common ligaments.

When the source of the pus is situated above the diaphragm, its entrance into the psoas is facilitated by the intimate connection of the iliac fascia with the ligamentum arcuatum internum.

In the lumbar region the entrance of pus into the psoas is aided by the formation of pouches between the heads of origin of the muscle (body of the vertebra and intervertebral substance and front of the transverse process of the vertebra). These pus pouches rupture into the body of the muscle.

Abscesses resulting from tuberculosis of the sacrum, from sacro-iliac disease or from tuberculosis of the lumbar glands, may also perforate the sheath of the psoas muscle.

Rigidity or contraction of the affected psoas muscle and perhaps neuralgia of the anterior crural nerve are the most frequent symptoms. The contraction of the muscle may lead to great deformity, demanding weight-and-pulley extension, or even tenotomy for its correction.

Frequently the distended psoas sheath can be detected by palpation, and if the pus has reached Scarpa's triangle it can be pressed up and down under Poupart's ligament, following the course of the psoas muscle.

This is the usual course taken by the pus, which is directed by the sheath toward the insertion of the psoas and iliacus muscles; but it may burrow farther, pointing lower down on the limb.

The pus on reaching Poupart's ligament may enter the iliacus muscle, or may leave the psoas sheath along its external border and burrow to the surface in the loin; or it may invade the gluteal or the ischiorectal region.

The direction taken by the abscess is determined by the usual position of the body. If the dorsal position is most constant, the pus may point in the loin or may even sink upward into the pleural cavity. Other organs and tissues are occasionally invaded, and the pus may open into the lungs, bladder, intestines, blood-vessels, or peritoneum.

An early diagnosis will often allow of a successful operation through an incision in the loin. The abscess cavity should be made aseptic and any diseased bone scraped away. The drainage must be free and into an antiseptic and elastic dressing.

Curetting the sac wall should not be attempted unless the whole cavity is accessible.

Although a large collection of pus may become cheesy or encapsulated, yet its presence is a possible focus for the development of miliary tuberculosis or cerebrospinal meningitis. Then, besides, it is a well-known fact that amyloid changes are likely to take place in the viscera when suppuration continues for a prolonged period. Consequently, early operative interference is to be recommended in the hope that it may prevent the development of such changes in the viscera.

When the pus approaches the surface, especially in the groin where antiseptic treatment is difficult, and when the sac is known to be large, aspiration is to be preferred to incision and drainage. The trocar should be passed in a slanting direction, piercing the tissues about an inch before entering the pus sac. The lumen of the trocar should be frequently cleaned with a plunger or wire hook, as the pus contains much semi-solid necrotic granulation tissue, cheesy matter, and often small particles of bone.

After the sac has been washed out with a weak boracic-acid or tincture-of-iodine solution, it should be injected with twenty or thirty grains of iodoform dissolved in ether or suspended in glycerin.

The trocar should then be withdrawn, its retiring point being followed by the finger from the sac to the exit so as to prevent the entrance of any purulent material into its track. The wound should then be sealed with collodion.

During the process of aspiration and flushing of the abscess cavity the entrance of air must be prevented by pressure upon the sac. The quantity of flushing fluid should not exceed that of the pus withdrawn. Compresses should be applied in such a way as to insure the apposition of the walls of the sac, in order to promote healing and to lessen the oozing of serum or blood because of the diminished pressure within the cavity.

Aspiration aseptically performed gives good results, although it may require to be repeated several times. The pus becomes more viscid, and the semi-solid masses of necrosed tissue and fibrin disappear as the healing progresses.

If the abscess has opened spontaneously it should be protected with dressings which promote drainage by capillarity, such as jute or lambs' wool. At each daily dressing two grains of carbolic acid in about fifty parts of water should be injected into the sinus.

The treatment may extend over weeks or months, but the danger from infection becomes less as healthy granulations form in the cavity. Sometimes a counter opening becomes necessary in order to allow of better drainage and more thorough disinfection of the sac.

Pus from an inflamed appendix, a perinephritic abscess, or an empyema may invade the psoas muscle, but a study of the constitutional disturbances will facilitate the differential diagnosis in such cases. The differential diagnosis of diffuse abdominal aneurism may be made by its impulse and perhaps bruit.

The diagnosis from iliac abscess rests chiefly on the age of the patient, for psoas abscess occurs generally in the young with tuberculous history, and iliac abscess in the adult.

The impulse transmitted to the swelling by coughing must be carefully distinguished from that present in hernia; a diagnosis may be made by observing the manner in which the tumor can be reduced and in which it reappears after reduction, and also by the fulness of the iliac fossa, apparent on palpation.

Varicose veins, cysts, undescended testicle, and glandular swellings in Scarpa's triangle must also be differentiated. *Jasper J. Garmany.*

PSORIASIS.—Psoriasis is a disease of the skin which possesses three characteristics that should render its diagnosis easy. These are: 1. The formation of dry, papery, thin, silvery-gray scales, mica-like in their arrangement, and as a rule easily detached, is a constant phenomenon. 2. Dryness is an absolute characteristic of the disease at all stages and in every situation. There is never, in a pure type of the affection, the slightest moisture, greasiness, or tendency to ulceration. 3. The development of points or discs of a color varying from pale red to a red of a brighter hue, and showing a certain degree of inflammatory thickening—sometimes quite marked, but usually only moderate or slight—is another characteristic of the disease. These lesions are always well defined at their borders and tend to enlarge peripherally, sometimes with evidence of greater activity at the border than in the centre. Contiguous lesions often meet, forming irregular, map-like figures, the points of confluence becoming like the centre of the original patch or disc.

At the onset of the disease there is noticed, commonly at some part of the surface of the body where the skin is

www.libtool.com.cn
Digitized by Microsoft®

thicker than elsewhere, a well-defined spot or patch of a pale red color (but of a somewhat brighter red in an acute outbreak of the disease) and of variable size (from the head of a pin to a half-dime silver piece). At the affected spot the skin is a little thickened, and its surface consists of one or two layers of thin, dry, easily removable scales which are quite small in proportion to the size of the lesion. This lesion gradually enlarges—as a rule, symmetrically—and in the part newly involved the characteristic slight thickening of the skin and the formation of loosely attached scales may be observed. When the loose scales are removed it will be seen that the natural lines of the skin, which under normal conditions are quite faint, are now accentuated by the upraising of the intermediate areas through the products of inflammation. When the lesion attains the full limit of its growth, it may be as large as a silver half-dollar and of about the same thickness. Through coalescence two or three adjacent lesions may eventually form quite a large area, of irregular shape. I have known an apparently single lesion, on the extensor surface of the forearm, to attain an area of about four by six inches. At no time in the course of its development did this patch fail to show the pathological alterations which are so characteristic of the affection and which have already been enumerated.

www.libtool.com.cn

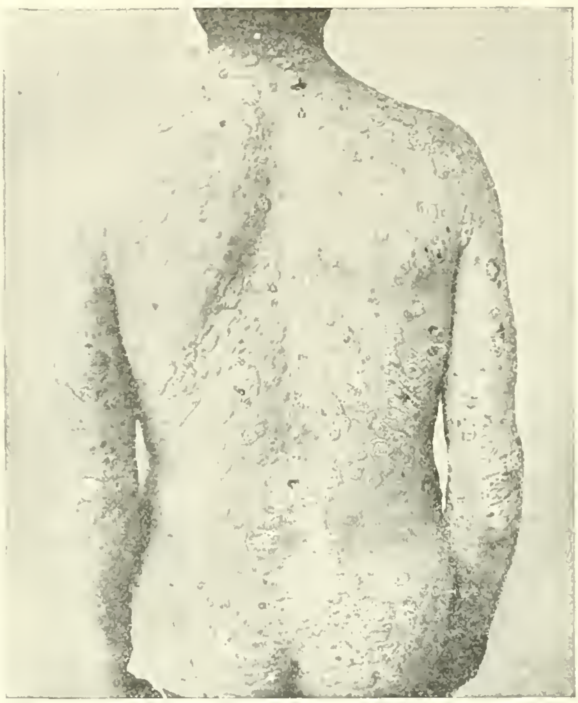

FIG. 3895.—Psoriasis. (From the collection of photographs of skin diseases belonging to Dr. John A. Fordyce, of New York.)

If the scales are allowed to accumulate they form dry, mortar-like masses. In some cases the central parts of the large lesions will remain relatively quiescent for a considerable period of time; the thickening process and the formation of scales being confined to a narrow border (from one-twelfth to one-fourth of an inch wide).

"Punctate hemorrhage" constitutes another and thoroughly characteristic distinguishing feature of the disease. If, in the younger or thinner lesions, the scales are removed down to and including the basal layer, bleeding will take place from a number of isolated spots, not larger than the point of a pin and corresponding to inflamed papillæ, the blood-vessels of which have been torn.

Upon the scalp, when covered with the natural growth of hair, the disease presents an appearance somewhat different from that which it generally does on other parts of the body. There is less infiltration, as a rule, although quite characteristic discs and patches, like those observed on other parts of the body, may occur. The scaling is often excessive, forming piled-up masses of the dry, silvery, papery, and quite easily removable scales. Along the margin of the hairy region, especially on the forehead, there often appears a gyrate band of the disease, one-half of it being located on the hairy surface and the other half on the natural skin surface. Then again, in other cases, the disease develops in the skin of the forehead and extends to a greater or less extent upon the hairy surface of the scalp. In this extended area of the disease the affected skin is red and slightly thickened, and upon it are seated the irrepressible dry, gray scales.

Wherever the disease assumes a somewhat acute character there we may be sure of finding more marked redness and a more rapid formation of scales of varying size, but always of marked thinness.

Although itching is not a characteristic symptom of psoriasis, my records show that it was present in some degree in nearly all my cases. In some of these cases the symptom appeared in connection with an acute outbreak of the disease—either simultaneously with or just preceding the outbreak,—but in others it appeared to be due simply to the accumulation of scales.

While it is generally held that the disease shows a predilection for the regions of the knees and elbows, my own experience does not give any very strong support to this belief. It certainly has a preference for the scalp and for the extensor or thick-skin surfaces, but in a general outbreak the disease respects no limits. In one case, for example, its manifestations were to be seen on practically every part of the surface of the body save the scrotum and feet.

Exfoliative dermatitis may occur as the result of an acute outbreak of psoriasis, the entire skin being involved in the attack. Such an attack is characterized by general redness of the skin (although there may be free or partially free areas) and by the rapid and constant formation and throwing off of paper-like, thin, dry scales; often surprising quantities being exfoliated in a day. The skin is not much thickened, the redness varies from a bright red to a red of a dull lustre, and the inflammatory action is of moderate degree. Itching in some measure may be present. These extensive outbreaks usually subside, thus differing from pityriasis rubra, which ends only with loss of hair and nails, wasting away, involvement of vital organs, and, finally, death.

Psoriasis has been called a disease of the healthy. While this is to some extent true, my observation leads me to amend this statement by saying that the people who have it are in as good average health as their less afflicted fellows, while some of them even deserve the appellation of robust.

I have been unable to trace this disease to heredity, and have seen but slight evidence in favor of the belief that it affects the members of certain families. It develops, according to my experience, in the more vigorous years of life—that is, from infancy to middle age; my cases being mostly adults and under the middle decennium of life. The duration of the disease in these cases has varied from a short time to a period of a few years. Furthermore, males have preponderated over females in the proportion of two to one. On the other hand, it must be remembered that psoriasis is quite a rare disease in this latitude, and that there have been too few cases to justify us in formulating any statistics.

Prosperity and poverty, sobriety and intemperance, cleanliness and filth, seem to exert no appreciable influence in warding off the disease or in favoring its development. These influences, however, when once the disease has become established, may turn its further course toward the better or toward the worse.

The disease does not appear to have any depressing influence upon the general health. Often it constitutes simply a bodily discomfort, with perhaps, in addition, a certain amount of mental worry consequent upon its presence.

Etiology.—As to the cause of psoriasis, we know nothing positively. There are many theories. In some respects the disease behaves as if it were due to germ influence, the manifestations resembling somewhat those of an exaggerated action of the ringworm fungi—as, for example, the peripheral extension, the frequent clearing up at the centre, and the persistent activity at the border. Psoriasis presents a further resemblance to a parasitic disease in the character of its relapses; it being an easy matter to ascribe them to re-infection from small uncured points, such as can always be found on some part of the body.

Course of the Disease.—Recurrences are the rule; often the central parts of the pale patches left after the subsidence of an outbreak are the sites of a new eruption. These relapses often occur immediately or very soon after the subsidence of an acute outbreak. It is probable that a person affected with psoriasis is never absolutely free from the disease after the first onset. I have been able to follow one such case for a period of over ten years—that is, from the time when the patient was only three and a half years of age to that when he was fourteen years old. It is interesting to note that this patient has always been strong and robust and that he has been in no way retarded in his development.

Diagnosis.—The diagnosis of psoriasis should offer little difficulty, if the features already described are kept in mind. In the following paragraphs I will mention briefly the characteristics which should enable the physician to distinguish it from the various affections with which it is most likely to be confounded.

Dry seborrhœa of the scalp shows little if any inflammation or thickening. The scales in this affection are smaller than those observed in psoriasis, and if they are present in a mass the latter is usually more friable; often, too, these scales form sheaths around the hairs at their insertion in the follicles. Removal of the masses of scales may show a reddening beneath and a slight moisture.

Seborrhœic eczema of the scalp usually shows fewer scales; if there are patches they are thinner and slightly moist, and the scales are greasy. When the disease extends from the scalp upon the forehead it may resemble psoriasis, but there is little infiltration, the scales are not dry and papery, and the inflamed surface presents a somewhat more moist appearance.

Syphilis of the scalp may show the so-called corona or frontal extension. The color is, however, of a deeper shade, the infiltration more marked, and the scales are smaller, more adherent, less papery looking and less abundant. Syphilitic patches on the scalp lack the features which have already been described as characteristic of psoriasis.

Ringworm of the scalp is dry, scaly, not infiltrated in any marked degree, has fewer, finer scales, and shows a well marked, not greatly elevated border which bears evidence of slight exudation. The hairs in the patch are broken or lustreless from the growth of the microorganism.

Eczema of the scalp does not occur in the form of sharply limited patches; then, besides, there is a peculiar stiffening and thickening of the parts affected, and there is either a frank, sticky exudation upon the surface or there are points and lines of broken epidermis where the exudation is just beginning to break forth. Upon drying, the exudation assumes the form of gummy, brownish, or yellowish crusts.

Seborrhœic eczema on the body shows scarcely any infiltration, the scales are few and often greasy, and the affected surface has not the absolute dryness of psoriasis.

Syphilitic patches of the dryest form, when located elsewhere than on the scalp, often show a tint of lividity, and they have a less regular shape than the patches of psoriasis; the scales also are smaller and less plentiful, and they are formed at a less rapid rate than in the latter disease.

In none of the diseases enumerated above can the punctate hemorrhage be produced.

When compared with psoriasis even the dryest eczema of the body shows less symmetry of lesions, more thickening, a less well-defined border, fewer scales, and these not like the scales of psoriasis. Furthermore, the patches have a stiffer look and feel, and itching is more marked.

Ringworm of the body shows fewer scales, and less, if any, thickening of the part affected. On the other hand, the lesion has a sharply defined border, which appears to be the seat of an exudative inflammation. At the centre of the lesion the skin is generally found to be nearly free from inflammatory action.

When psoriasis is associated with other morbid conditions of the skin the physician will have to base his diagnosis upon the presence of certain features which are characteristic of this disease.

Prognosis.—The prognosis of psoriasis is unfavorable as regards a cure, and doubtful as regards the removal of the eruption. In all my experience I have seen but one case of psoriasis—at least so diagnosed—in which recovery was perfect; but even in this case it is not perfectly clear that an error in diagnosis may not have been made, for upon reading my notes of the case again at the present time I find that it may possibly have been one of a slightly atypical seborrhœic eczema. Recovery followed the use of treatment administered on the supposition that the case was one of psoriasis. This patient was a woman in good circumstances who died of alcoholism.

It is best to promise a patient with psoriasis nothing more than a certain amount of relief.

Treatment.—The treatment of psoriasis is both external and internal, the former being the more efficacious of the two. Arsenic has been for years the chief reliance in the internal treatment of the disease, it being often pushed to large dosage and continued for long periods of time. Its effects show such a mixture of good and evil that I seriously question whether the benefits of the remedy are not more than offset by its disadvantages. Some people reach the limit of tolerance (conjunctival irritation, puffiness of lids, gastric irritation) very early. If they escape these, they may, under a long-continued use of the drug, acquire other dermatoses scarcely preferable to psoriasis. However, it is well to give arsenic a trial, but only in cases in which there is but a small degree of cutaneous irritation. It is usually employed in the form of Fowler's solution (liquor potass. arsenit.); the dose being, for an adult, five drops after each meal. This dose should be gradually increased (an additional drop at the end of every twenty-four hours) until the limit of tolerance is reached.

Another arsenical preparation is what is called "Asiatic pills," the formula for which is as follows: ℞ Acid. arseniosi, gr. i.; piper nigris, gr. xx.; pil. mas. q.s. M. ft. pil. xx. Sig.: Begin with one after each meal; increase by one every day. As a result of taking these pills, some patients have complained of stomachic irritation which they, quite reasonably, attributed to the black pepper, this irritation preventing in itself the object sought—viz., to obviate irritation by the arsenic.

Iodide of potassium administered in large doses has acquired considerable renown as a means of relief for psoriasis, but my experience with this drug has been of such a discouraging character that I have given it up in the treatment of this disease.

Thyroid extract, in the form of tablets (gr. ij.–x. t. i. d.), has seemed, by actual comparison with other remedies, to be decidedly beneficial; it constitutes, perhaps, our best remedy for use internally in the treatment of psoriasis. This opinion is at variance with that of excel-

Digitized by Microsoft®

lent authorities, but is entirely sustained by my observation. All depends upon obtaining the pure, and therefore not inert, substance. As thyroid extract is capable of inducing depression of the heart's action and possibly dizziness, the dose must be small at first, the effect watched, and it may even be necessary to attempt to neutralize these effects by the administration of strychnine.

www.libtool.com.cn

As is self-evident, the patient's general condition must be kept at its best by such internal treatment as the symptoms may require, just as if there were no psoriasis.

Faithful following of directions as to external treatment, while onerous, must be required. The first requisite is the removal of scales to permit the action of remedies. Naturally, the treatment generally outlined below is to be much modified if the skin is found to be abnormally irritable.

Hot baths at night, in combination with the liberal use of soap, greatly assist in removing the scales. Sapo viridis may be used in full strength for removing scales, or an alcoholic solution (sap. vir., ℥ ij.; alcohol, ℥ i.) may be employed; but any strong soap will do quite as well. As alkalies exert a special effect upon epidermic scales it is easy to understand the beneficial action of soaps in removing them in psoriasis. Hot tar baths or tar well rubbed into the patches before an ordinary hot bath is taken will often be found helpful.

To aid in the removal of accumulated scales from the scalp, it is advisable to apply freely a mixture containing salicylic acid and olive oil in the proportion of one part of the former to eight of the latter. After the mixture has been well rubbed in, it should be allowed to soak into the parts for some time before it is finally washed away. The addition of formalin to this mixture (two and a half minims to each ounce) seems to heighten its beneficial effect. If a milder application is desired, the addition of twenty grains of salicylic acid to one ounce of simple ointment will be found to answer satisfactorily.

In my own experience with the treatment of psoriasis of the scalp, the ammoniate of mercury, preferably in salve form, has proven the most useful remedy. The following are some of the formulæ used: (1) ℞ Hg. ammoniat., ʒ ss.–i.; Ung. simp. (seu. Ung. aq. ros.), ℥ i. M. Rub well in at night. (2) ℞ Ung. hg. ammon., ol. oliv., āā ℥ ss. M. Sig.: Use at night. If there is not much irritation, Ung. hg. ammon. (U. S. P.) may also be used.

These mercurial preparations can be employed only on a limited portion of the general cutaneous surface, as there is always some risk of inducing salivation if the drug is too extensively applied.

I have used the following, but it produced slight ptyalism: ℞ Hg. ammon., gr. xl.; acid. salicyl., ʒ i.; Ung. zn. ox., ℥ i. M. Sig.: Apply well morning and night. This ointment may be considered perfectly safe if it is applied over a limited area.

When there is a more general involvement of the skin, chrysarobin in salve form is the best local remedy. Chrysophanic acid is much weaker in its action, and I have abandoned its use. Chrysarobin usually exerts its best action when its characteristic dermatitis is produced. Under its action the skin becomes deep red, almost lilac in color, hot, and itches. The subsiding, clearing patches stand out as gray-white and uninflamed upon this reddened surface. The proneness of chrysarobin to cause irritation precludes its use on the scalp or face, for fear that this irritation may involve the eyes.

The most useful salve is the following: ℞ Chrysarobin, ʒ ss.–ij.; Ung. zn. ox., ℥ i. M. Sig.: Rub well in patches freed of scales at night—leave some on. To this may be added acid. salicylic., ʒ ss.–i., which often increases its effect.

The varnishes so frequently employed in affections of the skin seem to interfere with the action of the drugs contained, but occasionally a varnish containing chrysophanic acid has proved somewhat beneficial in the treatment of psoriasis.

The following formulæ have been found useful: (1) ℞ Chrysarobin., gr. xv.–ʒ i.; liq. gutt. perchæ, ℥ i. M. Sig.: Shake. Paint on patches freed of scales. (2) ℞ Acid. chrysophanic., ʒ i.; collodii flex., ℥ i. M. Sig.: Paint on. (3) ℞ Chrysarobin., ʒ i.; collodii, ℥ i. M.

Lanolin, when used as the base, makes a more adhesive ointment, but the zinc oxide salve seems to prevent severe irritation. It is customary to suspend the chrysarobin treatment upon the appearance of marked dermatitis, but if this is not severe the use of the drug may be continued. To relieve this dermatitis, one of the following preparations may be employed after suspending the chrysarobin: (1) ℞ Zn. ox. pulv., ʒ iv.; phenol. (ninety-five per cent.), ʒ i.; amyli pulv., ʒ ij.; aq., ℥ iv. M. Sig.: Shake; apply often. (2) ℞ Zn. ox. pulv., ʒ ij.; amyli pulv., ʒ i.; ol. oliv., ℥ ij. M. Sig.: Shake; apply.

Pyrogallic acid at one time was considered a good second to chrysarobin as regards its efficacy in the treatment of psoriasis; and it may still be found an efficient remedy. The following is a suitable form in which it may be employed: ℞ Acid. pyrogallic., ʒ ss.–ij.; Ung. zn. ox., ℥ i. M. Sig.: Use in the same manner as the chrysarobin ointment, and in those cases in which the chrysarobin ointment proves too irritating.

The tar preparations have proven useful in some cases, especially where the skin will not bear stronger treatment. The following are convenient formulæ: (1) ℞ Ol. cadenii, ʒ ij.; acid. pyrogallic., ʒ i.; ether. sulphuric., alcohol. āā ℥ i. M. Sig.: Apply night and morning. (2) ℞ Picis liq., ʒ i.–ij.; Ung. zn. ox., Ung. diachyli., āā ℥ ss. (or omit the diachylon). M. Sig.: Rub well in once or twice a day. Leave on. (3) ℞ Picis liquid., ʒ iij.–iv.; acid. salicyl., ʒ i.; Ung. zn. ox., ℥ iv. M. Sig.: Apply in the usual manner.

In the employment of these different remedial procedures it is well to remember that a lotion must be re-applied so often that the parts will be kept constantly covered with the fluid; that a varnish must be re-applied as soon as it peels off; that a salve must be well rubbed in, and a sufficient quantity must always be left on to keep the drugs in continuous action upon the skin; and, finally, that soap and baths and other scale-removing measures must be employed often enough for the attainment of the object desired. Then, when all this has been done, the patient will probably still have some psoriasis, or a new attack will supersede the old one, and the only certain hope of an end to the disease is such as is offered by his decease.

M. B. Hutchins.

PTERYGIUM. See *Conjunctiva, Diseases of.*

PTOMAÏNS.—Ptomaïns are basic, nitrogenous organic substances produced by bacteria.

The first writer to suggest the probability of the formation of a poison coming within the above definition during putrefaction seems to have been Kastner (*Arch. f. gesam. Naturlehre*, 1824, Bd. i., 448, 488; Bd. ii., 499), who advanced the hypothesis that poisonous sausages contained an "alkaloid of decay" (*Moderalkaloid*) combined with an organic acid.

In 1852 Schlossberger, in an extended paper upon the sausage poison (*Arch. f. physiol. Heilk.*, Ergänzhft., 1852) supposed "the poisonous substances occurring in sausages and cheese to be organic bases, which have their origin in the decomposition of the protein materials rich in nitrogen, under certain conditions." He supported this hypothesis by the following observations: (1) When ammonia is produced in considerable amount by the decomposition of animal or vegetable substances, it is accompanied by volatile bases; (2) by the action of dilute potash upon poisonous sausages, much ammonia, accompanied by a peculiar repulsive odor, is given off; (3) the physiological action of the putrid poison is very similar to those of the known volatile alkaloids nicotin, coniïn, sparteïn, and to those of the artificial amid, imid, and nitril bases of Hofmann; (4) one of these bases, trimethylamin, is contained in herring pickle.

Four years later (1856) Panum was probably the first to obtain a ptomaïn, although in an impure condition, and to demonstrate that the putrid poison is a chemical

Digitized by Microsoft®

substance and not a living organism ("Bibl. for Laeger.," 1856; *Schmidt's Jahrb.*, 1859, ci., 213, *Arch. f. path. Anat.*, 1874, lx., 328–352). This substance was described by Panum as being soluble in water, from which it was precipitable by alcohol; capable of extraction from putrid meat, and not identical with any of the known odorous products of putrefaction. It is capable of withstanding a boiling temperature, evaporation, and the influence of absolute alcohol, conditions inconsistent with the presence of organized life.

www.libtool.com.cn

In 1866 Bence Jones and Dupré obtained from animal matters a substance which they called "animal chinoidine," which gave precipitates with the general reagents for the alkaloids then known, and whose solution exhibited a blue fluorescence (*Med. Times and Gaz.*, 1866, 163). In 1868 Bergmann and Schmiedeberg obtained from putrid blood a small quantity of a crystalline substance, which was poisonous to dogs and to frogs, and to which the name "sepsine" was applied (*Med. Centralbl.*, 1869, 497). In 1869 Zuelzer and Sonnenschein obtained from cadavers a crystalline substance having physiological actions resembling those of atropin (*Berl. klin. Wochenschr.*, 1869, vi., 121).

Between 1872 and 1878 Selmi published an extended series of observations upon the reactions and properties of putrid products, without, however, having determined their chemical composition, and in 1875 proposed the name "ptomaïn," written by some recent German authors, "ptomatine," derived from the Greek, πτῶμα, *i.e.*, that which is fallen; a corpse. The contributions of Selmi and his Italian followers—Mortigia and Battistini, Trottarelli, Raffaele, Ziino, Albertoni and Lussana, Paterno, Spica, Brugnatelli and Zenoni, Bocci, Guareschi and Mosso, and Monari—have been numerous and important. It remained, however, for Nencki and his pupil Brieger to determine the chemical character of these compounds. The former was the first to establish the composition of a ptomaïn by the analysis of a base having the formula $C_8H_{11}N$, probably α-phenyl-ethylamin, in 1876. The latter, in the most important researches upon the chemistry of the ptomaïns ("Ueber Ptomaine," i., 1885; ii., 1885; iii., 1886; *Berl. klin. Wochenschr.*, 1890, xxvii., 241, 267, 1133), established the constitution of a number of the putrid bases.

The ptomaïns have been, and still are, frequently referred to as "animal alkaloids," a designation which is misleading and improper for two reasons: They are not necessarily produced from animal substances, but many are formed by putrefaction of vegetable proteins; nor are they usually the products of animal metabolism, as are their relatives, the leucomaïns. Only a few of them are known to be alkaloids in the present acceptation of the term, *i.e.*, basic substances derived from heterocyclic nuclei containing but one nitrogen atom in any nucleus. The great majority, and those best known, are of much simpler molecular structure, and are monamins, diamins, guanidins, hydramins, betaïns, or amido-acids. It will be observed, therefore, that the designation "ptomaïn" applies, not to the individuals of a distinct class of chemical compounds, but rather to the bacterial origin of members of several different chemical functions, which may also be produced by synthetic methods, having in common only the two qualities that they contain nitrogen and are basic. Strict regard for the derivation of the name would limit its applicability to ptomaïns produced by saprophytic bacteria, either outside of the living body or within it, as in intestinal putrefaction or in gangrene; but it is now applied also to the basic products of parasitic bacteria, the "toxins" of Brieger.

Some of the ptomaïns, as the diamins and the lower terms of the monamin series, are either non-poisonous or poisonous only in very large doses. Others, and notably those formed by pathogenic bacteria, are actively poisonous. When it had been found that pathogenic bacteria produced in culture media and in the living body definite basic substances, such as Brieger's tetanin, which, when injected into animals, produced symptoms similar to those caused by the bacteria themselves, it was inferred that the manifestations of the disease were caused by these ptomaïns. It has been shown, however, that the basic substances obtained from cultures of the tetanus bacilli, for example, are vastly inferior in toxic potency to the bacteria-free cultures themselves. The inference is plain that the bacteria produce other substances more actively toxic than the ptomaïns, and it is now considered as proven that the basic bacterial products play but a secondary part in the production of the manifestations of disease caused by bacteria, while these other substances, the "toxins," concerning whose chemistry but little is known, beyond the facts that they are non-basic, and that some are possibly proteins, while others are certainly not, are the essential bacterial poisons.

While the toxins are in all probability synthetic products, the ptomaïns are undoubtedly decomposition products derived from the proteins or from complex phosphorus-containing organic substances, either by simple cleavage or by hydrolysis, and many of them are thus produced from the parent substances by agencies other than bacterial life. Cholin is thus produced from the lecithins by hydrolysis by barium hydroxid; the amido acids and indole and skatole are similarly formed from the proteins; the pyridin bases are found in oil of Dippel, produced by the dry distillation of bones; and arginin, the most abundant of the hexon bases, formed by the action of hydrochloric acid and tin chlorid upon the proteins, yields putrescin on further decomposition.

As the process of putrefaction is a gradual and progressive one, different basic products are produced at different stages, and bases obtainable in considerable amount during the first days of putrefaction will have more or less completely disappeared at a later stage, when other bases, not previously present, will have made their appearance. The nature of the bases (as well as of other products) produced varies also with those conditions which modify the progress and nature of putrefactive changes, viz.: (1) The kind of bacteria, particularly whether aërobic or anaërobic, and, consequently, the access or non-access of air; (2) the nature of the protein undergoing decomposition; (3) the temperature; (4) the degree of moisture. It is also probable that in cadaveric putrefaction the nature of the ptomaïns produced is influenced by the results of the simultaneous changes which the carbohydrate and fatty constituents undergo; as, for example, in the formation of adipocere.

As the ptomaïns represent several different classes of chemical compounds, no general characters other than those above indicated can be ascribed to them. Nor can it be expected that they should exhibit any qualities or reactions which could serve to distinguish them as a class from other compounds.

Although the chemical constitution of many of the ptomaïns remains to be determined, that of quite a number has been established, sufficient to warrant their classification, so far as possible, according to chemical function. Such a classification is here attempted.

MONAMINS.—*Methylamin*, $CH_3.NH_2$, and *dimethylamin*, $(CH_3)_2:NH$, gases, and *trimethylamin* $(CH_3)_3:\,:N$, a liquid, boiling point 9°, have long been known to exist in herring brine, and together constitute the greater part of the commercial "trimethylamin," prepared by distillation of beet sugar vinasse. They are also formed during the decomposition of fish and of a number of other animal and vegetable substances. Trimethylamin occurs naturally in, or is easily liberated from, cod-liver oil, ergot, chenopodium, yeast, guano, human urine, the blood of the calf, and many flowers. It probably originates from the decomposition of cholin (see below), from which it may be obtained, along with glycol, by the action of caustic potash: $CH_2OH.CH_2N:\,:(OH)(CH_3)_3 = CH_2OH.CH_2OH + N(CH_3)_3$. All three of these bases have the odor of stale fish, are very soluble in water, forming strongly alkaline solutions of hydroxids, and soluble, deliquescent hydrochlorids. Each forms a platinochlorid, easily soluble in hot but sparingly soluble in cold water, and a readily soluble aurochlorid. They are practically non-poisonous.

Digitized by Microsoft®

Ethylamin, $C_2H_5.NH_2$, *diethylamin* $(C_2H_5)_2$: NH, and *triethylamin* $(C_2H_5)_3N$, are strongly alkaline, oily liquids, boiling points, 18°, 56°, 89°, which accompany the methylamins in herring pickle, beet-sugar vinasse, and the products of putrid fish, yeast, and gluten. Their hydrochlorids and platinochlorids are easily soluble in water. They are practically non-poisonous.

www.libtool.com.cn

Propylamin, probably the iso-compound $(CH_3)_2:CH.NH_2$, boiling point 32°, *butylamin* (iso?), $(CH_3)_2:CH.CH_2.NH_2$, boiling point 68°, *iso-amylamin*, $(CH_3)_2:CH.CH_2.CH_2.NH_2$, boiling point 95°, and a *hexylamin* $(CH_3)_2:CH.(CH_2)_3.NH_2$, are colorless, strongly alkaline liquids occurring in cod-liver oil, beet-sugar vinasse, and decomposing yeast. The amyl compound is actively poisonous.

Nencki's base, $C_8H_{11}N$, obtained from a mixture of pancreas and gelatin after five days' putrefaction at 40°, seems to have been β-phenyl-ethylamin, $C_6H_5.CH_2.CH_2.NH_2$, boiling point 197°. The free base is oily, has a peculiar, not disagreeable odor, absorbs carbon dioxid from the air to form a crystalline carbonate, and forms a sparingly soluble platinochlorid, crystallizing in long flat prisms. Its aurochlorid is a yellow oil, which is rapidly decomposed by reduction. A base, probably identical with this, is formed by decomposition of β-phenyl-α-amido propionic acid, or phenyl alanin, $C_6H_5.CH_2.CH(NH_2).COOH$, itself a product of putrefaction (see below).

Mydin, $C_8H_{11}NO$, is a base obtained by Brieger from human cadaveric matter which had been in putrefaction four months at a temperature from + 5° to − 9° in closed vessels. The free base is strongly alkaline, has an ammoniacal odor, and is a strong reducing agent, and therefore forms no stable aurochlorid. Its platinochlorid is very soluble. This base is believed to be β-oxyphenylethylamin, $HO.C_6H_4.CH_2.CH_2.NH_2$, derived from the decomposition of tyrosin, which is p-oxyphenyl-alanin, $HO.C_6H_4.CH_2.CH(NH_2).COOH$, by loss of CO_2.

Diamins.—*Tetramethylenediamin*, $H_2N.CH_2.CH_2.CH_2.CH_2.NH_2$; *putrescin*—is one of several diamins which were found by Brieger to be products of putrefaction. It is formed, along with penta- and hexamethylenediamin, during the putrefaction of fish, muscular tissue, gelatin, and other animal tissues, appearing about the third day and increasing in quantity for two to three weeks. It is found in the urine and fæces in cystinuria, in amounts proportionate to the quantity of cystin eliminated (diaminuria), and also in cholera stools. Putrescin has been shown to be a diamin, and to be identical with the tetramethylenediamin synthetically prepared by Ladenburg's method, although with methyl iodid it yields only a tetramethylated derivative, but no hexamethylated derivative. The origin of putrescin from the proteins occurs through the hexon base arginin (δ-guanidin-α-amido valerianic acid: $HN:(NH_2):C.NH.CH_2.CH_2.CH_2.CH(NH_2).COOH$, which is formed from the proteins by tryptic digestion. Arginin is split by hydrolysis into urea and ornithin (δ-α-diamido valerianic acid), and ornithin has in turn been converted into putrescin, by loss of carbon dioxid, by bacterial action: $CH_2(NH_2).CH_2.CH_2.CH(NH_2).COOH = H_2N.CH_2.CH_2.CH_2.CH_2.NH_2 + CO_2$. Putrescin and other diamins may be separated from most other substances by taking advantage of the formation of the insoluble dibenzoyl compounds which they form with benzoyl chlorid in presence of alkalies; a property which they share with polyatomic alcohols and aldo- and keto-alcohols. Its dibenzoyl compound crystallizes in plates or needles, difficultly soluble in alcohol, insoluble in water.

The free base is a clear, rather thin liquid, boiling point 156°–157°, having a disagreeable, seminal odor, strongly alkaline, and absorbing carbon dioxid from the air. Its hydrochlorid crystallizes in colorless needles, soluble in water, insoluble in absolute alcohol, not hygroscopic. Its platinochlorid and aurochlorid both form hexagonal plates, difficultly soluble in cold, more soluble in hot water. Its picrate crystallizes in needles, sparingly soluble in water or in cold alcohol, soluble in hot alcohol. It is practically non-poisonous.

Pentamethylenediamin, $H_2N.(CH_2)_5.NH_2$, *cadaverin*, is another diamin found by Brieger to accompany putrescin as a product of putrefaction of muscular tissue, heart, lung, liver, and other animal protein material, from the third day to four months. It also accompanies putrescin in the urine and fæces in cystinuria, and in cholera stools. It has been found in the intestinal contents in a case of intestinal fistula, and is probably a normal product of tryptic digestion, although it is not found in normal fæces. It has been shown to be identical with the normal pentamethylenediamin (formula above) prepared by Ladenburg's method. Cadaverin originates through the hexon base, lysin (probably α-ϵ-diamido caproic acid, $CH_2(NH_2).(CH_2)_3.CH(NH_2).COOH$, from which it is produced by putrefaction, as putrescin is formed from arginin. Cadaverin is a thick, transparent liquid, having a very disagreeable odor, somewhat resembling that of coniïn; boils at 175°; fumes, and absorbs carbon dioxid rapidly when exposed to air, being converted into a crystalline compound. With methyl iodid it forms a dimethylated derivative. Its hydrochlorid is crystalline, deliquescent, readily soluble in water and in dilute alcohol, but insoluble in absolute alcohol and in ether. On dry distillation it splits off hydrochloric acid and ammonium chlorid and forms piperidin: $C_5H_{14}N_2.2HCl = HCl + NH_4Cl + C_5H_{11}N$, an instance of the pyrogenic origin of a cyclic from an acyclic compound, of an alkaloid from an amin. Its platinochlorid forms needles or short rhombic prisms, soluble in alcohol, difficultly soluble in water. Its aurochlorid crystallizes in cubes, needles, or plates, easily soluble in water. Its picrate forms plates, soluble in hot water, sparingly soluble in cold water or in alcohol. Its dibenzoyl compound crystallizes in needles, soluble in alcohol, insoluble in water. With potassium chromate and sulfuric acid it gives a reddish-brown, evanescent precipitate. It is practically non-poisonous.

Neuridin, $H_2N.(C_5H_{10}).NH_2$, another of Brieger's diamins, is isomeric with cadaverin, but of unknown constitution. When heated with caustic potash it yields dimethylamin and trimethylamin, a decomposition which shows it to be not identical with amylamin, with which it is also isomeric. Indeed, there are twelve possible isomeres of this amin. Neuridin is produced, along with cholin, during the first stages of putrefaction, particularly of gelatinoid substances, and increases in quantity as putrefaction advances, while the quantity of cholin diminishes. It is no longer present after fourteen days. The free base is gelatinous, and decomposes even during evaporation of its solution. It has a disagreeable, spermatic odor, and is insoluble in absolute alcohol and in ether, difficultly soluble in amylic alcohol, readily soluble in water. It forms white precipitates with mercuric chlorid and with neutral and basic lead acetate. Its hydrochlorid crystallizes in long needles, and is very soluble in water, insoluble in alcohol, ether, chloroform, petroleum-ether, benzene, or amylic alcohol, except in presence of other animal substances, when it dissolves in the immiscible solvents mentioned. Its platinochlorid forms flat needles, soluble in water, insoluble in alcohol. Its aurochlorid crystallizes in short needles, difficultly soluble in cold water. Its picrate forms needles, almost insoluble in water, sparingly soluble in alcohol. When pure it is non-poisonous.

Saprin is another diamin, formed along with putrescin, cadaverin, and mydaleïn, during the putrefaction of glandular tissues. Brieger assigned to it the formula $C_5H_{16}N_2$, but it is now believed to be isomeric with cadaverin and neuridin, $C_5H_{14}N_2$. It is distinguished from cadaverin by the greater solubility and different crystalline form of its platinochlorid, by the absence of an aurochlorid, by the permanence of its hydrochlorid in air, and by its failure to give the reaction with potassium chromate and sulfuric acid. It is non-poisonous.

Hexamethylenediamin, $H_2N.(CH_2)_6.NH_2$, is formed during putrefaction of muscular tissue and pancreas. It

Digitized by Microsoft®

is a crystalline solid, fusing at 40° and boiling at 195°. Its platinochlorid forms rhombic needles, soluble in water, sparingly soluble in alcohol.

Brieger's base, $C_2H_8N_2$, isomeric but not identical with ethylenediamin, $H_2N.(CH_2)_2.NH_2$, and supposed to be *ethylidenediamin*, $CH_3.CH(NH_2)_2$, was obtained from putrefying fish. Its hydrochlorid crystallizes in long, brilliant needles, easily soluble in water, insoluble in absolute alcohol. It does not form an aurochlorid. Its platinochlorid crystallizes in small scales, sparingly soluble in water. This base, administered hypodermically in small quantity to mice and guinea-pigs, produces in a short time increased secretion of the nasal mucus, saliva, and tears, which are subsequently temporarily arrested, to begin again later. The pupils are dilated and the globes protruded. There is marked dyspnœa, which continues until the death of the animal, within twenty-four hours.

Another base was obtained by Brieger in very small quantity from cultures of the comma bacillus, which may possibly be *trimethylenediamin*, $H_2N.(CH_2)_3.NH_2$.

Mydalein was obtained by Brieger in small quantity after seven days' exposure to air of putrefying viscera, and increased in amount up to three weeks. The amount obtained was insufficient to determine its composition further than that its platinochlorid contained Pt 38.74, C 10.83, H 3.23 per cent., from which the inference is drawn that it is a diamin, probably containing four or five carbon atoms. Its hydrochlorid crystallizes with great difficulty, and is very hygroscopic. Its platinochlorid forms needles, very soluble in water.

This base is actively poisonous. In small doses in rabbits and guinea-pigs it causes greatly increased nasal and lachrymal secretion, dilatation and insensibility of the pupils, increased body temperature, acceleration of respiration and cardiac action, a tendency to sleep, and increased peristalsis. With larger doses (less than 0.005 gm.) the increased secretions become very profuse, the pupils are widely dilated, and the eyes protruded. The animal falls, the posterior extremities being first paralyzed, then the anterior, and there occur fibrillar spasms of various groups of muscles. Sometimes the animal springs up and immediately falls, making faint movements of the legs. The respiration, at first very frequent, becomes slow and labored. The body temperature diminishes gradually, the movements become more and more faint, and the animal dies in a condition of sopor. The heart is arrested in diastole, and the intestines and bladder are found contracted after death.

Spermin, $C_2H_5N(?)$, a base of uncertain composition, but probably an imin, has been obtained from semen, testicles, ovaries, thyroid, pancreas, and spleen, and from cultures of the comma bacillus. Its phosphate forms crystals, known as Leyden, Böttcher's, or Charcot's crystals, which are met with in anatomical preparations preserved in alcohol, in dried semen, in sputa and nasal secretions, in the blood, spleen, and other organs of leucocythæmics and anæmics, and in fæces. These crystals are insoluble in alcohol, ether, or chloroform, difficultly soluble in water, easily soluble in dilute acids or alkalies. The free base forms crystals, which rapidly absorb carbon dioxid from the air, are readily soluble in water and in alcohol, insoluble in ether, and strongly alkaline in reaction. Its hydrochlorid crystallizes in hexagonal prisms, very soluble in water, insoluble in absolute alcohol or ether. Its platinochlorid crystallizes in plates, its aurochlorid in prisms. It is non-poisonous.

TRIAMINS.—Guanidin or carbotriamin, $HN:C:(NH_2)_2$, is formed by oxidation of guanin, but is not a ptomaïn. Its methyl derivative, *Methyl-guanidin* or *methyl-uramin*, $HN:C:(NH_2)(NH.CH_3)$, which is a product of oxidation of creatin and of creatinin, was obtained by Brieger from horseflesh which had undergone putrefaction at a low temperature and without exposure to air for four months, and it has since been obtained from the cultures of several species of bacilli. It is undoubtedly derived from creatin, to which it is closely related. It is a colorless, imperfectly crystalline, highly hygroscopic and strongly alkaline base. Its hydrochlorid crystallizes in prisms, insoluble in alcohol. Its platinochlorid forms very soluble needles. Its aurochlorid crystallizes in short rhombic prisms, soluble in ether, sparingly soluble in water and in alcohol. Its picrate crystallizes in needles, sparingly soluble in water, which fuse at 192°.

In guinea-pigs methylguanidin causes copious diarrhœa and increased secretion of urine. The pupils are dilated and insensible to light. The animal remains in one position, even when irritated, but soon becomes restless and seeks to move the anterior extremities, while the posterior are paralyzed. The respiration becomes progressively deeper and more labored, and there is marked dyspnœa. The legs become paralyzed, and the animal falls on its side and dies, after short, general clonic convulsions. After death the heart is found in diastole the intestine filled with fluid, the bladder contracted, the cortical portion of the kidneys hyperæmic, and the papillary portion pale.

HYDRAMINS (*Oxyamins*).—These are derivatives of the dihydric alcohols, retaining one hydroxyl, and containing one amido group, more or less modified by substitution. The ptomaïns of this class are trimethylated quarternary ammonium hydroxids.

Cholin, $(CH_2OH).CH_2.N::(CH_3)_3(OH)$, *trimethyloxethylammonium hydroxid*, was originally obtained by Strecker from ox bile in 1849, and was subsequently shown by Diakonow to be derived from the lecithins, which, when hydrolyzed, yield cholin, phosphoglyceric acid, and fatty acids. It is now known to be very widely distributed in both animal and vegetable organisms, and it is one of the first of the ptomaïns to be produced by a number of bacteria, having its origin undoubtedly in the decomposition of the lecithins, which occur in almost all animal tissues, and are very prone to decomposition. As putrefaction advances, cholin gradually disappears, partly by conversion into neurin, or possibly into muscarin, and partly by more complete decomposition, with formation of trimethylamin, until after seven days it is no longer present. Cholin is a syrupy, highly alkaline liquid soluble in all proportions in water, which absorbs carbon dioxid rapidly from air, with formation of a crystalline carbonate. Its chlorid forms highly deliquescent needles, very soluble in water and in alcohol, insoluble in ether, chloroform, or benzene. Its platinochlorid crystallizes in prisms or in plates, readily soluble in water, insoluble in alcohol or ether. Its aurochlorid crystallizes in prisms, soluble in hot water or in alcohol, almost insoluble in cold water. Its picrate forms needles, soluble in water and in alcohol. It is not poisonous except in large doses, when it produces effects similar to those of muscarin.

Neurin, $CH_2:CH.N::(CH_3)_3(OH)$, *trimethylvinylammonium hydroxid*, an unsaturated compound, differing from cholin by H_2O less, was obtained by Liebreich from protagon, and has been obtained from brain tissue and suprarenal capsule, and by the action of boiling baryta water upon cholin. It was found by Brieger, along with neuridin, in the products of putrefaction of horseflesh for five or six days at the temperature of incubation. It may originate by dehydration of cholin or by decomposition of lecithins, in whose constitution it replaces cholin, the existence of which is probable. The free base is a syrupy, highly alkaline liquid, soluble in water in all proportions, and decomposed by boiling of its aqueous solution, with liberation of trimethylamin. Its chlorid crystallizes in needles, hygroscopic, and very soluble in water and in alcohol. Its platinochlorid forms octahedra, almost insoluble in water. Its aurochlorid crystallizes in prisms, difficultly soluble in water. Its picrate forms long needles, sparingly soluble in water and in alcohol.

It is actively poisonous, producing effects resembling those of muscarin. When administered to rabbits it causes movements of mastication, accompanied by profuse secretion of saliva, which is at first thick and viscid, then thin and alkaline. The increased secretion of saliva continues until the terminaton of the poisoning, and varies

Digitized by Microsoft®

in degree with the magnitude of the dose. Subsequently there is increased secretion from the Schneiderian mucous membrane and the lachrymal glands, the latter of short duration. The respiratory movements are at first more frequent and deeper than normal; the extraordinary respiratory muscles are brought into action, the head is thrown back, and the nostrils are dilated. These symptoms of dyspnœa alter in character as death approaches, in that the movements become irregular, superficial, and less frequent. The heart's action immediately after the injection is accelerated, so that the pulse cannot be counted; in a short time it becomes slower, and diminishes constantly in frequency. The pulsations are at first very strong, but subsequently become progressively weaker until the heart is arrested in complete diastole. The heart's action continues after cessation of respiration. Section of the vagi has no influence, and the heart responds to artificial stimuli. Occasionally contraction of the pupils occurs, an effect which almost always follows an application of a strong solution of the poison to the eye. Powerful peristalsis is an early symptom, causing an uninterrupted voiding of matters, at first consistent, subsequently watery. Ejaculation and dripping of urine also occur. If the abdomen be opened at this stage, tetanic contractions of greater or lesser portions of the intestine are seen. The spleen is also strongly contracted. Only when lethal doses are given do strong clonic convulsions occur, in which the animal soon dies. These convulsions are partially controlled by artificial respiration, but they soon recur. Locomotion is interfered with, the posterior extremities being first paralyzed, then the anterior, before the beginning of the convulsions. In cats there is an increased secretion of alkaline perspiration. Atropin is a powerful antidote; but atropinized animals are still subject to the action of the poison. When taken by the mouth this alkaloid produces the same effects as when administered hypodermically, but ten times the dose is required.

Muscarin (?), $C_5H_{15}NO_3$, a base having the above composition, and corresponding in physiological action to the muscarin which occurs in toadstools (agaricus, boletus, amanita), was obtained by Brieger from putrefying fish. It forms a deliquescent, difficultly crystallizable chlorid; a platinochlorid which crystallizes in sparingly soluble octahedra; and an aurochlorid which forms needles, also difficultly soluble in water. It is not certain that this base is identical with the muscarin of fungi, or that either is identical with the "synthetic muscarin" obtained by oxidation of cholin. The last named undoubtedly has the constitution sometimes assigned to oxycholin, and expressed by the formula $CH_2OH.CHOH.N::(CH_3)_3(OH)$, from its derivation from cholin: $CH_2OH.CH_2.N::(CH_3)_3(OH)$.

Brieger's ptomaïn, administered in very small quantities to frogs, causes total paralysis, and arrest of the heart in diastole. The administration of atropin to frogs under the influence of this base revives the action of the heart, and the effects of the ptomaïn are not observed in atropinized animals. Minute doses, administered to rabbits, cause greatly increased salivary and lachrymal secretions, contraction of the pupils, profuse diarrhœa, ejaculation, voiding of urine, and death after convulsions of short duration.

BETAÏNS.—These compounds, closely related to the hydramins, are anhydrids, or, more properly, lactams, derived from acids corresponding to the hydramins, such as $(COOH).CH_2.N::(CH_3)_3(OH)$ (see cholin), by elimination of H from COOH and OH from the ammonium hydroxid group. Thus:

Betaïn or *trimethylacetic betaïn*— $\begin{array}{l} COO \\ | \quad \diagdown \\ CH_2.N:.(CH_3)_3 \end{array}$, is ranked as a ptomaïn because of its occurrence in fresh poisonous muscles (which undoubtedly owe their toxicity to bacterial action) and among the products of putrefying gluten. It was first obtained from beet root (whence its name), and also exists in malt, in cotton seed, and in a number of other vegetables; and is formed by several synthetic methods, as by the interaction of monochloracetic acid and trimethylamin.

It forms large, deliquescent crystals, with one molecule of water of crystallization, very soluble in water and alcohol. It is strongly basic and forms crystalline salts. Heat decomposes it, with evolution of trimethylamin. Its chlorid forms non-deliquescent plates, insoluble in absolute alcohol. Its platinochlorid forms soluble prisms; and its aurochlorid sparingly soluble plates or needles. It is non-poisonous.

Mydatoxin, $C_6H_{13}NO_2$, which may be *trimethylpropionic betaïn*, $\begin{array}{l} COO \\ | \qquad \diagdown \\ CH_2.CH_2.N:.(CH_3)_3 \end{array}$, or the corresponding iso-compound, was obtained by Brieger from decomposing horse-flesh under the same conditions as mydin. The free base is a strongly alkaline syrup, which crystallizes *in vacuo*, insoluble in alcohol and ether, decomposed by distillation. Its chlorid is a thin, colorless syrup, which forms no double salt with auric chlorid, and with platinic chlorid a very soluble double salt which fuses and is decomposed at 193°.

Mydatoxin is not very actively poisonous. Administered subcutaneously to guinea-pigs, the chlorid of this base causes increase in the frequency of the respiration; at first contraction, and later dilatation and insensibility, of the pupils; and diminution of temperature with short chills. Clonic convulsions, frequently of such intensity that the animal is involuntarily projected forward, recur at short intervals. The secretions of the salivary and lachrymal glands become more abundant. The body temperature falls, and the respiration becomes less frequent. The ears, at first injected, become pale and cold. The extremities are paralyzed. The cardiac action becomes irregular and less frequent. Convulsions are provoked by striking upon the table supporting the animal. Shortly before death the convulsions become less strong, the extremities are extended, the animal falls upon its side and dies. After death the heart is found arrested in diastole, the intestines are strongly contracted, and the bladder is empty and contracted.

Mytilitoxin $C_6H_{15}NO_2$, a base of undetermined constitution but also possibly a betaïn, was obtained by Brieger from the poisonous mussels which caused the poisonings at Wilhelmshaven. The free base has a disagreeable odor which it loses on exposure to air and at the same time becomes non-poisonous. It is decomposed by heating with caustic potash. Its chlorid crystallizes in tetrahedra and is intensely poisonous, causing the same symptoms as do the mussels (see Vol. IV., p. 189). The aurochlorid crystallizes in microscopic cubes which fuse at 182°.

AMIDO ACIDS.—The amido acids, formed by substitution of one or more amido groups (NH_2) for hydrogen in the hydrocarbon groups of other acids, are not usually considered as ptomaïns, probably because they were known as products of the decomposition of proteins, by putrefaction or otherwise, long before Selmi suggested the name "ptomaïn" for substances which he considered to be alkaloidal. Thus tyrosin was found to be a product of decomposition of casein by Liebig in 1846; and Proust discovered leucin as a product of putrefaction of gluten and of cheese in 1819. But these bodies contain nitrogen, and although they are acids by virtue of their carboxyl groups (COOH), they are also distinctly basic, by virtue of their amido groups. They therefore come within the limitations of the class of ptomaïns as given above. Among the diamido acids are included substances, such as lysin and ornithin, and among their guanidin derivatives substances, such as arginin and probably histidin, which, although not ptomaïns, so far as is known, are products of the earlier steps in the decomposition of the proteins, and intermediate in the generation of some, at least, of the ptomaïns.

The amido acids of the acetic series may be obtained synthetically, either by the action of ammonia upon the monochloro derivatives of the acids, or by the action of nascent hydrogen upon the cyano derivatives, as well as

www.libtool.com.cn
Digitized by Microsoft®

by other methods. Thus glycocoll, or amido-acetic acid, may be derived from monochloracetic acid: $CH_2Cl.COOH + NH_3 = CH_2(NH_2).COOH + HCl$, or from cyanoformic acid: $CN.COOH + 2H_2 = CH_2(NH_2).COOH$. They appear to be practically non poisonous.

Deltaamido-n-valerianic acid, $CH_2(NH_2).(CH_2)_3.COOH$, one of the butalanins (Salkowski's base), is the lowest term of the series which is known to be a putrid product, and is formed by decomposition of fibrin and of muscular tissue. It is a solid, fusing point 156°, very soluble in water. Its hydrochlorid crystallizes in stellate bundles, and is very soluble in water and in alcohol. Its platinochlorid is soluble in hot water, difficultly soluble in cold water and in alcohol. It is not identical with the amido-valerianic acid obtained by Gorup-Besanez from ox pancreas, or produced synthetically from monochloro-valerianic acid, as it does not form precipitates with ammoniacal silver nitrate or with cupric acetate.

Inactive-a-amido-isobutyl-acetic acid, $(CH_3)_2.CH.CH_2.CH(NH_2).COOH$, *animal leucin*, is one of the twenty-nine isomeric amido caproic acids, or leucins, whose constitution is demonstrated by its formation from isovaleric aldehyd, $(CH_3)_2:CH.CH_2.CHO$. It is produced, along with tyrosin, in the decomposition of proteins with dilute acids or alkalies, by putrefaction, and by tryptic digestion. It is found in the cultures of the bacillus of malignant œdema, and, along with tyrosin, in those of anthrax and comma bacilli, and in the products of decomposition of fibrin by streptococci. It appears to exist also as a normal constituent of the pancreas, spleen, thymus, lymphatic and salivary glands, liver, and kidneys. Pathologically the quantity of leucin is much increased in the liver in diseases of that organ, in typhus and in variola; in the bile in typhus; in the blood in leukæmia, and in yellow atrophy of the liver; in the urine in yellow atrophy of the liver, in typhus, in variola, and in phosphorus poisoning; in choleraic discharges; in pus; and in the fluids of dropsy and of atheromatous cysts. It is probable that leucin exists as a constituent factor of the proteins, and is split off during their decomposition, as is the case with the hexon bases, arginin and lysin, both of which are related to it, the former being the guanidin compound of a diamido-valerianic acid, and the latter a diamidocaproic acid

Leucin crystallizes from alcohol in pearly plates; but is more usually met with in rounded masses of closely grouped, radiating needles. It is sparingly soluble in water, almost insoluble in alcohol and ether, but readily soluble in hot water or alcohol. It is odorless and tasteless, and its solutions are neutral. It dissolves readily in acids and in alkalies, forming crystalline compounds with the former. It fuses without decomposition, and sublimes at 170°. Hydriodic acid under the influence of pressure and heat decomposes it into caproic acid and ammonia. Its hot solutions form precipitates with hot solutions of cupric acetate; and they dissolve cupric hydroxid, but do not reduce it on boiling. When heated with mercurous nitrate solution it liberates metallic mercury

Amidostearic acid, $C_{18}H_{35}(NH_2)O_2$, has been found by Schutzenberger among the products of putrefaction of muscular tissue. The amido acids, $C_{11}H_{22}N_2O_6$ and $C_9H_{20}N_2O_4$, obtained by the same experimenter, are probably mixtures. The former, on decomposition by caustic potash, yields, besides ammonia, potassium carbonate, valerate and butyrate, while the latter under like treatment yields caproate, caprylate, and acetate.

Schutzenberger has also described a class of substances to which he has given the name "leuceins," differing from the leucins by containing two hydrogen atoms less, possibly amidoacrylic acids. Of these he found butyric leucein, $C_4H_5(NH_2)O_2$, and valeric leucein, $C_5H_7(NH_2)O_2$ among the products of putrefaction of muscular tissue.

Aspartic acid, or amidosuccinic acid, $COOH.CH(NH_2).CH_2.COOH$, and glutamic acid, or amidoglutaric acid, $COOH.CH(NH_2).CH_2.CH_2.COOH$, although known as products of decomposition of proteins by the action of acids and in tryptic digestion, have not been found to be products of putrefaction. Schutzenberger obtained an amido acid having the formula $C_9H_{15}NO_4$, which yielded an isomere of allylamin, $C_7H_{15}N$, on decomposition, from putrefying muscular tissue, and Guareschi obtained a base, $C_{14}H_{20}N_2O_4$, from putrid fibrin. These two bases appear to be amido derivatives of dicarboxylic acids, although they are not homologues of the aspartic series.

Tyrosin, or *p-oxyphenylalanin* $(HO)_{(4)}C_6H_4.CH_2.CH(NH_2).COOH$, is one of the earliest known products of decomposition of the proteins, and is formed from them by the action of proteolytic enzymes, by putrefaction, and by the action of acids or of alkalies, always accompanied by leucin. It also exists normally in the intestinal contents, and pathologically in the urine. It has been obtained synthetically from phenyl-acetaldehyde, $C_6H_5.CH_2.CHO$. It crystallizes in silky needles, arranged in stellate bundles, difficultly soluble in cold water, soluble in 150 parts of hot water, insoluble in alcohol or in ether, rather soluble in the presence of acids or of alkalies. It is not poisonous. Tyrosin is a phenolic derivative of *β-phenyl-a-amidopropionic acid*, $C_6H_5.CH_2.CH(NH_2)COOH$, or *phenylalanin*, which is also a product of putrefaction.

ALKALOIDS.—There are nine ptomaïns known which may, with more or less reason, be called alkaloids. Of these seven are pyridin or dihydropyridin derivatives, related to the bases which occur in bone oil. The other two are benzopyrrole derivatives.

De Coninck's base, $C_8H_{11}N$, (*a collidin?*) was obtained, along with the base $C_{10}H_{15}N$, from putrid jelly-fish after one to two weeks. It is a yellowish, mobile liquid, having an acrid odor, very sparingly soluble in water, soluble in ethylic and methylic alcohols, ether and acetone. Spec. grav. 0.9865. Boils without decomposition at 202°. Turns brown, and absorbs water rapidly from air, but dose not appear to absorb carbon dioxid. Its hydrochlorid forms a fine, yellowish, crystalline, deliquescent mass, very soluble in water. Its platinochlorid is an orange-colored powder, almost insoluble in cold water, soluble in hot water, and is moderately stable. It forms a modified platinochlorid $(C_8H_{11}N)PtCl_4$, with boiling water. Its aurochlorid is a yellow precipitate, permanent in the cold. It forms two crystalline mercurochlorids. Its iodomethylate crystallizes in needles, and is colored red by caustic potash. When oxidized by potassium permanganate it yields nicotinic, or β-picolinic acid, also formed by oxidation of β-picolin, which by distillation with lime yields pyridin (C_5H_5N). This base is isomeric with Nencki's base, β-phenyl-ethylamin (see above), and appears to be one of the twenty-two possible collidins, the third superior homologues of pyridin. It is not α-propylpyridin, or conyrin, a product of the action of zinc chlorid and heat upon coniïn, which boils at 165°–166°, but is said to be either β-propyl- or β-isopropylpyridin. If it be the former, $C_5H_4N(C_3H_7)_{(3)}$, it is that ptomaïn which most nearly approaches the constitution of the most simply constituted of the vegetable alkaloids, coniïn, which is α propylpiperidin, $C_5H_{10}N(C_3H_7)_{(1)}$.

Gautier and Étard's base, $C_9H_{13}N$, (*a parvolin?*) was found, along with the base $C_8H_{13}N$, among the products of the prolonged putrefaction of fish and of horseflesh. It is an amber-colored liquid, having the odor of hawthorn, sparingly soluble in water, turning brown and resinous in air, and boiling above 210°, at which temperature it also decomposes into ammonia and a substance having a phenolic odor. Its platinochlorid is crystalline, flesh colored, sparingly soluble in water, and decomposed by light. Its aurochlorid is rather soluble in water. Whether or not this base is one of the fifty-seven possible parvolins of which five only are at present known, remains to be determined.

Guareschi and Mosso's base, $C_{10}H_{15}N$, (*a coridin?*) was obtained from fibrin after five months' putrefaction. It is a brownish oil with a faint odor of pyridin and of coniïn, sparingly soluble in water, strongly alkaline, and resinifies rapidly in air. Its hydrochlorid crystallizes in thin, colorless plates, slightly deliquescent, resembling cholesterin. Its platinochlorid is flesh-colored, crystal-

www.libtool.com.cn
Digitized by Microsoft®

line, insoluble in water, alcohol, or ether, not decomposed at 100°, and does not resinify. The same base was also extracted from fibrin after eight to nine months' putrefaction. The quantity of hydrogen obtained in all analyses of this base caused the authors to doubt whether its formula should not be $C_{10}H_{13}N$, in place of $C_{10}H_{15}N$, which would make it an isomere of tetrahydromethylquinolin. On dry distillation the base yields ammonia and a liquid boiling at 200°, which had a composition neighboring to that of Gautier's hydrocollidin. Gautier and other chemists called this base corindin, or better, coridin, a name already given by Thenius to the base $C_{10}H_{15}N$ which he extracted from coal tar. It is not demonstrated that this base is identical with Thenius' base, which boils at 211°, spec. grav. 0.950; whose platinochlorid is dark orange, sparingly soluble in water, alcohol, and ether; and whose aurochlorid is dark yellow. Guareschi and Mosso's base has a poisonous action resembling that of curare, but much less intense.

De Coninck obtained from jelly-fish, after one to two weeks' putrefaction, a base having the same composition as the above, which forms yellowish needles, which becomes viscid and resinous in air, has an odor which is not disagreeable, spec. grav. 1.18, boiling at 230°, sparingly soluble in water, soluble in alcohol, ether, and acetone. Its hydrochlorid crystallizes in yellowish, very deliquescent needles. Its platinochlorid forms a reddish powder, insoluble in water, but forming a modified platinochlorid $(C_{10}H_{15}N)\ PtCl_4$, which fuses at 206°. Gautier considers this as identical with Guareschi and Mosso's base. It does not seem, however, to be identical either with that or with Thenius' base. It is probable that each of the three is one of the one hundred and five possible coridins. The formation of the modified platinochlorid is strong evidence that de Coninck's base is a pyridin homologue.

Gautier and Mourgues' base, $C_7H_{11}N$, (*a dihydrolutidin?*) constitutes about one-ninth of the bases obtained by them from brown cod-liver oil. It is a colorless liquid, oily, alkaline, not disagreeable in odor, absorbs carbon dioxid from the air, lighter than water, boiling point 199°, and sparingly soluble in water. Its hydrochlorid crystallizes in flat needles, bitter in taste. Its nitrate reduces silver nitrate. Its platinochlorid forms a silky, yellow precipitate, and yields the modified platinochlorid $(C_7H_{11}N)\ PtCl_4$, when boiled with water. Its aurochlorid crystallizes in needles or in lozenges. The base unites with methyl iodid, forming a colorless iodomethylate, $C_7H_{11}N.CH_3I$, soluble in water and in ether, and having a disagreeable, nauseous odor. Caustic potash separates from it a colorless, highly alkaline oil, which is said to be dihydromethyllutidin. When oxidized by potassium permanganate in boiling solution it gives off an agreeable odor of coumarin, and, on continuing the heating at 100° in sealed tubes, a methyl-carbopyridic acid, $C_5H_3(CH_3)N.COOH$, is obtained. That this base is a hydropyridic compound is shown by the action with silver nitrate, the formation of the modified platinochlorid, and the composition of the iodomethylate. The formation of the methylcarbopyridic acid shows that it is not one of the three ethyldihydro derivatives, but one of the six dimethyl compounds.

It is very poisonous. In small doses it diminishes the general sensibility. In larger doses it causes localized tremors, particularly in the head, deep depression, with periods of extreme excitement, paralysis, beginning with the posterior extremities, and death.

Gautier and Etard's base, $C_8H_{13}N$, (*a dihydrocollidin?*) was obtained from the products of the prolonged putrefaction of fish. It is an oily liquid, having a tenacious odor of lilac, spec. grav. 1.0296, boiling point about 210°. In air it absorbs carbon dioxid, and resinifies rapidly. It has an energetic reducing action. Its hydrochlorid crystallizes in needles, soluble in water and in alcohol. Its platinochlorid is flesh-colored, sparingly soluble, and is decomposed by light or heat. Its aurochlorid is soluble and reduces easily. It was supposed by Gautier and Etard to be identical with the dihydrocollidin obtained by Cahours and Etard by the action of selenium upon nicotin, but as that base boils at 205°, and is lighter than water, it is more probably an isomere. It is actively poisonous. Even in small doses it causes vomiting, staggering, tetanic spasms, followed by paralysis and death, with the heart in diastole.

The existence of the base $C_{10}H_{17}N$, described by Griffiths, requires confirmation. The composition is that of the dihydrocoridins.

Morrhuic acid, $C_9H_{13}NO_3$, was obtained by Gautier and Mourgues, along with the bases elsewhere referred to, from brown cod-liver oil. It is oily or resinous, but crystallizes in flat prisms, or lozenges on standing. It has an odor resembling that of seaweed. It is both acid and base, and decomposes the carbonates. It forms no precipitate with cupric acetate, even on boiling. Distilled with lime, it yields an oily, alkaline base, which forms an iodomethylate with methyl iodid. It is a pyridin derivative, and is supposed by Gautier and Mourgues to be a monocarboxylic oxyacid, $C_5H_5N(OH)(C_3H_6.COOH)$, derivable from a dihydropropylpyridin. It is said to yield a monobasic acid on oxidation, but it is such itself.

Indole, C_8H_7N, is benzopyrrole, theoretically formed by fusion of a pyrrole ring, C_4H_5N, upon a benzene ring, C_6H_6, with loss of C_2H_4, the nitrogen atom occupying a position vicinal to the benzene ring. It is one of the products of putrefaction of the proteins by anaërobic bacteria, occurs in the cultures of the comma bacillus and of that of tetanus, and is formed in the intestine. When produced by intestinal putrefaction it is partly discharged in the fæces, and is in part reabsorbed, appearing in the urine in combination with sulfuric and glucuronic acids as the so-called urinary indican. It crystallizes in large, shining, colorless plates, having the disagreeable odor of naphthylamin, sparingly soluble in water, soluble in alcohol and in ether, fuses at 52° and distils with vapor of water. It is weak base, and its salts are decomposed by boiling water. Its aqueous solution, acidulated with hydrochloric acid, is colored rose-red by potassium nitrite. By fusion with caustic potash it yields anilin. Its alcoholic solution, acidulated with hydrochloric acid, colors a pine shaving red. With picric acid it forms a compound crystallizing in red needles. With sodium nitroprussid and alkali it produces a red-violet color, which changes to blue with acetic acid (Legal).

Skatole, C_9H_9N, is β-methyl-indole. It accompanies indole in the intestinal contents and in fæces, in which it is the more abundant of the two, and is also formed during putrefaction of the proteins, or by the action upon them of caustic potash in fusion. It crystallizes in brilliant plates, fusing point 95°, insoluble in cold water, less soluble than indole in boiling water, soluble in alcohol and in ether, has a strong fæcal odor. Its solution in concentrated hydrochloric acid is violet. Its solution in sulfuric acid is colored deep purple when heated. It forms a red, crystalline compound with picric acid. It does not give the pine-shaving reaction, nor the red color with acid and nitrite, and with Legal's reaction the alkaline solution is yellow, and turns violet with acetic acid and heat. Like indole, it is in part reabsorbed from the intestine and eliminated with the urine in combination with sulfuric and glucuronic acids. Neither indole nor skatole has any notably toxic action.

PTOMAÏNS OF UNKNOWN CONSTITUTION.—*Morrhuin*, $C_{19}H_{27}N_3$, and *asellin*, $C_{25}H_{32}N_4$, are two of the six bases obtained by Gautier and Mourgues from brown cod-liver oil, the former constituting about one-third of the total, and the latter a small fraction. *Morrhuin* is a thick, yellowish liquid, having the odor of hawthorn and of lilac, lighter than water, in which it is sparingly soluble, strongly alkaline and caustic, and absorbs carbon dioxid from air. Its hydrochlorid is very deliquescent. Its platinochlorid crystallizes in needles, soluble in water, and is decomposed by heat. Its aurochlorid is soluble in water. It is non-poisonous, but is an active diuretic. *Asellin* is an amorphous, white solid, odorless in the cold, but fusing and giving off an aromatic odor when heated. It is almost insoluble in water, soluble in alcohol and in ether, alkaline, and bitter in taste. Its

Digitized by Microsoft®

salts are soluble in water. Its hydrochlorid is crystalline; its platinochlorid and aurochlorid are unstable. In small doses it produces disturbances of respiration and stupor, and in larger doses convulsions and death. Possibly the former, or both, of these bases may be complex amido acids.

Scombrin, $C_{17}H_{38}N_4$ (not to be confounded with the protamin of the same name obtained from the milt of the mackerel) was obtained in very small quantity by Gautier and Etard from the mother liquors of their alkaloidal bases, above referred to. Its hydrochlorid crystallizes in needles, soluble in water, which decompose slowly at 100°, giving off an odor of lilac. Its platinochlorid crystallizes in light yellow needles, and is soluble in water.

Brieger's base, $C_6H_{13}NO_2$, isomeric with mydatoxin and with leucin, and probably a betaïn, was obtained from tetanus cultures, and is formed by decomposition of tetanin, $C_{13}H_{30}N_2O_4$. Its platinochlorid crystallizes in plates, soluble in water and in alcohol, fusing point 197°, at which temperature it decomposes.

Brieger's bases, $C_7H_{17}NO_2$. Brieger has described three bases having this composition: *Gadinin*, from putrid fish, after five days; *typhotoxin*, from cultures of the Koch-Eberth bacillus; and an unnamed base from horseflesh after prolonged putrefaction at low temperature with limited access of air.

Gadinin (not to be confounded with the brown substance of the same name obtained by De Jongh from codliver oil), obtained from the mother liquors of Brieger's "muscarin," forms a hydrochlorid which crystallizes in thick needles, soluble in water, insoluble in alcohol. Its platinochlorid crystallizes in scales, sparingly soluble in water. It forms no aurochlorid. It appears to be non-poisonous.

Typhotoxin is a strongly alkaline base. Its hydrochlorid is deliquescent. Its platinochlorid crystallizes in needles, easily soluble in water. Its aurochlorid crystallizes in prisms, difficultly soluble in water, fusing point 176°. It forms a difficultly soluble picrate. With Ehrlich's reagent (sulfodiazobenzene) it immediately gives a yellow color, which is discharged by bases. In moderate doses typhotoxin causes increased flow of saliva, and acceleration of respiration. Later there is loss of control of the muscles of the extremities, without true paralysis, the animal falling upon its side. The pupils gradually dilate widely, and become insensible. Convulsions do not occur. The frequency of the heart's action and respiration gradually diminishes. During the entire poisoning there is copious diarrhœa. After death the heart is found contracted in systole, the lungs are highly hyperæmic, the other organs pale. The intestines are strongly contracted, and their walls pale.

The unnamed base, $C_7H_{17}NO_2$, crystallizes in very deliquescent plates, and has a faintly acid reaction, but it does not form salts with bases, and does not respond with Hofmeister's reaction with ferric chlorid. It is not an amido acid. Its hydrochlorid crystallizes in needles, insoluble in absolute alcohol. Its aurochlorid crystallizes in plates or in needles, difficultly soluble in water, fusing point 176°. It does not react with Ehrlich's reaction, and forms no picrate. It has the physiological action of curare. A base having this composition has also been obtained by Baginsky and Stadthagen from cultures of a bacillus allied to the Finkler-Prior spirillum.

Tetanin, $C_{13}H_{30}N_2O_4$.—Brieger, in his earlier experiments with cultures of an anaërobic bacillus found by Nicolaier in earth samples, and capable of producing symptoms of traumatic tetanus in animals, and with cultures of the same bacillus bred by Rosenbach from the wound of a man who died with tetanus, obtained two bases with a similar physiological action—tetanin and tetanotoxin.

Tetanin is a yellow, strongly alkaline syrup, which gives no blue color with ferric chlorid and potassium ferricyanid. Its hydrochlorid is deliquescent, and forms an easily soluble, crystalline compound with phosphomolybdic acid. Its platinochlorid crystallizes from alcohol in light yellow plates, very soluble in water. The free base, or its hydrochlorid, when injected into mice or guinea-pigs, soon causes clonic or tonic convulsions of the greatest intensity, which terminate in death. The course of the poisoning is divisible into two stages: In the first the animal is depressed and lethargic, then it suddenly becomes uneasy, and the diaphragm contracts energetically. The second is marked by convulsions, usually tonic, but occasionally clonic. Death occurs frequently in a violent convulsion. Frogs withstand the action of the poison better than warm-blooded animals, but when they succumb they become perfectly rigid in a position of pronounced opisthotonos. Guinea-pigs, when thoroughly under the influence of the poison, exhibit very clearly the characteristic spasms of tetanus in the human subject and marked opisthotonos.

Tetanotoxin, $C_5H_{11}N$(?), is a volatile substance, boiling at 100°. In relatively large doses it produces in animals fibrillar contractions of diverse groups of muscles, particularly those of the neck and face. Motion is more or less interfered with, until paralysis is established. Convulsions increase in intensity, attacking groups of muscles very violently. The animal lies with the head thrown back and the extremities extended, and, when pressed upon, makes movements as in swimming. Finally the animal falls upon its side, and dies in a violent convulsion.

Two other bases have subsequently been obtained by Brieger from cultures of the tetanus bacillus, both of unknown composition.

Spasmotoxin, which forms a soluble platinochlorid, fusing point 210°, causes violent tonic and clonic convulsions in animals. The other base, unnamed, forms a very deliquescent hydrochlorid; a platinochlorid which crystallizes in scales, decomposed at 240°; and a very soluble aurochlorid and picrate. It produces complete tetanus, salivation, and lachrymation in animals.

It is not surprising that when the physiological action of these bases was first recognized they were considered to be the specific poisons produced by the bacillus of tetanus. But it has been shown that the filtered culture is vastly more active than the combined bases, and that the culture contains a non-basic, non-albuminous toxin, which, still in an impure condition, has a lethal toxicity estimated at 0.23 mgm. for the human subject. Therefore, while the bases above mentioned undoubtedly have some action in producing the manifestation of tetanus, such action is greatly subordinate to that of the toxin.

Lepierre's base, $C_{10}H_{23}N_2O_4$, obtained in small amount from poisonous cheese, is crystalline, odorless, bitter, faintly acid, and sparingly soluble in water. Its hydrochlorid crystallizes in needles, very soluble in water. Its platinochlorid and aurochlorid are crystalline. It causes diarrhœa in guinea-pigs.

Delézinier's base, $C_{32}H_{31}N$ or $C_{34}H_{33}N$ (?), whose composition is quite uncertain, is an almost colorless, oily liquid, very sparingly soluble in water, soluble in alcohol, ether, and benzene, rapidly oxidized in air, and forming deliquescent salts. It is supposed to be identical with a base obtained by Brouardel and Boutmy, which bore some resemblance to veratrin.

Susotoxin, $C_{10}H_{26}N_2$ (?), a base whose hydrochlorid was obtained by Novy from cultures of the hog-cholera bacillus. The free base was not isolated. The hydrochlorid is a light yellow syrup which does not crystallize, somewhat hygroscopic, and soluble in water and in alcohol. It gives off an amin odor when heated with fixed alkali. Its platinochlorid is granular and light flesh colored, or crystallizes in long, thick needles, soluble in water, from which it is precipitated by alcohol. It is toxic only in large doses. It is said to be identical with the *sucolotoxin* of von Schweinitz.

Pyocyanin, $C_{14}H_{14}NO_2$ (?), is the coloring matter of blue pus, first obtained by Fordos. It crystallizes in blue prisms or scales, soluble in water, alcohol, and chloroform, less soluble in ether. Its blue aqueous solution is neutral, and is changed to cherry-red by acids, and back to blue by alkalies. It is oxidized in air to the yellow *pioxanthose*, which also accompanies it in the pus. Ac-

Digitized by Microsoft®

cording to Kunz, it contains sulfur. It is supposed to be an anthracene derivative.

Anthracin is the name given by Hoffa to a base, $C_3H_6N_2$ (?) obtained from cultures of the anthrax bacillus.

The following bases are of unknown composition:

A base obtained by Brieger from human livers and spleens after two weeks' putrefaction with free access of air. Its hydrochlorid crystallizes in small, deliquescent needles; and its platinochlorid in fine needles, containing 41.30 per cent. of platinum. It causes long-continued diarrhœa in rabbits and guinea-pigs.

Another base obtained by Brieger from the same source; fluorescent, boiling point about 284°, whose hydrochlorid crystallizes in long needles, soluble in absolute alcohol. Its platinochlorid crystallizes in fine needles, very soluble in water, or in plates, containing 30.36 per cent. Pt.

A base obtained by Brieger from putrid fish. Its hydrochlorid and platinochlorid crystallize in small needles; the latter containing 36.03 per cent. Pt and 7.81 per cent. N.

A base obtained by Bocklisch from herring after twelve days of putrefaction, whose platinochlorid crystallizes in large, thin plates, easily soluble in water, and containing 28.57 per cent. Pt.

Peptotoxin is the name given by Brieger to a toxic substance (or mixture of substances) having some of the characters of the nitrogenous bases, obtained from peptone, produced by the action of pepsin from the pig upon fresh fibrin. The same body was obtained from Witte's peptone, and from putrefying fibrin, casein, and brain, liver, and muscular tissues. If putrefaction has continued for eight days, it is no longer obtainable. It crystallizes with difficulty, passes from both acid and alkaline solutions into amylic alcohol, is insoluble in ether, benzene, or chloroform, but very soluble in water. Its solutions are neutral. It is quite stable, and is not decomposed by boiling, or by treatment with hydrogen sulfid or with caustic alkalies. With Millon's reagent it gives a white precipitate, which turns bright red on the application of heat. It precipitates with many of the general reagents for alkaloids, and gives the blue reaction with fœric chlorid and potassium ferricyanid. It is actively poisonous in small doses, causing paralysis of the posterior extremities, sopor, and death.

Phlogosin is the name given by Leber to a substance which is probably not a base, obtained from cultures of staphylococcus aureus. It crystallizes in needles, soluble in alcohol and in ether, sparingly soluble in water, and may be sublimed. It forms no compound with platinic or auric chlorid, and does not precipitate with phosphotungstic, phosphomolybdic, picric, or tannic acid. It appears to contain sulfur and no nitrogen.

Tyrotoxicon is the name given by Vaughan to a material extracted from poisonous cheese, whose chemical characters are not well defined.

The individual existence of the numerous bases described by Griffiths requires confirmation.

Nitrogenous bases are also formed during alcoholic fermentation. These are not properly ptomaïns, being produced by yeast fungi, which are not bacteria.

Morin's base, $C_7H_{10}N_2$, is the best known of these. It was obtained from the fraction of crude fusel oil, distilling at 171°–172°. It is a colorless, mobile, oily liquid, having a nauseous odor, spec. grav. 0.9826, not alkaline in reaction. Its hydrochlorid forms needles, soluble in water and in alcohol, very sparingly soluble in ether. Its platinochlorid is crystalline, soluble in water and in alcohol, very sparingly soluble in ether. It is decomposed by hot hydrochloric acid, with formation of ammonia. It combines with ethyl iodid to form a yellow, crystalline compound, very soluble in alcohol and in water, very sparingly soluble in ether. Its aqueous solution does not precipitate with Mayer's reagent, but on acidulation with hydrochloric acid there forms a flocculent, yellow precipitate, which unites into long, brilliant, yellow needles—a reaction which is not given by the pyridic or quinolinic bases. It is poisonous, and in rabbits causes stupor and paralysis, beginning with the posterior extremities, diminished sensibility, dilatation and insensibility of the pupils, diminution of the temperature and cardiac action, and death in coma. This base is probably identical with Tanret's *glucosin*, obtained by the action of ammonia and ammonium salts upon glucose.

Oser's base, $C_{13}H_{20}N_4$, is produced during the fermentation of pure saccharose by yeast. It is not volatile, and is decomposed when heated with acids. Its hydrochlorid is very hygroscopic, very unstable, and turns brown in air. Its aurochlorid is a yellow, flocculent precipitate, which becomes crystalline, and is very sparingly soluble in water.

A base, said to be pyridin, has been found in commercial alcohol by Haitinger and by Guareschi and Mosso to the amount of 0.4 to 0.5 in 1,000. Schrötter has described two bases, $C_7H_{12}N_2$ and $C_{10}H_{16}N_2$, obtained from the fraction of molasses-fusel distilling at 180–233°. Krämer and Pinner obtained bases, which they considered to be pyridic, from commercial alcohol. Other imperfectly defined bases have been described as existing in beer or in distilled spirits by Surgères, Lindet, Modermann, Lermer, von Geldern, Dannenberg, Meyer, and Fassbender and Schoepp.

Pouchet's bases, $C_5H_{12}N_2O_4$ and $C_7H_{14}N_2O_6$, cannot be regarded as ptomaïns, as they were obtained from the liquid residues of an industrial process of treatment of bones, flesh, and other animal refuse by sulfuric acid, and the action of the acid was undoubtedly a factor in their production.

The ptomaïns and basic products of yeast fungi above described are split products of protein material, eliminated by the organisms producing them, and not constituents of those organisms. The distinction between constituent and excretory bacterial products is one of importance biologically and pathologically, but is one which is undesirable from the point of view of analytical toxicology, because the bacteria, as well as their elimination products, are present in materials submitted to analysis, and, although the entire bacteria do not give up their constituent substances to solvents by any means as readily as they do after comminution by Koch's method, they do so to a certain extent.

The only instance of the formation of a protamin by bacteria of which we have knowledge, is the *tuberculosamin* of Ruppel, which he obtained from the tubercle bacilli, but not from their cultures. It is, therefore, a constituent of their organism, in which it exists in combination with a nucleic acid, and not an elimination product. Tuberculosamin has the properties of the protamins: it is extracted by cold, dilute sulfuric acid (one per cent.), is precipitated from neutral solution of the sulfate by sodium picrate, forms an alkaline solution in water, is strongly basic, does not give the color reactions of the proteins except the biuret reaction, contains no phosphorus, and precipitates the proteins from ammoniacal solutions. The protamins form precipitates with phosphotungstic acid, Mayer's reagent, and other general reagents for alkaloids. They are actively poisonous, causing at first acceleration, then slowing of the respiration, marked diminution of the blood pressure, and death.

Chemico-Legal Considerations.—The ptomaïns are now mainly of interest in connection with forensic toxicology. From the first discovery of these substances, and until their chemistry and that of the vegetable alkaloids became better known, it was feared that their existence might seriously interfere with or entirely prevent the detection of vegetable alkaloids, with sufficient certainty for the purposes of justice, in cases of criminal poisoning. The ptomaïns were called "putrid alkaloids," were considered to be of the same chemical class as the vegetable alkaloids, and almost all were found to respond to many of the general tests for the alkaloids. In short, everything seemed to point to a much closer rela-

Digitized by Microsoft®

www.libtool.com.cn

tionship between the ptomaïns and the vegetable bases than that which actually exists. But the development of the chemistry of the ptomaïns has shown that those of them which have the most complex molecular structure are more simple in constitution than their nearest relatives among the vegetable alkaloids, and very much more simple than the ester-alkaloids, such as atropin, or the still more complex polynuclear alkaloids, such as morphin.

While the parasitic bacteria probably cause synthetic combinations, as in the generation of the toxins, the function of the saprophytic bacteria, which alone are of interest in this connection, is essentially analytical. It may be considered to be within the limits of possibility that, starting with the complex protein molecule, a substance having the constitution of a vegetable alkaloid might be produced during the series of hydrolytic decompositions caused by the saprophytes. But all observations are against such an hypothesis, no such substance has been found among all of the putrid products which have been obtained. Moreover, the known products of decomposition of the proteins by other means, through the protamins, the hexon bases, the nucleins, the purin bases, the amido acids, and the amins, lead in a direction not tending to the formation of the alkaloids, except in the case of the formation of the pyridic bases by the action of heat. The formation, however, of pyridic and, particularly, of hydropyridic ptomaïns as late products of putrefaction indicates the possibility that the analytical processes of the saprophytes may be followed by the transformation of certain of the acyclic products into heterocyclic compounds, in a manner similar to the conversion of pentamethylene hydrochlorid (cadaverin) into piperidin: $H_2N.(CH_2)_5.NH_2:HCl = NH_4Cl + C_5H_{11}N$.

No ptomaïn has been discovered which corresponds in all of its characters with a vegetable alkaloid. Two substances alike in all respects are two samples of the same substance, and no vegetable alkaloid is known which is also a product of putrefaction. But there are certain vegetable alkaloids which resemble certain ptomaïns in several of their properties, while differing in others, and, at the same time, exhibit no known well-marked and distinctive chemical reactions. Probably the closest resemblance is that between the so-called cadaveric coniïn and true coniïn. Both are liquid, oily, volatile, intensely alkaline, similar in odor, soluble in water and in petroleum ether, and form precipitates with platinic chlorid, auric chlorid, mercuric chlorid, and several of the general reagents. They differ in that coniïn is actively poisonous, while the ptomaïn has been found to be inert, except in one case in which Otto obtained a poisonous substance, which probably owed its toxicity to the presence of another ptomaïn. The "cadaveric coniïn" is, however, not coniïn (α-propyl piperidin) but cadaverin (pentamethylenediamin). Therefore, while it must be admitted that we have no method to separate coniïn from a putrid cadaver, and, in the minute quantity in which it would probably be obtained, distinguish it from cadaverin, or from a mixture of ptomaïns containing cadaverin; it may also be anticipated, the two substances not being identical, that distinguishing characters of sufficient delicacy will be found to exist.

Attempts have been made to find a characterizing reaction common to all ptomaïns, whereby they might be distinguished from the vegetable alkaloids. Among those suggested were the reactions of Brouardel and Boutmy, and of Trotarelli. But no such reaction can exist, because the ptomaïns do not constitute a distinct chemical class, but include among their number representatives of several chemical classes of tolerably diverse character; and for the further reason that, while the great majority of ptomaïns are non-alkaloidal, some are pyridin or hydropyridin derivatives, as are also the alkaloids. As the "general tests" for the alkaloids for the most part form precipitates with ptomaïns, albumins, and nitrogenized bases other than alkaloids, they are only of negative value in the rare cases in which they fail to react, or of confirmatory value by reason of peculiarities in the qualities of the precipitates which they produce with certain alkaloids.

The ptomaïns which are frequently referred to as "strychnin-like" or "morphin-like" are quite as noticeable because of the differences from those alkaloids which they present, as by reason of their resemblances thereto.

The bases obtained by Brieger from the cultures of the tetanus bacillus, while resembling strychnin in the production of tetanic spasms, differ from the alkaloid in not giving the color reaction, in not being bitter, and in crystalline form. Amthor's product was neither bitter nor crystalline, nor did it give the color reaction of strychnin, but an entirely different one. In Ciotto's case the material supposed to have been strychnin appears to have given the color reaction, as Selmi, who differed from Ciotto in his conclusions from the observed facts, concedes this much. But the colors obtained are not described beyond the statement that they were "the colors proper to the reaction of strychnin," and Selmi, in the course of the same paper, says that aspidospermin "behaves with bichromate as does strychnin," while in fact there are marked differences between the color reactions of strychnin and of aspidospermin under like treatment. But Ciotto's substance was not shown to be either crystalline, alkaline, or distinctly bitter, and when administered to frogs in quantity sufficient to kill them it did not cause tetanic spasms. Lombroso and Dupré obtained from the spoiled maize which is regarded as the cause of pellagra a mixture of bases (pellagrozeïn) which is bitter in taste, causes tetanus in frogs, and is said to give the color reaction of strychnin, but whose reaction only resembles that of strychnin in its initial stage. It also differs from strychnin in its crystalline form, and in that its sulfuric-acid solution assumes a permanent violet color when exposed to vapor of bromin. But pellagra is confined to a comparatively narrow strip of territory (six degrees) in the south of Europe. Moreover it is not proven that the constituents of pellagrozeïn are bacterial products; certainly they are not cadaveric ptomaïns.

We find reference in toxicological literature to alleged "morphin-like" ptomaïns in three cases. In the Sonsogno case, in Italy, the substance mistaken for morphin did not give either the Pellagri reaction, the ferric-chlorid reaction, the nitric-acid reaction, or the Erdmann reaction; and it only resembled morphin in that it behaved as a reducing agent toward iodic acid, auric chlorid, and certain other reducible substances. In the Portuguese case of Urbino de Freitas not one of the three most nearly characteristic of the tests for morphin, the Pellagri, the Husemann, and the ferric chlorid was even tried, and the experts erred in asserting the presence of morphin in a cadaver upon the evidence of a not entirely satisfactory Fröhde reaction, the iodic reaction, and the formation of a green color with the Lafon test, the last a reagent whose merits had been insufficiently tested. In the Buchanan case in New York, Vaughan makes the unwarranted assertion that "all the tests obtained by the experts were duplicated with putrefactive products." This alleged duplication was attempted in open court, in the presence of the author, with the following results: The ferric chlorid gave a brilliant grass-green, not a blue color. The Husemann was improperly applied, and failed, as it would have done had morphin been present. The Pellagri was also improperly applied, and failed, as it would have failed with morphin in the manner in which it was used. The Fröhde gave a distinct orange color, passing to yellow, in place of the purple, passing through blue, dirty green, and yellow to pink as it gives with morphin. The nitric acid gave an immediate yellow, but not the orange-red changing to yellow of morphin. The iodic acid gave a faint reaction similar to that obtained with morphin and with many other reducing agents. The six "duplications" therefore consisted of five failures to produce similarity, and one faint resemblance.

Whether a vegetable alkaloid is detectable in cadaveric material or no depends now, as it did before our knowledge of the existence of the ptomaïns was gained, upon the existence or non-existence of a sufficient number of

Digitized by Microsoft®

well-marked physical qualities, chemical reactions, or physiological actions of that alkaloid. If such exist, and are not duplicated or interfered with by ptomaïns, the alkaloid may be detected with certainty. If they do not, it cannot be, ptomaïn or no ptomaïn. In the frequently cited case of General Gibbone in Rome, it was shown by Selmi that the substance which was claimed to have been delphinin could not be that alkaloid, because it did not have its physiological action. But this affirmative proof was simply confirmative of the already convincing argument that delphinin has no physical characters and gives no chemical reactions which are sufficiently distinctive to permit of its identification when present in the minute quantity obtainable in such an analysis.

That the presence of ptomaïns may militate against the detection of a vegetable alkaloid, both by interference with its reactions and by similarity of its physiological action, is well shown in the case of atropin. From the viscera of a woman, after nine months' burial, the author obtained a residue (which would have contained atropin had it been present) which caused wide dilatation of the pupil and insensibility to light, persisting for several hours, gave the peculiar crystals with bromin in hydrobromic acid, and reddened phenolphthalein; but did not produce Kratter's crystals, or respond to the Vitali reaction. But portions of the same residue, to which atropin sulfate was added in notable proportion, also failed to give the Vitali reaction.

While, therefore, the presence of ptomaïns may interfere to prevent the detection of certain alkaloids which may be actually present in the materials examined, we know of no instance in which a ptomaïn or mixture of ptomaïns has given reactions which would cause it to be mistaken for an alkaloid possessed of sufficiently distinctive characteristics to permit of its certain identification in the assured absence of all ptomaïns. A survey of the reactions manifested by the reputed "alkaloid-like" ptomaïns shows that their similarities to those of the vegetable alkaloids consist chiefly in resemblances of physiological action, and in their behavior toward "general reagents" and toward iodic acid. We have stated above that the general reagents play only a very secondary rôle in the identification of vegetable alkaloids, and iodic acid is merely a test for reducing agents, which is used for morphin because the reducing action of that alkaloid is one of the characters which differentiates it from most of the other vegetable bases. If we except one veratrin reaction obtained by Brouardel and Boutmy, the somewhat doubtful case of Ciotto mentioned above, and the statements of Vaughan, there is no reference in toxicological literature to a ptomaïn which has given a well-characterized reaction of a vegetable alkaloid.

Rudolph A. Witthaus.

PTYALIN. See *Saliva.*

PTYALISM. See *Mouth, Diseases of,* in THE APPENDIX.

PUBERTY.—DEFINITION.—The term puberty was formerly used to designate the whole period of sexual development, and is still occasionally so used. Jules Voisin[1] refers to the age of puberty as the time between the ages of fourteen and twenty two years. In general, however, writers now confine the term puberty to the initiatory and formative period of sexual development, while to the entire period of sexual development is applied the broader term adolescence.

The Age of Puberty.—The average age of puberty in the male is 14.3 years; the average age of first menstruation in the female is about 13.7 years. The period differs according to race and climate, and may be hastened by the reading of erotic literature, by suggestion, and by an early participation in social life.

The pubescent period begins in girls at least a year and a half before the first menstruation. This preliminary period is, according to Armand Delpeuch,[2] the time when the child needs the greatest care, for at this time the trunk is relatively the shortest, the thorax relatively the narrowest, and the heart relatively the smallest, and at the same time the child is doing his most rapid growing. The female makes the most rapid growth from twelve to fourteen, and the male from fourteen to seventeen. The pubescent child should, therefore, be guarded against too violent exercise, and yet should be provided with much pure air.

Physical Changes.—A general physical disturbance takes place, shown by the rapid bodily growth, the elongation of the vocal cords, increased pilosity, a change in the size and condition of the reproductive organs, and a profound disturbance of the nervous system. Indeed, muscles, blood-vessels, glands, and all organs share in the general disturbance.

Psychical Changes.—The psychical no less than the physical being is affected by puberty. Marro of Turin[3] says that "puberty exercises a notable influence upon the psychical life, which is manifested, in some instances, by giving to mental symptoms qualities which they did not have before or which they had only to a slight degree, and in others by preparing a way for the invasion of psychoses. Hereditary predisposition is the prominent cause of the affection."

Periodic Phenomena.—The most notable accompaniment of puberty in the female is *menstruation* (which see). In the male there is throughout sexual life and beginning with puberty a periodicity which is probably analogous to that of the female. The seminal vesicles possess glandular walls and retain the secretion of these walls for periods varying from one to four weeks normally.

The retained secretion distends the walls, and through pressure stimulates nerves which pass to the erection centre, which is in turn excited.

By day erotic emotions are easily aroused; at night when the subject sleeps he may experience an erection accompanied by an erotic dream and culminating in an emission ("nocturnal emission"). In this way is the pressure of accumulating vesicular secretion relieved and the subject should pass another period free from sexual impulses. After the period of pubescence is established, the testes of the male form spermatozoa rapidly under sexual excitement and slowly during periods which are free from excitement. In neither case do the spermatozoa pass into the seminal vesicles; they are retained in the testes, the vasa deferentia, and ampullæ. The testes form not only the spermatozoa but a milky fluid in which the spermatozoa float. The secretion of the testes contains a mysterious principle whose reabsorption gives to the male those characteristics which we recognize as distinctive of virility. In the nocturnal emission coming without sexual excitement no spermatozoa are lost; hence these emissions cause no depletion. *J. W. Hall.*

PUERPERAL INFECTION.—(Puerperal fever, puerperal sepsis, puerperal septicæmia, childbed fever.)

DEFINITION.—An acute contagious disease of the puerperium characterized by an inflammation of some part of the genital tract, and frequently associated with a variety of systemic manifestations. It is caused by a number of pathogenic and saprophytic micro-organisms.

HISTORY.—The disease has been known from the earliest times. Hippocrates, Galen, Avicenna, and others of the early writers, as well as many in the sixteenth, seventeenth, and eighteenth centuries, have described cases. In the first half of the nineteenth century there were many frightful epidemics of the disease.[1] It was the scourge of the great lying-in hospitals of Europe, and patients were decimated regularly by its ravages. Oliver Wendell Holmes in his essay, "The Contagiousness of Puerperal Fever," published in 1843, logically proved the contagious nature of the disease; and Ignaz Philipp Semmelweiss, who recognized the identity of the disease with wound infection and devised a practical method

of hand disinfection, published, in 1861, his monograph, "Die Etiologie des Begriffs und die Prophylaxis des Kindbettfiebers." He introduced hand disinfection in the great Maternity Hospital in Vienna, and immediately the mortality fell from ten per cent. to about one per cent. The teachings of these classical essays were bitterly opposed, however, and it was not until after Lister had introduced antisepsis in surgery that its importance in obstetrics was generally recognized. The ancients attributed the affection to a retention of the lochia, and this has been the most common explanation until recent times. After the introduction of antiseptic and aseptic methods in obstetrics, there was a marked reduction in the mortality from puerperal infection in hospital practice. At the present time, in the better maternity hospitals, the mortality is a small fraction of one per cent. In private practice, however, cases are frequently seen, especially in the hands of untrained midwives and careless or ignorant physicians.

Etiology.—Puerperal infection is essentially wound infection. As Semmelweiss and others have shown, the *materies contagii* is carried to the parturient woman on the hands of those who have made recent autopsies or dissections, or who have dressed suppurating or inflammatory cases of any kind. With the advance of our knowledge of the causal relation of bacteria to disease in the last fifty years, the infectious nature of the disease has been clearly established. Puerperal infection, however, is not a specific disease, but like wound infection in general may be caused by a variety of micro-organisms. Among these the streptococcus is found most frequently, and is present in nearly all the fatal and most serious cases. The gonococcus comes next in frequency of occurrence, but causes much less serious infections, and few fatal cases have been caused by it alone. The staphylococci, the colon bacillus, and a number of putrefactive anaërobic bacilli are frequently found. Among the rare forms are the gas bacillus (aërogenes capsulatus,[2] Welch), the pneumococcus,[3] the diphtheria bacillus[4] (Bumm, Nisot, Williams), and the typhoid bacillus[5] (Williams). In addition to these a number of unidentified aërobic bacilli have been found.

Mixed infections, as the streptococcus with the colon bacillus, the staphylococci with anaërobes, etc., occur more frequently than infections with a single organism.

The recently emptied uterus with its lacerated bleeding surface presents a peculiarly favorable field for the invasion and growth of micro-organisms. The retention of blood clots and fragments of the placenta or membranes favors infection. Incomplete contraction of the uterus with consequent dilatation of the lymphatics and the formation of large thrombi in the venous sinuses is also a factor, for it is along these vessels that infection most readily extends.

Source of Infection.—Bacteria must either be present in the uterus or vagina or be introduced from without. The doctrine of auto-infection has been advanced by a few observers. Albert[6] attributes to a latent microbic endometritis, which does not prevent conception, many cases of abortion and premature labor as well as some cases of puerperal infection.
